Abstracts

34th Annual Meeting of the
European Society of
Human Reproduction and Embryology,
Barcelona, Spain – 1 to 4 July 2018

The abstracts are available on-line to all Human Reproduction/Update/Molecular Human Reproduction subscribers and are also freely available to all visitors to the following website www.humrep.oxfordjournals.org, and on the ESHRE website: www.eshre.eu

Note to the media: All abstracts are strictly embargoed until the time and date of presentation at the conference. The opinions or views expressed in this abstracts supplement are those of the authors and do not necessarily reflect the opinions or recommendations of ESHRE. The abstracts have been reviewed by the Congress Scientific Committee and revised accordingly by the authors. The selection of abstracts is based on the scores given by an international panel of peer reviewers. Dosages, indications and methods of use for products that are referred to in the abstracts by the authors are not necessarily appropriate for clinical use and may reflect the clinical experience of the authors or may be derived from the professional literature of other clinical sources. Because of differences between in-vitro and in-vivo systems and between laboratory animal models and clinical data in humans, in-vitro and animal data may not necessarily correlate with clinical results. The investigators of these abstracts have stated in their submission letter that prospective studies where patients are involved have institutional Ethics Committee approval and informed patient consent, and that the studies using experimental animals have institutional approval. The Publishers have endeavoured to reproduce faithfully all of the abstracts as accepted by the Conference Organisers, but can accept no responsibility for inaccuracies or omissions caused by the late receipt of abstracts.

ESHRE COMMITTEES

Executive Committee (2017 – 2019)

Chair
Roy Farquharson (United Kingdom)

Chair-elect

INVITED SESSION

SESSION 01: KEYNOTE SESSION

Monday 2 July 2018 Forum (Auditorium) 08:30–09:30

O-001 Human Reproduction Keynote Lecture - Semen quality of young adult ICSI offspring: The first results

F. Belva[1], M. Bonduelle[1], M. Roelants[2], D. Michielsen[3], A. Van Steirteghem[4], G. Verheyen[4], H. Tournaye[4]

[1]UZ Brussel, Center for Medical Genetics, Brussels, Belgium
[2]KU Leuven, Environment and Health/Youth health Care- Department of Public health and Primary Care, Leuven, Belgium
[3]UZ Brussel, Department of Urology, Brussels, Belgium
[4]UZ Brussel, Centre for Reproductive Medicine, Brussels, Belgium

Background: Up till now, the health of children conceived by ART has been described from infancy up to pubertal age, but not beyond. Also, adverse cardiometabolic and vascular outcomes have been described in both IVF and ICSI offspring, but the impact of ART on the reproductive health of the offspring remained unknown. Whether ICSI- conceived men born to fathers with impaired spermatogenesis are at risk of inheriting deficient spermatogenesis from their fathers, could not be answered due to their young age. Since the oldest ICSI offspring cohort worldwide has recently reached adulthood, their reproductive health can now be investigated. Moreover, since these children were conceived by ICSI because of severe male-factor infertility, there is reasonable concern that male offspring have inherited the deficient spermatogenesis from their fathers. Previously normal pubertal development and adequate Sertoli and Leydig cell function has been described in pubertal ICSI boys, however, no information on their sperm quality is currently available. Therefore, we investigated the semen quality of young adult men that were conceived 18-22 years ago by ICSI for male infertility.

Material and Methods: The present study was conducted at UZ Brussel between March 2013 and April 2016 and is part of a large follow-up project focussing on reproductive and metabolic health of young adults, between 18 and 22 years and conceived after ICSI with ejaculated sperm. Results of both a physical examination and semen analysis were compared between young ICSI men being part of a longitudinally followed cohort and spontaneously conceived controls who were recruited cross-sectionally.

Results of a single semen sample in 54 young adult ICSI men and 57 spontaneously conceived males are reported. All young adults were individually assessed and the results of their physical examination were completed by questionnaires. Data were analysed by multiple linear and logistic regression, adjusted for covariates. In addition, semen parameters of the ICSI fathers dating back from their ICSI treatment application were analysed for correlations.

Results: Young ICSI adults had a lower median sperm concentration (17.7 million/ml), lower median total sperm count (31.9 million) and lower median total motile sperm count (12.7 million) in comparison to spontaneously conceived peers (37.0 million/ml; 86.8 million; 38.6 million). The median percentage progressive and total motility, median percentage normal morphology and median semen volume were not significantly different between these groups. After adjustment for confounders (age, BMI, genital malformations, time from ejaculation to analysis, abstinence period), the statistically significant differences between ICSI men and spontaneously conceived peers remained: an almost doubled sperm concentration in spontaneously conceived peers in comparison to ICSI men (ratio 1.9, 95% CI 1.1-3.2) and a two-fold lower total sperm count (ratio 2.3, 95% CI 1.3-4.1) and total motile count (ratio 2.1, 95% CI 1.2-3.6) in ICSI men compared to controls were found. Furthermore, compared to males born after spontaneous conception, ICSI men were nearly three times more likely to have sperm concentrations below the WHO reference value of 15 million/ml (AOR 2.7; 95% CI 1.1–6.7) and four times more likely to have total sperm counts below 39 million (AOR 4.3; 95% CI 1.7-11.3). In this small group of 54 father-son pairs, a weak negative correlation between total sperm count in fathers and their sons was found.

Conclusion: Although these first results in a small group indicate a lower semen quantity and quality in young adults born after ICSI for male infertility in their fathers, results cannot be generalised to all ICSI offspring because the indications for ICSI have nowadays been extended and ICSI is also being performed with non-ejaculated sperm and reported differences may thus either decrease or increase.

O-002 Oocytes from stem cells and back

K. Hayashi[1]

Faculty of Medical Sciences- Kyushu University, Developmental Stem Cell Biology, Fukuoka, Japan

Abstrat text

The female germline undergoes a unique sequence of differentiation processes that finally endows the eggs with totipotency. The reconstitution *in vitro* of oogenesis using pluripotent stem cells, which eventually produces functional oocytes, has long been sought in reproductive biology and developmental biology, since it would contribute not only to a better understanding of the basic mechanisms underlying totipotency, but also to an alternative source of gametes for reproduction.

We recently developed a culture systemthat reconstitutes the entire process of oogenesis from mouse pluripotent stem cells, yielding *in vitro*-generated eggs that gave rise to healthy offspring. In the culture system, primordialgerm cells (PGCs), origin of eggs and sperm, are induced from from ESCs/iPSCs, and then are aggregated with somatic cells from fetal ovaries. The aggregates, named reconstituted ovaries, pass through three different culture stages: *in vitro* differentiation (IVDi), *in vitro* growth (IVG) and *in vitro* maturation (IVM), which in total take approximately 5 weeks. After these stages, a number of mature oocytes are produced in the reconstituted ovaries.

The culture system is extremely useful, as genetic manipulation can be easily done in pluripotent stem cells, and outcome can be seen quickly in culture. In the symposium, I will introduce recent advances in oocyte production from pluripotent stem cells and updatecurrent experiments to address molecular mechanisms underlying oocyte differentiation.

O-003 Oocyte DNA repair capacity of controlled sperm DNA damage is affected by female age

F. Horta[1], S. Catt[1], B. Vollenhoven[1,2], P. Temple-Smith[1]

[1]*Monash University, Obstetrics and Gynaecology, Melbourne, Australia*
[2]*Monash IVF, Reproductive medice, Melbourne, Australia*

Study question: Does female aging have a negative effect on oocyte DNA repair capacity of controlled DNA damage levels introduced by spermatozoa?

Summary answer: Oocytes from older females have reduced capacity to repair damaged DNA introduced by spermatozoa, compared to oocytes from younger females.

What is known already: The reproductive lifespan in women declines with age predominantly due to poor oocyte quality. This leads to decreased reproductive outcomes for older women undergoing assisted reproductive technology (ART) treatments compared to young women. Aging and oocyte quality have been clearly associated with aneuploidy, but factors determining oocyte quality remain unclear.

DNA repair activity prior to embryonic genomic activation is considered of maternal origin, with maternal transcripts and proteins controlling DNA integrity. With increasing maternal/oocyte age, stored mRNAs decrease, which could result in diminished efficiency of DNA repair and/or negative effects on embryo development, especially considering the presence of DNA damage.

Study design, size, duration: Oocytes from two groups of 30 superovulated female mice (Young: 5-8 weeks old, n = 15; Old: 42-45 weeks old, n = 15) were inseminated with sperm from 5 males with three different controlled DNA damage levels; control:≤10%, 1GY:11-30% and 30GY:>30%. Inseminated oocytes (Young:125, Old:78) were assessed for the percentage zygotes (per oocyte) and blastocysts (per zygote). Five replicates of 5 GVs and 5 MII oocytes from each age group were analyzed for gene expression.

Participants/materials, setting, methods: Using the C57BL6 mouse strain, swim-up epididymal sperm samples were divided into: control (no irradiation); 1GY and 30 GY. Treated spermatozoa were irradiated at 1 Grey and 30 Grey respectively using a linear accelerator Varian 21iX. Following irradiation, samples were removed for DNA damage assessment (Halomax) and for insemination. Presumed zygotes were cultured in a time-lapse incubator (MIRI, ESCO). Gene expression of 91 DNA repair genes was assessed using the Fluidigm Biomark HD system.

Main results and the role of chance: Average sperm DNA damage for the 3 groups was statistically different (Control: 6.1%, 1GY: 16.1%, 30GY: 53.1%, $p < 0.0001$), but following IVF showed no significant differences in fertilization rates within or between age groups [(Young; Control: 86.79%, 1GY: 82.75%, 30GY: 76.74%) (Old; Control: 93.1%, 1GY: 70.37%, 30GY: 68.18%) *Fishers exact*]. However, blastocyst rates were significantly different ($p < 0.0001$) among groups [(Young; Control: 86.95%, 1GY: 33.33%, 30GY: 0.0%) (Old; Control: 70.37%, 1GY: 0.0%, 30GY: 0.0%)]. Between age groups, 1GY samples showed a significant decrease in the blastocyst rate in old females compared to young females (Young; 1GY: 33.33%, Old; 1GY: 0.0, $p = 0.0166$). Gene expression analysis revealed a decreased relative expression of 21 DNA repair genes in old GV oocytes compared to young GV oocytes ($p < 0.05$) and similarly, old MII oocytes showed 23 down-regulated genes compared to young MII oocytes ($p < 0.05$). The number of down-regulated genes in older GV and MII oocytes significantly affected pathways such as Double Strand Break (GV: 5; MII: 6), Nucleotide excision repair (GV: 8; MII: 5), and DNA Damage Response (GV: 4; MII: 8). The down-regulation in DNA repair gene expression of oocytes from older females suggests a decrease in DNA repair capacity during IVF.

Limitations, reasons for caution: Ionizing radiation was used only for experimental purposes, aiming for controlled levels of sperm DNA damage, however it can also damage spermatozoa proteins. The female age groups selected in mice were intended to model effects in young and old women, but clinical studies are required to demonstrate a similar effect.

Wider implications of the findings: Fertilisation can occur with sperm populations with medium and high DNA damage but subsequent embryo growth is affected, and to a greater extent with aging females, supporting the theory that oocyte DNA repair capacity decreases with age. The assessment of oocyte DNA repair capacity could be a useful diagnostic tool.

Trial registration number: N/A.

O-004 Pronuclear transfer in zygotes from diet-induced obese mice suggests a cytoplasmic origin of transgenerational transmission of mitochondrial dysfunction leading to cardiac dysfunction in offspring

K. Moley[1], K. Latham[2], J. Ferey[3], M. Reid[3]

[1]*Washington University School of Medicine, Obstetrics and Gynecology, St. Louis, U.S.A.*
[2]*Michigan State University, Animal Science, East Lansing, U.S.A.*
[3]*Washington University, Obstetrics and Gynecology, St. Louis, U.S.A.*

Study question: Is the epigenetic inheritance of mitochondrial dysfunction in offspring from obese mothers of nuclear or mitochondrial DNA origin?

Summary answer: The cytoplasmic fraction of the zygote from obese mice and not the pronucleus (PN) appears responsible for the abnormal cardiac phenotype in the subsequent generations.

What is known already: Maternal obesity impairs offspring health. We have previously shown that maternal programming of metabolic disease in offspring can be passed through the maternal oocyte. Specifically, offspring from the obese mice demonstrated significant mitochondrial dysfunction and morphologic changes in the heart leading to profound changes in cardiac function. We showed by IVF with oocytes from the obese vs control mice that this phenotype was replicated in the IVF conceived pups, confirming an oocyte origin. In this study we use pronuclear transfer to distinguish nuclear vs mitochondrial DNA contribution to the phenotype.

Study design, size, duration: C57Bl/6 females were fed high fat/high sugar (HF/HS) diet vs control (CD) diet for 6-8 weeks and mated. One-cell zygotes were recovered from both groups and four cohorts were created by control PN transfer into enucleated HF/HS zygotes and visa versa. The manipulated zygotes were transferred into pseudopregnant ICR females mice on a control diet and weaned to CD. Cardiac function and heart tissues were obtained at 8 weeks.

Participants/materials, setting, methods: Four treatment groups were created: 1) PN from HF/HS zygote transferred into enucleated zygote (EZ) from CD; 2) PN from CD zygote into EZ from HF/HS; 3) PN from CD zygote into EZ from CD; and 4) PN from HF/HS zygote into EZ from HF/HS. Cardiac function was assessed by echocardiography (ECHO) and high resolution respirometry was used to measure tissue oxygen consumption (Oxygraph). Tissue morphology was analyzed by electron microscopy.

Main results and the role of chance: Offspring from zygotes created from HF/HS cytoplasm and CD pronucleus demonstrated significant alterations in cardiac muscle morphology, and cardiac function as determined by Oxygraph and ECHO. These changes were not seen in offspring from zygotes created from CD cytoplasm and HF/HS pronucleus. The controls responded as predicted with no changes seen in the CD PN/CD cyto and significant changes seen in the HF/HS PN//HF/HS cyto. These findings suggest that the mitochondrial contribution, and most likely the mitochondrial DNA (mtDNA) from the HF/HS zygotes in the cytoplasm, is responsible for the epigenetic changes regulating the mitochondrial dysfunction phenotype in these mice. We have shown previously that this change is seen for 3 generations, suggesting a transgenerational inheritance.

Limitations, reasons for caution: Although this is a mouse study, the same changes to mitochondrial function are also seen in human oocytes from obese women. With pronuclear transfer it is difficult to remove the PN without some mitochondrial contamination. This could explain increased variability in this study.

Wider implications of the findings: Epigenetic modifications to oocyte mtDNA may occur as a result of maternal overnutrition and obesity. These modifications affect mitochondrial function leading to cardiac dysfunction that persists for three generations. These findings in mice may explain the epidemiologic data suggesting a strong correlation between maternal BMI and offspring cardiovascular disease risk.

Trial registration number: N/A.

O-005 Tripolar mitosis underlies direct unequal cleavages in human embryos and is associated with maternal genotype at a quantitative trait locus spanning the centrosomal regulator PLK4

N. Zaninovic[1], R.C. McCoy[2], Q. Zhan[1], E.R. Hoffmann[3], L.J. Newnham[4], C.S. Ottolini[5], Z.P. Demko[6], Z. Rosenwaks[1], A.H. Handyside[5]

[5]University of Kent, School of Biosciences, Canterbury, United Kingdom
[6]Natera- Inc., Natera. Inc, San Carlos, U.S.A.

Study question: What causes blastomeres in diploid embryos to cleave into three or more daughter cells during preimplantation embryo development, and what is the underlying mechanism?

Summary answer: Direct unequal cleavages (DUCs) are induced by multipolar mitosis and are associated with common maternal genetic variants spanning *PLK4*, the master regulator of centrosome duplication.

What is known already: Multipolar mitosis (including tripolar mitosis, or DUCs) has recently been documented in a substantial proportion (26%) of diploid cleaving embryos based on time-lapse microscopy (TLM) and karyomapping. DUCs exhibit reduced rates of blastocyst formation and implantation with increased rates of complex aneuploidies. The gene Polo-like kinase 4 (*PLK4*) plays an essential role as a master regulator of centrosome duplication. Altered expression of *PLK4* is associated with centrosome amplification, generating multipolar spindles. Chromosome segregation on multipolar spindles may in turn induce complex aneuploidies. Common maternal genetic variants spanning *PLK4* have previously been associated with complex aneuploidies via an unknown molecular mechanism.

Study design, size, duration: IVF cases that had previously undergone TLM as well as SNP genotyping for PGT-A were included. A total of 58 IVF patients with 742 embryos (77 biopsied on day 3 and 665 biopsied on day 5/6 embryos) were analyzed.

Participants/materials, setting, methods: DUC embryos were identified by TLM. DUC was defined as cleavage of a single blastomere into 3+ daughter blastomeres. Blastomeres (day 3) or trophectoderm cells (day 5/6) were used for genotyping by SNP microarray. Copy number and parental origin of all chromosomes were inferred from the SNP data using the Parental Support algorithm. Binomial linear regression was used to test for an association between the diploid tripolar pattern and maternal genotypes at rs2305957.

Main results and the role of chance: The diploid tripolar PGT-A signature was significantly enriched among blastomeres from embryos documented by TLM to have undergone one or more tripolar mitosis (i.e., DUC) during the first three cleavage divisions compared to embryos that underwent normal cleavage (i.e., Non-DUC; Fisher's exact test: $OR = 6.64$ [95% CI: 1.34–37.4]; $P = 0.0087$). The signature was most prevalent (up to 50%) among embryos undergoing tripolar cleavage during the first division (DUC-1) or undergoing multiple tripolar cleavages (DUC-Plus), indicating that these cleavage phenotypes may confer a wider distribution of abnormal cells at the time of biopsy. For direct validation of the association with the maternal *PLK4* genotype, data from cases undergoing day-5 blastocyst biopsy were also incorporated, as the availability of time-lapse data from these cases does not depend on embryo survival to the blastocyst stage. The minor allele of rs2305957 ("A" allele) was positively associated with time-lapse–based incidence of tripolar mitosis (i.e., DUC; quasi-binomial GLM: $OR = 1.53$ [95% CI: 1.01–2.31]; $P = 0.047$).

Limitations, reasons for caution: Retrospective analysis with relatively few genotyped patients and DUC embryos. *PLK4* has yet to be validated as the causal gene, and the causal variant remains to be identified.

Wider implications of the findings: Our data support DUC/tripolar mitosis as a key mechanism generating complex aneuploidies in cleavage-stage embryos and implicate the maternal genotype at a quantitative trait locus spanning *PLK4* as a factor influencing its occurrence. Our DUC data also elucidate the molecular origins of chaotic aneuploidies affecting embryo development and IVF success.

Trial registration number: none.

O-006 Factors associated with mitochondrial DNA (mtDNA) levels in human blastocyst

J. Ortiz[1], B. Lledo[1], R. Morales[1], A. Turienzo[1], J. Ten[2], J. Llacer[3], R. Bernabeu[3]

[1]Instituto Bernabeu, Biología Molecular y Genética, Alicante, Spain
[2]Instituto Bernabeu, Embriología, Alicante, Spain
[3]Instituto Bernabeu, Medicina Reproductiva, Alicante, Spain

Study question: Are embryo and maternal factors related with the mtDNA content in human euploid blastocyst?

Summary answer: Maternal age, the day where the embryo biopsy is performed and the embryo quality are associated with mtDNA levels in trophoectoderm biopsies.

What is known already: The main function of mitochrondria is to provide energy by ATP production. The role of mitochondrial in the developing human embryo is thought to be critical to a successful delivery. Although initial reports supported the hypothesis that high levels of mtDNA in trophoectoderm biopsies are associated with low implantation potential, other publications were unable to confirm previous results. It is possible that unidentified counfounding factors may influence the mtDNA copy number in euploid embryos. The aim of this study is identified the main factors that could increase the mtDNA in euploid blastocyst.

Study design, size, duration: A retrospective study was performed. We included 159 blastocysts biopsies from 142 couples who attended to Instituto Bernabeu for PGT-A from 2016 to 2017. The aneuploid testing was performed by NGS using Veriseq® kit and the BlueFuse Multi software (Illumina). All blastocysts were diagnosed as euploid non-mosaic. The mtDNA analysis were performed once the diagnosis was known. We evaluated the relationship between several maternal and embryo factors and trophoectoderm mtDNA levels.

Participants/materials, setting, methods: Sequencing reads mapping to the mtDNA genome were extracted from bam files to identify copy number. The relative measure of mtDNA copy number was calculated by diving the mtDNA reads by the nuclearDNA value to normalize for technical variants and the number of cells collected at the biopsy. All the results were subjected to correction factor according to the embryo genome. The association between variables and mtDNA was evaluated by logistic regression and chi-square (Rv3.4).

Main results and the role of chance: Quantification of mtDNA was successful in all cases. The mean average of mtDNA was 0.0016 + 0.0012. Concerning to maternal factors, there are not statistically significant differences according to the oocyte origin, donated or own oocyte (0.0017 vs 0.0017; $p = 0.423$). However, mtDNA was negatively correlated with female age when we compare with different female age ranges (ranges 25y-30y: 0.0017, 30y-35y: 0.0012, 35y-40y: 0.0016, older 40 y: 0.0024, $p = 0.044$). At last, no significance differences were reported according to the indication for PGT-A recurrent implantation failure (0.0016 vs 0.0015; $p = 0.365$) or repeated miscarriage (0.0016 vs 0.0017; $p = 0.523$). With regard to embryo factors, embryos biopsied on day 5 were more likely to have higher quantities of mtDNA compared with those biopsied on day 6 (0.0017 vs 0.0009; $p = 0.0014$). Embryo quality is not associated with mtDNA (A:0.0017, B:0.0015, C: 0.0006; $p = 0.304$). Finally, we also examined the possible relationship between the sex of the embryo and mtDNA copy number. We did not observe any significant

differences in mtDNA levels between male and female embryos (0.0016 vs 0.0016; p = 0.851).

Limitations, reasons for caution: Limitation may be due to the size of the sample and the high-troughput sequencing technology. More research in the mitochondrial function are needed. Evaluating the entire cohort of embryos from each patient could detect patient variability.

Wider implications of the findings: Our data suggest that blastocyst from older women had higher mtDNA, thus oocyte ageing could affect ooplasmic factors. Moreover, our results show that the mtDNA in a given cell of an embryo is dependent upon the cell divisions that preceded biopsy because higher mtDNA were found in D5 biopsied embryos.

Trial registration number: Not applicable.

O-007 Estimation of age-dependent decrease in blastocyst euploidy in in vitro fertilization/intracytoplasmic sperm injection cycles

S. Esteves[1,3], P. Humaidan[1,2], J. Carvalho[4], M. Ciro[5], A. Dias[54], C. Alviggi[6], A. Conforti[6], R. Fischer[7], C. Andersen[8], K. Bühler[9], F. Ubaldi[10]

[10]*GENERA, Center for Reproductive Medicine, Rome, Italy*

Study question: Is it possible to estimate the effect size of female age-dependent decrease in the probability of a blastocyst being euploid?

Summary answer: The decrease in blastocyst euploidy is age-dependent, progressing with every year of female age, from 1.2% to 24.5% in 28-44 years-old women.

What is known already: Array comparative genomic hybridization (CGH) data show that female age is the most significant determinant of embryo genetic status. Aneuploidy affects more than one-half of human embryos and is the main reason for the decrease in live birth rate among aging women undergoing Assisted Reproductive Technology (ART) cycles. However, estimation of the age-dependent probability of a blastocyst being euploid and the effect size of the decrease in this probability with every year of female age using next-generation sequencing (NGS) analysis has not been performed yet.

Study design, size, duration: Retrospective analysis of 1,220 trophectoderm biopsies from 436 infertile couples undergoing intracytoplasmic sperm injection and preimplantation genetic testing for aneuploidy (PGT-A) between 2016 and 2017. PGT-A was used for reasons of advanced maternal age, severe male factor infertility, recurrent miscarriage, repeated implantation failure, as well as patients who were concerned about euploidy of their embryos.

Participants/materials, setting, methods: Biopsied trophectoderm cells were subjected to lysis, whole genome amplification, construction of libraries, and NGS using the Ion PGM™ platform. Logistic regression was fit to the dataset. The dependent and independent variables were embryo genetic status (euploid/aneuploid) and female age, respectively. The method of fitting was quadratic on age, and the model was validated by splitting the data (80% and 20% to train and test the model respectively). Computations were performed using JMP 13 (www.jmp.com).

Main results and the role of chance: The model is $\log[p(t)/(1-p(t))] = 7.575\text{-}0.21\cdot\text{age}\text{-}0.011\cdot(\text{age}\text{-}38.41)^2$, where p(t) is the probability of a blastocyst being euploid for age (t) in years. There was no statistical evidence against the fitted model ($p > 0.10$). The model is not biased as there is linearity in the relationship between the estimated probability distribution and the distribution of empirical data. The % decrease in probability from year (t) to year (t + 1) was defined as the ratio $p(t+1)/p(t)\times100$. There was a significant ($P < 0.0001$) decrease in the probability of a blastocyst being euploid with every year of female age. The geometric mean of the yearly variation was 13.6%. However, the decrease is progressive with every year of female age. At age 29 it was 1.2%, whereas at ages 30, 32, 35, 37, 39, 41 and 44, the decreases were 2.0%, 3.5%, 6.7%, 9.8%, 13.6%, 17.9%, and 24.5%, respectively.

Limitations, reasons for caution: The impact of other covariates that could affect embryo genetic status and effect of cycle number were not analyzed. Furthermore, the estimations cannot be generalized to IVF patients undergoing cleavage-stage embryo transfer.

Wider implications of the findings: The decrease in the probability of a blastocyst being euploid increases progressively with every year of female age, from 1.2% to 24.5% in 28-44 years-old women. This information will aid clinicians counsel patients concerning their individual chances of having euploid blastocysts for transfer.

Trial registration number: N/A.

O-008 Global DNA methylation profiling of mouse embryo inner cell mass following IVF

P. Rinaudo, A. Donjacour, X. Liu, E. Ruggeri

University of California, OB/GYN, San Francisco- CA, U.S.A.

Study question: Is preimplantation embryo culture (in vitro fertilization; IVF) associated with global DNA methylation changes in the mouse inner cell mass (ICM)?

Summary answer: Preimplantation embryo manipulation results in widespread DNA methylation changes in ICM.

What is known already: Numerous imprinting disorders are correlated with assisted reproductive technologies (ARTs) and animal models indicate that offspring generated by IVF have increased metabolic alterations in adulthood. Given that the preimplantation embryos undergo dramatic changes in DNA methylation, there is a need to understand the global DNA methylation changes occurring in the embryo following embryo culture. Since the ICM will give rise to the fetus and adult individual, limiting the analysis to this tissue will provide valuable information regarding candidate gene alterations.

Study design, size, duration: Mouse blastocysts were obtained from CF-1 females crossed with B6D2F1 males and utilized for in vitro fertilization or flushed out of the uterus (FB = flushed blastocyst = control). IVF was performed using KSOM with amino acids and 5% O_2.

Participants/materials, setting, methods: Blastocysts were collected (IVF and in vivo) and immuno-surgery performed isolating ICM. Pooled ICM of IVF or FB (n = 15/group, 2 replicates/group) were utilized for whole genome bisulfite sequencing (WGBS). Methyl-MaxiSeq was used for WGBS and sequenced on the Illumina HiSeq4000. Reads were mapped to the mouse genomes (mm9) using Bismark and differentially methylated regions (DMR) identified using BSSEQ Bioconductor package in R. DMR were functionally characterized using Genomic Regions Enrichment of Annotations Tool (GREAT).

Main results and the role of chance: The low amount of starting material allowed for an excellent quality but relatively low mapping efficiency (~ 12%). As expected, only 20% of CpG were methylated, confirming the low level of DNA methylation in the blastocyst. There were 3195 differentially CpG methylated regions (DMR: 1661 hypomethylated and 1534 hyper-methylated) between IVF and control ICMs. The majority of DMR were located between 5 and 500 nucleotides from the transcription start site (TSS) and approximately 50% were located in the body of the genes.

The hypomethylated regions corresponded to genes whose function was related to endosomal transport, regulation of neurotransmitter secretion, protein O-linked glycosylation, cytokinesis, ventricular development and adipose tissue development,

The hypermethylated regions were in proximity of genes whose function was involved in negative regulation of gliogenesis, cell junction assembly, gluconeogenesis, cellular response to peptide hormone stimulus, cell junction organization, positive regulation of Rho GTPase activity.

Limitations, reasons for caution: The low amount of starting material (15 pooled ICM, corresponding to a total of approximately 200 cells) could introduce amplification errors.

Wider implications of the findings: This is the first report of global DNA methylation changes in isolated ICMs of IVF or spontaneously conceived blastocysts. The candidate gene identified as being differentially methylated in ICM of IVF embryo can elucidate the phenotypic alterations noted in adult animal conceived by IVF.

Trial registration number: not applicable.

SESSION 03: ENDOMETRIOSIS AND ENDOMETRIUM: DISCOVERY SCIENCE

Monday 2 July 2018 Room 211 + 212 10:00–11:30

O-009 Discovery of novel loci for endometriosis in genome-wide association analysis of 63 K cases and 700 K controls

N. Rahmioglu[1], I. International Endometriosis Genomics Consortium[1], K. Zondervan[1], A. Morris[2]

[1]*University of Oxford, Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom*
[2]*Liverpool University, Blostatistics Department, Liverpool, United Kingdom*

Study question: What common genetic variants and corresponding functional mechanisms underlie endometriosis, and its surgical sub-types (ASRM-stages), clinical sub-types (Infertile-endometriosis) and symptom-based sub-types (Severe pelvic-pain with endometriosis)?

Summary answer: With the largest sample size to date for endometriosis genome-wide-association-study (GWAS) meta-analysis, we expect to identify many novel-susceptibility-loci for this debilitating condition and its sub-types.

What is known already: Endometriosis has an estimated heritability of ~ 50%, with ~26% estimated to be related to common genetic variation. To date, meta-analysis of endometriosis GWAS (17 K cases and 191 K controls) have robustly identified 19 variants explaining 5.2% of disease variance. Previous GWAS analyses also highlighted that the signals for most of the genome-wide significant loci are driven by ASRM stage III/IV disease, highlighting the need for further phenotype-stratified analyses.

Study design, size, duration: IEGC consists of 25-centres contributing in total, 63 K endometriosis cases, 7800 stage III/IV, and 700 K controls to the GWAS meta-analysis. Some of these are population-based cohorts such as the UK Biobank, and also clinical-investigations such as ENDOX, which is a prospective study recruiting women undergoing laparoscopy, that has dense clinical-phenotype data. Some of the centres have expression and eQTL-datasets for endometrium, fat and ectopic-disease-tissue, allowing for evaluation of functional mechanisms of the identified genetic variants.

Participants/materials, setting, methods: Each GWAS was imputed up to reference panels from the Haplotype Reference Consortium or 1000 Genomes Project. Association testing by each centre was conducted in a regression framework under an additive genetic model, with adjustment for confounding due to population structure. Association testing was conducted for overall, stage I/II, stage III/IV and infertile endometriosis groups. Association summary statistics were aggregated across GWAS via fixed-effects meta-analysis.

Main results and the role of chance: The GWAS meta-analysis is on-going, and results will be presented at the meeting. Preliminary results from the UK Biobank (n = 8,190 cases) identified two novel associations at near genome-wide significance ($p < 5 \times 10\text{-}8$) that map outside previously reported loci. The first maps to IGF2BP3 (rs550554633, $p = 4.4 \times 10^{-8}$), which is involved in regulation of metabolism and adiposity, supporting the genetic link between endometriosis and fat distribution. The second maps to GDAP1 (rs554964149, $p = 7.2 \times 10^{-8}$), which is involved in neuronal development that may play a role in endometriosis-associated pain, and previously has been associated with pain severity in dysmenorrhea. Moreover, a further 18 loci with nominal significance ($p < 5 \times 10^{-6}$) were identified, many of which are expected to increase in association strength in the complete IEGC meta-analysis.

Limitations, reasons for caution: For phenotype-stratified analysis we are limited by the datasets with dense phenotypic data (i.e. infertility, pelvic pain severity).

Wider implications of the findings: The identified genetic variants shed light on the underlying pathogenesis of endometriosis and may point to novel therapeutic interventions.

Trial registration number: N/A.

O-010 Understanding endometriosis heterogeneity—sub-phenotype analysis of genetic associations

C.S.K. Cheuk[1], N. Rahmioglu[2], C. Becker[1], K. Zondervan[1]

[1]*University of Oxford, Nuffield Department of Women's and Reproductive Health, Oxford, United Kingdom*
[2]*University of Oxford, Wellcome Centre for Human Genetics, Oxford, United Kingdom*

Study question: The aim of this study is to investigate whether sub-phenotype analysis of established genetic variants associated with endometriosis reveals differential mechanisms underlying surgical and symptomatic sub-types of the disease.

Summary answer: Preliminary results from a reduced dataset showed suggestive differential effects for genome-wide association study (GWAS) loci across surgical sub-phenotypes.

What is known already: Most of the known 14 genetic loci have been reported based on association with overall endometriosis, with sub-phenotypic investigations limited to ASRM stages I/II vs. III/IV. Studies using the World Endometriosis Research Foundation-Endometriosis Phenome and Biobanking Harmonisation Project (EPHect) standardized data collection protocols now afford the investigation of these loci for detailed surgical and symptomatic phenotypes.

Study design, size, duration: Cross-sectional study in which genotype information from 358 women in the Oxford ENDOX study (294 cases, 64 controls) undergoing laparoscopic surgery was analysed for association with EPHect-compliant surgical and symptomatic phenotype data.

Participants/materials, setting, methods: Preliminary analysis of 108 endometriosis cases included 51% with an endometrioma (not exclusive to other surgical subtypes), 68% with peritoneal disease and 31% with deep endometriosis; 40%, 14%, 19% and 27% of women were diagnosed with ASRM Stage I to IV respectively.

All 14 known GWAS loci for endometriosis were tested for association with sub-phenotypes using Pearson's chi-squared and linear-by-linear association test.

Main results and the role of chance: The GWAS locus on 2q35 (rs1250241, located in *FN1*), with genotype T/A, showed a borderline association ($p = 0.035$) with peritoneal endometriosis (odds ratio (OR) of TT vs. TA = 0.08, 95% confidence interval (CI): 0.01-0.78; OR of TT vs. AA = 0.13, 95% CI: 0.01-1.25; OR of TA vs. AA = 1.68, 95% CI:0.69-4.07), but not with endometrioma ($p = 0.856$) or deep endometriosis ($p = 0.307$). Analysis on additional genotype data (n = 250) with more sub-phenotypes including infertility and pain status are underway and results will be presented at the meeting.

Limitations, reasons for caution: Sample size was small in the preliminary analysis, with limited power to discover differential association pattern.

Wider implications of the findings: Insight into aetiological heterogeneity of endometriosis elucidated by genetics is an important avenue to ultimately develop targeted non-invasive markers of disease and novel treatment strategies.

Trial registration number: Not applicable.

O-011 Exosomes as biomarkers in endometriosis

H. Nazri[1], M. Imran[2], R. Fisher[3], B. Kessler[3], K. Zondervan[1], T. Tapmeier[1], C. Becker[1]

[1]*University of Oxford, Nuffield Department of Women's and Reproductive Health, Oxford, United Kingdom*
[2]*Wellcome Sanger Institute, Hinxton, Cambridge, United Kingdom*
[3]*Nuffield Department of Medicine, Target Discovery Institute, University of Oxford*

Study question: Could exosomes be considered as biomarkers of endometriosis?

Summary answer: Potentially – we found exosomes in peritoneal fluid of endometriosis and control samples. The differences observed in number and size likely translates into qualitative differences.

What is known already: Endometriosis, the presence of endometrial lesions outside the uterus, is a common condition affecting up to 10% of women of reproductive age. Patients suffer from pain and infertility. The current diagnostic model relies on non-specific symptoms, the (inconsistent) application of endometriosis risk factors, and invasive diagnostic laparoscopy as the gold standard. There is no clinically relevant biomarker for endometriosis yet.Recently, nano-sized extracellular vesicles – exosomes – produced by virtually every cell, have been described in diseases such as cancer, diabetes and pre-eclampsia. Exosomes could similarly be important in endometriosis and serve as biomarkers of the disease.

Study design, size, duration: Peritoneal fluid (PF) samples were obtained from participants in the ENDOX study at the Endometriosis CaRe Centre, Nuffield Department of Women's and Reproductive Health, University of Oxford (REC ref. 09/H0604/58) under WERF EPHect standards. Women between 18-49 years of age (n = 28) who had undergone diagnostic laparoscopy for abdominal or pelvic pain and/or subfertility investigation were classified according to menstrual cycle phase (proliferative or secretory) and severity of endometriosis (ASRM stages I + II or stages III + IV).

Participants/materials, setting, methods: Groups, control proliferative, n = 4; control secretory, n = 2; StI+II proliferative, n = 9; StI+II secretory, n = 7; StIII+IV proliferative, n = 3; StIII+IV secretory, n = 3. Exclusion criteria: Hormonal treatment, malignancy, pregnancy, breastfeeding and inability to understand the consent form. 1 mL PF was centrifuged to remove cells, debris and microvesicles. Exosomes were enriched by size-exclusion chromatography and confirmed by nanoparticle tracking analysis (NTA), immunoblotting and transmission electron microscopy (TEM). The study of exosome cargo by mass spectroscopy and RNA-sequencing is ongoing.

Main results and the role of chance: We confirmed the presence of exosomes in PF from women at different stages of endometriosis and from disease-free patients at different menstrual cycle phases by TEM (n = 6 pooled group samples) and NTA (n = 6 pooled group samples). Enriched exosomes were positive for CD9 and Syntenin. The mean size of PF particles from women with endometriosis was 217 ± 11.2 nm (n = 4 pooled group samples), whereas in non-endometriotic women it was 182.9 ± 9.11 nm (n = 2 pooled group samples). We observed a higher concentration of PF particles in stage I-II endometriosis compared to controls in both proliferative and secretory phases ($p < 0.0001$) (n = 2 pooled group samples). In stage III-IV endometriosis, the opposite was seen in the proliferative phase ($p < 0.0001$) (n = 2 pooled group samples).

Limitations, reasons for caution: Due to the very limited material obtained, PF samples had to be pooled according to menstrual cycle phases and ARSM staging for analyses.

Wider implications of the findings: The difference in concentration and size of exosomes in the patient groups is likely to translate into qualitative differences in exosome populations given genetic and phenotypic differences in endometriosis of different stages. This will be shown by the pending proteomics and RNA-seq results.

Trial registration number: Not applicable.

O-012 The baboon miRNAome: small RNA sequencing of 25 baboon tissues

A. Vanhie[1], D. Chai[2], A. Nyachieo[2], D. O[3], D. Peterse[3], C. Meuleman[1], P. Mestdagh[4], T. D'Hooghe[3]

[1]University Hospital Leuven, Obstetrics and Gynaecology, Leuven, Belgium
[2]Institute of Primate Research, Reproductive Sciences, Nairobi, Kenya
[3]KU Leuven, Development and Regeneration, Leuven, Belgium
[4]UGent, Center for Medical Genetics, Ghent, Belgium

Study question: Can we identify orthologous miRNAs between baboons (papio Anubis) and humans through deep sequencing of baboon RNA and annotation to the human genome.

Summary answer: Mapping of the small RNA sequencing reads from a pooled baboon sample to the human genome identified 941 orthologous miRNAs between humans and baboons.

What is known already: Baboons (papio Anubis) are a very good model for reproductive research because of the small phylogenetic gap and the very high similarity in reproductive physiology and anatomy. They have been used to study endometriosis, embryo-implantation, uterine transplantation and in the development of contraceptives. MicroRNAs are important gene expression regulators and their role in the pathophysiology of several reproductive diseases has been implicated. The use of baboons in miRNA research is currently limited because only a few miRNA genes have been described and annotated.

Study design, size, duration: One baboon was euthanized and during post-mortem examination biopsies of 25 tissues were collected and snap frozen (ovary, endometrium, myometrium, fallopian tube, cervix, heart, aorta, lung, kidney, liver, pancreas, bladder, peritoneum, lymph nodes, muscle, spleen, skin, tongue mucosa, rib cartilage, stomach mucosa, thyroid glands, pituitary glands, intestine, brain cortex, plasma). Prior to RNA extraction tissue samples were subsampled using a microtome (10-12 scrolls of 55 µm thickness/samples) and stored in Qiazol reagent (Qiagen).

Participants/materials, setting, methods: RNA was isolated using the miRNeasy serum/plasma kit (Qiagen) and the miRNeasy mini kit (Qiagen). RNA of the 25 samples was pooled and processed as a single sample pool using the TruSeq small RNA library preparation kit (Illumina). Single end sequencing was performed (140 million reads, read length 75 nt) on a NextSeq 500 sequencer (Illumina). After filtering and adapter trimming, the reads were collapsed, mapped and annotated to the human reference genome.

Main results and the role of chance: Quality of the extracted RNA was assessed by determining RNA concentration (Qubit 2.0 fluorometer, Thermo Fisher Scientific) and RNA integrity (Fragment Analyzer automated capillary electrophoresis system, Advanced Analytical Technologies). On average, an RNA concentration of 783 ng/µl and an RNA Quality Number (RQN) value of 8.1 was obtained. In total, 143 million sequencing reads were generated. Read length distribution and annotation was evaluated to ensure enrichment of miRNAs in the 20-24 nucleotide read fraction. Mapping the baboon sequencing reads to the human reference genome, allowing no mismatches, detected 708 mature canonical miRNAs with identical nucleotide sequences in baboons (papio Anubis) and humans. In a second step, the unmapped fraction of sequencing reads was remapped allowing 1 and 2 mismatches, respectively. This resulted in the detection of 233 additional miRNAs. In total, 941 unique miRNAs were detected (708 with 0 mismatches, 749 with 1 mismatch, 607 with 2 mismatches). Because of the very high sequence homology between baboons and humans these 941 miRNAs can be considered as orthologous between humans and baboons.

Limitations, reasons for caution: In this study we analyzed 25 tissue samples from one baboon. Validation in more animals is required. Analysis of other tissues than those included or deep sequencing of the individual tissues included in this study could identify other miRNAs with tissue specific or very low levels of expression.

Wider implications of the findings: The identification of orthologous miRNAs in baboons is a first step in establishing the baboon miRNAome and will facilitate miRNA research in baboons. All our data will be made open access and online available so they can be used by other researchers to develop primers for their miRNAs of interest.

Trial registration number: Not applicable.

O-013 Human endometrium demonstrate a dynamic TERRA expression and hormone regulation: implications in endometrial proliferative conditions

M. Adishesh[1], R. Alnafakh[1], J. Drury[2], G. Saretzki[3], B. Decruze[4], D. Hapangama[1]

[1]Institute of Translational Medicine- University of Liverpool, Women's Health, Liverpool, United Kingdom
[2]Institute of Translational Medicine - University of Liverpool, Women's Health, Liverpool, United Kingdom
[3]Institute for Cell and Molecular Biosciences and Newcastle University Institute for Ageing, Ageing Research, Newcastle, United Kingdom

[4]Liverpool Women's Hospital, Gynaeoncology, Liverpool, United Kingdom

Study question: Does healthy endometrium express TERRAs and is their expression altered with endometrial proliferative conditions and by ovarian steroid hormones?

Summary answer: Healthy human endometrium expressed TERRAs with an individual TERRA-specific dynamic thus hormonally regulated expression pattern and an altered expression observed in endometrial pathologies.

What is known already: Telomeres are transcribed as long non coding RNAs, called TERRAs (Telomeric repeat containing RNA) that are proposed to participate in a variety of cellular regulatory functions and DNA damage response activation. Endometrial telomere transcription has not yet been studied. Telomere length and telomerase activity change according to ovarian hormones in the human endometrium and high telomerase is associated with endometrial proliferative conditions, such as endometriosis and endometrial cancer. The effect of ovarian steroid hormones on telomere transcription in human endometrium is not known.

Study design, size, duration: A prospective observational study, included endometrial biopsies of 66 women was carried out in the academic labs of University of Liverpool/ Liverpool Women's Hospital.

Participants/materials, setting, methods: Endometrial samples were collected from women with (n = 10) or without endometriosis (n = 16), women using mirena (n = 9), healthy postmenopausal (PM) women (n = 7) and women with endometrial cancer (EC, n = 24). Ethical approval was obtained from Liverpool Adult Local Research Ethics Committee (LREC) and informed written consent was obtained from all patients. Endometrial samples analysed for TERRA (chromosome 1, 16, 20) and hTERC levels by qPCR, TRAP assay, ki67 proliferative index and steroid receptor expression by immunohistochemistry.

Main results and the role of chance: All three TERRAs from chromosomes 1, 16, and 20, were expressed in the human endometrium. Pre-menopausal endometrial TERRAs did not change according to cycle phase but Ch-20 TERRA levels were significantly increased in the PM samples compared with premenopausal proliferative phase ($p = 0.017$). There were no significant differences in TERRA levels in the secretory phase endometrium of women with endometriosis compared with the healthy women without endometriosis ($p > 0.05$), however the hTERC mRNA levels were significantly upregulated in secretory endometrium of women with endometriosis ($p = 0.02$). EC samples had significantly reduced levels of Ch-16 and Ch-20 TERRA ($p = 0.001$; $p = 0.000$ respectively) compared to PM endometrium. Ch-16 TERRA levels positively correlated with hTERC but none of the TERRA levels correlated with telomerase activity (TRAP assay). Ch-16 TERRA levels negatively correlated with progesterone receptor and both Ch-16 and Ch-20 TERRA levels negatively correlated with the proliferative marker Ki67 ($p = 0.03$; $p = 0.009$ respectively). Treatment of local progesterone, Mirena did not significantly changed TERRA levels compared with untreated proliferative endometrium. TERRA expression was found to be downregulated with *in vitro* treatment with progesterone and also combined oestrogen and progesterone treatment for 72 hrs ($p = 0.02$ and $p = 0.04$ respectively).

Limitations, reasons for caution: This is an observational study including a modest samples number including only three different TERRAs. However, corresponding Telomerase and hTERC levels, proliferative indices of the samples are included to examine TERRA levels in the context of cellular proliferation and telomerase biology.

Wider implications of the findings: The negative correlation of TERRA with cellular proliferation, significant reduction in endometrial cancer and their hormonal regulation indicate a regulatory role for TERRA in the human endometrium. Further studies are warranted to explore TERRAs as therapeutic targets in endometrial pathologies.

Trial registration number: Not applicable.

O-014 CAS as a novel interacting protein of CD147 is involved in the epithelial-to-mesenchymal transition in human endometriosis

H. Chen[1], C. Wang[2], J. Liu[1], M. Ye[1], K.L. Fok[2], H.C. Chan[2]

[1]Guangdong University of Technology, Institute of Biomedical and Pharmaceutical Sciences, Guangzhou, China

[2]The Chinese University of Hong Kong, Epithelial Cell Biology Research Center, Hong Kong, Hong Kong

Study question: Does the elevated CD147 regulate the epithelial-to-mesenchymal transition (EMT) during endometriosis progression?

Summary answer: A novel CD147-interacting protein, CAS was identified. The upregulation of CD147 led to the disruption of CAS/E-cadherin/β-catenin complex, which promoting EMT of endometriotic cells.

What is known already: Our previous studies have demonstrated elevated CD147 in the ovarian endometriosis with enhanced cell survival.

Study design, size, duration: Experimental clinical study and laboratory-based investigation. The endometriotic lesions samples were collected from 47 ovarian endometriosis women, and the normal endometrial tissues were collected from 12 women without endometriosis and endometritis. CD147 and CAS overexpression or knockdown in human endometrial Ishikawa cells (ISK) were designed to examine the effect on cell migration and EMT marker and related signaling.

Participants/materials, setting, methods: Expression levels of CAS were evaluated in endometriotic tissues by quantitative real-time polymerase chain reaction (qPCR) and western blot. The interactions of CD147, CAS and E-cadherin were confirmed by co-immunoprecipitation. ISK cells were transfected with the CD147-overexpressing plasmid or infected with lentivirus packaged human CAS. CAS-knockdown was achieved by transfection of CAS siRNA in ISK cells. Gene-manipulated ISK cells were used to do cell migration and invasion assay or explore the signaling pathway.

Main results and the role of chance: In human endometriotic tissues, both mRNA and protein expression levels of CAS were significantly decreased in endometriosis lesions with elevated expression of CD147. We next determined a complex formed with CD147/CAS/E-cadherin, which stabilized the interaction between E-cadherin and β-catenin. Furthermore, overexpression of CD147 disrupted the interaction between CAS and E-cadherin, resulting in the EMT process via the release of β-catenin from CAS/E-cadherin/β-catenin complex. Of note, overexpression of CD147 or knockdown CAS led to the nuclear translocation of β-catenin and further activated its downstream EMT signaling such as EMT-promoting gene Snail. In addition, overexpression of CAS was able to inhibit the migration and invasion capacity in CAS-overexpressing ISK cells.

Limitations, reasons for caution: In vivo study is lacking to further confirm the function of CD147 and CAS in animal models.

Wider implications of the findings: The demonstrated increase of cell migration and invasion through CD147-CAS-E-cadherin interactions suggest the involvement of the CD147-regulated signaling in the progression of human endometriosis and provide potential targets for endometriosis treatment.

Trial registration number: Not applicable.

SESSION 04: RECURRENT IMPLANTATION FAILURE AND UNEXPLAINED INFERTILITY

Monday 2 July 2018 Room 111 + 112 10:00–11:30

O-015 Androgen receptor (AR) mRNA expression is positively associated with live birth in women undergoing in-vitro fertilization independently of the type of ovarian response

C. Vaitsopoulou[1], E. Kolibianakis[1], E. Neofytou[1], A. Makedos[1], M. Malandri[1], A. Kalpatsanidis[1], J. Bosdou[1], D. Sabbaidou[1], K. Chatzimeletiou[1], S. Lymperi[1], A. Lambropoulos[2], G. Grimbizis[1], B. Tarlatzis[1]

[1]Medical School- Aristotle University of Thessaloniki, Unit of Human Reproduction-1st Department of Obstetrics and Gynecology, Thessaloniki, Greece

[2]Medical School- Aristotle University of Thessaloniki, Laboratory of Molecular Biology-General Hospital of Thessaloniki "Papageorgiou", Thessaloniki, Greece

Study question: Is androgen receptor (AR) mRNA expression associated with live birth in normal and poor responders undergoing in-vitro fertilization (IVF)?

Summary answer: AR mRNA expression is positively associated with live birth in women undergoing in-vitro fertilization independently of the type of ovarian response.

What is known already: AR is a steroid hormone receptor that regulates various genes' expression and affects cellular proliferation and differentiation. Androgens interact with AR, exert their paracrine action on granulosa cells and regulate gonadotropin synthesis, follicle development, oocyte maturation and corpus luteum function. Estrogens increase AR mRNA and testosterone binding site in uterine endometrium and leiomyoma. In human cancer cells, low estradiol increases AR levels, suggesting the estrogen/androgen ratio as a predictor of sex steroid response. AR mRNA expression is, also, regulated by progesterone. Although AR mRNA is expressed in the female reproductive tissues, its expression has never been studied in peripheral blood.

Study design, size, duration: A prospective clinical trial was performed from 2014 to 2017, in 40 normal responders and 27 poor responders according to Bologna criteria, undergoing IVF/ICSI. Ovarian stimulation was performed with 200 IU recombinant follicle stimulating hormone (rFSH) and gonadotrophin releasing hormone (GnRH) antagonists. Triggering of final oocyte maturation was performed by recombinant human chorionic gonadotrophic (rhCG).

Participants/materials, setting, methods: Vaginal ultrasound evaluation of follicular development, peripheral blood collection for RNA extraction, c-DNA synthesis, mRNA expression and hormonal assessments were performed on days 1, 6 and 10 of stimulation. Serum FSH, luteinizing hormone (LH), estradiol and progesterone were measured by ELISA. AR mRNA expression was evaluated by Real-time PCR and analyzed by the ΔΔCT method. Statistical analysis was performed using multivariable analysis.

Main results and the role of chance: On day 6 of stimulation, AR mRNA expression was negatively associated with LH level ($p = 0.027$), adjusting for patient type. On day 10 of stimulation, AR mRNA expression was negatively associated with estradiol ($p = 0.010$) and progesterone ($p < 0.001$) levels, adjusting for patient type. Concomitantly, AR mRNA expression was positively associated with the number of developing follicles (11-17 mm) ($p = 0.010$), adjusting for patient type. Achievement of live birth was positively associated with AR mRNA expression prior to initiation of stimulation ($p < 0.001$), adjusting for female age and number of embryos transferred.

Limitations, reasons for caution: This is the first study of AR mRNA expression in peripheral blood mononuclear cells during ovarian stimulation for IVF. However, it is performed on a limited number of normal and poor responders.

Wider implications of the findings: If the association of AR mRNA expression with live birth is confirmed in further studies, its assessment prior to initiation of ovarian stimulation, could be used as a novel prognostic factor for the achievement of pregnancy regardless of the type of ovarian response.

Trial registration number: NCT01984286

O-016 Endometrial receptivity analysis (ERA) using a next generation sequencing (NGS) predictor improves reproductive outcome in recurrent implantation failure (RIF) patients when compared to ERA arrays

Study question: Does next generation sequencing (NGS) based endometrial receptivity analysis (ERA) predictor improve reproductive outcome in recurrent implantation failure (RIF) patients when compared to arrays based ERA predictor?

Summary answer: Reproductive outcome in RIF patients increases significantly when performing personalized embryo transfer (pET) based on ERA NGS predictor compared to previous ERA arrays predictor.

What is known already: ERA identifies the window of implantation (WOI) of a given patient based on the transcriptomic signature of 236 genes in an endometrial biopsy. Subsequently, it allows pET according to this ERA result. Several groups have reported that pET increases pregnancy rates (PR) and implantation rates (IR) in RIF patients (Ruiz-Alonso 2013; Mahajan 2015; Hashimoto 2017; Tan 2018). To improve the diagnostic accuracy and reproductive outcome in RIF patients of endometrial origin, a NGS ERA predictor based on our experience with more than 20,000 endometrial samples, has recently been developed.

Study design, size, duration: This study comprises NGS predictor development and clinical follow-up to validate its diagnostic accuracy after pET. The NGS predictor was developed by sequencing 411 endometrial biopsies previously diagnosed by arrays. Then, 1,432 endometrial biopsies (716 patients with two endometrial samples per patient) were used for prediction analysis. Clinical follow-up of the NGS predictor was performed in 261 patients collected from 5 different clinics. These clinical results were compared with previously known outcome using ERA arrays.

Participants/materials, setting, methods: Endometrial biopsies were collected using a pipelle catheter during the expected WOI in natural cycles (at LH + 7) or hormone replacement therapy cycles (at P + 5). RNA was extracted and sequenced using the ERA gene panel. Several machine learning methods were compared to select the one with better performance. A statistical proportion test was used for reproductive outcome comparison between samples diagnosed with NGS ERA predictor and arrays ERA predictor.

Main results and the role of chance: The machine learning method with best performance was Random Forest, with a global accuracy of 0.88, sensitivity 0.90 and specificity 0.97. Reproductive outcome for RIF patients performing arrays based ERA and subsequent pET was obtained based on results from 352 patients (age: 37.4 ± 4.2) previously published (Ruiz-Alonso 2013; Ruiz-Alonso 2014; Mahajan 2015; Hashimoto 2017). PR was 56.5%, IR 39.9% and ongoing pregnancy per transfer (OT) of 43.2%. The clinical follow-up after pET based on NGS ERA predictor in 261 patients (age: 37.3 ± 5.1), however, was 70.9% PR, 55.7% IR and 59.4% OT. The reproductive outcome comparison thus shows a significant increase in PR (p-value = 0.000390), IR (p-value = 0.000003) and OT (p-value = 0.000101) in case of NGS ERA predictor.

Limitations, reasons for caution: The failure of an embryo to implant is a complex process that not only involves endometrial receptivity but also embryo quality. ERA only focuses on the endometrial origin or contribution of RIF.

Wider implications of the findings: These results demonstrate that the ERA NGS predictor enhances the clinical effectiveness of endometrial diagnosis in RIF patients when compared to ERA arrays predictor. This more accurate predictor tool, based on a wide reference set of samples with known clinical result, has led to significantly better reproductive outcome following pET.

Trial registration number: Not apply.

O-017 Interventions for unexplained infertility: a systematic review and network meta-analysis

R. Wang[1], N.A. Danhof[2], R.I. Tjon-Kon-Fat[2], M.J.C. Eijkemans[3], P.M.M. Bossuyt[4], M. Mochtar[2], F. Van der Veen[2], S. Bhattacharya[5], B.W.J. Mol[6], M. Van Wely[2]

[3]Department of Biostatistics and Research Support, Julius Center, UMC Utrecht

[4]Department of Clinical Epidemiology, Biostatistics and Bioinformatics, Academic Medical Center
[5]Institute of Applied Health Sciences, University of Aberdeen, Aberdeen, united Kingdom
[6]Department of Obstetrics and Gynaecology, Monash University and Monash Health, Clayton, Australia

Study question: Which is the most effective and safe intervention in couples with unexplained infertility, expectant management, ovarian stimulation (OS), intrauterine insemination (IUI), OS-IUI or IVF?

Summary answer: IVF and OS-IUI were the most effective but least safe interventions, while expectant management and IUI were the least effective but safest interventions.

What is known already: Existing systematic reviews have conducted head to head comparison of interventions using pairwise meta-analyses to evaluate the effectiveness of interventions in couples with unexplained infertility. As this approach only allows the comparison of two interventions at a time and is dependent on the availability of appropriate primary evaluative studies, it is difficult to identify the best intervention in terms of effectiveness and safety. Network meta-analysis compares multiple treatments in a single statistical model by using both direct and indirect evidence and provides a hierarchy of these treatments which can better inform clinical decision making.

Study design, size, duration: We performed a systematic review and network meta-analysis of relevant randomised controlled trials (RCTs). We searched electronic databases including MEDLINE, Embase, PsycINFO, CINAHL, the Cochrane Gynaecology and Fertility Group specialised register of controlled trials, the Cochrane Central Register of Studies Online, as well as reference lists to identify eligible studies. We also searched trial registers for ongoing trials.

Participants/materials, setting, methods: We included RCTs comparing at least two of following interventions in couples with unexplained infertility: 1) expectant management (including timed intercourse); 2) ovarian stimulation using gonadotropins, aromatase inhibitors or anti-estrogens; 3) IUI alone; 4) OS-IUI; and 5) in vitro fertilisation (IVF) or combined with intracytoplasmic injection (ICSI). The primary effectiveness outcome is a composite of cumulative live birth or ongoing pregnancy and the primary safety outcome is multiple pregnancy.

Main results and the role of chance: Of 906 titles and abstracts initially identified, we included 29 trials reporting on 4514 couples with unexplained infertility. The most frequent direct comparisons were OS versus OS-IUI (7 studies, 743 couples), OS-IUI versus IVF (6 studies, 1101 couples), and IUI versus OS-IUI (6 studies, 895 couples). Thirteen studies reported data on live birth or ongoing pregnancy in 3181 couples and 15 studies reported data on multiple pregnancy in 2834 couples.

Network meta-analysis showed that IVF resulted in more live births/ongoing pregnancies than expectant management (OR 2.87, 95%CI 1.31-6.29) and OS (OR 2.63, 95%CI 1.12-6.17); and it may also result in more live birth/ongoing pregnancies than IUI alone (OR 1.98, 95%CI 0.99-3.97) and OS-IUI (OR 1.58, 95%CI 0.96-2.59). OS-IUI may lead to higher live birth/ongoing pregnancy rate compared to expectant management (OR 1.82, 95%CI 0.98-3.39). The ranking showed that IVF was the most effective intervention, followed by OS-IUI, IUI alone and OS alone, with expectant management as the least effective intervention. Both IVF and OS-IUI resulted in more multiple pregnancies compared to IUI alone (OR 5.08, 95%CI 1.15-22.51; OR 5.55, 95%CI 1.34-23.06). There were no significant differences in multiple pregnancy between other interventions.

Limitations, reasons for caution: The included studies were heterogeneous in study population, treatment protocol and duration of follow-up. IVF in earlier studies was not always applied with single embryo transfer. Also long-term safety was not considered. As multiple pregnancy was not reported in many early publications, our findings should be interpreted with caution.

Wider implications of the findings: In couples with unexplained infertility, IVF provides the fastest way to have a baby while OS-IUI is also a competitive intervention. Both long-term safety of the offspring and financial costs should be considered in the timing of IUI and IVF in the context of shared decision making.

Trial registration number: not applicable.

O-018 Infertility diagnosis in female adolescent and young adult survivors of non-gynecological cancers: a population-based cohort study

M.P. Velez[1], N.N. Baxter[2], R. Barr[3], E.M. Greenblatt[4], K. Lajkosz[5], A. Korkidakis[6], H. Richardson[7], C.M. Booth[8], T.P. Hanna[8], A. G. Robinson[8], M. Green[9]

[1]Queen's University, Obstetrics and Gynecology, Kingston, Canada
[2]University of Toronto, Dalla Lana School of public Health, Toronto, Canada
[3]McMaster University, Department of Pediatrics, Hamilton, Canada
[4]Mount Sinai Hospital, Department of Obstetrics and Gynecology, Toronto, Canada
[5]Queen's University, ICES Queen's, Kingston, Canada
[6]Queen's University, Department of Obstetrics and Gynecology, Kingston, Canada
[7]Queen's University, Department of Public Health Sciences, Kingston, Canada
[8]Queen's University, Department of Oncology, Kingston, Canada
[9]Queen's University, Department of Family Medicine, Kingston, Canada

Study question: Do female adolescent and young adults (AYAs) survivors of selected non-gynecological cancers have a higher risk of subsequent infertility diagnosis than AYAs without cancer?

Summary answer: Female AYAs survivors of certain non-gynecological cancers have a higher risk of subsequent infertility diagnosis. The risk is influenced by previous parity.

What is known already: Cancer therapies have improved substantially, leading to dramatic increases in survival. As survival improves, there is increasing emphasis on optimizing quality of life among survivors. Many cancer therapies increase the risk of infertility. At this time, no population-based studies have been conducted to determine the risk of subsequent infertility diagnosis in female AYAs with non-gynecological cancers. The literature is limited to epidemiological studies comparing birth rates after cancer, or small studies using markers of the ovarian reserve as a proxy of infertility.

Study design, size, duration: A population-based cohort study using universal health care databases in the province of Ontario, Canada. All women 15-39 years of age diagnosed with brain, breast, hematological, head/neck, thyroid, melanoma, colorectal, or urological cancer from 1992-2011 who lived at least 5 years recurrence-free were identified (Exposed, n = 15107). Each cancer survivor was matched by age, census subdivision, and parity to 5 randomly selected cancer-free women (Unexposed, n = 64314), and followed subjects until December 31, 2016.

Participants/materials, setting, methods: Infertility diagnosis after one year of cancer was identified using information on physician billing claims through the Ontario Health Insurance Plan database (ICD-9 code). Women with infertility, tubal ligation, bilateral oophorectomy, or hysterectomy previous to cancer diagnosis were excluded. Log-binomial regression models were used to calculate the risk of infertility diagnosis adjusted for sociodemographic factors (adjusted Relative Risk -aRR). Adjusted models were further stratified by parity at the time of cancer diagnosis (nulliparous and parous).

Main results and the role of chance: Mean age at cancer diagnosis was 31.2 years (SD 6.3). The median follow-up time for cancer survivors was 13.9 years and for unexposed women 14.3 years ($p < 0.001$). Overall, the frequency of infertility diagnosis was higher in cancer survivors compared to unexposed women (12.0% vs. 9.4%, $p < 0.001$). Mean age of infertility diagnosis was 34.5 years (SD 5.7) in survivors and 34.9 years (SD 5.5) in unexposed women ($p < 0.001$). Differences between AYAs survivors and unexposed women varied by type of cancer, notably survivors of breast (aRR 1.38; 95% CI 1.23–1.55), hematological (aRR 1.42; 95% CI 1.28-1.59), thyroid (aRR 1.17; 95% CI 1.08–1.27), and melanoma (aRR 1.13; 95% CI 0.99-1.30), had a higher risk of infertility diagnosis than women without cancer. After stratification by parity, the association remained strong in nulliparous survivors of breast and hematological cancers, while it disappeared in parous women. Parity did not modify the effect on infertility in survivors of thyroid cancer, and the association remained significant in both groups. In survivors of melanoma and urological cancer a significant association was observed only in nulliparous women. Survivors of brain, head/neck, and colorectal cancers did not have a higher risk of infertility diagnosis compared to women without cancer.

Limitations, reasons for caution: The accuracy of infertility diagnosis using ICD-9 codes in administrative datasets has not been validated. Non-biologic factors that may influence the likelihood of seeking a fertility assessment may not be captured in administrative databases. Information regarding cancer stage or treatment was not available for this analysis.

Wider implications of the findings: Reproductive health surveillance in female AYAs with cancer is a priority, especially those with breast and hematological cancer diagnoses. Our finding of a potential effect of thyroid cancer (subject to over-diagnosis) and melanoma needs to be further studied, and if any effect is confirmed, possible mechanisms elucidated.

Trial registration number: not applicable.

O-019 Differential proteomic analysis of endometrial fluid suggests increased inflammation and extracellular matrix remodeling in non-implantative IVF cycles

M. Azkargorta[1], I. Escobes[1], I. Iloro[1], N. Osinalde[2], B. Corral[3], A. Exposito[3,4], B. Prieto[3,5], F. Elortza[1], R. Matorras[3,4,5]

[3]*Human Reproduction Unit., Cruces University Hospital., Bilbao, Spain*
[4]*BioCruces Health Research Institute, Basque Country University, Bilbao, Spain*
[5]*Instituto Valenciado de Infertilidad., IVI Bilbao, leioa, Spain*

Study question: Is there any difference in the protein composition of the endometrial fluid aspirate obtained the day of embryo transfer in cycles achieving and not achieving pregnancy?

Summary answer: We found 212 differentially expressed proteins when comparing 'implantative' and 'non-implantative' cycles, that is, those resulting in implantation success and failure.

What is known already: Endometrial fluid allows non-invasive characterization of the endometrium, and may contain important information on its receptivity when performing in vitro fertilization (IVF) cycles. Endometrial side of implantation has usually been studied with endometrial biopsy in a cycle prior to embryo transfer, focusing on "receptive/non-receptive" endometria, and with low-throughput proteomic techniques.

Study design, size, duration: We have compared the protein expression patterns in endometrial fluid aspirated from 38 women undergoing IVF, corresponding to 18 implantative and 20 non-implantative cycles using a high-throughput differential proteomic approach. The study period was 12 months.

Participants/materials, setting, methods: The population under study consisted of 38 women aged 18-40 years old, undergoing their first or second IVF/ intracytoplasmic sperm injection cycle, with normal uterus and endometrium, and 1-2 good quality embryos, and embryo transfer being performed on day 3. Endometrial fluid aspiration was performed immediately before the embryo transfer.

Filter-aided sample preparation was used for the in-solution tryptic digestion of the proteins present in the samples, followed by label-free mass spectrometry analysis.

Main results and the role of chance: From the 716 proteins detected in the differential proteomics analysis, 212 significantly differed in abundance between the groups under analysis ($p < 0.05$). Bioinformatic analyses denoted the deregulation of important processes governing receptivity, such as extracellular matrix remodeling, proteolytic activity and inflammatory signaling, and antimicrobial activity within the set of differential proteins. The results suggest higher activity of cytokines, including TNF, OSM and IL6, as well as lower activity of progesterone in non-implantative cycles. In addition, a number of pregnancy-related differential proteins were pinpointed in the mechanistic association analysis.

Limitations, reasons for caution: Our results were obtained from patients with normal uterus and endometrium and with good quality embryos, who had fresh day-3 embryo transfer, in stimulated cycles. Therefore, our observations may not be applicable to poor prognosis cases or non-stimulated cycles.

Wider implications of the findings: This work provides insights into the molecular features of implantative IVF cycles using non-invasive methods. It reveals that endometrial fluid aspirate may reflect an increased inflammatory state in non-implantative endometrium. This knowledge opens a new avenue for improving embryo transfer strategies and increasing pregnancy rates.

Trial registration number: Not applicable.

O-020 Pilot study investigating concentration of colony-stimulating growth factor (CSF) in uterine flushing as prognostic criterion of IVF cycle outcome in patients with recurrent implantation failure

D. Obidniak[1], A. Gzgzyan[2], D. Niauri[2], A. Kalugina[1]

[1]*AVA-Peter, Assisted Reproductive Technology, Saint-Petersburg, Russia C.I.S.*
[2]*Saint Petersburg State University, Medical Faculty, Saint-Petersburg, Russia C.I.S.*

Study question: Study question was if colony-stimulating growth factor can be used as reliable prognostic criterion of clinical pregnancy in "fresh" cycles of assisted reproductive technology.

Summary answer: Evaluation of CSF level in uterine flushing can be considered perspective prognostic criterion for IVF cycle outcome with sensitivity of 87.5% and specificity of 94.3%

What is known already: The concept of recurrent implantation failure (RIF) in assisted reproductive technology has been enlarged and the tactics for such patients have included searching prognostic criteria of IVF outcome with the aim to minimize the number of unsuccessful attempts and the risk of patient's drop-out. However the studies on this topic are limited as most suggested methods require endometrial biopsy and subsequently do not allow to perform fresh embryo transfer therefore there is still need for non-invasive model for prediction of IVF cycle outcome.

Study design, size, duration: Study type: Interventional.
Design: randomized controlled pilot study.
Intervention Model: Parallel Assignment.
Masking: open-label
Size: 83 patients.
Duration: 12 months.

Participants/materials, setting, methods: After obtaining board approval 83 women aged 22–39 years were recruited. Matching criteria: recurrent implantation failure, normal karyotype, absence of uterine factors of infertility. The patients were randomized into study group (N = 43) and control group (N = 40): no intervention. At the day of oocyte retrieval the uterine flushing was collected using insemination catheter (CCD). CSF concentration in uterine flushing was determined using ELISA with following calculation per gram of protein.

Main results and the role of chance: As a primary assessed outcome the clinical pregnancy rate was analysed: there was no significant difference comparing between groups ($X^2 = 0.018$, $p > 0.05$, CC = 0.015). Thus the method of collection of uterine flushing doesn't affect IVF cycle outcome and can be used routinely. The CSF concentration in uterine flushing was significantly higher in women with clinical pregnancy. The ROC-curve showed sensitivity of 87.5% and specificity of 94.3% with cut-off value of CSF being 0.151

Limitations, reasons for caution: As the study was considered as pilot the number of recruited participants is limited. Thus further investigation is needed.

Wider implications of the findings: These data prove the necessity for further research of CSF role in implantation process and need for consideration the lack of CSF as a possible cause of recurrent implantation failure.

Trial registration number: not applicable.

Monday 2 July 2018 Room 113 + 114 + 115 10:00–11:30

O-021 The seminiferous tubule caliber pattern as evaluated at high magnification during microdissection testicular sperm extraction predicts sperm retrieval in patients with non-obstructive azoospermia

E. Caroppo[1], E.M. Colpi[2], G. Gazzano[3], L. Vaccalluzzo[2], E. Piatti[4], G. D'Amato[1], G.M. Colpi[4]

[1]*Asl Bari, Dpt Maternal and Child Health- Reproductive and IVF Unit- PTA F Jaia Conversano BA- Italy, Bari, Italy*

[2]Clinica San Carlo, Andrology and IVF Unit, Paderno Dugnano MI, Italy
[3]Istituto Auxologico Italiano IRCCS, Division of Anatomic Pathology, Milano, Italy
[4]Procrea Institute, Andrology Unit, Lugano, Switzerland

Study question: Is the seminiferous tubule caliber pattern as evaluated during microdissection testicular sperm extraction (microTESE) predictive of sperm retrieval success in patients with non-obstructive azoospermia (NOA)?

Summary answer: sperm retrieval was successful in 90% of cases when dilated tubules were found, but only in 7% of cases when only not-dilated tubules were retrieved.

What is known already: MicroTESE proved to be the gold standard surgical approach to patients with NOA. However, despite it was introduced in the clinic about 20 years ago, still a great variability in sperm retrieval rates is recorded among centers.Among the factors able to explain this issue, the pattern of semiferous tubules caliber found at high magnification has been suggested to be associated with the chance of retrieving sperm. Few studies in the past, most with small sample size, have dealt with this issue, but none provided diagnostic accuracy measures in support of the association between seminferous tubules pattern and sperm retrieval rates.

Study design, size, duration: The present cross-sectional study was conducted between January 2015 and July 2017 on 143 infertile men with non-obstructive azoospermia (NOA) undergoing unilateral (64) or bilateral (79) microTESE. Assessment of sperm retrieval was evaluated as per testis (N = 222). Stepwise binary logistic regression was run to identify predictive factors of successful sperm retrieval (SSR) and seminiferous tubules pattern among serum FSH, LH and testosterone level, mean testis volume, testis histology and seminiferous tubules pattern.

Participants/materials, setting, methods: During microTESE, if present, dilated tubules (DT) were retrieved, otherwise any tubule whose caliber was greater than that of the surroundings was taken (slightly dilated tubules – SDT). When no DT or SDT were found, not dilated tubules (NDT) were excised according to a sort of mapping. A fragment of one or more of the tubules of the same diameter (DT, SDT or NDT) was fixed in Bouin's solution and sent for histological analysis.

Main results and the role of chance: Sperm were retrieved in 95 out of 222 testes (42,8%); DTs were found in 90% of testes with successful sperm retrieval (SSR), SDTs in 47% and NDTs in only 7% ($p < 0.0001$). The median number of sperm retrieved was significantly higher in DTs compared to SDTs and NDTs (5.000, IQ range 9.000-300.000, 1.000, IQ range 500-450.000, 500, IQ range 500 respectively; $p < 0.0001$). Stepwise binary logistic regression for SSR prediction excluded FSH, LH, testosterone and testicular volume from the model; on the other hand the tubules caliber pattern allowed the correct classification of 82,4% of testes (chi square 133.731, $p < 0.0001$, intercept odds ratio [IOR] 0.84), while histology classified 72,7% of them (chi square 63.329, $p < 0.0001$, IOR 38.9), with a good (AUC 0.89) and fair (AUC 0.70) diagnostic accuracy respectively as demonstrated by ROC AUC estimate computed on the predictive probabilities. The combination of both variables, however, explained the results in terms of SSR in 86,7% of cases (chi square 156.749, $p < 0.0001$, IOR 28.4,) with an excellent diagnostic accuracy (0.93). Stepwise binary logistic regression for the prediction of seminiferous tubules pattern individuated testis histology as the only significant predictor (chi square 33.843, $p < 0.0001$), although with a poor diagnostic accuracy (AUC 0.67).

Limitations, reasons for caution: the seminiferous tubules patter was subjectively evaluated, but the skill and experience (about 900 microTESE procedures performed to date) of the surgeon can account for the reliability of the results.

Wider implications of the findings: the present study provides reliable accuracy measures in support of the relationship between seminiferous tubules caliber pattern and SSR in patients with NOA. The tubules pattern may represent an additional outcome measure of microTESE and, together with histology, provide additional information on the degree of spermatogenesis impairment in individual patients.

Trial registration number: N/A.

O-022 Characterization of spermatogenic function in NOA men aiming at predicting success of testicular sperm retrieval

C. O'Neill, A. Parrella, M. Irani, Z. Rosenwaks, G. Palermo

Weill Cornell Medical College, CRMI, New York City- NY, U.S.A.

Study question: Can germ cell characterization of testicular biopsy samples provide information on seminiferous tubule function in NOA men and enhance our ability to identify spermatozoa?

Summary answer: Using germ cell stage-specific markers, we can predict the extent of spermatogenic dysfunction in NOA men and relate it to the eventual retrieval of spermatozoa.

What is known already: In men with non-obstructive azoospermia (NOA) that undergo micro-TESE, about 40-60% of cases fail to yield spermatozoa. In these patients, the array of spermatogenetic progress within the seminiferous tubule vary from hypospermatogenesis, to maturation arrest, or germ cell aplasia (sertoli-cell only syndrome). These features can be difficult to identify even during surgical sperm extraction and about half of the cases fail to provide injectable sperm cells. The utilization of immunofluorescence or the isolation of RNA targeting specific germ cell maturational stages can help to identify the progression of spermatogenesis and offer a more complete profile to the reproductive physician.

Study design, size, duration: Over the course of the past year, ten samples retrieved from NOA men were analyzed for germ cell stage identification. Additionally, two OA (obstructive azoospermia) samples served as control. Patients were then categorized as to their extent of spermatogenesis using immunofluorescence markers previously validated in the OA control. Gene expression analysis of samples ($n = 6$) confirmed the presence of specific germ cell stages and helped to map the extent of the spermatogenic process.

Participants/materials, setting, methods: A total of 12 men underwent micro-TESE to identify spermatozoa for use with ICSI. All specimens were fixed and processed for immunofluorescent analysis using germ cell markers, DAZL (all germ cell stages), BOULE (meiotic), and PNA (post-meiotic). To confirm immunofluorescent findings, RNA-seq assessing 60,448 genes was carried out on some specimens for corresponding gene expression of the markers.

Main results and the role of chance: OA samples were positive for all immunofluorescent germ cell markers tested and spermatogenic line presence was further validated via RNA-seq. Immunofluorescent analysis of testicular specimens (NOA) revealed a varying proportion of germ cells at intermediate stages of meiosis. Of these, two NOA men displayed signal for DAZL, BOULE, and PNA, suggesting retention of the spermatogenic line and indeed they yielded scant spermatozoa that were used for ICSI, although neither resulted in a pregnancy. NOA patients, in which no spermatozoa were retrieved, evidenced a scattered number of immature germ cells compared to the control, which appeared smaller in size and irregular in shape. No post-meiotic stages were identified using the acrosomal marker, PNA. Analysis of differential gene expression corroborated our findings, revealing a significant decrease in expression of spermatogenic markers for the germ cell stages of interest. All NOA patients had poor expression of DAZL (all germ cells), BOLL (meiotic marker), and ACRBP (post-meiotic marker) compared to the OA control, with the lowest expression in NOA patients where no spermatozoa were identified ($P < 0.001$). Correspondingly, NOA men with spermatozoa identified in the testicular biopsy portrayed an increased expression of DAZL as compared to NOA patients that failed to yield spermatozoa ($P < 0.01$).

Limitations, reasons for caution: A refined method for characterization of germ cells will further portray a detailed depiction of seminiferous tubule function. Due to sample availability, not all specimens were analyzed for both immunofluorescence and RNA-sequencing. Querying unfamiliar genes will help in gaining information on the etiology of this severe form of male infertility.

Wider implications of the findings: The utilization of a non-invasive method to query specific genes that predict seminiferous tubule function will help to identify the best candidates for TESE likely to yield spermatozoa, sparing patients costs and emotional distress. Careful interpretation of RNA transcripts will help to illuminate the etiology behind this severe condition.

Trial registration number: N/A.

O-023 MSOME I + II: a new cut-off value for male infertility and embryo development prediction on intracytoplasmic sperm injection cycles

E. Borges Jr.[1], B.F. Zanetti[2], D.P.A.F. Braga[3], R.R. Provenza[4], R.C.S. Figueira[5], A. Iaconelli Jr.[1]

[1]*Fertility Medical Group, Clinical Department, Sao Paulo, Brazil*
[2]*Instituto Sapientiae - Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific Department, Sao Paulo, Brazil*
[3]*Fertility Medical Group, Scientific Department, Sao Paulo, Brazil*
[4]*Fertility Medical Group, Andrology laboratory, Sao Paulo, Brazil*
[5]*Fertility Medical Group, IVF laboratory, Sao Paulo, Brazil*

Study question: Can motile sperm organelle morphology examination (MSOME) improve semen analysis by better defining male infertility and providing better prediction for intracytoplasmic sperm injection (ICSI) outcomes?

Summary answer: MSOME I + II ≥ 5.5% is a predictor for severity of the male factor and for the rate of blastocysts.

What is known already: Human sperm morphology has been described as an essential parameter for the diagnosis of male infertility and a prognostic indicator of natural or assisted pregnancies. Nevertheless, standard morphological assessment remains a subjective analysis and its impact on ICSI is also of limited value. The direct selection of spermatozoa by MSOME has proved to lead to better ICSI outcomes, such as higher implantation, pregnancy and live birth rates. However, whether the proportion of normal spermatozoa by WHO parameters can be correlated with MSOME classification and whether this could be correlated with ICSI outcomes are questions that remain to be elucidated.

Study design, size, duration: This prospective-cohort study included data from 483 patients undergoing conventional seminal analysis from June/2015 to June/2017. The spermatozoa were graded as: MSOME I, normal form and no vacuoles; MSOME II, normal form and ≤2 small vacuoles; MSOME III, normal form >2 small vacuoles or one large vacuole; and MSOME IV, large vacuole and abnormal head shapes or other abnormalities. The sum of MSOME Grades I and II was used as a normal spermatozoa parameter.

Participants/materials, setting, methods: The study was performed in a private university-affiliated IVFncenter. The proportion of MSOME grades were correlated with semen volume, concentration, total sperm count, motility, morphology and total motile sperm count (TMSC) by linear regression models. The correlation of MSOME with ICSI outcomes (i.e. fertilization rate, high-quality embryos and blastocyst rate, implantation, cycle's cancelation, and pregnancy rates) were evaluated by linear and logistic regression models. The MSOME normality cutoff was defined by ROC curve.

Main results and the role of chance: MSOME I + II was positively correlated with semen concentration ($\beta = 0.281$ $p < 0.001$), total sperm count ($\beta = 0.224$ $p < 0.001$), motility ($\beta = 0.178$ $p < 0.001$), progressive motility ($\beta = 0.192$ $p < 0.001$), morphology ($\beta = 0.341$ $p < 0.001$), and TMSC ($\beta = 0.2010$ $p < 0.001$). The MSOME I + II was statistically different between WHO seminal classifications, with normozoospermia group having the highest percentage of MSOME Grades I + II (14.10%). We observed a decreased incidence of MSOME I + II with the increased severity of the seminal classification, and oligoasthenoteratozoospermia was the most affected group (MSOME I + II 3.95% $p < 0.001$). MSOME I + II was positively correlated with fertilization ($\beta = 0.197$ $p = 0.044$), high-quality embryos ($\beta = 0.306$ $p = 0.013$), and blastocyst($\beta = 0.248$ $p = 0.047$) rates. The highest area under the curve (AUC) to discriminate blastocyst rate <50% from that ≥ 50% was obtained with MSOME Grades I + II ($AUC_{ROC} = 0.66$), with cut-off value of ≥ 5.5%, in which a sensitivity of 0.72 and specificity of 0.41 were obtained. Using this parameter to define normality, a significant difference in the blastocyst rate between MSOME I + II < 5.5% and MSOME I + II ≥ 5.5% could be noted (28.53 ± 5.69 vs 50.14 ± 5.05 %, $p = 0.005$) even when adjusted for confounding variables such as: male and female ages, ejaculatory abstinence and number of retrieved oocytes.

Limitations, reasons for caution: The limitation of the present study is the small samples size and the lack of correlation between MSOME results and clinical outcomes.

Wider implications of the findings: MSOME I + II ≥ 5.5% is a useful cut-off for the diagnosis of infertility severity and for the prediction of ICSI outcomes. The future use of MSOME as a routine method may be reliable for assessing male infertility and its impact on ICSI.

Trial registration number: None.

O-024 Effect of reactive oxygen species on the methylation status of human sperm imprinting genes, seminal plasma metabolites, and semen parameters

M. Darbandi[1], S. Darbandi[2], A. Agarwal[3], S. Esteves[4,5,6], P. Sengupta[7], S. Dutta[7], H.R. Khorram Khorshid[8], M.M. Akhondi[2], S. Al-Hasani[9], M.R. Sadeghi[2]

Study question: Is there an association between seminal plasma reactive oxygen species (ROS) levels and alterations of imprinting gene methylation patterns, seminal plasma metabolites, and semen parameters?

Summary answer: A positive association exists between ROS levels and alterations in H19-Igf2 methylation as well as metabolite concentration, with an overall detrimental effect on semen quality.

What is known already: Oxidative stress (OS) is associated with sperm dysfunction via distinct pathophysiology mechanisms. Recent studies suggest that ROS affect methylation of genes involved in male fertility. Furthermore, OS may alter the seminal plasma (SP) metabolite milieu and contribute to sperm dysfunction. However, it remains unknown as to what extent the effect of seminal ROS on gene methylation, seminal metabolites, and sperm quality is level-dependent. Also, a possible association between ROS-induced H19/Ig2 methylation and SP metabolites with semen quality is yet to be confirmed. Such studies may help unravel pathophysiologic pathways leading to unexplained male infertility and allow development of targeted therapies.

Study design, size, duration: Prospective study including fresh semen specimens of 150 men between April and May 2016. Each patient contributed one specimen which was analyzed for ROS by chemiluminescence, and classified according to seminal ROS levels [in relative light units (RLU)/sec/106 sperm]: Group 1 (n = 39): Low (ROS < 20 RLU), Group 2 (n = 38): Mild (20 RLU≤ROS < 40 RLU), Group 3 (n = 31): Moderate (40 RLU≤ROS < 60 RLU), and Group 4 (n = 43): High (ROS≥60 RLU).

Participants/materials, setting, methods: Participants were normozoospermic (WHO 2010) men attending an infertility clinic. Specimens were collected after 3-5 days abstinence. A comprehensive analysis of SP and sperm function parameters were carried out, including conventional semen characteristics (computer-assisted semen analysis; CASA), measurement of total antioxidant capacity (TAC), sperm DNA fragmentation (sperm chromatin dispersion test), chromatin maturation index (aniline blue), H19-Igf2 methylation status (methylation-specific polymerase chain reaction), and untargeted seminal metabolic profiling using nuclear magnetic resonance spectroscopy (1H-NMR).

Main results and the role of chance: The methylation status in promoter region of H19 and Igf2 genes was significantly different in specimens with high/moderate ROS levels than mild/low counterparts ($P < 0.001$). Metabolic fingerprinting by 1H-NMR revealed upregulation of trimethylamine N-oxide ($P < 0.001$) and downregulation of tryptophan ($P < 0.05$) as well as tyrosine/tyrosol ($P < 0.01$) in SP samples with high ROS levels. A significant reduction in total sperm motility ($P < 0.05$) and concentration ($P < 0.001$) was noted in

specimens with high ROS levels, whereas higher CMI and sperm DNA fragmentation index (DFI) were noted both in specimens with moderate ($P < 0.05$) and high ROS ($P < 0.005$). In contrast, TAC values were decreased in all specimens but those with low ROS levels ($P < 0.001$). Pearson's and Spearman correlations showed that ROS levels were positively correlated with Igf2 methylation ($r = 0.19$, $P < 0.05$), DFI ($r = 0.27$, $P < 0.001$), CMI ($r = 0.21$, $P < 0.01$), and trimethylamine N-oxide ($r = 0.45$, $P < 0.05$) and negatively correlated with H19 methylation ($r=-0.20$, $P < 0.05$), tryptophan ($r=-0.45$, $p < 0.05$), sperm motility ($r=-0.18$, $P < 0.05$), sperm vitality ($r=-0.35$, $P < 0.001$), sperm concentration ($r=-0.38$, $P < 0.001$).

Limitations, reasons for caution: Although none of the subjects reported a history of pelvic and genital infections, chronic diseases, and endocrine abnormalities, risk factors such as use of medication and smoking habits were not consistently recorded. Also, the effect of ejaculatory abstinence duration was not controlled.

Wider implications of the findings: Our study suggests a link between ROS-induced H19/Ig2 methylation and seminal plasma metabolites with semen quality. We speculate that deterioration of semen quality and sperm DNA integrity in specimens with moderate/high ROS levels is mediated by alterations in the methylation status of H19/Ig2 genes and SP metabolite concentrations.

Study question: Does seminal plasma proteome play a role in the preservation of sperm fertilizing ability in men with high levels of reactive oxygen species (ROS)?

Summary answer: Increased antioxidant activity and endopeptidase inhibitory mechanisms in seminal plasma may contribute to the preservation of the fertilizing potential of men with high ROS levels.

What is known already: During spermatogenesis, spermatozoa shed majority of their cytoplasm and thereby lose most of their antioxidant defenses. Therefore, they become dependent on antioxidant protection provided by seminal plasma which is largely made up of secretions from the male accessory glands. It is known that an imbalance between ROS production and antioxidant protection results in oxidative stress, which is linked with impaired sperm function and fertilization, ultimately contributing to male infertility. Seminal plasma also plays a major role in preventing premature capacitation. However, the molecular mechanisms behind the importance of seminal plasma in the preservation of male fertilizing ability are largely unknown.

Study design, size, duration: Semen analysis including liquefaction, viscosity, volume, and pH was performed in 17 semen samples. Samples were divided into two groups according to the ROS levels measured by chemiluminescence: Control group – ROS level <102RLU/s/million sperm ($n = 8$); ROS positive group – ROS level >102 RLU/s/million sperm ($n = 9$). Proteomic analysis of seminal plasma samples was performed to identify possible differential expressed proteins (DEPs) between the experimental groups, which were further selected for validation by Western Blot (WB).

Participants/materials, setting, methods: Semen samples were voluntarily provided by proven fertile men (men with at least one child). Seminal plasma was collected after centrifugation of liquefied semen at 4000Xg and protein concentration was estimated by the BCA assay. A pool of 5 samples from each experimental group was used for quantitative proteomic analysis (LC-MS/MS). The main core networks were identified by functional enrichment using STRING software and key DEPs were selected for validation by WB.

Main results and the role of chance: A total of 44 proteins were found to be differentially expressed between the experimental groups. Serine-type endopeptidase inhibitor activity (GO:0004867, false discovery rate $p = 0.00006$) and antioxidant activity (GO:0016209, false discovery rate $p = 0.00523$) were among the main molecular functions in which these DEPs were involved. In the ROS positive group, semenogelin-1 and semenogelin-2, which are proteins involved in seminal coagulum formation, were underexpressed ($p = 0.00074$, $p = 0.00023$, respectively). On the other hand, some proteins involved in antioxidant defense, haptoglobin (HP) and peroxiredoxin-4 (PRDX4) were overexpressed ($p = 0.00349$, $p = 0.00099$, respectively). Similarly, Serpin B6 (SERPINB6), a serine protease inhibitor, was also overexpressed in ROS positive group ($p = 0.00424$). The expression of these DEPs was identified by WB, for control ($n = 8$) and ROS positive ($n = 9$) groups, and fold variation to the control group was calculated by densitometry. MedCalc software was used for statistical data analysis. Firstly, the Tukey test was used for outlier detection, followed by a two-tailed Mann-Whitney test. The protein expression obtained by WB for the selected DEPs was not statistically significant between the experimental groups: SEMG1 ($p = 0.5286$) SEMG2 ($p = 0.2002$), HP ($p = 0.3865$), PRDX4 ($p = 0.6304$) and SERPINB6 ($p = 0.6304$).

Limitations, reasons for caution: The distinct results obtained between proteomics and WB could be explained by the differences in the sensitivity and reproducibility of these methods. Furthermore, only 5 of the 44 DEPs identified by proteomics were validated by WB.

Wider implications of the findings: Different expression pattern of seminal plasma proteins in fertile men with high levels of ROS may be responsible for the preservation of the spermatozoa fertilizing capacity. This may be attributed to the overexpression of proteins with antioxidant and endopeptidase inhibitor activity. Other DEPs must be investigated to test this hypothesis.

Trial registration number: not applicable.

O-026 Exosomal miRNAs in seminal plasma are markers of the origin of azoospermia and can predict the presence of sperm in testicular tissue

S. Larriba[1], M. Barceló[1], A. Mata[2], L. Bassas[2]

[1]*Institut d'Investigació Biomèdica de Bellvitge-IDIBELL, Human Molecular Genetics Group, Hospitalet de Llobregat- Barcelona, Spain*
[2]*Fundació Puigvert, Andrology Service, Barcelona, Spain*

Study question: Are exosomal microRNAs (miRNAs) in seminal plasma (SP) useful as markers of the origin of azoospermia and the presence of sperm in the testis?

Summary answer: The potential of SP miRNAs contained in exosomes as biomarkers for selecting azoospermic individuals with real chances of obtaining spermatozoa from the testis is shown.

What is known already: There are no precise non-invasive diagnostic methods for classifying the origin of the sperm defects and the spermatogenic reserve of the testis in azoospermic infertile men. The diagnosis of such individuals is often based on the practice of biopsies. In this context it is reasonable to study the presence of organ-specific markers in human semen that contains fluid from the testis and the male reproductive glands, which could help in the diagnosis and prognosis of azoospermia. Additionally, SP contains high concentrations of small extracellular vesicles (sEVs), particularly exosomes, which originate from multiple cellular sources in the male reproductive tract.

Study design, size, duration: Case and control prospective study. This study compares the miRNA content of exosomes in semen samples obtained from 9 normozoospermic fertile individuals (control group); 14 infertile men diagnosed with azoospermia due to spermatogenic failure and 13 individuals with obstructive azoospermia and conserved spermatogenesis. Additionally, three severe oligozoospermic individuals ($<5 \times 10^6$ sperm/ml) were included in the study.

Participants/materials, setting, methods: A differential high-throughput miRNA profiling analysis using miRNA qPCR panels (Exiqon) was performed in

SP exosomes from azoospermic and fertile individuals. Unpaired two-tailed t test was used to analyze the differences in expression of miRNAs. Validation of miRNA candidates was performed by RT-qPCR analysis in a larger cohort of individuals. Multivariate logistic regression and receiver operating characteristic (ROC) curve analysis of the expression values were used to predict/identify azoospermia origin, as well as residual spermatogenesis.

Main results and the role of chance: A total of 623 miRNA were included in the study and 397 miRNAs (63,7%) were consistently detected in samples from the groups of the study and statistically analysed, which revealed altered patterns of miRNA expression in infertile patients. We focused on the miRNAs that were differentially expressed between azoospermia as a result of an obstruction in the genital tract (having conserved spermatogenesis) and azoospermia due to spermatogenic failure, and described the expression values of one miRNA (miR-A*) in exosomes from semen as a predictive biomarker test for the origin of azoospermia with high sensitivity and specificity (>90%). Furthermore a model that included the miR-B* and the miR-C* expression values is also described as useful for predicting the presence of residual spermatogenesis in individuals with severe spermatogenic disorders with diagnostic accuracy.

*Note: The specific names of the miRNAs included in the model are not shown as a patent is being applied for their use as diagnostic markers.Please, consider all this information as confidential material.

Limitations, reasons for caution: Further studies which involve a larger cohort of individuals would be needed.

Wider implications of the findings: Our findings contribute to the search for the most valuable genetic markers which are potentially useful as tools for predicting the origin of azoospermia and the presence of residual spermatogenesis.

Trial registration number: Not applicable.

SELECTED ORAL COMMUNICATIONS

Monday 2 July 2018 Room 117 10:00–11:30

O-027 Is follicular size at oocyte pick-up (OPU) a predictor of blastocyst development? A study evaluating morphokinetic development and cumulus cell (CC) gene expression

S. Kahraman, C. Pirkevi Cetinkaya, M. Cetinkaya

Istanbul Memorial Hospital-, ART and Reproductive Genetics Center, Istanbul, Turkey

Study question: Is follicular size at OPU a predictor of blastocyst development when evaluated by morphokinetic variables and CC gene expression?

Summary answer: Follicular size correlated significantly with blastocyst quality and viability as reflected in morphokinetic variables and is a more reliable indicator than CC gene expression.

What is known already: A correlation between follicular size and embryo development as reflected in morphokinetics was found in our previous study, (Kahraman et al, 2017). We conducted this further study of CCs obtained from follicles of different sizes, for the first time evaluating both morphokinetic development to the blastocyst stage and gene expression of CCs.

Study design, size, duration: This prospective cohort study was based on 2495 COCs belonging to 184 patients and was performed between July 2014 and September 2015. Patient inclusion criteria: age ≤ 39 years, BMI < 30 kg/m^2, ≥ 8 oocytes retrieved, < 2 previous treatment cycles, and exclusion criteria: recurrent pregnancy loss, severe endometriosis, PGD or PGS, oocytes > 24, embryo transfer (ET) on day 5, PCOS, uterine anomaly, severe male infertility.

Participants/materials, setting, methods: Morpokinetic variables for cleavage events (t2) up to the expanded blastocyst stage were annotated according to follicular size. Five genes (TNFAIP6, PTGS2, HAS2, PTX3 and GDF9) were evaluated. CC gene expressions were analysed according to patient specific variables: age, BMI, AMH and follicular size. Embryos reaching (eRB) or failing to reach blastocyst (eFRB), developing into bad (BQ), top (TQ) and good quality (GQ) blastocysts were analysed using generalized linear mixed models (GLMMs) with logit link.

Main results and the role of chance: When morphokinetics of embryos coming from large and small follicles were compared, those from small follicles were found to develop faster than embryos coming from large follicles for all cleavage timings. The highest rate of top and good quality blastocysts was achieved in embryos coming from large follicles, a higher rate of direct cleavage and developmental arrest were observed in embryos obtained from small follicles. There was also a correlation between blastocyst quality and CC gene expression of HAS2 and GDF9, but only when evaluated together with follicular size, age, BMI and AMH. Furthermore, no such correlation was found in the case of other gene expressions studied. Our study suggests that, for clinical purposes, follicular size together with morphokinetic variables are a more practical indicator than CC gene expression of the likelihood of oocytes developing into transferable blastocyst.

Limitations, reasons for caution: Results were obtained in a defined IVF setting and cannot necessarily be translated in another laboratory.

Wider implications of the findings: Our study suggests that, for clinical purposes, follicular size together with morphokinetic variables are a more practical indicator than CC gene expression of the likelihood of oocytes developing into transferable blastocyst.

Trial registration number: clinicaltrials.gov NCT02230449.

O-028 Acetyl-CoA enrichment from acetate is higher in cumulus cells associated with mature oocytes

S. Anderson[1,2], N. Snyder[3], B. Gocial[1,2], D. Brasile[1,2], E. Davies[1], M. Glassner[1,2], J. Orris[1,2]

[1]*Main Line Fertility Center, Reproductive Medicine, Bryn Mawr, U.S.A.*
[2]*Ob/Gyn Department, Drexel University College of Medicine, Philadelphia, U.S.A.*
[3]*Drexel University, A.J. Drexel Autism Institute, Philadelphia, U.S.A.*

Study question: Is enrichment of acetyl-CoA from acetate in individual cumulus cell complexes (CCC) associated with oocyte maturity?

Summary answer: Enrichment of acetyl-CoA from acetate is higher in cumulus cells associated with mature metaphase II oocytes compared to immature oocytes.

What is known already: Cumulus cells have been reported by others to be highly glycolytic. However, in previous research we found that cumulus cells had low labeling of the acetyl-CoA pool derived from glucose. In contrast, labeling with acetate was remarkably high into acetyl-CoA, which is indicative of active metabolism. The objective of this study was to develop a method to study metabolism in individual CCC to determine if this enrichment of acetyl-CoA from acetate is associated with corresponding oocyte maturity.

Study design, size, duration: This prospective, controlled, and blinded study was conducted at a private fertility center and collaborating university biochemistry research laboratory. Patients were screened using strict inclusion/exclusion criteria, and all patients received the same controlled ovarian stimulation protocol. CCC were transported to the biochemistry research laboratory, where they were individually analyzed. Acetyl-CoA enrichment from acetate was measured in 490 individual sets of CCC from 31 patients pursuing in vitro fertilization (IVF) in 2017.

Participants/materials, setting, methods: CCC were removed from oocytes after oocyte retrieval procedure and placed individually into labeled microcentrifuge tubes for metabolic testing. CCC were incubated with stable isotope ^{13}C-labeled acetate substrate. The % relative enrichment of acetyl-CoA was determined using liquid chromatography-high resolution mass spectrometry (LC-HRMS), which maintains a quantitative substrate to product relationship. Therefore, the total number of cells in the CCCs, which varies between oocytes, did not factor into the metabolic analysis.

Main results and the role of chance: Statistical significance was set at $P<.05$, and data were analyzed with SAS/STAT software. The mean % enrichment of acetyl-CoA in CCC from mature metaphase II oocytes (45.9 ± 1.2) was significantly higher ($p < 0.05$) than in those CCC associated with immature prophase I and metaphase I oocytes (39.2 ± 1.4). In addition, the mean %

enrichment of acetyl-CoA in CCC collected from women less than 34 years of age (45 ± 1.45) was higher than ($p < 0.05$) in those CCC from woman greater than 34 years of age (40.8 ± 2.2).

Limitations, reasons for caution: Our ongoing clinical trial is being conducted to determine if % enrichment of acetyl-CoA in CCC can be considered to be predictive of oocyte maturity. In addition, biochemical analysis of CCC using LC-HRMS may not be economically feasible in most clinical IVF settings.

Wider implications of the findings: The % acetyl-CoA enrichment from acetate, which is indicative of active metabolism, was found to be higher in individual CCC associated with mature oocytes compared to immature oocytes. This stable isotope tracing methodology of individual CCC may be a promising new non-invasive approach to study metabolism in associated oocytes.

Trial registration number: clinicaltrials.gov/ct2/show/NCT02793752

O-029 Oocyte meiotic spindle morphology is a predictive marker of blastocyst ploidy. A prospective cohort study

L. Tilia[1], C. Venetis[2], S. Cooke[3], M. Chapman[2]

[1]IVF Australia, Eastern Sydney, Maroubra, Australia
[2]University of New South Wales, School of Women's and Children's Health, Sydney, Australia
[3]IVF Australia, Scientific Director, Greenwich- Sydney, Australia

Study question: Is oocyte meiotic spindle (OMS) morphology at the time of intra-cytoplasmic sperm injection (ICSI) a predictive marker of blastocyst ploidy?

Summary answer: OMS morphology is a predictive marker of blastocyst ploidy. Oocytes with normal meiotic spindle morphology are associated with a significantly higher rate of blastocyst euploidy.

What is known already: Euploid embryos result in higher pregnancy rates, fewer miscarriages and the birth of healthy offspring. However, preimplantation genetic testing (PGT) is invasive and costly while morphologic or morphokinetic markers are unreliable. Oocyte aneuploidy is the main cause of embryonic aneuploidy and can result from OMS abnormalities leading to chromosome alignment and segregation errors. The oocyte meiotic spindle can be non-invasively visualised using polarised light microscopy (PLM). Morphologically normal meiotic spindles are positively associated with cleavage stage embryonic euploidy and pregnancy. The association of OMS morphology with blastocyst ploidy has not previously been investigated.

Study design, size, duration: This is a prospective analysis of patients (194 patients, 221 cycles) undergoing ICSI with the intention to biopsy blastocysts for PGT between 2014 and 2017. At the time of ICSI, OMS morphology was visualized by PLM and classified as: normal, dysmorphic, translucent, not visible or in telophase. Day 5/6 blastocyst biopsy was performed on suitably progressing embryos by embryologists blind to the OMS classification. Whole genome sequencing was used to analyse the biopsied trophectoderm cells.

Participants/materials, setting, methods: The association between spindle morphology and embryo PGT results was evaluated using generalized equation estimating regression methods while accounting for non-independence of data. The additional value of OMS morphology to morphology and female age in predicting euploidy was also examined. All analyses were performed both by a) 'intention-to-treat (ITT)" where oocytes not resulting in biopsied blastocysts were considered equivalent to an aneuploid blastocyst and b) 'as treated analysis (ATA)" where only biopsied blastocysts were analysed.

Main results and the role of chance: Mean female age was 37.8 years (95% CI: 37.2-38.4) and number of oocytes collected per cycle was 12.1 (95%CI: 11.2-13.1). Overall, OMS morphology was classified for 2056 oocytes at ICSI. Most oocytes had a normal spindle($n = 1080$), followed by dysmorphic($n = 463$), not visible($n = 268$), translucent($n = 157$) and in telophase($n = 88$). OMS morphology was strongly associated with the probability of the oocyte being fertilized ($p < 0.001$), producing a day-3 embryo ($p < 0.001$) and resulting in a biopsied blastocyst ($p < 0.001$). Oocytes with normal spindles showed the best potential followed by dysmorphic, translucent, not visible & telophase spindles. The presence of a normal OMS was positively associated with euploidy compared to oocytes with all other OMS types combined, either per ITT: odds ratio (OR): 2.16 [95%CI: 1.64-2.85] or ATA: OR: 1.57 (95%CI: 1.11-2.21). The type of OMS was associated with the probability of euploidy (ATA:$p = 0.043$ & ITT: $p < 0.001$). Blastocysts originating from oocytes with normal spindles had the highest probability of being euploid (44.7% of biopsied blastocysts) (dysmorphic:40.3%; translucent: 26.4%, not visible:21.9 and telophase: 0%). Even after controlling for female age, blastocyst quality (top vs. good) and developmental stage (blastocyst vs. expanding vs. hatching), the presence of a normal spindle was strongly associated ($p = 0.008$) with the probability of euploidy (normal:44.8% vs. other:33.8%).

Limitations, reasons for caution: This study was performed in patients with an indication for PGT and hence might not be representative of the general IVF population. The oocyte meiotic spindle reflects oocyte quality and only the maternal contribution to embryo ploidy. Its assessment requires specialized equipment and staff training.

Wider implications of the findings: Non-invasive visualisation of oocyte meiotic spindle morphology can be used as a marker of its genetic normality and reproductive potential. If validated in randomized controlled trials this selective tool could benefit both patients and fertility clinics by optimising embryo selection and cycle outcome.

Trial registration number: Not Applicable.

O-030 Non-invasive imaging of embryo metabolism in response to anoxia using fluorescence lifetime imaging microscopy (FLIM)

E. Seidler[1], T. Sanchez[2], M. Venturas Pedro[2], D. Sakkas[3], A. Penzias[4], D. Needleman[2]

[1]Harvard University- Beth Israel Deaconess Medical Center/Boston IVF, Molecular and Cell Biology- Reproductive Endocrinology & Infertility, Cambridge- Boston/Waltham, U.S.A.
[2]Harvard University, Molecular and Cell Biology, Cambridge, U.S.A.
[3]Boston IVF, Scientific Director, Waltham, U.S.A.
[4]Beth Israel Deaconess Medical Center/Boston IVF, Reproductive Endocrinology & Infertility, Boston/Waltham, U.S.A.

Study question: How does embryo metabolic function depend on oxygen availability at different stages of development?

Summary answer: Depending on developmental stage, mouse embryos displayed distinct metabolic responses to anoxia. This yields new insight for the study of embryo metabolism and, therefore, viability.

What is known already: Fluorescence lifetime imaging microscopy (FLIM) can be used to non-invasively and quantitatively measure the metabolic state of embryos. FLIM measures the fluorescence of both NADH and FAD. These endogenous molecules are integral to cellular metabolism and are auto-fluorescent, thus avoiding the need to expose embryos to any potentially unsafe reagents or dye.

Study design, size, duration: We conducted a prospective observational study utilizing a mouse model. Using an engineered on-stage incubation system, embryos/oocytes were probed by dropping oxygen from 5% to 0% over 90 minutes, monitoring metabolic state throughout. Additionally, the use of an O2-sensitive fluorophore allowed us to plot metabolic state as a direct function of O2 concentration. Experiments were conducted over one year, in triplicate.

Participants/materials, setting, methods: Samples were equilibrated to 5% O2 for 30 minutes. 0% O2 gas was flushed into the culture system for 90 minutes, causing media O2 concentration to drop according to an exponential decay, after which 5% O2 gas was restored for 30 minutes. Metabolic measurements were obtained every 6 minutes to capture the dependence of metabolic state on O2 concentrations and mitochondrial function/recovery from anoxia. Embryos were subsequently cultured until the blastocyst stage in standard conditions.

Main results and the role of chance: Mouse embryos between 1-cell and 6-8 cell stages showed similar metabolic responses to transient anoxia, with an increase in NADH fluorescence intensity [1-cell: 36.6 ± 5.7%] (reflective of total concentration) and a decrease in FAD intensity [1-cell: -13.7 ± 1.4%]. These trends then reversed with restoration of oxygen. Morulae and blastocysts, however, showed less of a metabolic response to anoxia, with minimal change in NADH [Blastocyst: 8.3 ± 5.5%] and FAD [Blastocyst: -4.7 ± 3.6%] intensity.

This finding is in line with previous evidence of distinct metabolic shifts that occur as embryos develop into blastocysts. However, our observation that

oxygen dependence decreases at blastocyst stage was surprising, as oxygen consumption is known to increase at blastocyst. This suggests more subtle mechanisms for metabolic regulation, and provides a direct framework for further elucidating these metabolic shifts.

Of note, the decrease in oxygen dependence does reflect a likely adaptation to known physiologic changes in vivo. As embryos develop, they pass into the uterus, which is known to have a lower oxygen concentration (2%). Transient O2 deprivation proved not to be a significant long-term perturbation, as embryos exposed to anoxia subsequently developed to blastocysts at >80%.

Limitations, reasons for caution: Although these findings represent an innovative mechanism of embryo evaluation, a defined standard for interpreting metabolic FLIM parameters has not been fully developed. The hardiness of the mouse model may represent that caution is still needed when applying this technique to human embryos and gametes.

Wider implications of the findings: We have also shown that FLIM-based metabolic imaging provides a highly sensitive basis for detecting metabolic state, which is known to be essential for viability. This study thus provides further evidence that this technique could serve as a powerful tool for assessing embryo quality in the future.

Trial registration number: not applicable.

O-031 A pilot study to investigate mechanical characteristics of oocytes as a predictor of preimplantation embryo development

B. Behr[1], J. Kort[2], D. Meyer[3], M. Fleischmann[4], J.Y.J. Huang[5], C.H. Chen[6], N. Zhao[7], X. Yi[8], C. David[4]

[8]Shenzhen Army and Police Hospital, Reproductive Unit Embryology, Shenzhen, China

Study question: To determine if mechanical properties of oocytes can be obtained without harming subsequent development, and be used to predict blastulation.

Summary answer: Obtaining mechanical measurements of oocytes does not affect subsequent fertilization or development, and for a subgroup of oocytes, mechanical properties may predict blastulation.

What is known already: In multiple tissues, cells' mechanical characteristics often predict their intrinsic health and function. Many characteristics of oocytes noted by embryologists, including the ease of piercing the oolemma during ICSI or blastocyst expansion, are direct manifestations of an oocyte or embryos' mechanical properties. Our device was designed to provide objective measurements of these properties using a pipette to aspirate the cell with a uniform step negative pressure. Using this device, the mechanical properties of zygotes has been observed to predict blastulation in humans, and in a mouse model, measurement of the oocyte predicted fertilization after conventional insemination and blastocyst development

Study design, size, duration: This was a prospective split cohort study of patients undergoing IVF-ICSI at two private fertility clinics collaborating with an academic embryology lab over 6 months. Nineteen patients and the corresponding 100 measured and 368 unmeasured control oocytes from clinic A (primarily blastocyst culture), and 20 patients and the corresponding 116 measured and 111 unmesaured control oocytes from clinic B (primarily Day 3 culture) were included in the analysis.

Participants/materials, setting, methods: Patients consenting to participation and planning to undergo IVF-ICSI with >10 oocytes retrieved were approached for consent to have at most, half of their oocytes, measured with the micropipette aspiration device. The aspiration depth over time was measured and applied to a modified Zener bulk mechanical model to obtain mechanical parameters: k0, k1, tau, eta0, eta1, and zona pellucida thickness. Oocyte fertilization, day 3 morphology, and blastocyst development were recorded and compared to mechanical properties.

Main results and the role of chance: There was no observed differences in fertilization rates (74% vs. 78%, p = NS), good day 3 development per oocyte (44% vs.37%, p = NS), and a trend towards higher blastocyst development after measurement, (55% vs. 45%, p = 0.09) when comparing the measured and unmeasured oocytes. There was no correlation between maternal age or zona pellucida thickness and any of the five mechanical parameters, and the parameters do not seem to predict normal fertilization of the oocyte; however, among fertilized oocytes, 94% of oocytes with eta0 in the lowest quartile, 90% of oocytes with k1 in the top quartile, 88% of oocytes with tau in the lowest quartile, and 88% of oocytes with eta1 in the lowest quartile made blastocyst, all being significantly higher blastulation rates than oocytes in other quartiles ($p < 0.05$). No trend was observed to be predictive among other parameters.

Limitations, reasons for caution: The higher than anticipated blastocyst development rate (>70%/2PN) and good prognosis patients included in the study may limit the application of these preliminary findings to a more generalized patient population.

Wider implications of the findings: In this pilot, mechanical parameters of oocytes are highly specific but not sensitive for blastulation, and have potential for a non-invasive test of oocyte competence. Measurement is safe and does not affect fertilization or embryo development. Additional investigation with a more diverse patient population is needed to confirm these findings.

[5]9.baby family and fertility center, Reproductive Medicine IVF, Bologna, Italy

Study question: Can we improve our ability to assess embryo developmental and implantation potential by investigating the possible relationship between EEVA scores and embryo-derived microRNAs or sHLA-G?

Summary answer: Our preliminary results are consistent with the study hypothesis, suggesting a correlation between EEVA scores and expression profiles of both sHLA-G and microRNAs (miRNAs)

What is known already: Early prediction of embryo viability and implantation potential remains challenging although several non-invasive strategies have been developed. Among the latter, the EEVA (Early Embryo Viability Assay) system represents a time-lapse approach that applies a patented algorithm to automatically classify Day 3 embryos in five categories, according to their highest (SCORE-1, S1) or lowest (SCORE-5, S5) probability of reaching blastocyst stage. Furthermore, a central role of sHLA-G for successful implantation and pregnancy maintenance by cytokine secretion modulation inducing immunotolerance is well established. Moreover, recent studies have suggested that miRNAs are involved in molecular signaling during maternal-conceptus dialogue aiming at implantation success.

Study design, size, duration: This is a prospective randomized pilot study. Human embryos obtained during routine IVF/ICSI cycles were continuously monitored with the EEVA system just after fertilization check and EEVA scores were generated on day 3. After day 3, embryos were cultured up to blastocyst stage. Immediately before vitrification or transfer, 25 µl of spent blastocyst media (SBM) of 90 samples were individually processed for miR-20a-5p and miR-30c-5p analysis. Furthermore, 10 µl of SBM were assayed for sHLA-G protein quantification.

Participants/materials, setting, methods: MicroRNAs isolation was conducted with miRCURY RNA Isolation Kit for Biofluids (EXIQON) and miRNAs profiles evaluated by miRCURY LNA™ /Universal RT-SYBR® Green PCR assay (EXIQON). UniSp6 and Unisp2 were used as reference genes. sHLA-G levels were assessed by Bio-Plex Multiplex immunoassays (Bio-Rad). Data distribution was analyzed by Kolmogorov-Smirnov and Shapiro-Wilk tests. Correlation was investigated using Spearman's rho and Wilcoxon test. MiRNAs and sHLA-G expression levels among EEVA categories were compared using Kruskall-Wallis and Mann-Whitney post-hoc tests.

Main results and the role of chance: Out of 90 samples, 24 were S1, 16 S2, 16 S3, 16 S4 and 18 S5. MiR-20a-5p, miR-30c-5p and sHLA-G expression levels followed a non-normal distribution. sHLA-G concentrations increased with decreasing EEVA scores (negative correlation: r=-0,476, p = 0,000) and differed significantly among EEVA categories (Kruskall Wallis, p = 0,001). Pairwise comparisons as a post-hoc analysis revealed significantly increased sHLA-G levels in EEVA score 1 (ES1) group compared to EEVA score 5 (ES5) group (p = 0,000, ES1 mean rank = 54,16 vs ES5 mean rank = 22,31). MiR-20a-5p expression profiles were also negative correlated with EEVA scores normalizing miR-20a-5p CT values both respect to UniSp2 plus UniSp6 (r=-0,277, p = 0,01) or respect to UniSp2 (r=-0,283, p = 0,03) and UniSp6 (r=-0,285, p = 0,01) only. Nevertheless miR-20a-5p was not differentially expressed across EEVA categories (Kruskall-Wallis, p = 0,165) consequently multiple comparisons were not carried out. Unexpectedly, we found a positive relationship between EEVA scores and miR-30c-5p normalizing mir-30c-5p CT values both relatively to UniSp2 plus UniSp6 (r = 0,357, p = 0,001) than for UniSp2 (r = 0,294, p = 0,008) and UniSp6 (r = 0,354, p = 0,001) only. Statistical analysis comparing miR-30c-5p profiles between EEVA categories highlighted differential expression levels (Krusall-Wallis, P = 0,039) with statistically significant increased concentrations in SBM from ES5 compared to ES1 (p = 0,04, ES5 mean rank = 51,22 vs ES1 mean rank = 29,7).

Limitations, reasons for caution: Current findings are preliminary, therefore further evaluations are needed.

Wider implications of the findings: MiRNAs and sHLA-G characterization is a good non-invasive approach for embryo evaluation and provides helpful information regarding his implantation potential and his physiological state. Therefore, profiling miRNAs and sHLA-G from SBM might be integrated with EEVA scores predictivity to enhance embryo comprehensive assessment and selection for transfer.

Trial registration number: None.

Monday 2 July 2018 Room 116 10:00–11:30

O-033 A systematic review of fertility-related psychological distress and reproductive concerns in cancer patients of reproductive age: informing on improved oncofertility psychological care

S. Logan[1], J. Perz[2], J. Ussher[2], M. Peate[3], A. Anazodo[4]

[1]*School of Women and Children's Health, Fertility & Research Centre- Royal Hospital for Women, Randwick, Australia*
[2]*Translational Health Research Institute, School of Medicine- Western Sydney University, Sydney, Australia*
[3]*Psychosocial Health and Wellbeing unit, Department of Obstetrics and Gyneacology- Royal Hospital for Women, Melbourne, Australia*
[4]*Kids Cancer Centre & Nelune Comprehensive Cancer Centre, Sydney Children's Hospital & Prince of Wales Hospital, Randwick, Australia*

Study question: What is the level of psychological distress and reproductive concerns of cancer patients of reproductive age (<45 years) throughout cancer treatment and survivorship.

Summary answer: Significant anxiety, depression and trauma related stress persist into survivorship, with female cancer patients particularly at risk of long term fertility-related psychological distress.

What is known already: Actual or perceived infertility brought about by cancer disease and treatment leads to significant psychological distress and impairments to later quality of life for cancer survivors. However, research has yet to investigate the degree of psychological distress and reproductive concerns at different oncology treatment time points; diagnosis, treatment, survivorship. One way to diminish the impact of long term distress is via the provision of appropriate fertility-related psychological care throughout the cancer journey. A systematic review of the oncofertility literature would inform on an improved model of fertility-related psychological care.

Study design, size, duration: A systematic review of the literature conducted in January 2018 utilised electronic databases Medline, EMBASE, PSYCH Info, Web of Science and SCOPUS. Search terms reflected subheadings of cancer, psychological distress and fertility. Inclusion criteria included peer reviewed articles published in English, that reported on fertility-related psychological distress or reproductive concerns of cancer patients, diagnosed at reproductive age (<45 years). No limitations were placed on patient gender, cancer type or time since diagnosis.

Participants/materials, setting, methods: An initial search identified 701 potentially relevant studies, with full text of 174 studies further screened for eligibility. A second reviewer rated a subsection of the studies at full text to ensure inter-rater reliability. Any discrepancies on inclusion or exclusion were further discussed. Quality of all included studies was assessed via the Mixed Method Appraisal Tool, with all studies of reasonable quality. A total of 40 studies were included within the review.

Main results and the role of chance: Fertility-related psychological distress experienced by patients throughout the cancer journey were reported in 34 papers. Clinical levels of anxiety and depression were reported in one third of newly diagnosed patients, with anxiety and worry persisting through to survivorship. Trauma related stress were reported in survivorship, with stress greatest in female patients. Devastation, loss of control and loneliness were negative emotional responses experienced throughout the cancer journey. Psychological distress was related to perceived quality of oncofertility care.

Reproductive concerns were reported in 34 papers. Reproductive concerns were higher in younger and infertile patients, those whom life's narrative had been disrupted. Unfulfilled desire for a child in female patients was associated with greater trauma symptoms, higher depression and poorer mental health. Prevalence of pregnancy-related concerns were high, linked with depression or trauma in some samples. Menopause concerns were linked to greater emotional distress and higher symptoms of depression. Other common reproductive concerns linked to negative emotional expression included concerns about future children and current or future relationships.

Limitations, reasons for caution: Included studies do not focus exclusively on fertility-related psychological distress. As such, there is the risk that vital information has not been captured by current literature. The limited number of interventions also hinder the ability to draw definitive conclusions about how services may be improved to better incorporate psychological care.

Wider implications of the findings: Cancer patients and survivors would greatly benefit from fertility-related psychological support implemented into standard practice. The provision of this care may serve to mediate some of the later life impacts to psychological health and reproductive quality of life in cancer survivors of reproductive age.

Trial registration number: not applicable.

O-034 Ten pathways to elective egg freezing: A binational qualitative study of what leads healthy women to fertility preservation

M. Inhorn[1], D. Birenbaum-Carmeli[2], L. Westphal[3], J. Doyle[4], N. Gleicher[5], D. Meirow[6], M. Dirnfeld[7], D. Seidman[8], A. Kahane[9], P. Patrizio[10]

[8]Sheba Medical Center, Obstetrics and Gynecology, Ramat Gan, Israel
[9]Assuta Medical Center, Obstetrics and Gynecology, Rishoon Lezion, Israel
[10]Yale University, Obstetrics and Gynecology, New Haven- Connecticut, U.S.A.

Study question: Why are healthy women freezing their eggs?

Summary answer: We identified 10 different pathways leading to EEF, mostly revolving around women's lack of stable partnerships with men committed to marriage and parenting.

What is known already: The literature on oocyte cryopreservation suggests that EEF is being used primarily to defer or delay childbearing among women pursuing education and careers. However, emerging empirical data from both anonymous surveys and interview-based studies suggest that the lack of a stable partner might be the primary motivation for EEF.

Study design, size, duration: From June 2014 to August 2016, 150 women (114 in the United States, 36 in Israel) who had completed at least one cycle of EEF were interviewed by two senior medical anthropologists, one in each country.

Participants/materials, setting, methods: Study participants were recruited through 4 American IVF clinics (2 academic, 2 private) and 3 in Israel (1 academic, 2 private). In-depth, semi-structured, but open-ended interviews were audio-recorded, transcribed, and entered into a qualitative data analysis program (Dedoose) for thematic analysis, along with detailed interview summaries.

Main results and the role of chance: The majority (85%) of women in the study were without partners, reflecting 6 different life circumstances that led them to EEF (i.e., being single, divorced or divorcing, broken up, deployed overseas, single mother by choice or circumstance, career planner). EEF undertaken for career planning was the least common of these pathways. Those with partners (15%) faced 4 different life circumstances leading to EEF (i.e., not ready to have children, relationship too new or uncertain, partner refuses to have children, partner has multiple partners). As seen in these pathways, most women had already pursued and completed their educational and career goals, but had been unable to establish lasting reproductive partnerships. With only one exception (i.e., overseas deployment), these pathways varied relatively little among American and Israeli women in the study.

Limitations, reasons for caution: As a binational study, women were recruited somewhat differently between the two countries, and interviewed by two anthropologists in two languages. The number of participants was unequal, reflecting national differences in population size. These were the main limitations of this interview-based study, which is the largest to date.

Wider implications of the findings: Pathways to EEF may or may not be similar for women in other national settings. Further in-depth, interview-based research is essential. Furthermore, clinicians must be aware of the role that partnership 'troubles" play in the lives of EEF patients and make patient-centered care for single women a high priority.

Trial registration number:

O-035 Two-year follow-up of a randomised controlled trial: knowledge and reproductive outcome after online fertility education

E. Maeda[1], J. Boivin[2], S. Toyokawa[3], K. Murata[1], H. Saito[4]

[1]Akita University Graduate School of Medicine, Environmental Health Sciences, Akita, Japan
[2]Cardiff University, School of Psychology, Cardiff, United Kingdom
[3]The University of Tokyo, Department of Public Health, Tokyo, Japan
[4]National Center for Child Health and Development, Center of Maternal-Fetal-Neonatal and Reproductive Medicine, Tokyo, Japan

Study question: What are the long-term effects of fertility education on knowledge and reproductive outcome?

Summary answer: Participants in the intervention group retained some knowledge after two years and the partnered women had another child more quickly than those in control group1.

What is known already: Fertility education improves knowledge at least in the short term. Attitudes toward childbearing and its timing can change after exposure to educational materials.

Study design, size, duration: In the original randomised controlled trial (RCT), knowledge of reproductive-aged participants was assessed before (T1) and immediately after (T2) receiving one of three information brochures: fertility (intervention group), intake of folic acid during pregnancy (control group 1), or family policies in Japan (control group 2). This follow-up study was conducted two years later in January 2017 (T3).

Participants/materials, setting, methods: Of the T1 participants (n = 1,455), 383 men and 360 women (51%) responded to the T3 survey. Fertility knowledge measured with the Japanese version of the Cardiff Fertility Knowledge Scale (CFKS-J) and fertility status (e.g., new births, new medical consultations, and the timing of new birth) were assessed.

Main results and the role of chance: Baseline (T1) characteristics of the T3 participants were well-balanced between groups, whereas T3 participants were older, married, and more educated compared to those lost to follow-up. Group comparisons of the T3 scores on the CFKS-J showed no differences. Within-group comparison showed that, in the intervention group, the T3 score was significantly higher than the T1 score (4.5 and 3.6 percent higher among men and women, respectively) and significantly lower than the T2 score (6.0 and 11.5 percent lower among men and women, respectively). There were no differences between groups in the proportions of those who had a new birth or those who had a new medical consultation by T3. Among those who had a partner at T1, the proportion of those who had a new birth in the first year was higher in the intervention group than in control group 1 (folic acid): 8.8% versus 1.4% (odds ratio [OR] = 6.8, 95% confidence interval [CI]: 0.72 to 327.3) among men and 10.6% versus 2.3% (OR = 5.1, 95% CI: 1.00 to 49.5) among women.

Limitations, reasons for caution: High attrition rate may limit the generalizability of these findings.

Wider implications of the findings: Effects of one-time education were limited but retained. Follow-up education might help people retain knowledge and facilitate reproductive decisions. In view of the high attrition rate, especially among young populations, educational strategies should be explored.

O-036 Randomized controlled trial on the effect of an online decision aid for young female cancer patients considering fertility preservation

V. Ehrbar[1], C. Urech[1], C. Rochlitz[2], R. Zanetti Daellenbach[3], R. Moffat[4], R. Stiller[5], A. Germeyer[6], F. Nawroth[7], A. Dangel[7], S. Findeklee[8], S. Tschudin[1]

[1]University Hospital Basel, Gyn. Socialmedicine and Psychosomatics, Basel, Switzerland
[2]University Hospital Basel, Medical Oncology, Basel, Switzerland
[3]St. Claraspital Basel, Gynecology and Gynecologic Oncology, Basel, Switzerland
[4]University Hospital Basel, Gynecology and Obstetrics, Basel, Switzerland
[5]University Hospital Zurich, Gynecology and Obstetrics, Zurich, Switzerland
[6]University Hospital of Heidelberg, Gynecological Endocrinology and Reproductive Medicine, Heidelberg, Germany
[7]amedes Hamburg, Centre for Infertility- Prenatal Medicine- Endocrinology and Osteology, Hamburg, Germany
[8]University Hospital Friedrich-Alexander, University Women's Hospital-Comprehensive Cancer Center ER-MN, Erlangen-Nuernberg, Germany

Study question: Does the use of an online decision aid about fertility preservation (FP) in addition to FP counseling, reduce decisional conflict, compared to FP counseling alone?

Summary answer: The additional use of the online decision aid (DA) significantly reduced decisional conflict (DC) in female cancer patients compared to FP counseling alone.

What is known already: Female cancer patients may be confronted with impaired fertility due to cancer treatment. Nowadays, several options to preserve fertility are available, however having to decide whether or not to opt for FP, within the short time frame after cancer diagnosis and before treatment start is challenging. Various studies have already shown that there is a high DC amongst these women and support is highly in demand. According to previous research, DA's may be a helpful support in decision-making. To our knowledge, there is no evaluated DA about FP for German speaking women that, furthermore covers several cancer types.

Study design, size, duration: The study is a randomized-controlled trial including 51 women, who were referred to one of the participating fertility centers after having been diagnosed with cancer. Participants were either assigned to the control group (counseling only) or to the intervention group (counseling and additional use of the online DA immediately after counseling). Recruitment was ongoing from July 2016 to December 2017 at a total of 8 fertility centers in Switzerland and Germany.

Participants/materials, setting, methods: The online DA was developed by an interdisciplinary team of reproductive specialists, gynecologists and psychologists. Participants were asked to complete an online questionnaire at three time points: after counselling (control group) or after counseling and the use of the DA (intervention group) (T1) as well as one month (T2) and 12 months later (T3). The survey comprised questions about fertility-related knowledge, decisional conflict, decisional regret, attitude towards FP, willingness to undergo FP and socio-demographic data.

Main results and the role of chance: First analyses of the Decisional Conflict Scale show a statistically significant difference between the intervention and control group regarding decisional conflict at T1 ($p = 0.008$). Women, who used the DA in addition to counseling, showed a significantly lower total score on the Decision Conflict Scale ($M = 23.95$, $SD = 13.48$), compared to those in the control group ($M = 36.11$, $SD = 17.26$). The mean score of three out of the four subscales of the Decisional Conflict Scale were also significantly lower for the intervention group compared with the control group. First analyses show, that there seems to be an immediate positive effect of the DA by reducing DC about FP in female cancer patients. It is expected that the final analyses of the study will provide further insight in aspects such as patients' fertility-related knowledge and decisional regret.

Limitations, reasons for caution: Education was high in two thirds of the participants. It is difficult to say, whether the DA might be equally effective in women with a lower educational background. Further analyses of the final data must be conducted in order to complete the evidence about the effectiveness of the DA.

Wider implications of the findings: This study contributes to extending the range of nowadays available DA's about FP, as it is to our knowledge the first randomized controlled trial evaluating a DA covering several cancer types. The DA seems to serve as a helpful complement of the decision-making process for patients and professionals alike.

Trial registration number: NCT02404883 (clinicaltrials.gov)

O-037 Impact of fertility assessment and counselling on life changing decisions in women of reproductive age – status one year after the initial consultation

R. Sylvest[1], E. Koert[2], I. Vittrup[2], K. Petersen[3], A. Nyboe Andersen[2], A. Pinborg[1], L. Schmidt[4]

[1]*Copenhagen University Hospital Hvidovre, Department of Obstetrics/Gynaecology, Hvidovre, Denmark*
[2]*Copenhagen University Hospital- Rigshospitalet, Fertility Clinic, Copenhagen, Denmark*
[3]*University Hospital of Zealand, Fertility Clinic, Holbæk, Denmark*
[4]*University of Copenhagen, Department of Public Health, Copenhagen, Denmark*

Study question: What was the impact of attending fertility assessment and counselling on fertile women´s decisions and subsequent choices regarding their family formation, childbearing or relationship?

Summary answer: The fertility and assessment clinic provided an individualised approach that was frequently a catalyst for change concerning childbearing decisions and behaviour.

What is known already: Over the past 30 years women and men have postponed family formation in high income societies. Fertility assessment and counselling has been suggested as a method to reduce the negative consequences of delayed childbearing. There is a need to investigate the impact of this type of intervention to see if counselling influences choices on the critical issues of delayed childbearing and gaps in fertility awareness and knowledge.

Study design, size, duration: Follow up data from a longitudinal semi-structured qualitative interview study including 20 women aged 35-40 years seeking individual fertility counselling. The interviews were conducted one year after their consultation at the clinic.

Participants/materials, setting, methods: Study participants were five single and 15 cohabiting women, residents in the Capital Region of Copenhagen, Denmark and who had sought individual fertility assessment and counselling. Since their consultation at the counselling clinic, five women had gone through fertility treatment, three had delivered and seven had attempted to become pregnant. The interviews took place in their own homes or at the clinic. Data were analysed by qualitative content analysis.

Main results and the role of chance: Twenty different women, twenty different stories. The overall theme was: 'Knowledge increased'. The women increased their knowledge after they had attended the counselling. 'Catalyst for change', 'Staying in limbo' and 'Peace of mind' were subthemes. Some of the women saw the counselling as a catalyst for change – they changed behaviour and relationship status. Five started fertility treatment (with their partner or as a future solo mother), two left their partner and seven attempted to become pregnant. The women stopped thinking about the pros and cons of childbearing and acted instead. The counselling initiated conversations with their partner about childbearing. Some of the women felt that they were still in limbo as they were still in doubt concerning childbearing. The consultation had not given them an answer with a clear deadline, and this frustrated them. But for the others, the consultation gave them peace of mind because they realised that they had time to figure out their future plans concerning childbearing.

Limitations, reasons for caution: The study participants had all chosen to seek individual fertility counselling and all women were of advanced reproductive age over 35 years. Hence, the results may not be directly transferred to the general population in regards to attitudes towards family formation and concerns of reproductive lifespan.

Wider implications of the findings: Our study highlights the impact of fertility assessment and counselling intervention which included an increase in knowledge. What the women did with it depended on their current life circumstances, fertility status and readiness. The clinic allows for an individualised approach which is necessary given the unique nature of childbearing decisions.

Trial registration number: Not applicable.

O-038 'Doing it in the right order' – Childless young men's intentions regarding family formation

G.M. Malling[1], T. Pitsillos[2], T. Tydén[2], S. Ziebe[3], B. Friberg[4], K. Hammarberg[5], L. Schmidt[1]

[1]*University of Copenhagen, Department of Public Health, Copenhagen K, Denmark*
[2]*University Hospital Uppsala, Department of Women's and Children's Health, Uppsala, Sweden*
[3]*Copenhagen University Hospital- Rigshospitalet, Fertility Clinic, Copenhagen, Denmark*
[4]*Lund University, Molecular Reproductive Medicine- Department of Translational Medicine, Malmö, Sweden*
[5]*Monash University, Jean Hailes Reseach Unit- School of Public Health and Preventive Medicine, Melbourne, Australia*

Study question: Which factors influence young men's decision-making regarding timing of family formation?

Summary answer: Social and societal expectations, following the right chronology, being ready to give up individuality, and ensuring security influence young men's preferred timing of family formation.

What is known already: Postponing family formation increases risk of involuntary childlessness or having fewer children than desired. Despite Denmark and Sweden offering good opportunities to combine work life with having children, the age of childbearing has increased significantly in the last 40 years. Most previous studies regarding family formation and fertility awareness have focused on university-educated women. The few existing studies of men's attitudes to family formation indicate that prerequisites for men are to be in a stable relationship, having completed education, ensured a stable job, and having sufficient personal maturity.

Study design, size, duration: This qualitative study assessed fatherhood intentions among childless men in Denmark and Sweden in their last year of university education or vocational training. In total, 17 Danish and 12 Swedish male students were interviewed. The interviews were conducted between February-September 2017 and ranged between 30 and 90 minutes.

Participants/materials, setting, methods: The participants were recruited face-to-face or via postings at their educational institutions, and by snowball methods. Inclusion criteria were: being male, childless, aged 20-30 years and in the last year of education. The interviews were conducted wherever the participants preferred, either at their educational institution, their home, or in an office. The 29 interviews were transcribed and the content analysed through a thematic content analysis.

Main results and the role of chance: Study participants were on average 25 years old (range 20-30). Through the analysis five subcategories emerged: 1) Expectations from the society; 2) Influence from within the social circle; 3) Enablers for earlier family formation; 4) Giving up freedom and individuality; 5) Ensuring security and stability.

Almost all participants wanted children in the future. The young men wanted to find their path in life before having children. In relation to life events, they felt that they were required to follow the right chronology – first education, accommodation and career, then children. Further, they expressed the need to explore some of the many other life experiences available to young people in contemporary society, including travel, to figure out what they wanted in life. Moreover, being ready to have children was associated with being ready to give up individuality and freedom. While many stated that they felt mature enough, this was not equated with feeling ready to have children. Other factors influencing participants' preferred timing of parenthood were being in a stable relationship, having appropriate housing, ensuring financial security, and having fulfilled career aspirations. Further, both Danish and Swedish men expressed reflecting themselves in their parents in relation to age at first child.

Limitations, reasons for caution: Despite following the same interview guide, the interview technique between countries may have differed. This may have influenced the dialogue. Men who want children may have been more likely to agree to participate than men who do not want children.

Wider implications of the findings: In order to promote earlier family formation and prevent infertility this study highlights the need to educate young men about the limitations of fertility. Exploring the many opportunities of today's society and chasing a career is not limited by age, however fertility is.

INVITED SESSION

SESSION 08: LABORATORY MODELLING TO UNDERSTAND ENDOMETRIAL FUNCTION

Monday 2 July 2018 Room 211 + 212 11:45–12:45

O-039 Endometriosis and associated pain

E. Greaves[1]

University of Edinburgh, MRC Centre for Reproductive Health, Edinburgh, United Kingdom

Endometriosis is a complex chronic inflammatory condition associated with debilitating pain and infertility that affects 176 million women worldwide. Current research aims to understand the aetiology and pathophysiology of the disorder and develop novel effective non-surgical therapies that lack the unwanted side effects of current medical management. Tools for endometriosis research fall into two broad categories: patient-derived tissues and fluids (and cells isolated from these sources) and laboratory models based on the use of cells or animals. There are many different models (in vitro and in vivo) reported in the literature, all have their advantages and drawbacks and choice of model depends largely upon the research question. Rodent models of endometriosis in particular exist in many different variations and have different utilities depending whether the study is designed to explore pain or infertility. The rat has been used most consistently for studying mechanisms of endometriosis-associated pain with a number of different behaviour read-outs including those used to measure mechanical hyperalgesia, allodynia and anxiety. Many different versions of mouse models of endometriosis exist (with refinements and standardisation being a current focus in the field) and their utility for the assessment of pain in the condition is becoming a priority. In summary, hypothesis-driven endometriosis research can only be facilitated with careful experimental design and selection of the most appropriate human tissue from patients with and without endometriosis and combinations of physiologically relevant in-vitro and in-vivo laboratory models.

O-040 Implantation and early pregnancy, the maternal contribution

C. Simon Valles[1]

University of Valencia- INCLIVA- Igenomix, Obstetrics and Gynecology, Paterna - Valencia, Spain

Abstract text

Human reproduction is a very inefficient process with a probability of conception during a given menstrual cycle around 30%. In the last 40 years, reproductive medicine has emerged as one of the most rapidly developing areas of medical science propelled by clinical and basic research advances in ovarian physiology, induction of ovulation, and embryology. Despite all technological advances in the understanding of the "seed", the maternal endometrium has been the forgotten organ. Nowadays, when a morphologically normal blastocyst is transferred into a seemingly normal uterus, cycle reproductive success is still limited, and sadly, has not significantly improved since the 1990´s. This is the main reason the clinical community turn its attention to embryonic implantation as the end-point not only for the reproductive success but also for the obstetric outcome and the conditioning of the origin of some adult diseases.

The human endometrium is a hormonally regulated organ that is the anatomic pre-requisite to initiate and control human pregnancy while is a sentinel for protecting the upper female reproductive from infections by a variety of microbes. The transition from anatomical to molecular medicine has led to the discovery of the transcriptomic signature of endometrial receptivity and its clinical application in patients with implantation failure through personalized embryo transfer. The endometrial cavity has been classically considered to be a sterile organ, but reports challenging this dogma support the existence of an endometrial microbiota composed of different microorganisms (specifically *Lactobacillus* spp., *Mycoplasma hominis*, *Gardnerella vaginalis,* and *Enterobacter* spp.) that might affect the reproductive outcome. The maternal decidua controls conception and the course of pregnancy in humans. Also, failed decidualization is associated with a spectrum of reproductive defects including failed implantation and clinical miscarriage but also late gestational complications such as preeclampsia. New emerging data reinforce the concept that suboptimal uterine conditions lies upstream of not only inefficient conception, but also failed trophoblast differentiation and invasion driving placentation, paving the way to better diagnosis, prevention and treatment of late gestational diseases.

In this presentation, I will revisit the modern knowledge of the "soil" concept and its basic and clinical contribution to the embryo implantation process.

INVITED SESSION

SESSION 09: DATA REPORTING SESSION

Monday 2 July 2018 Room 111 + 112 11:45–12:45

O-041 Data from the ESHRE PGD Consortium

O-042 How do ESHRE members use and evaluate the ESHRE guidelines?

S. Gameiro[1], N. Vermeulen[2], M. Sousa Leite[3]

[1]*Cardiff University, School of Psychology, Cardiff, United Kingdom*
[2]*European Society for Human Reproduction and Embryology, Research Specialist, Brussels, Belgium*
[3]*University of Minho, Department of Psychology, Braga, Portugal*

Introduction: From 2013 ESHRE has been publishing evidence-based guidelines to support care providers and patients making every-day decisions about appropriate and effective health care {Vermeulen, 2017 #508}. So far ESHRE has mainly focused on the development and the dissemination of the guidelines and less on ensuring that they are being appropriately implemented across Europe. The current study reports on dissemination, implementation and impact of the first four published ESHRE guidelines: Management of Endometriosis (ENDO; Dunselman et al., 2014), Routine Psychosocial Care (RPC; Gameiro, et al., 2015), Premature Ovarian Insufficiency (POI; European Society for Human Reproduction and Embryology Guideline Group on POI, 2016) and Recurrent Pregnancy Loss (RPL; European Society for Human Reproduction and Embryology Guideline Group on RPL, 2018).

Methods: The online survey assessed dissemination (knowledge that the guidelines were published [Y/N] and download [Y/N]), implementation (using guidelines in daily practice [Y/N] and made changes to practice according to recommendations [Y/N]) and impact (perceived patient benefit [Y/N] and referral of patients to the guidelines [Y/N]). It further investigated perceived quality of the guidelines (1 'very poor' to 5 'excellent'), and barriers [open question] and beneficial support (list of available support options) for their implementation. The survey was online from February 20th to April 3rd 2018. It was advertised via the ESHRE website, social media and mailings to the ESHRE membership. Participants were offered the opportunity to win a free registration for the ESHRE Annual Meeting in Barcelona or an ESHRE Campus Course.

Results: A total of 723 ESHRE members accessed the survey.

540 (82.1%) participants know ESHRE published the ENDO guideline. From these, 356 (65.9%) downloaded it, 225 (41.7%) use it in their daily practice, 166 (30.7%) are changing their practice, 105 (19.4%) think that patients benefited from the guideline, and 48 (8.9%) referred them to it.

227 (54.6%) participants know ESHRE published the RPC guideline. From these 119 (52.4%) downloaded it, 67 (29.5%) use it in their daily practice, 43 (18.9%) are changing their practice, 37 (16.3%) think that patients benefited from the guideline, and 29 (12.8%) referred them to it.

205 (56.6%) participants know ESHRE published the POI guideline. From these 111 (54.1%) downloaded it, 69 (33.7%) use it in their daily practice, 44 are changing their practice, 33 (16.1%) think that patients benefited from the guideline and referred them to it.

199 (59.5%) participants know ESHRE published the RPL guideline. From these, 113 (56.8% downloaded it and 63 (31.7%) intend to change their practice.

The overall perceived quality of the guidelines was: ENDO 4.18 (0.71), RPC 4.11 (0.62), POI 4.26 (0.62), and RPL 4.26 (0.68).

Data on perceived barriers to implementation will be subjected to content analysis. Regarding perceived beneficial support, 180 (68.4%) participants would do an e-learning course on the guidelines, 164 (64.3%) would use an app, 166 (63.8%) would use a step-by-step manual, 153 (59.8) would use a printed pocket guideline, and 128 (50.0%) would attend a campus course.

Discussion: Considering the multi-faced dissemination strategies used by ESHRE, one would expect higher knowledge and access to the guidelines. Although ESHRE members perceive the quality of the guidelines to be very good and show interest in learning about how to implement them, only around one-third actually use them in their clinical practice. It is therefore not a surprise that perceived patient benefit is low. Results suggest that the current ESHRE guidelines strategy is insufficient to ensure their implementation. Knowledge about perceived barriers to implementation will inform about additional support that ESHRE can provide to its community. On-line media seems to be the members' preferred channel to receive such support.

INVITED SESSION
SESSION 10: FERTILITY SOCIETY OF AUSTRALIA EXCHANGE LECTURE

Monday 2 July 2018 Room 113 + 114 + 115 11:45–12:15

O-043 Rapid, non-invasive measurements of metabolic balance can stratify embryos based on ploidy

B. Arman[1], L. Sandeman[1], C. Carbone[1], F. Bell[1,2], M. Lane[1,2]

[1]*Robinson Research Institute- University of Adelaide, Obstetrics and Gynaecology, Adelaide, Australia*
[2]*Monash IVF, Monash IVF, Melbourne, Australia*

Aim: To determine whether measurements of glucose uptake and hydrogen peroxide production in human embryo secretome can be used to predict aneuploidy and subsequent viability.

Method: Samples of spent culture media (n = 123) from patients (mean maternal age 36.6 ± 0.6, mean maternal BMI 26.3 ± 0.8) undergoing IVF or ICSI with pre-implantation genetic screening (PGS) were collected following incubation of individual embryos in G2 Plus (Vitrolife) from day 3 to day 5. Samples were frozen and blinded before analyses of glucose (ultra-microfluorometric analysis) and hydrogen peroxide (Amplex UltraRed) concentrations. These concentrations were correlated to embryo ploidy status, morphology, and pregnancy outcomes. Statistical analysis was conducted using a Student's t-test.

Results: Metabolic profile was not correlated with either blastocyst expansion or inner cell mass or trophectoderm quality. When combining the rate of hydrogen peroxide production and glucose update to approximate mitochondrial function as a proportion of substrate uptake, then euploid embryos had a significantly higher metabolic ratio than aneuploid embryos (+2.9 fold, $p < 0.05$). Within euploid embryos, pregnancy rates were associated with an increase in glucose uptake (+3.0 fold, $p < 0.05$).

Conclusion: Metabolic balance between substrate uptake and pathway utilisation improves the ability to stratify embryos into viable and non-viable cohorts. This study also confirms that morphology is a poor predictor of viability and metabolic output. These results suggest that metabolic balance of embryos could be used as a rapid and inexpensive non-invasive screening tool for ranking embryo suitability for transfer. Further studies are required to determine the metabolic consequences of individual aneuploidies.

INVITED SESSION
SESSION 11: WHAT ABOUT THE CHILDREN?

Monday 2 July 2018 Room 117 11:45–12:45

O-044 Health of ICSI children

U.B. Wennerholm

University of Göteborg, Department of OB/GYN\rInstitute for Women's & Children's Health, Göteborg, Sweden

It is over 25 years since the first child was born after ICSI treatment. Since then there has been an ongoing debate on the use and safety of the technique. Initially, ICSI was used to treat severe forms of male factor infertility but today it is also used to treat mild male factor infertility, mixed male/female infertility, unexplained infertility and fertilization failures. Both the latest European ESHRE report and the global ICMART report reveal an increasing global use of ICSI, with one-third of fresh assisted reproductive technology (ART) cycles using conventional IVF and two-thirds using ICSI. Due to the invasiveness of the ICSI procedure as well as the arbitrary selection of the spermatozoon and genetic

and epigenetic parental factors, concerns have been expressed about the health of ICSI children.

Adverse perinatal outcomes in ART, which includes ICSI and conventional IVF techniques, are associated mainly with ART's higher rates of multiple pregnancies. In ART singletons, the rate of very preterm birth and very low birth weight is about two to three times higher than in the general population. When comparing ICSI and conventional IVF, most large studies have found similar or lower risks of very preterm and preterm birth, very low birth weight, low birth weight and peri/neonatal mortality.

Many large national registry studies show a slight increase in birth defects in ART children compared to the general population. Evidence regarding birth defects in ICSI versus IVF is less clear but most large cohort studies show no difference in the incidence of birth defects between ICSI and IVF newborns, and the different sperm sources used in ICSI do not seem to influence the rate of birth defects negatively. However, the incidence of de novo and inherited sex chromosomal abnormalities in ICSI offspring is slightly higher, which probably relates to the genetics of the infertile couples. Some studies, mainly case-control studies have reported associations between ART (but not to a specific reproductive technique) and imprinting disorders such as Beckwith-Wiedemann syndrome, Angelman syndrome and Prader Willi syndrome. These disorders may be related to the underlying infertility problem. All are rare disorders and the absolute risk of an imprinting disorder after ICSI/IVF is extremely small.

Studies of growth and physical health are few and limited to childhood. Looking at general physical health including such factors as hospitalizations, childhood illnesses, surgical interventions and medical therapies, there are similar results for ICSI and IVF-conceived children. Results are also similar for age and gender-matched controls in the general population. Most large cohort studies do not show any increase in childhood cancer in general in ART children and provide no evidence of increased numbers of adverse outcomes in the ICSI group.

Most studies comparing children up to eight years of age born after ICSI, IVF and spontaneous conception, suggest their neurocognitive development is comparable. Sperm source or individual semen parameters do not affect neurodevelopment. Two large recent studies reporting associations between ICSI and autism and autistic disorders should be interpreted with caution, since the absolute risks of autism and autistic disorders are small.

A few longitudinal reports on reproductive health in ICSI adolescents and young adults have also been published recently. Onset of puberty and pubertal development is similar for ICSI and spontaneously conceived boys and girls, but ICSI-conceived men seem to have lower sperm concentrations and total sperm counts than age-matched, spontaneously conceived controls.

Further monitoring and research is necessary before firm conclusions about the safety of ICSI, as opposed to IVF, can be drawn. Large well-designed cohort studies are still needed, taking into account parental factors and technical procedures as well as selection and surveillance biases.

O-045 Psychological and medical follow-up of children born after Pre-implantation Genetic Testing (PGT)

J. Nekkebroeck[1], B. Maryse[2]

[1]*UZ Brussel, Centrum voor Reproductieve Geneeskunde, Jette- Brussels, Belgium*
[2]*UZ Brussel, Centre for Medical Genetics, Brussels, Belgium*

Abstract text

Psychological and medical follow-up of children born after **Pre-implantation Genetic Testing** (PGT)

Follow-up studies on the health of PGT (and PGT-Aneuploidy) children are essential in order to provide reassurance about the safety of the technique (ESHRE 2007; ESHRE PGD Consortium 2012).

Psychological health is translated in the cognitive and motor development of children. Pioneering studies did not differentiate between children born after PGT or PGT-A (Banerjee, 2008; Nekkebroeck, 2008) but found reassuring results for cognitive development at age 2 (Nekkebroeck, 2008). In the study of Banerjee et al. (2008) the scores for locomotor capacities of the PGT(-A) children were significantly lower than those of the ICSI group. In the study of Nekkebroeck et al. (2008) PGT(-A) children presented normal motor development compared to ICSI and naturally conceived (NC) counterparts.

Only a few studies focused solely on PGT children. Thomaidis et al. (2012) examined 31 PGT children of different ages, 22.6% showed mild motor retardation quotients but there was a lack of matched controls. The same was the case in the study of Sacks et al. (2016) where 4-to-5 year old PGT children showed normal neuropsychological development. Winter et al. (2014) examined 5-to-6 year old PGT singletons for cognitive and motor development and found comparable scores to their matched ICSI and NC controls.

Psychological health is also defined in terms of psycho-social development and family functioning. In Nekkebroeck et al. (2008) the socio-emotional development of PGT(-A) children aged 2 did not differ from the control groups (ICSI and NC) neither did parental stress and mental health status. For PGT children aged 5-6 similar results were found for psychosocial development (Winter et al., 2015). In terms of family functioning the NC mothers, experienced more parental stress while PGT/ICSI mothers had higher feelings of competence and were more goal directed.

The neonatal and medical outcomes of PGT/PGT-A children compared to ICSI and sometimes NC are also described and are mainly reassuring.

Two months after birth PGT/PGT-A children were examined and compared with ICSI new-borns in research of Liebaers et al. (2010). More perinatal death was observed in PGT/PGT-A multiples than in ICSI multiples. Gestation, birthweight and major malformation rates were similar. In another neonatal follow-up study of 995 children (singletons and multiples) born after PGT no differences regarding: mean term, prematurity, birth weight, very low birth weight, perinatal death, major malformations and neonatal hospitalizations with ICSI singletons and multiples. However, fewer multiples born after PGT presented a very low birth weight in comparison to ICSI multiples (Desmyttere et al. 2012).

At age 2 no differences between PGT(-A) singletons regarding weight, height and head circumference were found when compared to ICSI singletons. Compared to NC children the birth weight tended to be slightly lower for PGT (-A) children. The latter were more frequently born after Caesarean section than ICSI children (and NC) but there were no more congenital malformations, hospital admissions and surgical interventions compared with ICSI/ NC children (Desmyttere et al., 2009). When comparing 2-year-old twins and singletons again no differences were observed compared to ICSI counterparts. In a Dutch cohort of PGT-A children there were no differences in blood pressure and anthropometrics at age 4 and 9 compared to IVF/ICSI (Seggers et al., 2013; Kuiper et al., 2018).

Conclusion: Methodological weaknesses are encountered in many follow-up studies on PGT(-A) children (e.g. no distinctions between PGT/PGT-A children, including singletons as well as multiples, including children of different ages, no matched controls, small samples sizes). Luckily, most studies with or without these flaws indicate that young PGT(-A) children develop very similar to ICSI and NC children. Continuous follow-up remains necessary to ensure this positive outcome at older ages.

INVITED SESSION

SESSION 12: DEBATE: IMMUNOSUPPRESSION FOR IMPLANTATION FAILURE - IS IT WORTH IT?

Monday 2 July 2018 Room 211 + 212 14:00–15:00

O-046 Pro

S. Quenby[1]

University Hospital Coventry Warwick Medical School, Division of Reproductive Health, Warwick- Coventry, United Kingdom

Implantation failure is an increasing problem. This is a result of advances in ART so that success rates following embryo transfer are now significantly better than intercourse. Hence today a lack of positive pregnancy test or a transiently positive pregnancy test after embryo transfer is now a source frustration from the

patient and clinician's perspective. Implantation and embryo-maternal interactions are complex and still the subject of intensive research. However, some features of this interaction are known. The embryo needs to be recognised by the endometrium as being of high quality, a function that is achieved by the process of decidualisation. The decidualised endometrium then needs to respond to this embryo in a controlled fashion with an initial inflammatory response that then needs to be modulated to allow trophoblast invasion. There are many lines of evidence that indicate that failure to respond to an embryo, excessive inflammation, lack of local glucocorticoid steroid synthesis and failure to down regulate inflammation are all associated with implantation failure and early pregnancy loss. This means that there are many plausible biological mechanisms by which immunosuppression could improve implantation. Randomised controlled clinical trials in this area have all been disappointing however, they have lacked a personalised approach. The clinicals trials have demonstrated safety of immunosuppression in implantation failure. It is possible that immunosuppression given to the right patient at the right time will improve pregnancy outcome.

INVITED SESSION
SESSION 13: MEIOSIS AND GENOME STABILITY
Monday 2 July 2018 Room 111 + 112 14:00–15:00

O-048 Dissecting gene function in oocyte meiosis

M. Schuh[1]

Max Planck Institute for Biophysical Chemistry, Department of Meiosis, Göttingen, Germany

The Department of Meiosis at the Max Planck Institute for Biophysical Chemistry investigates mechanisms that are involved in chromosome segregation during meiosis in mammalian oocytes, the progenitor cells of eggs. This topic is of great interest for fundamental research because chromosome segregation during meiosis is still much more poorly understood than in mitosis, especially in mammals. It is also of direct medical relevance because aneuploidy in eggs is a leading cause of pregnancy loss and several congenital disorders such as Down's syndrome. Our main aim is to understand how defects at the interface between chromosomes and cytoskeletal structures lead to aneuploid eggs and pregnancy loss in mammals. To this end, we study how the meiotic spindle is organized, how it segregates the chromosomes and how the spindle interacts with actin to drive the meiotic divisions. We are also interested in the mechanisms that lead to an increase in aneuploidy in eggs with advanced maternal age.

We are also very active in developing new tools to study meiosis in mammalian oocytes. For instance, we have recently developed a method, called Trim-Away, that can be used to acutely remove endogenous proteins from oocytes and embryos. We have also established methods that can be used to study the causes of chromosome segregation errors directly in live human oocytes. In this presentation, I will talk about our latest research on the causes of the maternal age effect, which describes the decline in female fertility with advanced maternal age.

O-049 DNA damage and genome stability in the preimplantation embryo

INVITED SESSION
SESSION 14: FEMALE FERTILITY PRESERVATION
Monday 2 July 2018 Room 113 + 114 + 115 14:00–15:00

O-050 Fertility preservation - ovarian stimulation, when, how and in whom?

A. Germeyer[1]

Universitäts-Frauenklinik, Gyn. Endocrinology and Reproductive Medicine, Heidelberg, Germany

Fertility preservation is getting more and more important for young women with gonadotoxic therapies, as their chance for survival is highly improved due to better therapies. Furthermore as childbearing is postponed due to social factors, such as female carriers, women are at increased cancer risk before their family planning is complete.

Therefore cancer survivors nowadays have an increased desire for parenting and the wish to conceive their genetic offsprings.

Currently available techniques for fertility preservation include ovarian suppression with GnRHa, ovarian stimulation and egg collection, ovarian cryopreservation and ovarian transposition in cases of radiation of the lower abdomen.

Ovarian stimulation for collection of mature oocytes is a, well established, option for fertility preservation in women at risk. The chance for later conception with these cryopreserved oocytes depends on the age at retrieval and the number of oocytes available.

An ovarian stimulation is feasible, when 2 weeks are available prior to the start of gonadotoxic therapies.

In contrast to conventional ovarian stimulation for in vitro fertilization, ovarian stimulation can be started in any cycle phase (so called random start) with similar outcome. In order to reduce the risk for ovarian hyperstimulation syndrome, despite a high oocyte yield, a dose intensified antagonist protocol followed by ovulation induction with GnRHagonist is highly recommended. Gonadotropin doses used are typically 50IE higher than in conventional ovarian stimulation, to optimize the number of oocytes retrieved. In women with estrogen dependent tumors, such as hormone receptor positive breast cancer patients, an aromatase inhibitor (Letrozol® 5 mg/d) is given during ovarian stimulation to minimize the estrogen production. When time is limited until gonadotoxic therapies, in vitro maturation can be an option in women with a high antral follicle count, as seen in PCOS. IVM is performed without prior ovarian stimulation however chances of conception with the recovered cells are lower than after conventional ovarian stimulation. On the other hand, if more than 4 weeks are available until gonadotoxic therapies are started, a double stimulation can be performed with a first stimulation at random start and a second stimulation started 2 days after ovum pickup, in order to increase the number of oocytes available.

Recovered mature oocytes can then either be frozen without or after fertilisation (preferably with intracytoplasmic sperm injection in order to reduce the risk of fertilization failure).

The only premise for the use of ovarian stimulation as fertility preservation technique is a postpubertal stage with remaining ovarian reserve at the time of consultation prior to the gonadotoxic therapy.

O-051 Use and efficiency of cryopreserved material for women with serious disease

SELECTED ORAL COMMUNICATIONS
SESSION 15: REPRODUCTIVE SURGERY
Monday 2 July 2018 Room 117 14:00–15:00

O-052 Validation of the Endometriosis Fertility Index (EFI) to predict pregnancy in an infertile argentine population

L. Solari[1], **G. Botti**[2], **G. Percivalle**[1], **M. Gutierrez**[1], **S. Marin**[1], **M.E. Mackey**[3]

[1]*Sanatorio Centro, Centro de Cirugía Ginecológica Mini Invasiva, Rosario, Argentina*
[2]*Sanatorio Centro, Centro de Cirugía Ginecològica Mini Invasiva, Rosario, Argentina*

[3]PROAR, Bioestadìstica, Rosario, Argentina

Study question: To evaluate if Endometriosis Fertility Index (EFI) is useful to estimate the reproductive outcome in infertile argentine patients with diagnosis and surgical treatment of endometriosis.

Summary answer: The EFI was validated as a useful tool to estimate the reproductive prognosis of infertile argentine patients diagnosed with endometriosis.

What is known already: Adamson y Pasta developed a scoring system, being the only classification of endometriosis for infertile patients that predicts the spontaneous pregnancy rate after laparoscopy and allows to determine what type of fertility treatment is appropriate for each patient. After being validated in the North American population, retrospective studies in other countries such as France, Italy, Belgium and China have also evaluated their usefulness, although it had not yet been studied in our country.

Study design, size, duration: Retrospective cohort study. We analyze medical records of 90 infertile patients (April 2011 to January 2015) with endometriosis diagnosed by laparoscopy. Data from surgical factors for categorization according to EFI was obtained from videos of laparoscopies and historical factors were collected from medical records. The pregnancy rate was evaluated after 12 months follow-up period. Patients were divided according to EFI in group 1 (0-4), 2(5-7), 3 (8-10), cumulative pregnancy rates among these groups were compared.

Participants/materials, setting, methods: We included infertile patients diagnosed with endometriosis by laparoscopy performed by the same surgical team. Patients with a uterine factor, an abnormal hysterosalpingogram, or whose partner had a severe male factor were excluded. The treatment performed was fulguration of peritoneal endometriosis lesions, adhesiolysis and endometriomas cystectomy. A double-blind retrospective review of these videos was performed to obtain the data of the surgical factors to categorize patients.

Main results and the role of chance: The probability of spontaneous pregnancy or pregnacy with ovulation induction or intrauterine insemination (IUI) within 12 months after laparoscopy was significantly higher in those with the greater EFI category compared with those with lower EFI category. The total pregnancy rate was 48.8%, 18.8% in group 1, 37.8% in group 2 and 66.66% in group 3. These rates presented a statistically significant linear trend ($p = 0.003$). When comparing the groups it is observed that the group 3 pregnancy rate was higher with respect to group 2 (RR: 1.76, 95% CI 1.10–2.81), and group 1 (RR: 3.67, 95% CI 1.03–13.08), both differences statistically significant. The pregnancy rate of the second group was double in relation to the group with lower EFI (RR: 2.09, 95% CI 0.56–7.79), however this difference was not statistically significant ($p = 0.22$). The 65.9 % of pregnancies achieved within the first 6 months after surgery.

Limitations, reasons for caution: A disadvantage of this system is the subjectivity when performing the Least Function Score because is possible to find differences between the surgeons. Also the calculation of EFI can be time consuming for the surgeon.

Wider implications of the findings: In patients with higher EFI category, the probability of spontaneous pregnancy or pregnancy with ovulation induction or IUI was increased within 12 months after laparoscopy. This allows us to validate the EFI as a useful tool to estimate the reproductive prognosis of infertile argentine patients diagnosed with endometriosis.

Trial registration number: Not applicable.

O-053 Whether the surgical indications for septate uterus are reasonable in infertile patients before in vitro fertilization?

X. Li, Y. Ouyang, Y. Wen

Reproductive & Genetic Hospital CITIC-Xiangya, Imaging Department, Changsha, China

Study question: Whether the surgical indications are reasonable for infertile patients with septate uteri before in vitro fertilization-embryo transfer (IVF-ET)?

Summary answer: The surgical indications for septate uteri proposed in this study are reasonable in infertile patients before IVF-ET.

What is known already: Up to date, there is no uniform surgical indications for septate uteri. This anomaly has been commonly considered to be associated with poor reproductive outcomes. However, the optimal surgical timing for septate uteri is still controversial. Should preventive treatments be given to reduce complications?

The incidence of uterine malformations in infertile patients is much higher than that in the general population. Normal uterine morphology is a prerequisite for successful embryo implantation, therefore, proper treatments are necessary for septate uteri before IVF-ET. Then, what kind of surgical indications are reasonable?

Study design, size, duration: A retrospective study was conducted of 937 infertile patients with septate uteri and 1578 patients with normal uteri who obtained singleton pregnancies via IVF-ET from January 2014 to December 2015.

Hysteroscopic metroplasty was performed before IVF-ET if patients meet at least one indication: (1) the septum depth ≥10 mm; (2) the septum depth between 5-10 mm accompanied by unexplained recurrent miscarriage or infertility history; (3) recurrent failures of IVF-ET. Conversely, patients would be managed expectantly.

Participants/materials, setting, methods: This study was conducted at the Reproductive and Genetic Hospital of CITIC-Xiangya (Changsha, China). The patients with septate uteri were divided into non-surgical ($n = 518$) and surgical ($n = 419$) groups and the uterine cavities were normal after surgery. The septate uteri were diagnosed according to the ESHRE-ESGE system. 1578 infertile patients with normal uteri were selected as the control group. The pregnancy and obstetric outcomes were compared among non-surgical, surgical and normal groups.

Main results and the role of chance: Multivariate regression analysis showed a significantly higher early pregnancy loss (EPL, OR 1.49 (1.07-2.07), $p = 0.018$) risk and much lower rates of term delivery (OR 0.72 (0.54-0.95), $p = 0.023$) and live birth (OR 0.67 (0.50-0.91), $p = 0.010$) in the surgical group than those in the non-surgical group; compared with the normal group, the surgical group showed significantly higher risks of EPL (OR 1.23 (1.08-1.40), $p = 0.002$), small gestational age at delivery (OR 1.26 (1.02-1.57), $p = 0.041$), low birth weight (OR 1.32 (1.03-1.70), $p = 0.019$), and the rates of term delivery (OR 0.79 (0.70-0.88), $p \leq 0.001$) and live birth (OR 0.79 (0.70-0.88), $p \leq 0.001$) were much lower; all pregnancy and perinatal outcomes were statistically similar between the non-surgical and normal groups ($P > 0.05$).

In the surgical group, the rates of miscarriage (OR 3.10 (2.08-4.61), $p \leq 0.001$) and ectopic pregnancy (OR 13.25 (6.46-27.17), $p \leq 0.001$) were significantly lower and the live birth rate (OR 0.05 (0.03-0.09), $p \leq 0.001$) was much higher than before surgery. According to the ROC curves, the cut-off values for surgery were septum length = 6.85 mm and the rate of internal indentation/uterine wall thickness = 0.895.

Limitations, reasons for caution: Firstly, all pregnancy outcomes were obtained via telephone calls or faxes, thus, some details were not studied. Secondly, the control group was not screened randomly, which may cause selection and confounding biases. Thirdly, not all patients received surgeries in our hospital, the inconsistency of surgical effects was inevitable.

Wider implications of the findings: The surgical indications proposed in this study can be used to guide proper treatments for infertile patients with septate uteri before IVF-ET.

Trial registration number: None.

O-054 Fertility after salpingotomy versus salpingectomy in women with tubal pregnancy; an individual patient data meta-analysis

N. Netteb[1], P. Capmas[2], H. Fernandez[2], P. Hajenius[1], B.W. Mol[3], M. Van Wely[1], F. Mol[1], O.N. Behalf of the DEMETER study group[2], O.N. Behalf of the ESEP study group[1]

[1]*Academic Medical Center, Q3-119 Obstetrics Gynaecology, Amsterdam, The Netherlands*

[2]*Hôpital Bicêtre, Service de Gynécologie Obstétrique, Le Kremlin Bicêtre Cedex, France*

[3]*Monash Medical Centre, Department of Obstetrics and Gynaecology, Clayton, Australia*

Study question: Before surgery for ectopic pregnancy: can we distinguish women who would benefit from salpingotomy in terms of a subsequent ongoing pregnancy, based on patient characteristics?

Summary answer: Salpingotomy did not improve fertility rates, although a small benefit could not be excluded. No subgroup was detected that would benefit more from salpingotomy.

What is known already: Tubal ectopic pregnancy can be surgically treated by salpingectomy in which the affected tube is removed, or by salpingotomy in which the ectopic pregnancy is removed and the tube is preserved. Salpingotomy bears the increased risk of persistent trophoblast, requiring additional treatment. Our conventional meta-analysis including data of two RCTs (DEMETER, ESEP) did not show a large benefit from salpingotomy, but a small benefit could not be excluded.

Study design, size, duration: We performed a meta-analysis with individual patient data (IPD) of RCTs based on a search of international scientific databases in collaboration with the Cochrane gynaecology and fertility group. We selected trials comparing salpingotomy and salpingectomy for tubal ectopic pregnancy and collected data on fertility prospects after surgery. The primary outcome was an ongoing pregnancy by natural conception. We aimed to determine the pregnancy chance over time, which will be analysed by survival methods.

Participants/materials, setting, methods: Follow up times were calculated from randomisation until last menstrual period of the ongoing pregnancy. All analyses were performed on an intention-to-treat basis. The estimated log hazard ratios were combined across studies using standard fixed-effect and random-effects meta-analysis methods. Subgroup effects were estimated by treatment-by-covariate interaction terms within studies and combining these across studies similarly. We explored the treatment modification for maternal age, serum hCG pre-operatively and size of tubal ectopic mass on ultrasound.

Main results and the role of chance: We identified two relevant trials, containing data of 653 women randomised to salpingotomy or salpingectomy. The cumulative ongoing pregnancy rate by natural conception was 58.3% after salpingotomy and 55.0% after salpingectomy (log rank p = 0.537). The mean time to an ongoing pregnancy was 21.9 months (95% CI 19.1 – 24.7) after salpingotomy and 23.8 (95% CI 21.1–26.5) after salpingectomy, resulting in a hazard ratio of 1.07 (95% CI 0.86–1.35). There was no interaction between maternal age, serum hCG level, size of tubal ectopic mass and treatment on ongoing pregnancy chance. We found no associations with maternal age or size of tubal ectopic mass. Serum hCG < 2,335 IU/l was associated with a higher ongoing pregnancy chance with a cumulative ongoing pregnancy rate of 63.8% after salpingotomy and 60.5% after salpingectomy (fecundity rate ratio 1.18; 95% CI 0.87–1.61; log rank p = 0.278).

Limitations, reasons for caution: In the ESEP study women with contralateral tubal disease were excluded whereas such women were not excluded in the DEMETER study. In the DEMETER study all women treated by salpingotomy also received a single shot methotrexate postoperatively. Analyses of other pre-specified treatment modifications are ongoing.

Wider implications of the findings: This IPD meta-analysis facilitates shared-decision- making. Salpingectomy might be the preferred treatment in view of safety of the intervention. Women with a preference for maximizing their pregnancy prospects might still opt for salpingotomy. Future studies need to take costs into account.

Trial registration number: DEMETER NCT00137982, ESEP ISRCTN37002267

O-055 Ovarian Reserve after uterine artery embolization in women with morbidly adherent placenta

A. Mohr Sasson[1], M. Spira[1], R. Rahav[1], D. Manela[1], E. Schiff[1,2], S. Mazaki-Tovi[1,2], R. Orvieto[1,2], E. Sivan[1,2]

[1]*Sheba Medical Center, Department of Obstetrics and Gynecology, Tel Hashomer-Ramat Gan, Israel*
[2]*Tel Aviv University, Sackler School of Medicine, Tel Aviv, Israel*

Study question: The aim of this study is to assess ovarian reserve in women after preservative cesarean section using uterine artery embolization (UAE) due to morbidly adherent placenta.

Summary answer: Women post preservative cesarean section using UAE due to placenta accrete have lower ovarian reserve compare to controls matched by age.

What is known already: Conservative management of morbidly adherent placenta can be considered when fertility preservation is desired, however, concern has been raised regarding the effect of embolization on ovarian function. One possible potential risk to fertility, is the exposure of the ovaries to ionizing radiation, being a procedure that is carried out under fluoroscopic control using contrast media for X-ray angiograms. Other mechanism, is the potentially unintentional migration of embolization material through anastomoses between the uterine and ovarian vessels. To the best of our knowledge, this is the first study evaluating hormonal status after UAE in patients with morbidly adherent placenta.

Study design, size, duration: A prospective historical study including all pregnant women admitted to a single tertiary care center, since November 2011 until July 2016 with a diagnosis of morbidly adherent placenta that had a successful preservative cesarean section delivery with bilateral uterine arteries embolization.

Participants/materials, setting, methods: Inclusion criteria included gestational age >24 weeks, singleton pregnancy and placenta increta / percreta. Exclusion criteria included maternal age >43 years at the time of recruitment and women after cesarean hysterectomy. Control group included women attending the infertility clinic due to male factor, or single women conceiving via sperm donation, matched by age. Blood samples were collected from all patients on day 2-5 of menstruations for hormonal profile and anti mullarian hormone levels.

Main results and the role of chance: 59 women underwent preservative cesarean section and uterine artery embolization due to morbidly adherent placenta during the study period. 21 women met inclusion criteria (33.9%) and were matched controls (n = 40). Median time for post operation blood sampling was 55 month (IQR 22.5-90.5). One woman was breastfeeding, 2 had intra uterine devices, and all other women reported they were not using hormonal treatment for contraception at the time of blood sampling. The study group had higher gravidity and higher rates of cesarean section as expected (2 IQR:2-4.75 vs 1 IQR:0-1, p = 0.001), (1IQR:1-2 VS 0, p = 0.001), respectively. Circulating levels of E2 and FSH did not differ significantly between the two groups (p = 0.665, p = 0.396, respectively). Anti mullarian hormone (AMH) was lower in the study group (0.8 IQR 0.44-1.80) compared to the controls (2.08 IQR 1.68-3.71),(p = 0.001). This finding was consistent in linear multivariate regression analysis where the group of cesarean section using bilateral artery embolization due to placenta accrete was significantly predictive for the levels of AMH (B=-1.308, p = 0.012).

Limitations, reasons for caution: Limitations of the study is the relatively small study group, though rarity of the condition, and the lack of information regarding baseline AMH levels before the procedure.

Wider implications of the findings: UAE in morbidly adherent placenta might be associated with reduced ovarian reserve, nevertheless, the alternative of hysterectomy is definite and do not offer solution to women desiring future fertility. Our findings support the use of UAE, while giving the proper consultancy on the possible effect on ovarian reserve.

Trial registration number: The study protocol was approved by the Institutional Review Board (ID 3178-16-SMC) and was supported by the National Institutes of Health (NCT02821702).

O-056 Maternal STAT3 regulates oocyte maturation and development of early embryos through autophagy

Y. Kawagoe[1], Y. Sato[2], N. Okamoto[1], B. Ishizuka[1], K. Kawamura[2]

[1]*Rose ladies clinic, Reproductive center, Tokyo, Japan*
[2]*International University of Health and Welfare, Obstetrics and Gynecology, Narita, Japan*

Study question: What is the role of maternal STAT3 signaling in preimplantation embryonic development?

Summary answer: Maternal STAT3 signaling is important for optimal oocyte maturation and cleavage-stage embryo development via autophagy activation.

What is known already: JAK2/STAT3 signaling is known as an intracellular signaling pathway. JAK2 is the member of Janus protein tyrosine kinase family and recruits and phosphorylates STAT3. Phosphorylated STAT3 is dimerized and translocated into the nucleus to regulate transcriptional activity. In addition, cytoplasmic STAT3 regulates the autophagy machinery in cells. In preimplantation embryos, STAT3 is constitutively active during fetal stage and shown to be important for embryonic development as demonstrated by embryonic lethality in STAT3 knockout mice. However, its role during early cleavage stage embryos is unknown due to the presence of maternal STAT3 in early embryos before zygote gene activation.

Study design, size, duration: GV-stage oocytes and preimplantation embryos were obtained from ICR mice (3-4 weeks of age) for quantification of STAT3 expression. In addition, these oocytes and embryos were used to examine the role of maternal STAT3 in oocyte maturation and embryonic development by inhibiting phosphorylation of JAK2 and STAT3 using STAT3 selective inhibitors, JAK2 selective inhibitors and JAK2/STAT3 signaling inhibitors.

Participants/materials, setting, methods: The expression levels of STAT3 in oocyte and embryos at different stages were measured using real-time RT-qPCR. GV-stage oocytes, zygote and 8 cell-stage embryos were cultured with different inhibitors to compare the proportions of oocytes underwent maturation and embryonic development. The spindle structure in cultured oocytes was examined using tubulin staining. To assess the autophagy activity, expression of microtubule-associated-protein-light-chain 3 (LC3) at mRNA and protein levels were measured by real-time RT-qPCR and immunofluorescence staining, respectively.

Main results and the role of chance: The expression levels of STAT3 peaked in oocytes and gradually decreased toward 4 cell-stage embryos. It was not detected after 8 cell-stage embryos, suggesting its maternal origin. In GV-stage oocytes, nuclear maturation rate was significantly decreased when both JAK2 and STAT3 signaling were inhibited (Control: 73.8 ± 5.4%, treat: 44.1 ± 4.9%, $P < 0.05$). When embryos were cultured with the STAT3 inhibitor S3I-201, embryo development was significantly suppressed at 4 cell-stage (Control: 94.5 ± 5.0%, STAT3 selective inhibitor: 9.7 ± 3.8%, $P < 0.01$), whereas JAK2 inhibitor Febratinib showed a weaker suppressive effects (Control: 94.5 ± 5.0%, JAK2 selective inhibitor: 57.9 ± 15.7%, $P < 0.01$). If both JAK2 and STAT3 inhibitors were used, they showed synergistic effect on suppression of embryonic development from 2 cell-stage embryos onwards (2 cell-stage; Control: 96.4 ± 2.1%, JAK2/STAT3 inhibitor: 31.3 ± 4.8%, $P < 0.01$, 4 cell-stage; Control: 94.5 ± 5.0%, JAK2/STAT3 inhibitor: 28.1 ± 4.4%, $P < 0.01$). Of note, embryo development was not affected when phosphorylation of JAK2 and/or STAT3 was inhibited after 8 cell-stage embryos. Furthermore, LC3 expression was significantly decreased in these embryos, indicating decline in autophagy activity.

Limitations, reasons for caution: Our study was performed using mouse oocytes and preimplantation embryos. Therefore, this result could not be directly translated to human cases.

Wider implications of the findings: Although similar studies using human oocytes are required to confirm the importance of STAT3 activity, our findings may provide a new strategy to help the patients with impaired oocyte maturation by culturing their GV-stage oocytes with STAT3 activators to induce oocyte maturation.

Trial registration number: Not applicable.

O-057 The human sperm basal body contributes a complex matrix of proteins important for proper preimplantation development of the oocyte upon fertilization

F. Amargant[1], A. Pujol[2], A. Ferrer-Vaquer[1], M. Durban[1], M. Martínez[1], M. Barragan[1], I. Vernos[3], R. Vassena[1]

[1]Clinica Eugin, Assisted Reproduction, Barcelona, Spain
[2]Centro de Infertilidad y Reproducción Humana CIRH, Assisted Reproduction, Barcelona, Spain
[3]Centre for Genomic Regulation CRG, Cell and Developmental Biology Programme, Barcelona, Spain

Study question: What does the sperm basal body contribute to the human zygote to ensure embryo early development?

Summary answer: The spermatozoon provides 288 centrosomal proteins to the zygote to form a functional centrosome, which is required in order to achieve optimal preimplantation developmental rates.

What is known already: During fertilization in the human species, the sperm provides a centrosome, the main microtubule organizing center (MTOC) essential for the development of a new organism, to the zygote. In somatic cells, the centrosome is comprised by 2 centrioles surrounded with pericentriolar material (PCM) composed of several essential proteins for its activity; the current view is that the human sperm basal body (BB) does not possess PCM, and PCM proteins are recruited from the oocyte cytoplasm after fertilization. Although alterations in the sperm centrosome function have been linked to infertility, its role in human preimplantational development has not been tested directly.

Study design, size, duration: To identify the sperm BB components, proteomic analysis was carried out on 4 experimental samples prepared from mixtures of 4 normozoospermic ejaculates. To study the BB function, headless sperm tails containing the BB, were generated by microsurgery, and injected into MII oocytes, which were further activated parthenogenetically ($n = 15$ sham and $n = 15$ tail injections) by sequential passages of ionomycin 10 µM. Morphokinetic recording of developing parthenotes was carried out every 5 minutes during 5 days.

Participants/materials, setting, methods: For proteomics studies, sperm were sonicated and the tail fraction, including the BB, was spun through a 30% sucrose cushion. Tails were solubilized with Laemmli Buffer and analyzed by mass spectrometry. In the functional study, sham- and tail-injected oocytes were cultured in SAGE and their development recorded. Times analyzed included second polar body extrusion, cell divisions and blastocyst expansion. Parthenotes were fixed at different times through D5 and tubulin, MTOCs, and DNA analyzed by immunofluorescence.

Main results and the role of chance: We identified 2,312 proteins as components of the sperm tail including the BB (validated by immunofluorescence with centrin). Gene ontology analysis identified 18% of the proteins as cytoskeletal, including 288 proteins from centrioles and PCM. As expected, most parthenotes (80%) arrested their development before reaching blastocyst stage, while morphokinetic developmental timings in both groups did not differ in any of the annotated times. However, while tail-injected parthenotes arrested throughout *in vitro* culture and irrespectively of developmental stage, 75% of the arrested sham-injected ones (lacking the sperm derived centrosome) could not proceed through compaction, and arrested around the time of embryonic genome activation. None of the sham- injected parthenotes that arrested before compaction, had detectable MTOCs in immunofluorescence, while MTOCs were visible in all those that developed past compaction. Altogether, our data suggest that the sperm BB is more complex than previously described; the high number of centriolar and PCM components it contains may provide an efficient conversion to a functional centrosome in the fertilized oocyte. The presence of MTOC-like structures in parthenotes suggests a developmental control of PCM protein expression during the early phases of development and a correlation between the presence of MTOCs and successful compaction.

Limitations, reasons for caution: The main limitations of these studies concern the sample size of the injection experiments and the fact that up to one third of the tails injected may not contain a BB, hence diluting the tail- injected parthenotes phenotype.

Wider implications of the findings: Our proteomic and functional results do not support the current view of "naked" centrioles in the human sperm BB; rather, they indicate that the centrioles are transferred to the oocyte at fertilization together with PCM proteins that may participate in the efficient assembly of the first centrosome of the zygote.

Trial registration number: Not applicable.

O-058 Human fertilization is completely blocked by egg Juno protein inhibition

C. Jean[1], F. Haghighirad[2], A. Ziyyat[3], Y. Zhu[2], E. Rubinstein[2], C. Gourier[4], J.P. Wolf[1], C. Boucheix[2], V. Barraud-Lange[5]

[5]Hôpital COCHIN-PORT ROYAL, Assisted Reproductive Technologies, Paris, France

Study question: Is Juno protein present at the membrane surface of human oocyte and involved in fertilization process?

Summary answer: Juno Protein is expressed on the plasma membrane of human oocyte and its inhibition by a monoclonal antibody completely blocks the gamete fusion.

What is known already: Gamete membrane fusion is the culminating event of the fertilization process, driving by poorly understood molecular mechanisms. Until now, three molecules have been proven to be essential: The egg's CD9 tetraspanin, the Izumo1 sperm protein and Juno, its receptor on egg. Gene invalidation of these three proteins causes a drastic decrease of mice fertility by the loss of gamete fusion ability. CD9 and Izumo have been described in human and the Izumo1-Juno interaction is conserved within several mammalian species, including human. The presence of Juno on human oocyte was not yet reported and its role in fertilization is not known.

Study design, size, duration: We investigate, in human, the presence of Juno on egg membrane surface and study its potential involvement in membrane gamete interaction during fertilization.

Participants/materials, setting, methods: Monoclonal antibodies against human Juno (anti-hJuno mAb) were produced by immunization of mice with HEK cells transfected with the putative human Juno sequence (HEK-hJuno). These antibodies were used for immunostaining experiments and *in vitro* fertilization assays on human gametes (GERMETHEQUE Biobank).

Main results and the role of chance: Three hybridoma's supernatants, tested by immunostaining, specifically revealed HEK-hJuno cells. The 3 purified monoclonal antibodies FJ2E4 (IgG1), FJ8E8 (IgG1) andFJ4F5 (IgG2a) recognized in western blot of HEK-hJuno extracts a protein with an expected MW of 25 kDa. Using these 3 anti-hJuno mAb for immunostaining, we identified the presence of Juno protein at the plasma membrane of human eggs. The distribution of the fluorescent signal appeared heterogeneous on fresh oocytes whereas it was homogeneous and finely punctuated when the eggs were fixed before staining; suggesting a relocation of the protein induced by the binding of the specific antibody. Furthermore, we highlighted a progressive expression of Juno depending on oocyte maturity. Finally, we showed that human oocyte inseminated in presence of anti-hJuno mAb wouldn't be fertilized by human sperm. These results suggest that anti-hJuno mAb block the interaction site of Juno protein with Izumo1 receptor, and, as in mouse model, that Juno is involved in membrane gamete interaction during human fertilization.

Limitations, reasons for caution: In order to respect French bioethics laws, functional tests have been performed using zona-free eggs, which is different from physiologic conditions.

Wider implications of the findings: This is the first report of the presence of Juno on human oocyte and of its involvement in human fertilization. It allows going further in the understanding of molecular mechanisms that drive gamete fusion; a crucial challenge in occidental and developing countries where infertility affects 16% of genitally active couples.

Trial registration number: not applicable.

O-059 PLCz knock-out sperm reveals the sole effect of altering calcium signals during assisted oocyte activation on later mouse embryogenesis

M. Ferrer Buitrago[1], L. Tilleman[2], V. Thys[1], A. Hachem[3], F. Van Nieuwerburgh[2], L. Leybaert[4], P. De Sutter[1], D. Deforce[2], J. Parrington[3], B. Heindryckx[1]

[1]University Hospital Ghent UZ, Ghent Fertility And Stem cell Team G-FAST- Department for Reproductive Medicine, Ghent, Belgium
[2]Ghent University, Laboratory for Pharmaceutical Biotechnology- Faculty of Pharmaceutical Sciences., Ghent, Belgium
[3]University of Oxford, Department of Pharmacology, Oxford, United Kingdom
[4]Ghent University, Physiology Group- Department of Basic Medical Sciences, Ghent, Belgium

Study question: Does a differing Ca^{2+} signature during assisted oocyte activation (AOA) have a later impact on pre-implantation mouse blastocysts?

Summary answer: Variations of Ca^{2+} at fertilization during ICSI-AOA do not prove detrimental for development of the blastocyst and its associated transcriptional status in mouse.

What is known already: Mammalian fertilization occurs in combination with a series of cytoplasmic Ca^{2+}oscillations initiated by the sperm-borne phospholipase C zeta (PLCz). Oocyte activation is achieved in response to the sum of individual Ca^{2+} spikes, irrespective of the Ca^{2+} oscillatory pattern. Hence, several pharmacological agents can induce oocyte activation by stimuli that diverge profoundly from the physiological Ca^{2+} signature. Although still controversial, some studies showed that altering the Ca^{2+} oscillatory regime at fertilization affects blastocyst establishment and post-implantation development. Novel genome-edited PLCz-null mouse sperm provide a neat way for evaluating the sole effect of different Ca^{2+} signals during ICSI-AOA on later embryogenesis.

Study design, size, duration: Assisted oocyte activation (AOA) was performed after ICSI of PLCz-null sperm into mouse oocytes. Four AOA strategies were applied: AOA1: human recombinant PLCz (Ca^{2+} oscillations), AOA2: strontium (Ca^{2+} oscillations), AOA3: ionomycin (single Ca^{2+} transient) and AOA4: TPEN (zinc chelator; absence of an initial Ca^{2+} trigger). Embryonic development and blastocyst transcriptome analysis were compared to control conditions: C1 (*in vivo* fertilization), C2 (ICSI using normal activating sperm) and C3 (parthenogenesis; induced by strontium and cytochalasin-D).

Participants/materials, setting, methods: MII oocytes were collected from B6D2F1 females after ovarian hyperstimulation. Frozen sperm samples were thawed before ICSI, according to standard procedures. Embryos were cultured for 5 days in sequential media. RNA isolation was carried out in individual blastocysts following manufacturer instructions (PicoPure-RNAi kit. Arcturus). RNA-seq was carried out on the NextSEq500. Data analysis was conducted in R in 9380 genes with a cpm >5 in at least 4 samples per group.

Main results and the role of chance: PLCz-null sperm were mostly not able to activate mouse oocytes (activation rate 9%). Failed fertilization was rescued in response to AOA, with all AOA strategies showing similar efficiencies in oocyte activation (91 ± 9%) compared to controls (87 ± 11%). The lack of PLCz did not compromise pre-implantation embryonic development, and blastocyst stage was achieved in all groups. Blastocyst formation rate (bfr) was significantly decreased in C2 (52%) in comparison to C1 (98%) and C3 (80%), reflecting the deleterious effect of ICSI in mouse embryonic development. We further evaluated the efficiency of the distinct AOA methods to support embryonic development compared to C2. The use of strontium (AOA2) yielded the highest bfr (75%, $p < 0.05$) within the AOA groups. Ionomycin (AOA3) resulted in similar output compared to C2 (49% vs 52%), but significantly reduced compared to C1 and C3. Despite the decreased bfr observed after using human recombinant-PLCz (AOA1; 29%) or TPEN (AOA4; 30%), differences were not statistically significant compared to C2. Both, AOA1 and AOA4 strategies showed significantly lower bfr compared to C1, C3 and AOA2. The transcriptional profile of individual blastocysts was further analyzed by RNA-seq, which did not identify significant differences in global gene expression within and between the groups.

Limitations, reasons for caution: RNA-seq analysis included only coding regions of well-annotated genes. This analysis involves only pre-implantation events.

Wider implications of the findings: Our findings provide a novel insight in understanding the role of Ca^{2+}oscillations beyond meiotic resumption in mammals. The use of PLCz-null sperm represents a potent translational model to explore the impact of AOA throughout early and late embryogenesis.

Trial registration number: (Non applicable).

O-060 Early steps of human embryo implantation explored in a 2D in vitro model

A. Aberkane[1], C. De Paepe[2], T. Addriaenssens[3], W. Essahib[1], C. Spits[2], S. Mackens[1], H. Tournaye[4], K. Sermon[2], J. Brosens[5], H. Van de Velde[1]

[1]Vrije Universiteit Brussel, Reproductive Immunology and Reproduction, Brussels, Belgium

[2]Vrije Universiteit Brussel, Research group Reproduction and Genetics, Brussels, Belgium
[3]Vrije Universiteit Brussel, Research group Follicle Biology, Brussels, Belgium
[4]UZ Brussel, Centrum voor Reproductieve Geneeskunde, Brussels, Belgium
[5]University of Warwick, Division of Biomedical Sciences, Warwick, United Kingdom

Study question: Can we use a 2D *in vitro* adhesion model to investigate molecular pathways involved in the early steps of human embryo implantation?

Summary answer: Human embryo implantation is initiated by apposition and adhesion and these steps are associated with different expression profiles of adhesion and extracellular matrix (ECM) transcripts.

What is known already: The few adhesion and ECM proteins analysed for human embryo implantation are derived from similarities found in the mouse model and leukocyte trans-endothelial migration. Both human and murine embryos have previously been co-cultured with Ishikawa cells in a 2D *in vitro* adhesion model. Only few data is reported on gene expression in human preimplantation blastocysts, however these studies do not provide large scale molecular knowledge to understand fundamental pathways involved during the implantation process.

Study design, size, duration: Vitrified human blastocysts were warmed and co-cultured in a 2D *in vitro* adhesion model, in which Ishikawa cells are used to represent the human endometrial epithelium. Attachment of the embryos to the Ishikawa cells was assessed in this study. Loosely (apposition) and firmly (adhesion) attached embryos were compared with unattached embryos. The early steps of implantation were investigated both on the observational (microscopy) and the molecular level (quantitative PCR (qPCR) and immunofluorescence (IF)).

Participants/materials, setting, methods: Six days post fertilisation (dpf) human embryos were co-cultured on the Ishikawa cells for 12 h, 24 h (7dpf) or 48 h (8dpf); and attachment rate and morphological development were investigated. Gene expression of 84 adhesion and ECM genes was analysed by qPCR. Proteins were localised by IF staining. Neutralizing antibody was used for functional blocking experiments. Data is reported on 109 human embryos. Mann-Whitney *U* and two-way ANOVA tests were used for statistical analysis ($P < 0.05$).

Main results and the role of chance: According to our *in vitro* attachment data, the majority of the embryos attach on the polar trophectoderm. We are also the first to show that human embryo implantation is initiated by apposition and followed by adhesion; the majority of the 6dpf embryos co-cultured for 12 h were loosely attached and this progressed to a firm attachment in 85.7% of the 7dpf embryos. HCG positive embryonic outgrowth formation at 8dpf indicates differentiation of the trophectoderm to the invasive syncytiotrophoblast.

Gene expression analysis was performed on loosely attached and unattached embryos co-cultured for 12 h with the Ishikawa cells. Loosely attached embryos were distinguished from the unattached embryos by the additional expression of *THBS1*, *TNC, COL12A1, CTNND2, ITGA3, ITGAV,* and *LAMA3*. Loose embryo attachment was also associated with the significant upregulation of *CD44* ($P = 0.014$). *TNC* and *THB1* were validated on protein level in 7dpf firmly attached embryos. THBS1 showed cytoplasmic localisation in the embryonic cells and TNC was present on the membrane of trophectoderm cells. Functional blocking of only TNC protein with a neutralizing antibody in 48 h co-cultured embryos did not affect the attachment rate nor hCG secretion.

Limitations, reasons for caution: The study was performed *in vitro* and made use of a carcinoma cell line. Also the sample size of the study was limited. Contamination of the analysed embryos by Ishikawa cells can be excluded due to the different gene expression profiles.

Wider implications of the findings: Taken our data together we have provided a "proof of concept" for fundamental understanding of the early steps of human embryo implantation. Confirmation of the data on a larger sample size and larger gene expression analysis will provide insights of defective molecular pathways involved in implantation failure.

Trial registration number: Not applicable

O-061 Effect of annexin-V positive sperm-cells removal with magnetic activated cell sorting (MACS) for ICSI procedures in couples with male infertility (teratozoospermia); A randomized controlled trial

C. Valdespin, L. Garcia, R. Avila, G. Robledo, A. Alvarez, G. Barroso
NASCERE, Reproductive Health Division, Mexico City, Mexico

Study question: Does the use of MACS and incubation with annexin-V conjugated microbeads (ANMB) before ICSI in couples with male infertility (teratozoospermia) improve the live-birth delivery rate?

Summary answer: The use of MACS-ANMB in men with teratozoospermia improves the development and quality of oocytes/embryos, consequently improving fertilization(FR), implantation(IR), pregnancy(PR), and live-birth-delivery rates.

What is known already: It is proved that human spermatozoa play an extensive role in the reproductive physiology, beginning with the fertilization process, continuing with early and late stages of embryo development, that ultimately impact on implantation and pregnancy rates. The expression of early apoptotic markers as plasma membrane translocation of phosphatidylserine (PS) is associated with abnormal embryo development and suboptimal results of FR, IR and PR. Annexin-V magnetic cell separation of non-apoptotic spermatozoa is simple, fast, inexpensive and highly specific, however, its role in late stages of embryo development and live-birth rate is unclear.

Study design, size, duration: A prospective, randomized, triple-blinded, and controlled trial was conducted using a parallel two-arm study. We included a total of 200 couples with teratozoospermia undergoing ICSI assigned in a 1:1 proportion either to the experimental or the control group. Samples from the study group were prepared by swim-up followed by MACS-ANMB to remove Annexin-V positive sperm cells. The study was conducted from June-2012 to March-2017 in a single reproductive center in Mexico City.

Participants/materials, setting, methods: Only those samples exhibiting teratozoospermia (morphology <4% according to Kruger's strict criteria) were included in the study. In addition, patients who presented with poor ovarian response ("Bologna" criteria) were eliminated. Samples were randomized in two groups: i)swim-up followed by MACS-ANMB, and ii)swim-up. All embryos were analyzed until day 5-6 (blastocyst stage) and all transfers were done on the same embryo stage. Statics: Mann-Whitney-test, Fisher-exact-test, and Person's-correlation were done to analyze the results ($p < 0.05$, significant).

Main results and the role of chance: Different results were obtained between groups, however, patients demographics were similar. The Annexin-V positive fraction was negatively correlated with sperm concentration ($r = -0.5435$ $p = <0.0001$), progressive motility ($r=-0.2975$ $p = 0.02$), and total motility ($r = -0.2975$ $p = 0.02$); and was positively correlated with type D morphology ($r = 0.4397$ $p = 0.0006$). Regarding embryo development and reproductive results, comparison between MACS-ANMB ($n = 100$), and control group ($n = 100$) showed the following results: i) FR of 40.8% (95% IC, 27.4-65.0) versus 45.2% (95% IC, 14.7-69.0) $p = 0.04$, ii) embryo survival on day-3 of 97.3% (95% IC, 89.7-100) versus 98.9% (95% IC, 96.8-100) Non Significantly (NS), iii) mean quality of embryos on day-3 of 2.9 (95% IC, 2.8-3.0) versus 2.9 (95% IC, 2.9-3.0) NS, iv) blastocyst development on day-5 of 61.2% (95% IC, 51.7-70.6) versus 48.8% (95% IC, 30.2-66.6) $p = 0.02$, v) quality of embryos on day-5 of 2.8 (95% IC, 2.6-3.1) versus 3.4 (95% IC, 3.3-3.6) $p = 0.001$, vi) percentage of arrested embryos of 32.9% (95% IC, 23.5-42.3) versus 49.9% (95% IC, 36.8-63.0) $p = 0.04$, vii) IR of 25.5% (95% IC, 12.7-67.1) versus

12.5% (95% IC, 6.2-32.8) p = 0.001, viii) PR of 51.1% (95% IC, 25.5-65.7) versus 26.1% (95% IC, 13.3-34.2) p = 0.001, and ix) live-birth delivery rate 24.5% (95% IC, 12.2-72.0) versus 9.5% (95% IC, 4.7-27.9) p=<0.0001, respectively.

Limitations, reasons for caution: In this study, we only included men with teratozoospermia, not evaluating other men with different types of male infertility. Despite the fact that we selected sperm-cells without indicators of apoptosis and measure its impact on live-birth delivery rate, we didn't evaluate its effect on chromosomal abnormalities.

Wider implications of the findings: Through ICSI there is the possibility of injecting a spermatozoon with an apoptotic process that by natural selection would be condemned to die generating suboptimal results in ART; with the help of MACS-ANMB we improve live-birth delivery rate in men with teratozoospermia and type-D motility.

Trial registration number: The main intervention of the study involved the handling of the sperm samples rather that human beings, clinical trial registration was not required.

O-062 Sperm Selection by either PICSI or MACS in cases with abnormal Sperm DNA fragmentation index for ICSI, a randomized control trial

E. Hassanen[1], H. Alkhader[2], S. El Tanbouly[2], K. El Koussy[2], H. Zaki[3], A.G. Hussin[2]

[1]clinical embryologist, IVF lab Ganin Fertility Center, Cairo, Egypt
[2]Ganin Fertility Center, IVF Lab, Cairo, Egypt
[3]Ganin Fertility Center, Gynaecology, Cairo, Egypt

Study question: which sperm selection technique PICSI or MACS is better for dealing with abnormal sperm DNA fragmentation patients undergoing ICSI.

Summary answer: there is no significant difference in cleavage, blastulation, implantation, pregnancy or ongoing pregnancy rates between both techniques.

What is known already: Sperm DNA fragmentation (SDF) has shown a negative correlation with fertilization rate, embryo quality, and ongoing pregnancy rate, and a positive correlation with miscarriage rate.

PICSI and MACS have been developed for selecting a healthy mature non apoptotic sperm for ICSI to obtain the best embryo quality and achieve higher ongoing pregnancy rates.

Sperm membrane binding to hyaluronic acid on a PICSI Dish can improve the likelihood of obtaining a sperm with lower SDF. MACS depends on the binding of protein Annexin V to phosphatidylserine which is a marker for apoptosis, giving an elution of sperm with lower SDF.

Study design, size, duration: Prospective randomized controlled trial enrolled 286 patients undergoing ICSI in Ganin Fertility Center, from November 2016 and still recruiting. On the day of ICSI patients with abnormal DNA fragmentation index were randomized into 2 arms; 1st arm is PICSI and it contains 145 Patients, the 2nd arm is MACS and it contains 141 Patients. Patients embryological parameters are recorded then pregnancy rate, implantation rate and ongoing pregnancy rate is followed up.

Participants/materials, setting, methods: Couples undergoing ICSI were included if the female age is below 40 years and had at last 5 mature oocytes, male must have abnormal DFI (> 19%) using TUNEL assay. Cases were randomized to the 2 groups, semen processing is done by double layer density gradient method then the resulted pellet is either placed on hyalornan dot of PICSI dish or labeled by Anexin V microbeads for further separation on the MACS column.

Main results and the role of chance:

Point of comparison	PICSI	MACS	P value	Significance
Total no. of cases	145	141	/	/
Average no. of MII oocytes	14.8	14.4	/	/
Primary outcome:				
Ongoing pregnancy rate (%)	56.3 %	50.8%	P = 0.3456	NS
Secondary outcome:				
Cleavage rate (%)	76.20%	75.56%	P = 0.5977	NS
Blasulation rate (%)	63.60%	60.61%	P = 0.0555	NS
Blastocyst quality rate (%)	62.70%	60.70%	P = 0.3172	NS
Pregnancy rate (%)	63.8%	59.10%	P = 0.4081	NS
Implantation rate (%)	38.35%	35.40%	P = 0.4214	NS

Limitations, reasons for caution: the number of enrolled patients is not enough to be 80% statistically powered so patient recruitment is open to complete 400 patients. The results could be more confident if it was applicable to use both of the techniques for injecting sibling oocytes (case controlled study).

Wider implications of the findings: Most of the published research agree with the benefit of using a sperm selection technique whether it's PICSI or MACS. This comparison will tell us novel data about ongoing pregnancy rate but more studies are needed to evaluate the live birth rate.

Trial registration number: Clinical trial registration number: NCT03398317

O-063 Antisperm-antibodies prevalence and relationship with seminal parameters and with post-coital test outcome. A retrospective analysis on over 10.000 men

C. Castellini[1], A. Barbonetti[2], S. D'Andrea[1], M. Totaro[1], A. Martorella[1], E. Minaldi[1], G. Cordeschi[1], S. Francavilla[1], F. Francavilla[1]

[1]University of L'Aquila, Department of Life- Health and Environment Sciences, L'Aquila, Italy
[2]San Raffaele Institute, Spinal cord injury, Sulmona- L'Aquila, Italy

Study question: To determine antisperm-antibodies (ASA) prevalence and the relationship of auto-immunization degree with seminal parameters and with post-coital test (PCT) outcome.

Summary answer: Only a 100% positivity of IgG-MAR test, detected in 2% of the study population, was significantly associated with lower sperm quality and poor PCT outcome.

What is known already: Although the IgG-MAR test has been recommended by WHO as an integral part of semen analysis for the screening of antisperm-antibodies (ASA), the prevalence of positive results and their relationship with seminal parameters as well as the cut-off values of clinical relevance are controversial.

Study design, size, duration: Retrospective analysis on 12.296 consecutive men attending the Andrologic Unit of the University/Hospital of L'Aquila for the evaluation of fertility potential.

Participants/materials, setting, methods: Immunological screening with IgG-MAR test was performed to all ejaculates as integral part of semen analysis. Positive samples (≥10%) were tested also for IgA-ASA. The prevalence of positive IgG-MAR tests and the relationship of the degree of the sperm-autoimmunization with seminal parameters were analyzed. The outcome of PCT performed in couples where the male partner exhibited a positive MAR test was also analyzed.

Main results and the role of chance: Excluding from the analysis semen samples with not-executable MAR-test due to azoospermia or severe oligo-asthenozoospermia, the prevalence of positive IgG-MAR test in the remaining 10.025 men was 4% (398), 3.4% (342) and 2% (200) using a cut-off of 10%, 50% and 100% positive MAR-test. Only 100% positive MAR-tests were significant associated with a higher prevalence of the mixed pattern of positivity, as well as with concomitant occurrence of IgA-ASA. Only 100% positive MAR-tests were significantly associated with a lower median value of total number of

spermatozoa: 69×10^6 vs 132×10^6 (p = 0,0003) in 50%-99% positive MAR test and vs 120×10^6 (p < 0,0001) in negative samples. Furthermore, Only 100% positive MAR-tests were significantly associated with a lower median value of progressive motility: 40% vs 53% (p < 0,0001) in 50%-99% positive MAR test and vs 54% (p < 0,0001) in negative samples. In 120 PCT performed in couples where the male partner exhibited a positive MAR, only 100% positive MAR-tests were significantly associated with a higher percentage of poor PCT outcome: 78% vs 30% (p < 0.0001) in 50%-99% positive MAR test and 17% (p < 0.0001) in >50% positive MAR-test. This association was independent from cervical mucus score and total progressive motile sperm in the ejaculate.

Limitations, reasons for caution: Only surrogate infertility-related endpoints have been analysed in this study. However, as the impairment of sperm penetration through the cervical mucus represents the primary mechanism of ASA interference with fertility, the PCT outcome may represent a suitable endpoint.

Wider implications of the findings: In the context of the controversial clinical relevance of ASA, this study, the largest reported, provides a more reliable estimate of their prevalence. Although 50%- positive MAR-test has been indicated by WHO as clinically-relevant cut-off, only 100%- positive MAR-tests were significantly associated with lower sperm quality and poor PCT outcome.

Trial registration number: not applicable.

O-064 Antioxidants in the treatment of male factor infertility: Results from the double blind, multi-center, randomized controlled Males, Antioxidants, and Infertility (MOXI) trial

A. Steiner[1], K. Hansen[2], M.P. Diamond[3], C. Coutifaris[4], M. Cedars[5], R. Legro[6], R. Usadi[7], V. Baker[8], R. Coward[9], N. Santoro[10], E. Eisenberg[11], H. Zhang[12], A. Reproductive Medicine Network.[11]

Study question: Among couples with male factor infertility, do antioxidants improve male fertility, as measured by semen parameters and sperm DNA integrity at 3 months, and pregnancy by 6 months of treatment?

Summary answer: Antioxidant treatment of the male partner does not improve semen parameters, sperm DNA integrity, or in vivo pregnancy rates in couples with male factor infertility.

What is known already: Clinical trials suggest that antioxidants have a positive effect on sperm motility, DNA integrity, and pregnancy rates in couples undergoing assisted reproductive technologies; however, there are significant gaps in our knowledge of their impact on male fertility. To date research studies have used: 1) small sample sizes, usually less than 50 subjects, 2) heterogeneous populations and a variety of single antioxidants, 3) changes in semen parameters or DNA integrity as the endpoint, rather than clinical outcomes, and 4) antioxidants in conjunction with in vitro fertilization with intracytoplasmic sperm injection (ICSI) when assessing effectiveness.

Study design, size, duration: 174 couples were enrolled in a multi-center, double blind, randomized, placebo-controlled trial of a daily antioxidant formulation, containing 500 mg vitamin C, 2000IU vitamin D3, 400IU vitamin E, 1 mg folic acid, 20 mg zinc, 200 mcg selenium, and 1000mg L-carnitine. Males were treated for a minimum of 3 months and a maximum of 6 months. Couples attempted to conceive naturally during the first 3 months and with clomiphene citrate with intrauterine insemination in months 4 through 6.

Participants/materials, setting, methods: Males with sperm concentration ≤ 15 M/ml, motility ≤ 40%, normal morphology ≤ 4%, or DNA fragmentation > 25% were eligible. Female partners were ≤ 40 years old, with documented tubal patency and ovulation. Semen parameters and DNA fragmentation were assessed at randomization and following 3 months of treatment. Data are presented as median (interquartile range) or mean ± standard deviation.

Main results and the role of chance: After 3 months of treatment, change in sperm concentration differed slightly between the antioxidant [-4.0 (-12.0, 6.0) M/ml] and placebo groups [+3.2 (-9.0, 15.5) M/ml] (p = 0.03). However, there were no significant differences between the two groups in the change in morphology, motility, or DNA fragmentation. Among the 66 oligospermic men at randomization, concentration did not differ at 3 months [8.5 (4.8,15.0) M/ml versus 15.0 (6.0,24.0) M/ml; p = 0.30] between antioxidant and placebo groups. Among the 76 asthenospermic men, motility did not differ at 3 months (34 ± 16.3% versus 36.3 ± 15.6%; p = 0.93). Among the 40 men with teratospermia, normal morphology did not differ at 3 months [2.0 (0.6,4.5)% versus 3.0 (2.0,4.0)%; p = 0.28]. Among the 34 men with high DNA fragmentation, DNA fragmentation did not differ at 3 months [28.9 (21.6,36.5)% versus 28.8 (21.6,37.4)%; p = 0.68]. In the entire cohort, cumulative pregnancy rates did not differ at 3 months (10.5% versus 9.1%; p = 0.76) or at 6 months (22.1% versus 29.6%; p = 0.26) between the antioxidant and placebo groups, respectively.

Limitations, reasons for caution: While the trial was adequately powered to examine changes in semen parameters, the trial is underpowered to assess differences in pregnancy rates between antioxidants and controls. However, the DSMB recommended not proceeding with the larger trial, given the results of the internal pilot.

Wider implications of the findings: Antioxidants do not appear to improve semen parameters or DNA fragmentation among men with male factor infertility. While previous data suggest that antioxidants improve pregnancy rates in in vitro fertilization, these data suggest they do not improve in vivo conception.

Trial registration number: NCT02421887

O-065 Features of metabolic disorder in late adolescence are negatively associated with testicular function aT 20 years of age; evidence from a birth cohort,

R. Hart[1], D. Doherty[2], L. Adams[3], R.C. Huang[4], T. Mori[5], N. Minae[2], R. MacLachlan[6], N. Skakkebaek[7], R. Norman[8], D. Handelsman[9], J. Olynyk[10], L. Beilin[5]

[10]Fiona Stanley Hospital & Fremantle Hospital Group, Department of Gastroenterology, Perth, Australia

Study question: In a population of men within a birth cohort, are features of an adverse cardiometabolic profile in late adolecence associated with impaired testicular function at 20 years of age?

Summary answer: Despite the majority of men being only 20 years old, with a normal BMI, features of cardiometabolic disorder were associated with signs of testicular impairment.

What is known already: An adverse cardiometabolic profile in adulthood has been reported to be associated with impaired testicular function; however no data exists from younger men. Hence it is unclear whether the metabolic disorder predates the adverse testicular function, or whether it is the lower serum testosterone concentration that predisposes the man to metabolic disorder in later life.

Study design, size, duration: The Raine Study recruited 2900 women in pregnancy and retained the 2868 children born to form the Raine Study cohort. At 17 years of age males underwent a liver ultrasound for fatty liver (n = 490), and serum cytokines were measured (n = 520). At 20 years, measures included blood biochemistry (n = 618), a DEXA scan (n = 634), and a testicular assessment performed; semen sample (n = 365), testicular ultrasound (n = 404) and serum testosterone, LH, FSH and inhibin B concentrations were assayed (n = 620).

Participants/materials, setting, methods: Fasting bloods were analysed for serum IL-18 by ELISA, tumor necrosis factor receptors (TNFR1 & 2) by cytometric bead array, and liver enzymes, insulin, glucose, lipids, high sensitivity CRP (hsCRP) and uric acid. Homeostasis model assessment (HOMA) was calculated and insulin resistance (IR) was defined by a HOMA>4. DEXA measurement was performed for lean and total fat mass.

A cluster analysis was used to derive high-risk groups with features consistent with the metabolic syndrome.

Main results and the role of chance: Participants that had testicular assessment were similar clinically to those that declined participation. The prevalence of metabolic syndrome was 4.1% (NCEP-ATPIII definition) (40) and 5.4% (IDF definition).

After adjustment for age, BMI, abstinence, a history of cryptorchidism and presence of a varicocele; total sperm output was reduced in men with a higher IL-18, and serum TNFR1, and sperm concentration was negatively associated with IL-18 (all $p < 0.05$). After adjustment, seminal volume was negatively associated with serum hsCRP, and serum testosterone was positively associated with serum HDL-cholesterol and lean mass, and negatively with serum insulin (all $p < 0.05$).

In an unadjusted dichotomized analysis of men within the high risk metabolic cluster compared to those low risk, their testosterone (3.6 ng/ml *vs* 4.8 ng/ml) and inhibin B (167.9 pg/ml *vs* 223.7 pg/ml) concentrations were lower ($p < 0.001$ for both). Participants with IR had a smaller testicular volume (12.8mls *vs* 15.2mls, $p = 0.010$), lower testosterone (3.2 ng/ml *vs* 4.6 ng/ml, $p < 0.001$) and inhibin B (172.4 pg/ml *vs* 217.8 pg/ml, $p = 0.001$), and higher serum FSH concentrations (6.1iu/l *vs* 4.3iu/l, $p = 0.046$).

Ultrasound evidence of fatty liver was associated with a reduction in; total sperm output (68.0×10^6 *vs* 126.0×10^6, $p = 0.044$), testosterone (4.0 ng/ml *vs* 4.7 ng/ml, $p = 0.005$) and inhibin B (209.1 pg/ml *vs* 218.4 pg/ml, $p = 0.032$) concentrations.

Limitations, reasons for caution: Although this study had a very good rate of recruitment there is potential for recruitment bias, and the possibility of confounding. Univariate associations were substantiated in multivariable analyses that controlled for confounding for age and BMI at 20 years, cryptorchidism and presence of a varicocele.

Wider implications of the findings: This study demonstrated a potential negative association of adverse cardiometabolic features in adolescence with testicular function by 20 years of age. Despite the majority of men having a normal BMI, and being relatively young, a significant minority were already showing some features of the metabolic syndrome and impaired testicular function.

SESSION 18: HEALTH RISKS IN CHILDREN BORN AFTER ART

Monday 2 July 2018 Room 111 + 112 15:15–16:30

O-066 Body composition and blood pressure of 6-year-old singletons born after Pre-implantation Genetic Testing (PGT): a matched cohort study

F. Belva[1], M. Roelants[2], S. Kluijfhout[1], C. Winter[1], F. De Schrijver[1], S. Desmyttere[1], A. Buysse[1], P. De Becker[1], M. De Rycke[1], W. Verpoest[3], I. Liebaers[1], M. Bonduelle[1]

[1]*UZ Brussel, Medical Genetics, Jette- Brussels, Belgium*
[2]*KU Leuven, Environment and Health/Youth Health Care- Department of Public Health and Primary Care, Leuven, Belgium*
[3]*UZ Brussel, Centre for Reproductive Medicine, Jette- Brussels, Belgium*

Study question: Do children conceived by PGT have an altered body composition or higher blood pressure?

Summary answer: Blood pressure and anthropometric measurements including body mass index (BMI) and indices of peripheral and central adiposity were comparable between PGT and ICSI children.

What is known already: Although neonatal outcomes after PGT conception have been found comparable to those after ICSI, few studies have reported on the medical outcome at older ages. We previously found that at age 2, mean body mass index tended to be lower in PGT children while the prevalence of congenital anomalies was similar. Others reported that blood pressure and anthropometrics did not differ in 4- and 9-year old children conceived after IVF/ICSI with or without aneuploidy testing (PGT-A). However, outcomes in PGT-A children cannot be extrapolated to PGT children given the dissimilar indications and parental reproductive background.

Study design, size, duration: In this single-center study, singletons conceived by PGT reaching between 5 and 6 years during the period May 2011 and June 2017 were matched as closely as possible for gender, age, maternal educational level and birth order to peers born after ICSI. Biopsy of cleavage-stage embryos was performed solely for the purpose of PGT (PGT-A cycles were excluded) and all fresh embryo transfers in PGT and ICSI cycles were carried out at day 5.

Participants/materials, setting, methods: Anthropometrics (weight, height, BMI, skinfold thickness, waist and mid-upper arm circumference) and blood pressure readings of 87 singletons born after PGT, including PGT for mongenic defects (PGT-M) and chromosomal structural rearrangements (PGT-SR), but not for aneuploidies (PGT-A), were compared with results of 87 peers born after ICSI.

Main results and the role of chance: From the 124 eligible PGD families, 110 could be contacted, 23 declined and 87 (70.2%) children participated of whom 39 (45%) were males. The reasons for declining were 'no time' and 'living too far from the hospital'. Neonatal characteristics, including birth weight Standard Deviation Score (SDS) and gestational age and parental characteristics, including maternal weight gain, smoking and alcohol consumption during pregnancy, maternal age, current maternal and paternal BMI were comparable between the groups (all $p > 0.05$). Mean age was 5.5 years in the PGT group and 5.6 years in the ICSI group ($P = 0.2$). All anthropometric measurements, including BMI SDS, waist and mid-upper arm circumference SDS were comparable between the PGT (-0.23; 0.27; 0.17 respectively) and ICSI (-0.29; 0.10; 0.11) group (all $P > 0.05$). Furthermore, skin thickness derived indices of peripheral and central adiposity were comparable (PGT: 14.7 mm; 11.6 mm and ICSI: 15.5 mm; 11.5 mm) as well as the calculated total body fat mass (PGT: 13.7% and ICSI: 13.9%) (all $P > 0.05$). Finally, also blood pressure SDS were comparable between the two groups (all $P > 0.05$). Results did not change taking neonatal (birth weight SDS, gestational age, birth order) and parental (pre-pregnancy maternal BMI, maternal educational level) characteristics into account.

Limitations, reasons for caution: The non-participating PGT children did not differ from the participating group in terms of gender, birth order, gestational age, birth weight or maternal educational level, which makes participation bias less likely.

Wider implications of the findings: Our results point to no adverse effect of embryo biopsy at cleavage-stage and fresh embryo transfer at day 5. However, more and long-term follow-up studies are indicated as there are currently no data available for PGT children born after trophectoderm biopsy and/or transfer of warmed embryos after vitrification.

Trial registration number: not applicable.

O-067 Birthweight and gestational age following blastocyst transfer compared to cleavage stage embryo transfer: an analysis of 68,042 singleton births

N. Marconi, E.A. Raja, S. Bhattacharya, A. Maheshwari

University of Aberdeen, Institute of Applied Health Sciences, Aberdeen, United Kingdom

Study question: Are there any differences in birthweight and gestational age in singleton births conceived after blastocyst transfer as compared to those following cleavage stage embryo transfer?

Summary answer: Birthweight and gestational age outcomes of singleton pregnancies following fresh blastocyst transfer are similar to those subsequent to cleavage-stage embryo-transfer.

What is known already: Previous observational studies and meta-analysis suggest that risks of preterm birth (PTB) and high birthweight babies (HBW) in singleton pregnancies are higher following blastocyst transfer than after embryo transfer at cleavage stage. The published studies have limitations including small sample sizes and inability to adjust for a number of potential confounders. Hence there is a need for definitive results based on analysis of a single large national dataset.

Study design, size, duration: This is a cohort study using anonymized Human Fertilisation Embryology Authority (HFEA) data from the United Kingdom (UK). This study included all fresh in-vitro fertilisation (IVF) and intracytoplasmic sperm injection (ICSI) cycles between the years 1999 and 2012 that resulted in a singleton birth after the transfer of two different types of embryo: cleavage-stage (2-3 days of culture) and blastocyst-stage embryo (5-6 days).

Participants/materials, setting, methods: IVF or ICSI cycles with singleton births following the fresh transfer of cleavage stage or blastocyst stage embryo(s) were included in the study. Logistic regression was used to assess the association between the stage of embryo transferred (cleavage stage or blastocyst) and birthweight and gestational outcomes adjusting for potential confounders. Risk ratios (RR) with 99.5% confidence intervals (CI) were used as a measure of strength of associations.

Main results and the role of chance: Out of 68,042 singleton pregnancies, 11,243 occurred after blastocyst-stage embryo transfer while 56,799 resulted from cleavage-stage embryo-transfer. The proportion of low birth weight babies in the two groups were 8.9% and 9.3% respectively ($p = 0.12$). The risk of having a low birthweight baby (aRR 0.93, 99.5% CI 0.83-1.05) and that of having a high birthweight baby (aRR 0.93, 99.5% CI 0.83-1.05) were comparable after adjusting for maternal age, IVF/ICSI, duration of infertility, primary cause, number of eggs, and previous pregnancy. The proportion of babies born preterm was 1.9% in the blastocyst-stage group and 1.8% in the cleavage stage group ($p = 0.68$). The risks of preterm birth (aRR 1.03, 99.5% CI 0.91-1.18) and very preterm birth (aRR 1.00, 99.5% CI 0.78-1.28) were similar between the two types of embryo transfer strategies. The odds of congenital anomalies was similar between the groups (aOR 0.89, 99.5% CI 0.69-1.16).

Limitations, reasons for caution: As the anonymized HFEA data presents gestational age and weight in bands rather than actual values, we were unable to adjust birth weight according to gestational age and calculate parameters such as Z scores. Additionally, one woman could have been represented more than once in this cycle based analysis.

Wider implications of the findings: Our findings provide reassurance to patients undergoing blastocyst-stage embryo-transfer, in contrast to other studies that have reported increased risk of high birthweight babies and preterm delivery. Follow up studies from randomised trials or individual patient data meta-analysis of registry based data will be needed to answer the question definitely.

Trial registration number: not applicable.

O-068 Diabetes risk among children born after assisted reproductive technology: An early population-based examination

Study question: What is the risk of developing diabetes among children born after Assisted Reproductive Technology (ART)?

Summary answer: ART children have a low absolute risk of developing diabetes by age 19, but the relative risk compared with non-Art children approaches statistical significance.

What is known already: Data from animal studies suggest a potential risk for diabetes among children born after ART, which may be mediated by epigenetic changes. In humans, however, the majority of diabetes cases develop later in life, most of which represent type-2 diabetes. In contrast, type-1 diabetes is less common overall, but more prevalent among children. One recent study found increases in both types among all children ≤19 years. The existing literature has not had sufficient follow-up time to evaluate diabetes development after ART. Early detection however, could have tremendous value, as many diabetic complications can be prevented or mitigated with current therapy.

Study design, size, duration: We examine the association between ART use and diabetes risk through 2011 within a historical population cohort consisting of all residents of Denmark. We examine the time to development of diabetes using population-based clinical registries for diabetes, and other national datasets. We focus on children born during the first six years of the Danish ART registry, i.e., born between 1994 and 1999. We use insulin status as a crude initial proxy for diabetes type.

Participants/materials, setting, methods: All children born in Denmark between 1994 and1999 are captured in the birth registry and eligible for the study. We examine the numbers of children who develop diabetes, as captured by the diabetes disease registry. We then compare the risk of developing diabetes among children born after ART treatment (using the ART registry) with that of children born without treatment (i.e., spontaneous births). We use proportional hazard models to assess the time to disease onset.

Main results and the role of chance: The maximum follow-up time was 19 years, i.e., for children born in 1994. Between 1994 and 1999, there were 5,912 live births after ART treatment and 400,131 spontaneous births. Among these, a total of 1,986 children developed diabetes by 2012 as captured by the national disease registry, or 4.9 per 1,000 spontaneous birth children and 5.9 per 1,000 children born after ART. The mean age at diabetes detection was 10.2 and 8.7 years, respectively; 82.0% and 82.9% were receiving insulin among spontaneous birth and ART children. After multivariate adjustment, children born after ART trended towards being more likely to develop diabetes (hazard ratio = 1.4; p-value = 0.08), but this association was not statistically significant at conventional thresholds (i.e., p-value = 0.05).

Limitations, reasons for caution: This study has limited follow-up time and numbers of total children in each group, decreasing both the power to detect events during childhood and adolescence, and the ability to detect disease later in life. The comparisons also reflect associations with diabetes and do not imply causality.

Wider implications of the findings: There is a potential increased risk and earlier onset of diabetes associated with ART treatment, compared with spontaneous births, though these preliminary analyses have limited statistical power. Ongoing work will increase the amount of follow-up time, thus improving both power and the ability to examine risks during early adulthood.

Trial registration number: Not applicable.

O-069 The risk of urogenital anomalies in children conceived with ICSI using fresh or frozen embryo cycles

R. Fernandez[1], V. Moore[1,2], K. Willson[2], A. Rumbold[1], M. Davies[1]

[1]*University of Adelaide, Robinson Research Institute, Adelaide, Australia*
[2]*University of Adelaide, School of Public Health, Adelaide, Australia*

Study question: Does the risk of urogenital anomalies in children conceived with intracytoplasmic sperm injection (ICSI) vary by use of fresh or frozen embryo cycles?

Summary answer: Relative to natural conceptions, urogenital anomalies were increased in children conceived with ICSI using fresh cycles but not frozen cycles, accounting for infertility aetiology.

What is known already: Urogenital anomalies are among the most commonly diagnosed congenital anomalies, affecting up to 16 per 1000 births per year. Higher rates of urogenital anomalies are also observed among births conceived using assisted reproductive technologies (ART), particularly ICSI. Male factor infertility, the most common indication for ICSI, is also a risk factor for some urogenital anomalies. There is evidence linking embryo freezing to improved perinatal outcomes. Previous studies of urogenital anomalies in ART populations have not investigated whether embryo freezing modifies the risk of anomalies, nor accounted for the possible role of male factor infertility.

Study design, size, duration: This study involved a whole of population data-linkage cohort for the state of South Australia, comprising 308,933 births and terminations of greater than 20 weeks gestation, from January 1986 to December 2002. Congenital anomalies are notified until children reached age 5 years.

Participants/materials, setting, methods: The South Australian Birth Cohort links data from infertility clinics with government perinatal and birth defects registries. Urogenital anomalies are coded to the British Paediatric Association modification of ICD-9 codes. Using children conceived naturally as the reference, we examined the risk of urogenital anomalies among children conceived with ICSI overall, and separately, ICSI with frozen or fresh cycles, using logistic regression with adjustment for potential confounders. The role of male factor infertility was also considered.

Main results and the role of chance: There were 308,933 births and terminations, including 1410 resulting from ICSI (79% using fresh cycles, 21% using frozen cycles). Male factor infertility only was the most common reason for treatment in the fresh and the frozen ICSI cycles (75% vs 73%, respectively). Overall, the risk of urogenital anomalies was increased in children conceived with ICSI compared with natural conceptions (adjusted OR = 1.89, 95% CI: 1.39-2.58). The increased risk was observed in ICSI with fresh cycles (n = 1115, adjusted OR = 2.22, 95% CI: 1.62-3.04) and remained when patients with male factor infertility were excluded from this group (adjusted OR = 2.08, 95% CI: 1.10-3.93). There was no increased risk of urogenital anomalies in children conceived with ICSI using frozen cycles (n = 291, adjusted OR = 1.04, 95% CI: 0.43-2.48).

Limitations, reasons for caution: There was not sufficient statistical power to investigate specific subtypes of urogenital anomalies. Residual confounding may be present, as not all patient- and treatment-related risk factors for urogenital anomalies, for example severity of male infertility, number of embryos and embryo quality, were fully captured in available data.

Wider implications of the findings: The risk of urogenital anomalies associated with ICSI may be reduced through the use of frozen embryo transfer cycles. These findings contribute robust evidence to enhance understanding of the relative contribution of patient and treatment factors to the increased risk of adverse perinatal outcomes among children conceived using ART.

Trial registration number: not applicable

O-070 Does transfer of multiple embryos affect perinatal outcomes of the resulting singleton live births? Analysis of 113 784 singleton live births following ART

M.S. Kamath[1], B. Antonisamy[2], H.Y. Selliah[3], S.K. Sunkara[4]

[1]*Christian Medical College and Hospital, Reproductive Medicine, Vellore, India*
[2]*Christian Medical College and Hospital, Department of Biostatistics, Vellore, India*
[3]*Christian Medical College and Hospital, Department of Biostatistics, Vellore, India*
[4]*Queen's Hospital- Barking Havering Redbridge University Hospitals NHS Trust, Reproductive Medicine, Essex, United Kingdom*

Study question: Does transfer of two or more embryos affect perinatal outcomes of resulting singleton live births following assisted reproductive technology (ART)?

Summary answer: The risk of adverse perinatal outcomes is higher in singleton births following transfer of two or more embryos mainly associated with plurality at conception.

What is known already: Singleton pregnancies following ART are at a higher risk of adverse perinatal outcomes compared to spontaneous conceptions. Underlying infertility, altered endocrine milieu following ovarian stimulation, *in vitro* gamete manipulation and embryo culture are some of the suggested reasons for adverse perinatal outcomes. Earlier studies have found an increased risk of preterm birth (PTB) and low birth weight (LBW) in singletons following transfer of multiple embryos versus single embryo transfer (SET). However, these studies did not address the contributory role of plurality at conception, the initial presence of more than one gestational sac.

Study design, size, duration: Anonymous data were obtained from the Human Fertilization and Embryology Authority (HFEA), which collects the data prospectively on all ART cycles performed in the UK. Data from 1991 to 2011 involving 508 410 fresh and 131 334 frozen autologous ART cycles resulting in 95 779 and 18 005 singleton live births respectively were analysed for perinatal outcomes based on the number of embryos transferred.

Participants/materials, setting, methods: Fresh or frozen ART cycles were analysed separately to compare perinatal outcomes of PTB and LBW in singleton live births resulting from transfer of two or more embryos versus SET. Logistic regression was performed adjusting for female age, infertility causes, previous live birth and embryo stage. Subgroup analyses was planned within ART cycles for perinatal outcomes of singleton live births following either initial single or initial multiple gestational sacs versus singleton live birth following SET.

Main results and the role of chance: There was a significantly higher risk of PTB (aOR 1.14, 95% CI 1.06–1.23) and LBW (aOR 1.14, 95% CI 1.06–1.23) in singleton births following transfer of two or more embryos compared to SET in fresh cycles. There was a significantly higher risk of PTB (aOR 2.70, 95% CI 2.37-3.05) and LBW (aOR 2.76, 95% CI 2.44–3.13) in singleton births with initial multiple gestational sacs compared to those following SET with fresh transfers. There was no significant difference in the risk of PTB (aOR1.08, 95% CI 1.00–1.16) and LBW (aOR 1.08, 95%CI 1.00-1.16) singleton live births when there was an initial single gestational sac after fresh transfer of two or more embryos compared to SET. There was no significant difference in the risk of PTB (aOR 1.05, 95% CI 0.91–1.21) and LBW (aOR 0.95, 95% CI 0.81-1.12) in singleton births after transfer of two or more embryos compared to SET in frozen cycles. There was a significantly higher risk of PTB (aOR 2.13, 95% CI 1.55–2.93) and LBW (aOR 2.61, 95% CI 1.87-3.64) in singleton live births with initial multiple gestational sacs compared to those following SET in frozen cycles.

Limitations, reasons for caution: While the analysis was adjusted for a number of known confounders, the dataset had no information on other confounders like smoking, body mass index, previous obstetric history or medical history of women during pregnancy to allow for adjustment.

Wider implications of the findings: Current study results suggests that there is an increased risk of adverse perinatal outcomes following transfer of more than one embryo in singleton live births following ART and plurality at conception or the initial multiple gestation reduced spontaneously to singleton gestation plays the major contributory role.

Trial registration number: not applicable

Monday 2 July 2018 Room 113 + 114 + 115 15:15–16:30

O-071 Genetic Deconstruction of Hypothalamic Neural Circuits for Obesity-induced Infertility

P. Wang[1], J. Xu[2], C. Bartolome[2], Y. Xinchi[2], C. Low[2], D. Kong[2]

[1]*Beijing Chao-Yang Hospital Affiliated to Capital Medical University, Department for Human Reproduction, Beijing, China*
[2]*Tufts University School of Medicine, Department of Neuroscience, Boston, U.S.A.*

Study question: To investigate how the brain, especially the hypothalamus, adjusts reproductive performance according to metabolic cues and contributes to the pathophysiological process of obesity-induced infertility.

Summary answer: In obesity, hyperactive agouti-related protein (AgRP) neurons shut down reproductive performance by innervating preoptic area (POA) of the hypothalamus, where critical reproduction-regulating neurons reside.

What is known already: Epidemiological evidence suggests that obesity is tightly related to infertility, and given the role of the hypothalamus in coordinating both metabolism and reproduction, such obesity-induced infertility is likely mediated by the hypothalamus. We propose that the AgRP neurons in arcuate nucleus of the hypothalamus to be the key neurons in this pathophysiological process, given that AgRP neurons are, a) known as a major regulator of body weight and energy balance; b) heavily project to the POA of the hypothalamus, a key reproduction-regulating region; c) dysfunctions of AgRP neurons can result in severe obesity, which can cause infertility.

Study design, size, duration: To test the sufficiency and necessity of AgRP neurons in obesity-induced infertility, genetic engineered mice were randomized into control group and treatment group. Typically, each group includes 8-10 mice and 3 weeks were waited to allow sufficient expression of the viral vectors, which are used to manipulate AgRP neurons.

Participants/materials, setting, methods: AgRP-IRES-Cre mice of 6-8 weeks age were used in the current study to achieve cell-type-specific neuronal manipulation. Taking advantage of recently developed Cre-enable viral tools, in vivo inhibition and activation of AgRP neurons was carried out using DREADDs (designer receptors exclusively activated by designer drugs) and optogenetic methods. Subsequenlty, routine evaluation of reproductive performance was followed. CRISPR/Cas9 technique was also used to knock out leptin receptor in AgRP neurons.

Main results and the role of chance: To test the necessary role of AgRP neurons in mediating obesity-induced infertility, hyperphysiological neuronal activity of AgRP neurons in high-fat-diet-induced obese mice was suppressed using inhibitory hm4Di/DREADDs methods. In these obese mice, meliorated reproductive performance, as indicated by recovered estrous cycle and improved pregnancy rate (33.3% Vs. 100%, $P < 0.05$), was observed following chronic AgRP neuronal inhibition. On the other hand, to identify the sufficient role of AgRP neurons, we activated AgRP neurons in mice of normal body weight using excitatory hm3Dq/DREADDs methods. After chronic AgRP neuronal activation, impaired reproductive performance was observed, as manifested by lower luteinizing hormone (LH) levels (0.75 ± 0.12 Vs. 0.31 ± 0.03, $P < 0.05$), reduced GnRH transcription and disrupted estrous cycles. Next, we aimed to clarify the downstream neural network of AgRP neurons. To selectively manipulate AgRP afferents to the POA without affecting other AgRP-neuron projection sites, optogenetic terminal stimulation was used. After 30-minutes stimulation, significantly lowered LH levels (0.81 ± 0.20 Vs. 0.25 ± 0.04, $P < 0.001$) and GnRH transcription was observed. Moreover, to identify the molecular mechanism underlying AgPR neurons hyperactivity in obesity and the subsequent infertile phenotype, we selectively knockout leptin receptor in AgRP neurons in adult female mice and found disrupted estrous cycles and impaired pregnancy rate (100% Vs. 20%, $P < 0.05$).

Limitations, reasons for caution: The neural mechanisms discovered in this study has only been tested in mice. In the future, we are planning to extend this results to patients and identify is this neural circuit could be used as a therapeutic target for obesity-induced infertility.

Wider implications of the findings: This study is likely to provide a better understanding of the neural basis of obesity-induced infertility, which will likely accelerate the development of novel therapies of infertility. Moreover, utilizing newly developed genetic approaches with neuron-specific and real-time characteristics will open a new vista for studying central reproductive modulation.

Trial registration number: B2014-94 (approved by institutional animal care and use committee of Tufts University)

O-072 DNA methylation modifications potentially participate in the intergenerational epigenetic inheritance of prenatal androgenized mice

Y. Cui, Z. Yan, L. Yan, J. Qiao

Peking University Third Hospital, Center for Reproductive Medicine, Beijing, China

Study question: Were there any epigenetic marks underpin the potential intergenerational epigenetic inheritance of prenatal androgenized (PNA) mice?

Summary answer: Prenatal androgenized could induce metabolic abnormalities in F2 offspring through paternal germline, when DNA methylation modifications were the potential epigenetic marks passing the phenotype.

What is known already: Polycystic ovarian syndrome (PCOS) could be recapitulated by prenatal androgenization across species, suggesting a developmental etiology for this disorder, when there are increasing evidences that certain acquired traits could be transmitted from one generation to the next. It arouses our interests that whether prenatal androgenization induced PCOS traits could be transmitted to the next generation and whether there exist epigenetic information carrier passing the phenotype.

Study design, size, duration: Twenty-four pregnant mice (F0) were injected with 200 ug/day dihydrotestosterone (PNA group) or sesame oil (Control group) at embryonic day 16-18. The offspring mice were studied as F1 when maternal F2 offspring and paternal F2 offspring were generated after adult female F1 and male F1 mating with normal individuals, respectively. The phenotypes of offspring mice were separately determined at 3 month's old and 8 month's old.

Participants/materials, setting, methods: Male and female C57BL/6J mice (F0) were paired and female F1 were studied with PCOS diagnostic and metabolic traits while male F1 were investigated with metabolic phenotypes. The PCOS diagnostic and metabolic traits of maternal and paternal F2 female individuals were determined to evaluate the intergenerational epigenetic effect. Single cell whole genome bisulfite sequencing (scWGBS) on F1 oocytes and WGBS on F1 sperms were performed to analyze their DNA methylation changes.

Main results and the role of chance: PNA female F1 mice had disrupted estrous cycles, elevated serum testosterone, increased preantral ovarian follicles, impaired glucose tolerance and unaffected insulin sensitivities as previously reported. We did not find any PCOS diagnostic traits or metabolic abnormalities in PNA maternal female F2 offspring as long as 8 month's old. Surprisingly, we found PNA male F1 mice represented significantly impaired glucose tolerance ($P < 0.01$) and insulin sensitivities ($P < 0.05$). More importantly, although PNA paternal female F2 offspring did not manifested PCOS diagnostic traits, they showed markedly reduced body weights ($P < 0.01$) and a clear tendency of glucose tolerance impairment ($P = 0.06$) at 3 month's old. And their glucose tolerance were even deteriorated ($P < 0.01$) and insulin sensitivities were also decreased ($P < 0.01$) at 8 month's old. In searching for epigenetic information carriers, we performed single cell whole genome bisulfite sequencing (scWGBS) on oocytes of female F1 mice and WGBS on sperms of male F1 mice. Bioinformatics analysis indicated the DNA methylation patterns of female F1 oocytes in PNA and control group did not clustered while PNA F1 sperms clearly clustered from control. We also identified 217 differentially methylated regions (DMRs) in PNA F1 sperm epigenome which could potentially be epigenetic information carriers pass the phenotype.

Limitations, reasons for caution: The exact role of DNA methylation alterations in prenatal androgenization induced epigenetic inheritance were not fully validated, and these observations were shown only in mouse species.

Wider implications of the findings: This study provide the first evidence for prenatal androgenization inducing intergenerational epigenetic inheritance potentially through paternal germline by DNA methylation modifications, shading light on explanations of PCOS prevalence and inheritance.

Trial registration number: not applicable.

O-073 Exploration of chemerin system in human granulosa cells: a new insight for polycystic ovarian syndrome

N. Mellouk, A. Bongrani, R. Christelle, G. Fabrice, D. Joëlle

INRA- CNRS- Université François Rabelais de Tours- IFCE, UMR85 Physiologie de la Reproduction et des Comportements, Nouzilly, France

Study question: Characterization of chemerin system in human granulosa cells from PCOS patients and cell line and modulation of its signaling activities using a CMKLR1 nanobody (C4910).

Summary answer: The chemerin system is differentially expressed and active in human granulosa cells and could have a role on PCOS syndrome.

What is known already: Studies on fertility disorders related to metabolic abnormalities have highlighted the importance of the role of hormones

produced by adipose tissue (adipokines) on the appearance of pathologies such as polycystic ovary syndrome (PCOS). Chemerin is a new adipokine able to bind three G protein-coupled receptors: CMKLR1 (chemokine-like receptor 1), GPR1 (G protein-coupled receptor 1), and CCRL2 (Chemokine (CC motif) receptor like 2). Recently, a role for the chemerin/CMKLR1 pathway in ovarian follicle function and steroidogenesis has been reported in mammals. In human granulosa (hCGs) and in the human ovarian granulosa-like tumour cell line (KGN), chemerin inhibited IGF-1-induced steroids production.

Study design, size, duration: Six groups of 10 patients aged 22 to 41 years old: control (undergoing in vitro fertilization for men infertility), obese (BMI > 30), PCOS (presenting two of the three Rotterdam criteria), ECHO (presenting only enlarged polycystic ovaries by ultrasound), PCOS-O (PCOS and obese) and ECHO-O (ECHO and obese). Cultured KGN cells were stimulated (5, 10, 30 and 60 minutes) or not with human recombinant chemerin (200 ng/ml, n = 3) and/or with C4910 (10^{-8} and 10^{-9} M, n = 1).

Participants/materials, setting, methods: Patient's clinical and biological parameters as well as granulosa cells were obtained in collaboration with the CHRU Bretonneau (Tours, France). The mRNA expression of chemerin and its receptors in granulosa cells was made by RT-qPCR.

After stimulation, proteins from KGN cells were extracted and co-immunoprecipitation experiments (homodimerization / heterodimerization of the CMKLR1) and western blot (signaling pathway) were carried out.

Main results and the role of chance: Chemerin mRNA was highly expressed in granulosa cells of obese (3.56 ± 0.51), PCOS-O (5.14 ± 1.02) and ECHO-O (2.47 ± 0.29) patients as compared to control (0.16 ± 0.02), PCOS (0.18 ± 0.02) and ECHO (0.28 ± 0.05) patients and we observed opposite profile for CMKLR1. The mRNA expression of CCRL2 was lower in PCOS (0.013 ± 0.001), obese (0.011 ± 0.001) and ECHO-O (0.013 ± 0.002) patients as compared to control (0.017 ± 0.002), ECHO (0.014 ± 0.002) and PCOS-O (0.014 ± 0.001). In parallel, we found that in KGN cells CMKLR1 and CCRL2 receptors formed a heterodimer after 5 minutes of stimulation with chemerin and gradually increased until 60 minutes. We also showed that chemerin rapidly activates (5 minutes) MAPK ERK 1/2, P38 and Akt phosphorylation and more slowly (30 minutes) AMPK and β-arrestin phosphorylation in KGN cells. Preliminary in vitro experiments of KGN cell co-incubated with chemerin and the CMKLR1 nanobody (C4910) showed a lower phosphorylation of P38 after 5 minutes than in cells only incubated with chemerin.

Limitations, reasons for caution: The characterization of the chemerin system in granulosa cells was carried out in the KGN cell line, we will confirm our results in primary granulosa cells from control women and patients.

Wider implications of the findings: According to the literature, chemerin system was expressed in granulosa cells and a deficit of CMKLR1 seems protect against follicular development disruptions in PCOS patients. We also described the chemerin signaling involved in inflammation and steroidogenesis that was partially blocked by a potential therapeutic nanobody targeting CMKLR1.

Trial registration number: not applicable.

O-074 Anovulation, insulin resistance and Akt/mTOR signaling pathway activated in LepRb-mutated mice

H. Xia, W. Zhang

OB/GYN Hospital of Fudan University, Gynecological endocrine, Shanghai, China

Study question: What is the reproductive alteration of female mice with mutation in leptin receptor(LepR)? And What is the mechanism?

Summary answer: The mutated female mice exhibited anovulation, follicle loss, obesity and insulin resistance, with a decreased phosphorylation of IRS-1/2 and an increased activation of Akt/mTOR pathway.

What is known already: Leptin and LepR play an important role in female reproduction. In the downstream pathways of LepR, protein kinase B (Akt)/mammalian target of rapamycin (mTOR) took part in primordial follicle activation. The phosphatase and tensin homolog deleted on chromosome 10 in humans (PTEN) is a main negative regulator of PI3K pathway. Intracellular insulin signal transduction was found to have interaction with LepRb signaling pathway via insulin receptor substrate (IRS). IRS was in the upstream pathway of Akt/mTOR in both LepR and insulin signal pathway, including IRS-1 and IRS-2, both involved in regulating blood sugar.

Study design, size, duration: From September 2013 to December 2015, adult heterozygous male and female LepR-mutated mice were raised in an animal care facility of Obstetrics and Gynecology Hospital, Fudan University; consequently, fetus mice were delivered, the female ones of which were genotyped by PCR analysis of toe/tail-tip DNA at age 4 weeks, before grouped into homozygous (HOM) LepR-mutated mice and Wild Type littermates, each group being composed of 10.

Participants/materials, setting, methods: At age of 10 weeks, a glucose tolerance test was performed after a 6-h (8:30-14:30) fast. Glucose concentrations were measured in blood collected by venous bleeding from tail vein, before and 30, 60, and 120 min after a bolus i.p. injection of glucose at 0.75 g/kg. Fasting insulin and anti-mullerian hormone (AMH) was detected. We compared the reproduction and metabolic characteristics in the mice, analyzing the expression of Akt/mTOR, PTEN and IRS in the ovaries.

Main results and the role of chance: The results showed that 10-week old female mutated HOM exhibited no estrus periods, infertility, obesity, insulin resistance, declined AMH levels in the serum and ovaries, reduced primordial follicles, primary follicles, secondary follicles, antral follicles and hardly no corpus lutea (all $P < 0.05$). The phosphorylation of downsream Akt, mTOR, p70 ribosomal S6 kinase 1 (S6K1) and eukaryotic initiation factor 4E binding protein-1 (4E-BP1) of LepR were all elevated in the ovaries of the mutated female mice. They also presented a decreased phosphorylation of IRS-1, IRS-2, and PTEN, and a strengthened phosphorylation of Forkhead box O-3a (FOXO-3A) in the ovaries, when compared with WT mice.

Limitations, reasons for caution: We have not examined follicles and detected the LepR mutation, Akt/mTOR and IRS pathway in clinical obese women.

Wider implications of the findings: Clinical trials enrolled obese women will be designed and programed in the Ob and Gyn Hospital. Ovarian function and LepR mutation will be detected.

Trial registration number: The current basic study has no trial registration number.

O-075 GDNF-induced down-regulation of miR-145-5p enhances human oocyte maturation

Y. Ye, L. Cui

Women's Hospital- Zhejiang University School of Medicine, Reproductive Endocrinology, Hangzhou, China

Study question: To examine the effects of glial cell line-derived neurotrophic factor (GDNF) on human *in vitro* oocyte maturation and to investigate the involvement of microRNAs (miRNAs) in GDNF-induced oocyte maturation.

Summary answer: Down-regulation of miR-145-5p may contribute to GDNF-induced enhancement of oocyte maturation and of cell viability against cell apoptosis.

What is known already: The maturation rate and the developmental potential of embryos derived from in vitro maturation (IVM) oocytes are significantly lower than those of embryos derived from oocytes matured in vivo. Though GDNF and miRNAs have been shown to regulate oocyte maturation, little is known about the underlying molecular mechanisms.

Study design, size, duration: A total of 200 human immature oocytes were used to evaluate the effects of GDNF on oocyte maturation. The involvement of miRNAs in GDNF-induced oocyte maturation were identified by comparing the miRNA expression profiles of cumulus cells either with or without GDNF stimulation. Human immature cumulus-oocyte complexes (COCs) were collected from infertile patients who underwent IVF treatment between January 2015 and November 2015.

Participants/materials, setting, methods: The experiments were performed in an IVF center. Immature oocytes were cultured with/without GDNF stimulation. Human miRNA arrays were used to examine the miRNA expression patterns of cumulus cells (CCs) either with/without GDNF stimulation. Luciferase reporter assays were performed to verify the targets of miRNA-145-5p. MiR-145-5p inhibitor and mimic transfections were performed to study downstream gene expression (GDNF, GDNF family receptor-alpha1(GFRA1), ret proto-oncogene (RET), and epidermal growth factor receptor (EGFR)) in human CCs.

Main results and the role of chance: During the IVM process, treatment with GDNF significantly increased the percentage of MII-stage oocytes and down-regulated the expression of miR-145-5p in cultured human CCs. Expression of MiR-145-5p in CCs is negatively correlated with oocyte maturation. Transfection with miR-145-5p mimic significantly decreased the mRNA and protein levels of GFRA1, RET, and EGFR in human CCs, whereas transfection with an miR-145-5p inhibitor reversed these effects. Treatment with GDNF inhibited cell apoptosis in cultured CCs, and this suppressive effect was reversed by transfection withthe miR-145-5p mimic.

Limitations, reasons for caution: The role of miR-145-5p was demonstrated by the fact that GDNF treatment down-regulated the expression of miR-145-5p and miR-145-5p mimic transfection decreased the expression of GFRA1, RET, and EGFR in human CCs. But we haven't directly shown that miR-145-5p mediate the effects of GDNF.

Wider implications of the findings: Our findings provide insight into the roles of GDNF and miR-145-5p in the regulation of oocyte maturation and may be clinically applied to improve the developmental potential of immature oocytes from infertile couples undergoing IVM.

Trial registration number: no.

[5]CHU Dijon Bourgogne- INSERM UMR1231, Service de Gynécologie-Obstétrique, dijon, France

Study question: Does the sperm of patients with Testicular Germ Cell Tumor, in particular seminoma, present imprinted defects?

Summary answer: Seminoma patients with oligozoospermia presented sperm DNA methylation alterations on imprinted genes like those observed in oligozoospermic patients.

What is known already: Testicular Germ Cell Tumor such as seminoma is strongly associated with male reproductive problems commonly associated with the alteration of sperm parameters as described in testicular dysgenesis syndrome. Interestingly, numerous studies have reported that the precursor of germ cell cancer: Germ Cell Neoplasia in situ (GCNIS), present similarities to fetal gonocytes, specifically characterized by global DNA hypomethylation particularly on imprinting sequences. These disorders may have a common origin derived from perturbations of embryonal programming during fetal development. Presently, there is no available information concerning the sperm DNA methylation patterns of testicular cancer patients.

Study design, size, duration: A total of 92 cryopreserved sperm samples from men who gave their consent for research were included, 31 before seminoma treatment (S) and 61 in the context of ART procedures who served as controls: 31 normozoospermic (N) and 30 oligozoospermic (O). Among seminoma patients, 23 (74%) of them were normozoospermic (SN) and 8 (26%) were oligozoospermic (SO).

Participants/materials, setting, methods: DNA methylation levels of seven differentially methylated regions (DMRs) of imprinted genes [*H19/IGF2*: IG-DMR: CTCF3 and CTCF6 of *H19* gene; *IGF2*-DMRs (DMR0 & DMR2); *MEG3/DLK1*:IG-DMR; *SNURF*:TSS-DMR; *KCNQ1OT1*:TSS-DMR] were assessed by pyrosequencing. All analyses were performed after adjusting for age.

Main results and the role of chance: Comparisons of sperm DNA methylation levels between seminoma (S) and normozoospermic (N) samples showed a significant difference for the *SNURF* sequence ($p = 0.017$), but after taking into account the sperm parameters no difference was observed for both SN vs N and SO vs O. However, we confirmed a significant association between oligozoospermia (O) and imprinting defects for *H19*-CTCF6 ($p = 0.001$), *MEG3/DLK1* ($p = 0.017$), *IGF2*-DMR2 ($p = 0.022$) and *SNURF* ($p = 0.032$) in comparison with control group (N). Moreover, significant imprinting defects were detected in oligozoospermic seminoma patients (SO) compared to normozoospermic controls (N) for *H19*-CTCF6 ($p = 0.013$), *IGF2*-DMR2 ($p = 0.019$) and *SNURF* ($p = 0.001$).

Limitations, reasons for caution: Despite careful microscopic control, cellular contamination cannot be fully excluded. The pyrosequencing method limits investigations on DNA methylation to few CpGs, but yields better resolution in imprinted sequences than for larger scale analyses.

Wider implications of the findings: This study highlights the high risk of sperm imprinting defects in oligozoospermia cases, and shows that seminoma patients with normal spermatogenesis presented sperm imprinting integrity. These data disprove the idea of a common fetal imprinting defect in germ cells leading to both CGNIS and subfertility.

Trial registration number: not applicable.

O-077 Identification of X-linked CNVs in women with extremely skewed X chromosome inactivation and miscarriage

E. Tolmacheva[1], N. Skryabin[1], A.- Kashevarova[1], L. Minaycheva[2], T. Nikitina[1], E. Sazhenova[1], I. Lebedev[1]

[1]Research Institute of Medical Genetics- Tomsk National Research Medical Center of Russian Academy of Sciences, Molecular Cytogenetics -Epigenetics- Reproductive Genetics, Tomsk, Russia C.I.S.
[2]Research Institute of Medical Genetics- Tomsk National Research Medical Center of Russian Academy of Sciences, genetic clinic, Tomsk, Russia C.I.S.

Study question: Do changes in copy number of X-linked regions in the maternal genome may be cause of skewed X-chromosome inactivation (sXCI) in her lymphocytes and miscarriage.

Summary answer: Copy number variations (CNVs) affected X-linked genes are apparently associated with the formation of sXCI in mother and linked to the death of her embryo.

What is known already: Recent data provide evidence, that sXCI is associated with X-linked disease manifestation, cancer or adverse reproductive outcomes. Extremely sXCI (95% or above) is associated with an advanced incidence (>4-times) of idiopathic recurrent pregnancy loss based on meta-analysis of 12 datasets (Su et al., 2015). Skewed XCI may have a protective effect for woman health by suppressing X-linked lethal gene mutations or CNVs. Therefore, one can suggest, that inheritance of these mutations or CNVs by embryo may be incompatible with its normal development. If this true, the male embryos or female embryos with normal X-inactivation are in the elevated risk group.

Study design, size, duration: We investigated the status of X chromosome inactivation in 111 women with a history of spontaneous abortions with normal karyotype in anamnesis. Eight samples of DNA of the woman with extremely sXCI were analyzed using aCGH. The presence and inheritance of probably pathogenic CNVs were analyzed by quantitative Real Time PCR both in mother and miscarriage.

Participants/materials, setting, methods: X-chromosome inactivation was assessed by classical methylation-specific assay at the AR locus. DNA samples from 8 woman with extremely sXCI were searched for CNVs using SurePrint G3 Human CGH + SNP 4×180 K Microarray Kit (Agilent Technologies, USA). Array CGH was performed according to the manufactures recommendations. Confirmation studies were performed on AriaMX Real Time PCR System (Agilent Technologies, USA) with DNA samples from mother's lymphocytes and extraembryonic tissues of spontaneous abortions.

Main results and the role of chance: X-inactivation status was found to be skewed in 8 of 111 (7%) women. Their karyotype was analyzed by aCGH. In one case woman with sXCI had delXq24, 239 kb in size, affected 8 genes (*SLC25A43, SLC25A5-AS1, SLC25A5, CXorf56, UBE2A, NKRF, SEPT6, MIR766*). This deletion was confirmed by Real-Time PCR both in mother and spontaneous abortion with 46,XY karyotype. The mother, 29 years old, had a history of 5 miscarriages, 1 induced abortion and 1 healthy female child. DelXq24 encompassing UBE2A gene was revealed previously in two unrelated boys with mental deficiency, heart defects, dysmorphic features (Thunstromet al., 2014) and related to X-linked syndromic mental retardation, Nascimento type (MIM 300860). The X-inactivation study in both patients' mothers showed skewed X-inactivation (99%). Xq24 deletions were also among the most common deletions in HER2-positive breast cancer and affected genes *SLC25A43, SLC25A5-AS1, SLC25A5* (Gabrielson et al., 2016). Products of affected genes are involved in cell proliferation, differentiation and post-transcriptional regulation of gene expression. Knockdown of *SLC25A43* in non-tumor cells significantly inhibited cell cycle progression during G1-S transition and reduce proliferation rate. Probably a lack of these genes expression leads to the shifting to sXCI in deletion carriers with subsequent risk for adverse pregnancy outcomes.

Limitations, reasons for caution: The possible variation in the X-chromosome inactivation level in different tissues as well as tissue specific expression profiles of genes escaping X-inactivation should be considered.

Wider implications of the findings: Our data are applicable to understanding of mechanisms responsible for coordinated control of the expression level of X-linked loci responsible for early embryo development by epigenetic and cytogenetic processes. They will provide new strategies for PGD in women with recurrent pregnancy loss. This study is supported by RFBR grant 18-015-00437_a.

Trial registration number: Not applicable.

O-078 Does fertility status in varicoceles depends on DNA acetylation and methylation processes; cross-link with Hsp70-2 in an experimental trial using Wistar rats

M. Razi, S. Salmani, A. Mahmoudian, F. Sarrafzadeh-Rezaei

Faculty of Veterinary Medicine- Urmia University- Urmia- Iran, Basic Science- division of Comparative Histology and Embryology, Urmia, Iran

Study question: Does DNA acetylation, methylation and heat shock protein (Hsp70-2) correlate with varicocele-induced DNA damage? What is the cross-link between epigenetic factors, sperm DNA integrity and blastocyst rate?

Summary answer: Impaired Hsp70/DNA methyltransferase-1 (DNMT1)/ histone acetyltransferase (HAT)/ histone deacetylases-1 (HDA1) network adversely affects the epigenetic pathways during spermatogenesis, reduces sperm fertilization potential and down-regulates blastocyst rate.

What is known already: Misregulation of histone modification and replacement during spermiogenesis has been linked with varicocele-induced oxidative DNA damage. Indeed, the epigenetic mechanisms are core regulators of DNA relaxation, replication, repairmen and histone replacement/modification. The DNMT1 is a key maintenance methyltransferase during early stages of developing germ cells, which allows transcription to occur at later stages. On the other hand, the HAT and HDA1-induced acetylation and deacetylation are involved in chromatin-protamine remodeling and DNA repairmen. Moreover, the Hsp70-2 protects DNA strands against oxidative stress. Thus, the correlation between altered acetylation, methylation, histone-protamine replacement, Hsp70-2 expression, and the pre-implantation embryo development is still uncovered.

Study design, size, duration: Thirty mature Wistar rats were divided into control, control-sham and varicocele-induced groups (NO = 10 rats). The experimental left hand side varicocele was induced by semi-ligation of left renal vein adjacent to caudal Vena cava. The animals in the control-sham group were undergone a simple laparotomy without varicocele induction. The control group did not undergo surgical application. Following 60 days, the left testicles were dissected out and different molecular and biochemical analyses were conducted.

Participants/materials, setting, methods: The DNMT1, HAT, HDA1 expressions were analyzed using qRT-PCR. The Hsp70-2 expression was assessed by using quantitative RT-PCR, western blot and immunohistochemistry. To show DNA methylation, the immunoflourescent staining of 5 methylcytidine was conducted. Testicular total antioxidant capacity (TAC), gluthatione peroxidase (GSH-px), superoxide dismutase (SOD), catalase, malondialdehyde (MDA) levels and sperm DNA integrity were evaluated. Following in vitro fertilization, correlation between blastocyst rate and each assessed epigenetic factor was analyzed.

Main results and the role of chance: The varicocele group exhibited decreased mRNA of DNMT1, HAT and HDA1 versus control groups ($P = 0.001$). The mRNA and protein levels of Hsp70-2 and the Hsp70-2^+ cells distribution *per* mm^2 of tissue were decreased in varicvocele group versus control animals ($P = 0.01$). The varicocele group exhibited down-regulation of 5 methylcytidine, representing suppressed DNA methylation. The testicular TAC, GSH-px, SOD and catalase levels were down-regulated and the MDA content was up-regulated in varicocele group. The percentages of sperms with DNA fragmentation were increased in varicocele animals. Analyses of HAT and HDAT1 mRNA levels revealed an inverse correlation between HAT and HDAT1 and sperm DNA damage ($p = 0.02$, $r^2 = -0.912$) as well as the blastocyst rate ($P = 0.01$, $r^2 = -0.812$). No correlation was found between DNMT1 mRNA and sperm DNA damage. Meanwhile, the sperm DNA damage was negatively correlated with decreased levels of TAC ($P = 0.01$, $r^2 = -0.812$), GSH-px ($p = 0.02$, r^2: -0.721), SOD ($p = 0.001$, r^2=-0.816) and catalase ($P = 0.01$, $r^2 = -0.830$). An inverse correlation was found between decreased expression of Hsp70-2 and sperm DNA damage ($P = 0.02$, r^2: -0.761). No correlation was found between mRNA and protein levels of Hsp70-2 and blastocyst rate. A negative correlation was found between sperm DNA damage and the blastocyst rate ($P = 0.02$, r^2: -0.932).

Limitations, reasons for caution: The results of the current study may differ in different laboratory settings. Moreover, the species differences can affect the spermatogenesis-related epigenetic pathways, and some differences between rat and human spermatozoa can partially change the results belonging to fertilization outcomes. Furthermore, additional studies are needed to represent the birth rates.

Wider implications of the findings: Present study increases our understanding that, (i) varicocele down-regulates the intra-testicular acetylation and methylation ratio, (ii) down-regulates the Hsp70-2 expression and antioxidant status and (iii) Impaired acetylation in association with suppressed Hsp70-2 and diminished antioxidant status amplifies sperm DNA damage and lowers the blastocyst rate.

Trial registration number: N/A

O-079 Distribution of MTHFR isoforms carriers and level of homocysteine in an infertile population with assisted reproductive technologies (ART) cycle failures

D. Cornet[1], E.H. Amar[2], P. Clement[3], A. Clement[3], Y. Menezo[3]

[1]Clinique de La Muette, Service d'AMP, Paris, France
[2]American Hospital of Paris, Andrology/Urology, Paris, France
[3]Laboratoire CLEMENT, Embryology lab, Paris, France

Study question: What is the impact of MTHFR isoforms in fertility? Can it be related to an increase of circulating homocysteine known to affect the gametes?

Summary answer: The proportion of MTHFR mutations carriers is significantly higher in the infertile population. The average level of homocysteine is significantly higher in the mutations carriers.

What is known already: MTHFR isoforms induce defective folic metabolism and affect the recycling of homocysteine to methionine. The increased levels of homocysteine due to MTHFR polymorphisms is responsible of oxidative stress (Guo, 2016). Oxidative stress is a common cause of infertility and ART failures.

MTHFR isoforms are responsible of spermatozoa anomalies, especially via a defect in nucleus compaction (Cornet, 2017). Furthermore, the IVF embryos originating from MTHFR isoforms carriers have high chromosomal problems for the heterozygotes and higher in the homozygotes patients (Enciso, 2017).

Study design, size, duration: From January 2016 to january 2018, we followed 198 women patients suffering from infertility and having had at least 2 ART (Assisted Reproductive Technologies) cycle failure. All those patients

were tested for MTHFR isoforms and we also measured their level of circulating homocysteine. We compared those results among our infertile population and with the general population.

Participants/materials, setting, methods: The presence of MTHFR isoforms was determined from a venous blood sample, using real time PCR with the RealFast™ assay (ViennaLab Diagnostic GMBH, Vienna, Austria).

The levels of homocysteine are measured with a competitive immunoassay using direct, chemiluminescent technology.

Main results and the role of chance: Among the infertile population of our study, 63.6% of the patients are carrying the MTHFR mutation (43.9% in a heterozygous and 19.7% in a homozygous state). This proportion is significantly more important ($p < 0.05$) than the proportion of patients carrying MTHFR mutations in the general population: 50.5% (Zappacosta, 2009).

The average level of homocysteine among homozygotes and heterozygotes patients is significantly higher than among the wild type patients (respectively 10.7 and 8.8 vs 7.9, $p = 0.01$ and $p = 0.02$). In total, the average level of homocysteine among MTHFR carriers (homozygotes+heterozygotes) is significantly higher than among non carriers (wild-type) patients (9.4 vs 7.9, $p = 0.02$).

Limitations, reasons for caution: The genetic analysis of the MTHFR gene needs to be enlarged to other mutations in order to screen all the patients in which fertility could be affected by oxidative stress. The proportion of MTHFR mutation carriers is probably more important and treatments could benefit to a larger number of patients.

Wider implications of the findings: Infertile patients with ART cycle failures should be tested for MTHFR mutations and their homocysteine levels should be measured. Indeed, the affected patients could benefit from a treatment available allowing to by-pass the problems linked to MTHFR impaired activity and thus decreasing oxidative stress, and improving their ART outcomes.

Trial registration number: None.

O-080 Novel loci for polycystic ovary syndrome (PCOS) identified in the largest genome-wide association study (GWAS) conducted to date

G. Galarneau[1], P. Fontanillas[2], C. Clementi[1], U. Schick[1], D.E. Parfitt[1], D.A. Hinds[2], P. Yurttas Beim[1]

[1]*Celmatix Inc., Research and Development, New York, U.S.A.*
[2]*23andMe, Inc., Mountain View, U.S.A.*

Study question: We aimed to explore the genetic components of PCOS by conducting a GWAS in >285,000 women, including 20,410 PCOS cases.

Summary answer: Our GWAS identified 5 novel loci that were associated with PCOS at genome-wide significance ($p < 5 \times 10^{-8}$).

What is known already: Although the pathophysiology of PCOS is known to involve multiple, heterogeneous mechanisms, the molecular components of these mechanisms are still being uncovered. GWAS conducted in Han Chinese and European populations have identified 17 loci, overlapping with genes involved in the hormonal, metabolic, and cellular aspects of the disorder. However, since the estimated heritability of PCOS may be as high as 70%, it is likely that only a portion of its underlying genetic landscape has been uncovered. A more complete understanding is necessary for the development of novel molecular strategies to diagnose PCOS and target its various clinical features.

Study design, size, duration: In collaboration with the personal genetics company 23andMe, Inc., we conducted a GWAS in women of European ancestry who had consented to participate in research. Among these women were 20,410 PCOS cases (4 times larger than the largest published GWAS to date) and 265,397 controls. Inclusion or exclusion of subjects was determined by responses to online surveys.

Participants/materials, setting, methods: Case subjects self-reported being diagnosed and/or treated for PCOS. Control subjects self-reported not having been diagnosed or treated for PCOS. Participant samples were genotyped on 1 of 4 custom genome-wide genotyping arrays targeting 556-955k SNPs. Participant genotypes were imputed against the 1000 Genomes Project Phase 1 reference haplotypes. We performed a logistic regression under an additive model with age, top 5 principal components, and genotyping array version as covariates.

Main results and the role of chance: Of the 17 loci previously identified in PCOS GWASs, 8 reached genome-wide significance ($p < 5 \times 10^{-8}$) in our analysis, and a further 7 reached nominal significance ($p < 0.05$), all with a consistent direction of effect. Further, we report 5 novel loci achieving genome-wide significance for the first time in the context of PCOS: *ZBTB16* (rs1784692, $p = 2.1 \times 10^{-15}$, OR[95% CI] = 1.12[1.09-1.15]), *FTO* (rs8047587, $p = 4.3 \times 10^{-9}$, OR[95% CI] = 1.07[1.04-1.09]), *ZKSCAN5-FAM200A* (rs10278040, $p = 5.6 \times 10^{-9}$, OR[95% CI] = 1.16[1.10-1.22]), and *ZEB2* (rs13028626, $p = 3.3 \times 10^{-8}$, OR[95% CI] = 1.06[1.04-1.09]). In addition, we identified a potential association in *MYO10* locus (rs9312937, $p = 4.0 \times 10^{-8}$, OR[95% CI] = 1.06[1.04-1.08]). The *FTO* and *MYO10* loci have been linked to BMI-related traits in previous GWASs but never linked to PCOS at genome-wide significance. However, variants in *FTO* have been associated with PCOS in several candidate genetic studies. Interestingly, *MYO10* has been identified as a meiotic regulator in animal studies. The *ZBTB16* locus was previously identified in a PCOS GWAS but did not reach genome-wide significance. *ZBTB16* is involved in brown adipocyte bioenergetics and the development of metabolic syndrome, as well as androgen receptor activity. Similarly, the *ZKSCAN5-FAM200A* locus overlaps with a locus previously associated with levels of steroid hormones, such as progesterone and dehydroepiandrosterone sulfate.

Limitations, reasons for caution: The novel associations in *FTO*, *ZKSCAN5-FAM200A*, *ZEB2*, and *MYO10* loci need to be replicated in an independent population. Further, additional characterization is warranted to identify putative causal variants and genes that may underlie the observed novel associations. Lastly, this study used self-reported phenotypic data, which could impact the case-control stratification.

Wider implications of the findings: In the largest PCOS GWAS to date, we provide evidence of novel associations with 5 genetic loci. This work extends the understanding of the genetic underpinnings of PCOS and emphasizes androgenic and metabolic mechanisms in the pathophysiology of the disease.

O-081 Potential leukaemic contamination in cryopreserved ovarian tissue

D. Gook[1], D. Westerman[2], M. McBean[2], V. Hughes[1], K. Stern[1]

[1]*The Women's Hospital, Reproductive Services /Melbourne IVF, Parkville- Victoria, Australia*
[2]*Peter MacCallum Cancer Centre, Department of Pathology, Parkville- Victoria, Australia*

Study question: Can xenografting of cryopreserved ovarian tissue from patients with leukaemia detect the presence of contaminating leukaemic cells within the tissue?

Summary answer: Leukaemic cells are present in ovarian tissue from the majority of patients' tissue examined and these cells multiply with time in an immunodeficient mouse.

What is known already: Two previous studies have examined the potential of ovarian tissue from leukaemia patients to harbour leukaemic cells. Although one study detected the presence of leukaemia in 5 out of 18 patients' tissue following xenografting, the other did not detect any contamination even in tissue found to be PCR positive for leukaemic cells. Similarly, in the former study, not all the tissue positive for leukaemic cells by PCR manifested in disease in the xenografted mice.

Study design, size, duration: To assess whether ovarian tissue from patients with leukaemia harboured leukaemic cells and whether these cells were capable of proliferation over time, cryopreserved ovarian tissue was transplanted into immunodeficient mice (3 mice per patient) and left for 24 weeks. At the completion of the study, the ovarian tissue and organs were removed, fixed and examined for evidence of leukaemic cells.

Participants/materials, setting, methods: Stored ovarian tissue from 18 patients with leukaemia (5 ALL, 9 AML, 4 CML) were donated to the study. Two slices of ovarian tissue were attached to the abdominal wall using non dissolvable sutures and 1 small piece placed under the kidney capsule in each NOD SCID mouse. At 24 weeks mice were examined for tumour development, blood taken, and spleen weight measured. One slice of ovarian tissue was prepared for PCR analysis.

Main results and the role of chance: Tumour development was observed in tissue from 13 out of the 18 patients examined (3/5 ALL, 6/9 AML, 4/4 CML) following xenografting. Generally 1 mouse out of the 3 xenografted with same patient tissue developed a tumour. Tumour was only associated with the grafted tissue in 5 mice, the remainder of tumours were detected in other organs or in nodes. Sectioning of tumours/nodes and staining with H&E showed infiltration with monomorphous leukaemic cells. In some mice other organs were also infiltrated with leukaemic cells and the spleens were enlarged to 2 to 6 times the normal size.

Tissue from 6 patients which had been cryopreserved less than 4 weeks after the last chemotherapy dose resulted in tumour development. To date, all PCR positive tissue resulted in tumours following xenografting (only CML evaluated).

Subsequent lineage characterization with immunohistochemistry is required to verify tumour origin. Examination of organs from mice without obvious tumour development is still ongoing.

Limitations, reasons for caution: Although more mice have been examined for each patient's tissue in the present study (3 per patient) than in the 2 previous studies (1 mouse per patient), insufficient numbers of mice may still be the reason for the negative result in those where no tumour was identified.

Wider implications of the findings: There is a high risk of re-introducing leukaemic cells to patients when grafting cryopreserved ovarian tissue. Other alternatives need to be developed to reduce or eliminate this risk.

Trial registration number: Not applicable

O-082 LH gonadoprotection against ovarian damage induced by alkylating drugs in adult mouse ovaries

L.M. Castillo[1], A. Buigues[1], L. Pellegrini[2], V. Rossi[3], F. Klinger[3], A. Pellicer[4], S. Herraiz[2]

[1]*University of Valencia, Department of Pediatrics- Obstetrics and Gynecology, Valencia, Spain*
[2]*Fundación IVI, Research, Valencia, Spain*
[3]*University of Rome Tor Vergata, Dep. Biomedicine and Prevention, Rome, Italy*
[4]*IVI-RMA, IVI Rome, Rome, Italy*

Study question: To evaluate if LH administration protects the follicular pool against gonadotoxic effects of oncologic treatment with alkylating drugs in adult mouse ovaries.

Summary answer: LH treatment prevents follicular depletion induced by Busulfan and Cyclophosphamide in adult mouse ovaries by preserving higher number of follicles, especially primordial and primary populations.

What is known already: Oncologic treatment with high-dose chemotherapy may impose deleterious effects on the ovary. Clinically, impact ranges through partial damage to a complete destruction of the follicular pool. The highest risk is associated to alkylating drugs, while platinum-based compounds like cisplatin associated a medium risk. Several methods are available to preserve fertility in cancer patients but further research is needed to develop new alternatives. Previous studies suggested that luteinizing hormone (LH) prevents the cisplatin-induced apoptosis in oocytes and preserves fertility in prepubertal mouse. We aim to validate the protective effects of LH on the mouse adult ovary against chemotherapy with alkylating agents.

Study design, size, duration: Experimental study, with eleven 6 week-old CD-1 female mice allocated to the following groups: Control (n = 3), Chemotherapy (ChT, n = 4) and ChT+LH (n = 4). Mice in the ChT groups received a dose of alkylating drugs to induce severe ovarian damage on day 0, at the same time with their own treatment (saline or LH, respectively). Animals were maintained during 12 days and then sacrifice to recover ovarian samples for further analysis.

Participants/materials, setting, methods: A single intraperitoneal injection with 12 mg/Kg busulfan and 120 mg/Kg Cyclophosphamide was administered to mice of the ChT treated groups while controls received saline. Simultaneously, animals of the ChT and Ch + LH group also received 100ul of saline or equal volume with 1IU of LH, respectively. A week after, ovarian hyperstimulation was induced, animals mated with fertile males and sacrificed. The ovarian size, follicular growth and populations, ovulation and early embryo development were then evaluated.

Main results and the role of chance: ChT administration reduced the ovarian weight after hyperstimulation (C:45.7 ± 2.0 mg, ChT:14.9 ± 0.9 mg and ChT-LH:14.6 ± 3.2 mg; p = 0.001) and LH administration was not able to recover control values.

When the total amount of follicles was analyzed, a 10-fold decrease was observed after chemotherapy administration (C:1260 ± 168, ChT:182 ± 31; p = 0.03). Nevertheless, LH administration reduced the severity of the follicular depletion (ChT-LH: 264 ± 59; p = 0.04). This improvement was mainly due to a better preservation of the primordial (ChT-LH:42 ± 14 vs. ChT:7 ± 5foll., p = 0.032) and the primary populations (ChT-LH:132 ± 8 vs. ChT:68 ± 12, p = 0.034). However, LH was not able to preserve the late preantral, antral and pre-ovulatory populations already impaired by ChT.

The percentage of quiescent follicles decreased in the ChT group due to the burnout of dormant follicles induced by alkylating agents but LH treatment was able to minimize this effect (p = 0.034) and to maintain values similar to controls (C: 15.7 ± 3.6%, ChT:4.2 ± 3.4% and ChT-LH: 15.8 ± 4.6%).

The amount of ovulated MII-oocytes and 2-cell embryos were seriously impaired in both ChT (MII: 8 ± 5; Embryos:7 ± 5) and ChT-LH treated mice (MII: 10 ± 9; Embryos:7 ± 10), when compared to controls (MII: 17 ± 2; E:10 ± 2). However, LH administration increased the viability of the obtained MII-oocytes (ChT:64.3 ± 27.5% vs. ChT-LH:90.4 ± 11%) and embryos (ChT:63.9 ± 29.3% vs. ChT-LH:95.2 ± 8.2%) although no statistically significant.

Limitations, reasons for caution: This is a preliminary study with a reduced sample size and therefore data should be confirmed in a larger population. Furthermore, LH effects on follicular development potential should be carefully assessed.

Wider implications of the findings: We found that LH administration protects primordial and primary follicles in adult ovaries against the depletion and over activation induced by alkylant agents. However, LH was not able to preserve the already growing populations but allows the surviving follicles to produce oocytes and embryos with increased developmental potential.

Trial registration number: Not applicable.

O-083 Towards an artificial ovary: Grafting preantral follicles on decellularized human ovarian tissue

S. Pors[1], S.G. Kristensen[2], K. Lundsgaard[2], M. Ramløse[2], C.Y. Andersen[2]

[1]*Rigshospitalet, Laboratory of Reproductive Biology, KØBENHAVN Ø, Denmark*
[2]*Rigshospitalet, Laboratory of Reproductive Biology, Copenhagen, Denmark*

Study question: Can decullularized human ovarian tissue support development of follicles and become a biocompatible and biofunctional artificial ovary?.

Summary answer: We have demonstrated an effective protocol for decellularization of human ovarian tissues and successful recellularization with isolated preantral follicles.

What is known already: Decullarization of ovarian tissue entails the removal of cells, including possible malignancies. The physiological extracellular matrix (ECM) left behind offers the complex milieu that facilitates the necessary interaction between ovarian follicles and their surroundings to ensure their growth and development. A bioengineered ovary would thus facilitate the growth and development of reseeded frozen-thawed early stage follicles, free of malignancies. Decellularized tissue (DCT) also benefits from its biocompatibility due to clearance of immunogenic substances. Further research in developing a

bioengineered ovary entails thorough studies into its biocompatibility and biofunctionality.

Study design, size, duration: Donated human ovarian tissue and isolated preantral follicles from women undergoing ovarian tissue cryopreservation for fertility preservation. Biofunctionality of the decellularized human ovarian tissue was evaluated by in vitro and in vivo studies. Furthermore, scaffolds were transplanted to immunocompetent mice and evaluated for inflammatory reactions.

Participants/materials, setting, methods: Ovarian cortical and medullary tissue were decellularized (0.1% SDS for 3, 6, 24 hours; followed by 24 hours DNase (1 mg/mL)). Decellularization and preservation of composition were characterized by DNA and collagen quantification, Periodic Acid-Schiff (PAS) staining, and immunoflourescence for Collagen IA and DNA (4',6-diamidino-2-phenylindole (DAPI)). Human granulosa cells (GCs) were reseeded on the DCT and cultured in vitro. Murine and human preantral follicles were isolated reseeded on the DCT and grafted subcutaneously to immunodeficient mice.

Main results and the role of chance: Incubation in 0.1% SDS for 6-24 hours adequately decellularized both human ovarian cortical and medullary tissue by eliminating all cells and leaving the ECM intact. DNA quantities in the DCT were significantly lower compared to matched native samples. Histological examination using PAS staining confirmed that the cortical and medullary tissues were completely decellularized, and no visible nuclear material was found within the decellularized sections. DCT also stained positive for collagen I and collagen quantities in DCT constituted 88-98% of the individual baselines for native samples (n = 4). Mature human GCs were able to recellularize the DCT in vitro by successfully repopulating and migrating into the scaffold. Xenotransplantation experiments showed that the DCT was able to support survival of isolated human follicles and growth of isolated murine follicles of which several grew to antral stages. The follicular recovery rates after 3 weeks grafting were similar for both human (25%) and murine follicles (26-32.5%). The average diameter of isolated murine follicles increased from 114 ± 26 μm to 195 ± 143 μm following 3 weeks grafting.

Limitations, reasons for caution: Further studies are needed to increase recovery and survival of the reseeded follicles. Furthermore, longer grafting periods should be evaluated for observing development of follicles. Survival of the follicles might be impaired by the lack of stroma cells. This challenge must be overcome to advance the bioprosthetic ovary further.

Wider implications of the findings: This is the first time that isolated human follicles have survived in a decellularized human scaffold. Therefore, this proof-of-concept could be a potential new strategy, to eliminate the risk of malignant cell re-occurrence in former cancer patients having cryopreserved ovarian tissue transplanted for fertility restoration.

Trial registration number: Not applicable.

O-084 Primordial follicle activation in vitro following PTEN inhibition is associated with increased DNA damage of bovine ovarian follicles

M. Maidarti[1], M. McLaughlin[2], Y.L. Clarkson[2], E.E. Telfer[2], R.A. Anderson[1]

[1]University of Edinburgh, Center for Reproductive Health, Edinburgh, United Kingdom
[2]University of Edinburgh, Institute of Cell Biology and Centre for Integrative Physiology, Edinburgh, United Kingdom

Study question: Does activation of ovarian follicle growth by phosphatase homolog of chromosome-10 (PTEN) inhibition result in altered indices of oocyte and granulosa cell health?

Summary answer: PTEN inhibition leads to increased primordial follicle activation, but increases DNA damage and suppresses the DNA repair capacity of bovine ovarian follicles *in vitro*.

What is known already: Although the PTEN inhibitor bpv(HOpic) has been widely used to activate primordial follicles, it's effects on DNA damage and repair in normal cells, including oocytes and granulosa cells, has not been determined since most of the investigations have used cancer cell lines. PTEN inhibition leads to cytoplasmic sequestration of DNA repair factors BRCA-1 and Rad-51 in breast cancer cells. Notably, unrepaired DNA damage due to impaired DNA repair capacity both in oocytes or granulosa cells is associated with ovarian aging. Meiotic errors are also more likely leading to chromosomal abnormalities in mature oocytes, ultimately impacting on oocyte quality.

Study design, size, duration: This study utilised bovine ovarian cortical fragments (4 × 2×1 mm). Ovarian fragments were cultured for 24 hour in medium with and without bpv(HOpic) then for a further 5 days in control medium without bpv(HOpic). A total of 57 ovarian cortical strips per group and 29,550 follicles from three independent experiments were analysed.

Participants/materials, setting, methods: After 24 hours treatment, tissues were subjected to Akt quantification by Western blotting. At the end of the culture period (total of 6 days) fragments were fixed and analysed histologically and by immunohistochemistry: λH2AX as a marker of DNA damage; RAD-51, BRCA-1 and BRCA-2 as DNA repair factors, and for nuclear exclusion of Foxo3 as a marker of follicle activation.

Main results and the role of chance: There was a significant increase in the proportion of growing follicles cultured with bpv(HOpic) 10 μM (88.6%) compared to 1 μM (76.8%, $P \leq 0.001$) or control (70.5%, $P \leq 0.001$) after 6 days. The proportion of morphologically healthy follicles however, was lower (10 μM bpV (HOpic) 49.4%vs78.3% in control, $p < 0.001$). Akt phosphorylation in bpv (HOpic) exposed tissue was increased ($P \leq 0.001$) and was associated with increased nuclear exclusion of Foxo3 ($P \leq 0.001$). DNA damage in oocytes was higher in bpv(HOpic) groups (1 μM: non-growing, 83%; primary, 78%, secondary, 77%; 10 μM: 74%, 84% and 89%) than control (30%, 59% and 50%) as shown by increased λH2AX expression ($P \leq 0.005$). RAD-51 and BRCA-2 expression were analysed to assess DNA repair proteins involved in homologous recombination. A reduction in RAD-51 expression occurred in bpv (HOpic) treated groups of primary (1 and 10 μM: 34% and 24%) and non-growing follicles (22% and 30%) compared with control (48% and 38%) ($P \leq 0.001$). Higher dose bpv(HOpic) also resulted in lower expression of BRCA-1 compared to control and bpv(HOpic) 1 μM ($P < 0.001$) in non-growing and primary follicles, indicating a reduced response to DNA damage. However, oocytes of primary follicles in 1 μM bpv(HOpic) exhibited a higher level of BRCA-2 expression (36%) compared with control (20%, $P = 0.011$) with a marked decrease in 10 μM (1%, $P \leq 0.001$).

Limitations, reasons for caution: This study focuses on primordial follicle activation after 6 days culture and may not reflect DNA damage and repair capacity in later stages of oocyte and follicle growth.

Wider implications of the findings: Exogenous activation of follicle growth may compromise the bidirectional signalling between oocyte and granulosa cells necessary for optimal follicle health. This large animal model may be useful in assessing follicle activation protocols prior to their use in human ovaries.

Trial registration number: not applicable.

O-085 Can we perform flexible antagonist protocol for luteal phase ovarian stimulation for breast cancer patients seeking fertility preservation?

M. Victoria, M. Comtet, M. Presse, C. Sonigo, I. Cedrin-Durnerin, M. Grynberg

Hospital Jean Verdier 93140 Bondy Avenue du 14 Juillet, Reproductive medecine and Fertility Preservation, Paris, France

Study question: Does the timing of GnRH antagonist initiation during the luteal phase impact the outcome of fertility preservation (FP) cycles?

Summary answer: Flexible GnRH antagonist initiation during luteal phase ovarian stimulation may not impact negatively FP outcome when compared to simultaneous administration with exogenous FSH.

What is known already: Evidence indicates that luteal phase ovarian stimulation may represent an efficient option for women seeking FP, leading to comparable results as those obtained with early follicular phase stimulation. Currently, GnRH antagonists are simultaneously administered with FSH in order to induce early luteolysis and prevent premature LH surge. The feasibility of postponing GnRH antagonist initiation during luteal phase stimulation has not been studied.

Study design, size, duration: This prospective randomized study was conducted between July 2013 and December 2017.

Participants/materials, setting, methods: Sixty-eight women undergoing ovarian stimulation for urgent FP before breast cancer chemotherapy were

randomized into 2 groups according to the beginning of GnRH antagonist administration on stimulation day 1 (S1) or flexibly. In the flexible group, GnRH antagonist was started when the leading follicle reached 12 mm in diameter. Stimulation outcomes were compared between both groups.

Main results and the role of chance: As expected, both groups were comparable in terms of age, body mass index, antral follicle count and AMH levels. Despite different timing in GnRH antagonist initiation, the duration of ovarian stimulation and total amount of gonadotropins were comparable between S1 and flexible groups (11.0 ± 2.5 vs. 11.05 ± 2.2 days and 3530.6 ± 1357.0 vs. 3446.3 ± 1207.7IU, respectively). Finally, the mean number of oocytes recovered and vitrified at metaphase 2 stage were similar in both groups (12.9 ± 10.3 vs. 14.3 ± 8.6 and 10.3 ± 9.9 vs. 10.2 ± 6.9 respectively). The mean day of antagonist introduction in the flexible group were the 6.7 day.

Limitations, reasons for caution: The limited number of patients randomized in each group may represent a limitation for the interpretation of the present results.

Wider implications of the findings: The flexible GnRH antagonist administration during luteal phase stimulation may represent a friendly and cost effective approach. Our preliminary results should be confirmed in a larger population. In addition, the endocrine profile associated with such a protocol and its further impact on oocyte quality will represent important issues.

Trial registration number: not applicable

INVITED SESSION

SESSION 22: CLINICAL UTILITY OF ANTI-MULLERIAN HORMONE MEASUREMENT

Monday 2 July 2018 Room 211 + 212 17:00–18:00

O-086 AMH measurement in fertility treatment

E. Ng[1]

Queen Mary Hospital, Dept. of Ob/Gyn, Hong Kong, Hong Kong

Anti-Mullerian hormone (AMH) is a dimeric glycoprotein that belongs to the transforming growth factor-beta family. In the female, AMH is solely produced by the granulosa cells of preantral and small antral follicles, and regulates ovarian folliculogenesis. Because of this exclusive source of production in the adult female, AMH is a potentially useful marker of ovarian function, and there have been increasing reports on its clinical utility (Dewailly et al, 2014).

Because of its stable production throughout the menstrual cycle with clinically insignificant intra- and inter-cycle variation and that its serum concentration is not influenced by the use of exogenous hormones (Li et al, 2011a), AMH serves as a useful diagnostic tool in differentiating the different causes of secondary oligo-amenorrhoea, particularly ovarian failure and polycystic ovary syndrome from the other causes, with very good diagnostic accuracy (Li et al, 2011b).

Basal serum AMH concentration is useful in prediction of suboptimal and excessive ovarian responses upon ovarian stimulation for in in-vitro fertilization (IVF) treatment cycles, (Broer et al, 2011). There is also some association between AMH level and fresh cycle live birth rate as well as cumulative live birth rate (Li et al, 2013), although most reports indicated a poor predictive value of AMH on the absolute occurrence of pregnancy or live birth rate from IVF treatment, as reviewed in meta-analyses (Iliodromiti et al, 2014). AMH may be another marker for determination of individualised ovarian stimulation regime and gonadotrophin dosing in IVF treatment programmes (La Marca and Sunkara, 2014).

Since there is yet no international standard for AMH measurement, and the numerical values obtained by the different existing assay methods are not equivalent, the discordance among different assay methods may misclassify a significant proportion of women to an inappropriate gonadotrophin dose (Iliodromiti et al., 2017).

O-087 Role of AMH in the pathogenesis and diagnosis of ovulatory disorders

INVITED SESSION

SESSION 23: CHROMOTHRYPSIS OR HOW REARRANGING OUR CHROMOSOMES CHANGES EVERYTHING

Monday 2 July 2018 Room 111 + 112 17:00–18:00

O-088 The characteristics and origin of chromothripsis

W. Kloosterman[1]

UMC Utrecht, Genetics, Utrecht, Neth. Antilles

Human genomes are continuously subjected to mutations, which can drive genetic diseases and cancer. An intriguing finding has been the discovery of chromothripsis, a spectacular and complex form of chromosome rearrangement that can occur in the genomes of cancer cells and patients with congenital diseases. Chromothripsis has been described in a large array of human cancers and various types of chromothripsis have appeared, which differ in complexity and genomic hallmarks. From the combined genomic data a consensus hypothesis has been inferred, involving aberrant DNA replication and chromosome shattering as the underlying processes explaining chromothripsis. In addition, recent work has established several cellular models that recapitulate chromothripsis under defined experimental conditions.

We have used long-read nanopore single-molecule sequencing technologies to unravel complex chromosomal rearrangement, including chromothripsis.

We demonstrate the power of long-read sequencing by the analysis of the genomes of two patients with congenital abnormalities. We developed a bioinformatic method to efficiently map genomic structural variants (SVs) from the long-read data. Using this method, we readily detected all *de novo* rearrangements involving multiple chromosomes originating from complex chromothripsis events. Long sequencing reads enabled efficient phasing of genetic variations, allowing the construction of genome-wide maps of phased SVs. We employed read-based phasing to show that all *de novo* chromothripsis breakpoints occurred on paternal chromosomes and we resolved the long-range structure of the chromothripsis. Our work demonstrates the value of long-read sequencing for analysis of complex chromosomal aberrations underlying human developmental disorders.

O-089 Chromothripsis in human reproduction

F. Pellestor

CHU Montpellier, Unit of Chromosomal Genetics- Department of Medical Genetics, Montpellier Cédex 5, France

Chromothripsis and the genesis of complex chromosomal rearrangements in human gametes and embryos.

Franck Pellestor.

Laboratory of Chromosomal Genetics and Chromostem unit, Department of Medical Genetics, Arnaud de Villeneuve Hospital, Montpellier CHRU, Montpellier, France.

INSERM Unit «Plasticity of the Genome and Aging », Institute of Functional Genomics, Montpellier, France.

Over the last 6 years, the discovery of an unexpected type of massive chromosomal rearrangements, called chromothripsis, came revolutionized our view of the genesis of complex chromosomal rearrangement in cancers and congenital disorders.

Chromothripsis is characterized by the shattering of one (or a few) chromosome segment(s) followed by a chaotic reassembly of the fragments generated through a single catastrophic cellular event.

Several features distinguish this phenomenon from other complex structural aberrations. Congenital chromothripsis are characterized by their low copy number changes and their relatively balanced status. This does not signify that unbalanced chromothripsis events don't occur in germline or during post-zygotic divisions, but it strongly emphasizes the effect of selective pressure as a bias factor in the assessment of congenital chromothripsis, since only balanced chromothripsis outcomes compatible with life have been found in individuals to date.

Various mechanisms, involving abortive apoptosis, telomere erosion, mitotic errors, micronuclei formation and p53 inactivation might cause chromothripsis.

The remarkable point is that all these plausible mechanisms have been identified in the field of human reproduction as causal factors for reproductive failures and chromosomal abnormalities genesis.

Specific features of gametogenesis and early embryonic development such as the weakness of cell cycle and mitosis checkpoints and the rapid kinetics of division in germ cells and early cleavage embryos, may contribute to the emergency of chromothripsis. Existing data indicate that constitutional chromothripsis occurs preferentially in the male germline. This confirms the great vulnerability of spermatogenesis to DNA damage and clearly points to spermatogenesis as a critical stage in the genesis of congenital chromothripsis. Also, the possibility of chromothripsis occurrence in female meiosis cannot be neglected because oocytes are particularly vulnerable to environmental attacks and DNA alteration, and can cumulate genomic and chromosomal damages. During the fertilization process, the premature chromosome condensation (PCC) of sperm nucleus may initiate chromothripsis. In preimplantation embryos, the high incidence of chromosome abnormalities and the frequent fragmentations observed support the assumption that chromothripsis may arise frequently during early human embryogenesis.

All the data support the hypothesis that this unanticipated catastrophic phenomenon may arise more frequently than previously thought in both gametogenesis and human embryogenesis, but also confirmed its compatibility with viability and transmission to subsequent generations.

The complexity of chromothripsis and the diversity of its causative mechanisms raise questions about the origin of this phenomenon, its ties to chromosome instability and its implication in human reproduction and congenital disorders formation. Further in-depth analyses on large samples of patients and cells (gametes and blastomeres) are needed to appreciate the contribution of this cataclysmic process to altered human development and the generation of congenital diseases.

INVITED SESSION

SESSION 24: SURGICAL TRAINING: EXPERIENCE FROM EXISTING TRAINING CENTERS FOCUSED ON TEACHING MINIMALLY INVASIVE TECHNIQUES AND POSSIBLE APPLICABILITY OF SIMULATION TRAININGS IN ART CENTERS

Monday 2 July 2018 Room 113 + 114 + 115 17:00–18:00

O-090 The impact of training center activities on the real-life operating room: how to shorten learning curves and to prevent common mistakes

O-091 Robotic surgery vs conventional laparoscopy in the field of infertility

F. Sendag[1]

Ege University, Obstetrics and Gynecology, Bornova - Izmir, Turkey

Abstract text

Robotic surgery vs conventional laparoscopy in the field of infertility.

Sendag, Fatih, M.D., Professor.

Ege University Department of Obstetrics and Gynecology, Bornova, Izmir, Turkey.

Procedures that are technically challenging with the conventional laparoscopy can be performed with robotic assistance. It has advantages of improved visualization and wrist movements allowing precise suturing. This helps to overcome the limitations of laparoscopy, especially in complicated procedures, and may shorten the steep learning curve in minimal invasive surgery.

Robot-assisted laparoscopy seems to be of interest in cases of complex surgical treatment of infertility. Myomectomy, tubal reanastomosis, and deep infiltrating endometriosis appear to be the preferred indications. It has been shown that robotic assistance in reproductive surgery resulted in decreased blood loss, less post-operative pain, shorter hospital stay, and faster convalescence, whereas reproductive outcomes were similar to laparoscopic approaches. The main limitation to the diffusion of this technique remains its cost.

But it will be crucial to have more long-term outcomes regarding fertility: pregnancy rate (natural and IVF), uterine rupture for myomectomy, impact on ovarian reserve, adhesion forming, etc. These results are necessary for showing the real contribution of robot-assisted laparoscopy in the field of infertility.

Randomized controlled trials focusing on long-term outcomes after robotic surgery are needed to determine which patients are likely to benefit from robotic surgery.

O-092 Powering the mitochondrial donation research by donating their powerhouses: Mitochondrial donors for research

M. Choudhary[1], J. Neilson[2], K. Lennox[1], S. Harrop[3], M. Nesbitt[4], L. Hyslop[5], A. Murdoch[6], M. Herbert[7]

[1]Newcastle Hospitals NHS Foundation Trust and Wellcome Trust for Mitochondrial Research, Newcastle Fertility Centre at Life, Newcastle upon Tyne, United Kingdom
[2]Newcastle University, Newcastle Fertility Centre at Life, Newcastle upon Tyne, United Kingdom
[3]Newcastle upon Tyne Hospitals NHS Foundation Trust and Wellcome Trust for Mitochondrial Research, Newcastle Fertility Centre at Life, Newcastle upon Tyne, United Kingdom
[4]Newcastle University and Wellcome Trust for Mitochondrial Research, Newcastle Fertility Centre at Life, Newcastle upon Tyne, United Kingdom
[5]Wellcome Trust for Mitochondrial Research and Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle Fertility Centre at Life, Newcastle upon Tyne, United Kingdom
[6]Newcastle Fertility Centre, Biomedicine West Wing, Newcastle upon Tyne, United Kingdom
[7]Wellcome Trust for Mitochondrial Research and Newcastle University, Newcastle Fertiltiy Centre at Life, Newcastle upon Tyne, United Kingdom

Study question: What was the impact of new UK regulations and compensation policy on donor recruitment and egg availability for pre-clinical research in preventing mitochondrial DNA disorders?

Summary answer: Despite the high initial expression of interest, only 5% of those women became mitochondrial donors donating 584 eggs for mitochondrial pre-clinical research.

What is known already: UK became the first country to legalise and permit clinical use of reproductive technologies to prevent transmission of mitochondrial DNA disease following scientific reviews, extensive public consultation, ethical and parliamentary debates. Until 2012, the source of freshly harvested oocytes for use in research in the UK was largely limited to 'egg sharing" schemes in which women undergoing IVF treatment donate half of their oocytes in return for a financial contribution towards the cost of treatment. Following publication of landmark reports from the Nuffield Council on Bioethics and the HFEA, UK implemented a policy permitting reasonable financial compensation to egg donors.

Study design, size, duration: A retrospective analysis of data over 35 month period from the first pilot scheme in UK of mitochondrial donor recruitment for research following implementation of new regulations and compensation policy.

Participants/materials, setting, methods: Ethics and HFEA regulatory approvals were obtained prior to mitochondrial donor recruitment for pre-clinical research aimed at prevention of inheritable maternally derived mitochondrial DNA disorders. The new pilot scheme offered compensation of £500 per donation cycle to mitochondrial donors for research as per approval granted. All women self-injected for ovarian stimulation and underwent oocyte retrieval under sedation. A total of 1290 women expressed interest in donating oocytes for mitochondrial donation research over 35 month period.

Main results and the role of chance: Of 1290 women expressing interest via a webmail contact page, only 223 (33%) attended an initial appointment after receiving further research information. Of these, 135 (61%) met the inclusion criteria for age (18-36 years), BMI (≤30) and ovarian function (antral follicle count >10 and AMH 10-50 pmol/l). Half of the eligible women made an informed decision to not proceed with mitochondrial donation following consultation. Remaining 71 women (mean age 26.5 years ± 4.2) went ahead with ovarian stimulation. Poor response led to 7 cancellations, thus resulting in 64 women successfully donating to research. In all, only 5% (n = 64) of those who initially expressed interest (n = 1290) eventually became mitochondrial donors donating a total of 584 oocytes for research. Following implementation of new regulations and compensation policy, the number of oocytes donated for research has doubled compared to our previous 'egg-sharing for research' scheme.

While the high levels of interest and the increase in oocyte availability for research are encouraging, the high drop-out rate suggests that the financial compensation does not hugely influence decision to donate and the donation procedure itself, rather than the concept of egg donation per se, is a disincentive to the vast majority of women.

Limitations, reasons for caution: As the mitochondrial donor recruitment was for research only, it is not possible to stipulate on the facilitators and barriers for mitochondrial donation for treatment purposes from this study. A qualitative study is indicated to garner insight and explore factors influencing the decision making process for mitochondrial donor recruitment.

Wider implications of the findings: Understanding, and addressing, the barriers to donation for the large fraction of women who initially express interest would help to ensure an adequate supply of oocytes for clinical treatment and for the ongoing underpinning research. Critical to this will be communicating the distinction between conventional egg donation and mitochondrial donation.

Trial registration number: Not applicable.

This study was supported by Wellcome Trust funding (grant number 096919). Thanks to volunteers who participated in the scheme and donated eggs for research.

O-093 The use of animals and human embryos in preclinical safety research: is there an ideal order?

V. Jans[1], W. Dondorp[1], H. Mertes[2], G. Pennings[2], G. De Wert[1]

[1]Maastricht University, Health- Ethics and Society, Maastricht, The Netherlands
[2]Bioethics Institute Ghent, Department of Philosophy and Moral Sciences, Ghent, Belgium

Study question: Should animal studies be preferred to / precede the use of human embryo's in preclinical safety research?

Summary answer: Although regulations suggest that animal studies should be preferred to / precede human embryo research, there are no convincing arguments for this.

What is known already: Legal and regulatory documents suggest that research using human embryos may only be considered when animal studies have either been performed or cannot answer the research question. For instance the British Warnock Report states that human embryos should only be used when research with animal models is not an option. Similarly, ESHRE's Task Force Ethics and Law has suggested an ideal chain of types of preclinical research with animal studies as a first and embryo research as a second step. However, arguments supporting this order are lacking.

Study design, size, duration: A literature study and a focus group interview with key figures in reproductive medicine were performed to identify scientific, legal and/or ethical arguments supporting the 'first animals then human embryos' rule.

Participants/materials, setting, methods: Literature study: articles have been selected from scientific journals focusing on normative aspects of ARTs, animal research and human embryo research. Additionally, relevant legal texts and regulative documents from several countries were studied. Focus group: key figures in reproductive medicine were invited to reflect on the 'first animals then human embryos' rule. Conceptual and ethical analysis: the findings were critically assessed in terms of the consistency of arguments and the normative soundness of conclusions.

Main results and the role of chance: From a scientific perspective, there are no valid arguments supporting the 'first animals then human embryos' rule. In fact, making this a rule stands in the way of doing good research, leading to unnecessary animal studies for questions where it is clear that human embryos are more appropriate research material. From an ethical perspective, welfare and moral status arguments can be distinguished. Welfare arguments seem not to support a moral preference for animal research, apart perhaps in view of concerns about the welfare of oocyte donors. Whereas animals may suffer discomfort and pain, preimplantation embryos are not sentient and would in so far be the preferred research material. Status arguments will not change this: although as 'potential persons' human embryos are thought to have a certain moral status that stands in the way of using them for trivial purposes, this status is relatively low as compared not only to that of human persons but also to that of sentient animals whose interests can be harmed. Therefore, the requirement that human embryos can only be used when the research question cannot be

answered by using animal models should be adjusted and the strict order of preclinical research steps should be loosened.

Limitations, reasons for caution: New developments may affect the reasoning leading to our conclusion. For instance when human embryos may in the future be cultured for research beyond 14 days, then against the background of the widely held view that their moral status increases with further development, this may lead to a different assessment.

Wider implications of the findings: Holding on to the 'first animals then human embryos' rule not only stands in the way of proper science, but is also problematic from an ethical perspective. Sacrificing animals for no good reason is at odds with the acceptance of the 'three Rs' (Replace, Reduce, Refine) in scientific research.

Trial registration number: not applicable.

O-094 National survey on the opinion of French specialists in ART about societal issues to prepare the future revision of the French bioethic law

H. Creux[1], M. Diaz[2], A. Papaxanthos[2], L. Chansel-Debordeaux[3], C. Hocke[2]

[1]Clinique Saint Roch, Reproductive medicine, Montpellier, France
[2]hôpital Pellegrin, Reproductive centre, Bordeaux, France
[3]hôpital Pellegrin, Reproductive laboratory, Bordeaux, France

Study question: National survey on the opinion of French specialists in ART about societal issues to prepare the future revision of the French Bioethics law.

Summary answer: French ART specialists promote social egg freezing, ART in single and homosexual women, genetic screening and financial compensation for donors. Opinions remains divided for surrogacy.

What is known already: The French Bioethics law concerning ART is more restricted than in other countries. Techniques can only be applied in heterosexual couples presenting a documented infertility with a woman under 43 yo. ART treatments are financed by the French Social Security up to 6 IUI and 4 IVF with fresh embryo transfer Donation is anonymous and free, responsible for a lack of donors. Fertility preservation is only allowed for cancer patients or medical reasons. Directed donation, surrogacy, social fertility preservation and genetic screening for maternal age, repeated abortions or implantation failures are forbidden in France.

Study design, size, duration: Descriptive study conducted in June 2017 in a University teaching hospital by using an anonymous questionnary. The questionnary consisted of 15 questions on current issues in ART.

Participants/materials, setting, methods: An anonymous online questionnary was sent by email to 650 French specialists in ART, both clinicians and biologists, with an average response time of 3 minutes.

Main results and the role of chance: After 3 reminders, 408 responses were collected resulting in a participation rate of 62.7%. Participants consisted of 130 men and 271 women; 259 clinicians and 144 biologists. Out of them, 245 were < 50 years old and 159 were ≥ 50 years old.

Concerning the genetic screening, 80% of the physicians were in favour to expand the indications that are presently limited in France to genetic diseases with a particular gravity.

To authorize social fertility preservation was acclaimed by 78.9% of the specialists, but without a social coverage for 69.3% of them and with the possibility to employ unused frozen eggs for the oocyte donation program for 40.3% of them.

Concerning gametes donation, 77.4% of the French specialists in ART were in favor to give a financial compensation to donors, 92% promoted to preserve the anonymity and 80,9% were not in favor to a directed donation.

The ART for single women and for homosexual women were supported by 63.5% and 69.8% of the French specialists, respectively.

The legalisation of surrogacy, all indications confounded (including male homosexuals), was asked by 55.2% of French specialists in ART.

Limitations, reasons for caution: Despite a satisfactory participation rate, some French specialists in ART did not answer the questionnary on line. Moreover, some physicians did not fill in all the questions. That represents a bias of selection.

Wider implications of the findings: This survey provides a support for the French Bioethics comittee to know the opinion of the specialists in ART in their country on the eve of the revised law.

Some situations could be discussed in the French legislative context while others could require the sollicitation of the neighboring European teams.

Trial registration number: Not applicable.

O-095 Outcomes of applications for information about a person related through donor treatment following legislative change removing donor anonymity retrospectively

L. Johnson, K. Bourne, T. Thomson, K. Hammarberg

Victorian Assisted Reproductive Treatment Authority, Victorian Assisted Reproductive Treatment Authority, Melbourne, Australia

Study question: What are the outcomes of retrospective removal of donor anonymity?

Summary answer: Of the donors who were located, most agreed to be contacted by their donor-conceived offspring.

What is known already: In the state of Victoria, Australia, legislation relating to donor conception was introduced in 1988 and has changed over time to increasingly consider the interests of the people born as a result. Since 1998 gamete donors have had to agree to the release of their identifying information if their donor-conceived offspring request it. In March 2017 new legislation retrospectively removed anonymity for pre 1998 donors. Applications for information about related parties are lodged with the Victorian Assisted Reproductive Treatment Authority (VARTA) where donor registries are managed. Donors who are located can stipulate contact preferences, including the preference for no contact.

Study design, size, duration: A prospective study of the outcomes of all applications for information by people related through donor conception from March to December 2017 where donors had consented to the use of their gametes in treatment prior to 1998.

Participants/materials, setting, methods: In the study period VARTA counsellors received 101 applications for information about a related party: 71 by a donor-conceived person and six by a parent of a donor-conceived person for information about the donor, and 24 by a donor for information about their donor offspring. Outcomes of the applications were recorded in a database.

Main results and the role of chance: By 31 January 2018, 65 of the 101 applications for information were still being processed and 36 had a known outcome. Of these 33 were applications for information about a donor (31 from a donor-conceived person and two from a recipient parent) and three were applications from a donor for information about donor-conceived offspring. Of the 33 applications for information about a donor, seven were withdrawn after counselling and two applicants only wanted non-identifying information which did not require the donor to be located. In the remaining 24 applications: 15 donors were located, six were not located or had missing information, and 3 donors were deceased. Of the 15 donors who were located, 11 agreed to be contacted and four lodged a preference for no contact. In the three applications for information about a donor-conceived offspring one agreed to be contacted by the donor.

Limitations, reasons for caution: There is no way of knowing how many donor-conceived people born before 1998 are aware of their donor origins. The findings cannot be generalised to all donor-conceived people or to donors who are not located or for whom no application for information is made.

Wider implications of the findings: Outcomes to date of the retrospective removal of donor anonymity are mixed but indicate that some donors who expected to remain anonymous are willing to be contacted by their donor-conceived offspring if approached.

Trial registration number: Not applicable.

INVITED SESSION

SESSION 26: THE AGEING MAN

Tuesday 3 July 2018 Forum (Auditorium) 08:30–09:30

O-096 Mechanistic basis of ageing effects

J. Aitken[1]

University of Newcastle, Dept. of Biological Sciences, Callaghan- NSW, Australia

Abstract text

Ageing has a significant impact on the reproductive competence of males. When men exceed the age of 35 there is a clear age-dependent impact on the ability of the spermatozoa to initiate a viable pregnancy, resulting in a progressive fall of fertility and a corresponding increase in the incidence of miscarriage. In addition, paternal ageing is associated with genetic changes in the progeny affecting telomere length (telomeres get longer with paternal age) and the incidence of spontaneous genetic and epigenetic mutations (both of which increase linearly with paternal age). All of these age-dependent changes (loss of fertility, increased miscarriage rates, increased mutational/epimutational load carried by the offspring and increased telomere length) can be attributed to two potential underlying causes. Firstly, as males age their reproductive system comes under increasing oxidative stress as reflected by an increase in oxidative damage, particularly oxidative DNA damage in the spermatozoa. Because the precursor germ cells of the testes (particularly spermatogonia) possess significant telomerase activity, they have the capacity to respond to such stress by increasing telomere length before the germ cell differentiates into a spermatozoon. Construction of an animal model for oxidative stress in the male reproductive system via the surgical induction of a transient testicular ischemia, has been found to result in the generation of spermatozoa with extremely long telomeres, which are then passed onto both male and female offspring. At this stage we have no idea what the inheritance of long telomeres from the paternal germ line means in terms of the health trajectory of the offspring. Telomere length aside, oxidative stress would also account for the age-dependent decline in fertility, as a consequence of the induction of lipid peroxidation in the spermatozoa and a consequential loss of sperm function. Antioxidants are clearly important for defending the germ line against oxidative attack since the functional depletion of genes encoding thioredoxin domain-containing proteins (Txndc2, Txndc3) results in accelerated age-dependent disruption of motility and DNA integrity as well as increases in reactive oxygen species generation, enhanced formation of lipid aldehyde-protein adducts, and impaired protamination of the sperm chromatin. The DNA damage seen in the spermatozoa of ageing males could also be responsible for the age-dependent increase in miscarriage rates as well as the increase in mutational load carried by the offspring. The aberrant repair of oxidative DNA damage in the oocyte immediately after fertilization is proposed as a major contributor to the mutational load carried by children, along with spontaneous mutations arising as a result of replication errors in the spermatogonial stem cell population. Together these mechanisms have a major impact on the paternal contribution to offspring health.

O-097 The ageing male germ cell

Abstract text

Parental age has been steadily increasing in Western societies. While in women the effects of age on reproductive function (e.g. decrease in fertility, increase in aneuploidies) are well known, little is known of the effects of ageing on the male germline. On the other hand, it is difficult to distinguish the effects caused by normal ageing from those of associated morbidities. Therefore, the objective of this study was to study molecular parameters of ageing on the germline of a cohort of healthy men.

The study cohort (FAMe – Fertility and Aging in healthy Men) is composed of healthy men (n = 197) between 18 and 84 years of age. All participants went through a thorough selection process which included physical evaluation and andrological assessment and provided sperm and blood samples. DNA was isolated from blood and swim-up (motile) sperm and relative telomere length (rTL) and DNA methylation of *LINE1* transposable elements were analysed. DNA fragmentation index (DFI) was measured by an acridine orange-based flow cytometric assay. In addition WGBS was performed on sperm samples and data validated by deep bisulfite sequencing (DBS).

Relative telomere length in blood decreased with age (ρ=-0,41, $p < 0,001$), while sperm rTL increased ($\rho = 0,39$, $p < 0,001$). DNA methylation of *LINE1* repetitive elements in blood did not show any age-related alterations in this cohort (mean methylation = 79,29 ± 0,14). The mean sperm DFI increased with age ($\rho = 0,49$, $p < 0,001$). WGBS revealed more than 180 age-related DMRs, some of them located in regions associated with genes important for embryonic development, between sperm of young and old men, which were not present in blood DNA. Validation of selected DMRs among all groups of the FAMe study revealed distinct patterns for DMRs with either linearly increasing or decreasing methylation levels.

Telomere attrition is considered a hallmark of ageing and in our cohort we could confirm that in peripheral blood telomeres become shorter with increasing age. In the male germline, however, telomerase has been previously shown to remain active. Our results are in agreement with this, showing sperm rTL increasing with age. Epigenetic drift has been suggested as a consequence of ageing, with some studies showing an overall age-associated decrease of DNA methylation, including in repetitive elements. In this cohort we were unable to detect any changes in *LINE1* DNA methylation with increasing age. Likely *LINE1* methylation is probably affected by co-morbidities associated with ageing but not by the ageing process itself. The effect of ageing on sperm chromatin structure has previously yielded conflicting results, probably due to the heterogeneity of the cohorts analysed. In our cohort, we could detect an increase in the mean DFI and therefore DNA damage with increasing age. The identification of germ cell specific DMRs, which are not present in blood, points to a unique intrinsic ageing process of germ cells. Since it seems highly unlikely that this takes place during spermatogenesis, the testicular stem cells, namely the spermatogonia, seem to be prone to ageing processes.

Taken together healthy ageing affects the DNA integrity of male germ cells and therefore could resemble a potential risk for the progeny of older fathers.

N. Plachta

Institute of Molecular and Cell Biology, Singapore, Singapore

O-099 Self-organization of the human embryo in the absence of maternal tissues

INVITED SESSION

SESSION 28: BIG DATA IN ENDOMETRIOSIS – HOPE OR HYPE?

Tuesday 3 July 2018 Room 111 + 112 08:30–09:30

O-100 Big data in understanding disease

O-101 Big data in endometriosis

S. Missmer

Michigan State University, OB/GYN & Reproductive Bio, Grand Rapids, U.S.A.

Abstract text

The excitement and potential surrounding "big data" and it's implications for advancement of precision medicine that will revolutionize care for women and men across the lifecourse is as pertinent to reproductive medicine as it is to other aspects of health and wellbeing. However, there are challenges unique, or at least of greater consequence, to reproductive medicine that must be addressed and for which solutions must be developed. The biologic and sociologic diversity of factors influencing gynecologic and reproductive health is great. This diversity is of benefit to precision medicine advancement if embraced, but this diversity also demands methodologic rigor in approaches to and interpretation of big data discoveries. Reproductive health and wellbeing impacts multiple windows across an individual's life as well as multiple generations within families. Critical elements of multidisciplinary exploration accounting for time-varying variables that assess data validity and reliability will be discussed.

INVITED SESSION

SESSION 29: ASRM EXCHANGE SESSION: MAXIMIZING THE CHANCE OF PREGNANCY FOR EVERY PATIENT: AN INTENTION-TO-TREAT ANALYSIS

Tuesday 3 July 2018 Room 113 + 114 + 115 08:30–09:30

O-102 A rational approach to the management of the older and low response patient undergoing ART

O. Davis

Weill Cornell Medicine, Center for Reproductive Medicine, New York- NY, U.S.A.

Abstract text

This lecture will examine strategies for treating the poor prognosis IVF patient (advanced age, diminished ovarian reserve), while stressing the importance and relevance of an "intention to treat" clinical approach. Ovarian reserve markers and definitions of diminished ovarian reserve will be reviewed, as well as ovarian stimulation strategies for the poor response patient (micro-flare, estrogen priming, minimal stimulation) as well as the evidence supporting the choice of protocol. An intention to treat strategy stresses the maximization of an individual patient's chances for success at the point of entry into treatment, i.e. once presenting for initial consultation. If one defines the denominator for success as the performance of an embryo transfer, it becomes clear that patient attrition can occur at several points before, e.g. through not offering/initiating treatment for the patient with a suboptimal prognosis, cycle cancellation for reduced numbers of developing follicles, prolonging in vitro culture to day 5-6 in the setting of few embryos and/or the performance of PGT-A as standard-operating-procedure. A rationale for transferring a larger number of cleavage stage embryos in women of advanced age (>43) will be presented. The focus of treatment should be on the individual patient's chance for success rather than an IVF clinic's per transfer pregnancy statistics.

O-103 Every last baby out of every last egg: Does PGS really improve the chance of pregnancy for every patient?

R.J. Paulson

University of Southern California, Obstetrics and Gynecology, Los Angeles, U.S.A.

Abstract text

Pre-implantation genetic testing for aneuploidy (PGT-A) is a method of selection of embryos for transfer. It has been shown to increase embryo implantation rates in selected groups of patients. This observation has led some clinics to advise all patients undergoing IVF to include PGT-A as part of their treatment. However, not all groups of patients benefit from this form of embryo selection, and embryo implantation rates are not increased. Furthermore, the testing itself results in the loss of potential implantations that are lost due to false positive test results and due to the trauma of the embryo biopsy. This loss of potential implantations may not be a major problem in women with large numbers of embryos, and those whose embryo implantation rates are already high. However, in women over 40, with low implantation rates and low numbers of embryos, the addition of PGT-A will result in decrease cumulative pregnancy rates on a per-aspiration basis. This lecture will review the approximate magnitude of both cost and benefit of PGT-A and show why women with poor prognosis should not use PGT-A to try and increase embryo implantation rates.

INVITED SESSION

SESSION 30: WHO SESSION: WHO AND FERTILITY CARE: TIME TO ENGAGE?

Tuesday 3 July 2018 Room 117 08:30–09:30

O-104 Introduction: HRP vision and goals regarding infertility

O-105 WHO priorities in infertility and fertility care

T. Matsaseng

WHO Headquarters, RHR, Geneva, Switzerland

Abstract text

Infertility has not been recognized as a public health priority with debates as to whether it's a disease or not. According to the WHO/World Bank report on Disability, infertility following maternal sepsis and unsafe abortion (a critical maternal morbidity) was ranked 8th highest in prevalence as a global serious disability and in the population group under the age of 60, infertility ranked 5th highest as a major global disability behind depression, ocular refractive errors, unintended accidents and alcoholism.

The commonest causes of infertility in the LMIC are, severe male infertility and bilateral tubal disease, that can only be treated by assisted reproductive technologies (ART) and yet these techniques are not widely available and often not affordable. Severe stigmatization, fear, shame and social complications surround vulnerable individuals and couples who are viewed as childless or unable to have children in many developing and transitional countries. Studies have shown that to have a healthy child, couples may accept a 20% risk of death and give up 29% of their income.

Barriers towards treatment access include, lack of infrastructure and/or high unaffordable costs. Where available the treatment is often associated with unsafe practices that results in undesirable complications including ovarian hyperstimulation syndrome (OHSS) and high order multiple pregnancies (HOMP) with inherent poor neonatal outcomes. Furthermore, ethical and

moral issues around third party reproduction (gamete/embryo donation & surrogacy), reproductive tourism and same sex couples (LGBT) have not received adequate attention they deserve.

As we implement strategies to achieve Sustainable Development Goals (SDG no. 3, 5) and the Global Strategy for Women's, Children's and Adolescents 'Health (2016–2030; Survive, Thrive & Transform) agenda, we strongly advocate for inclusion of fertility services within the Reproductive, Maternal, Newborn, Child and Adolescent health, RMNCAH plans in order to achieve gender equality and empower all women and girls. We also wish to promote universal access to Sexual Reproductive Health and Reproductive Rights (SRHR), to ensure that no one is left behind.

Therefore, the aim of the presentation is to highlight WHO engagement in infertility and fertility care and to outline key areas of priority in our agenda as we endeavour to improve access and availability of safe and effective fertility care equally across the globe.

O-106 Estimation of prevalence of infertility from cross-section surveys (DHS) using time-to-pregnancy approach: preliminary results of a pilot study

T. Matsaseng

WHO Headquarters, RHR, Geneva, Switzerland

Abstract text

Infertility is defined as a disease of the reproductive system that results in an inability to become pregnant or bring a pregnancy to term. Primary infertility is predominantly a result of delayed childbearing, complications of childbearing and/or congenital disorders. Secondary infertility is often a result of maternal sepsis (infection following delivery) or of complications associated with unsafe abortions. Both forms of infertility, primary and secondary can result from complications following sexually transmitted infections (STIs), genital tuberculosis (TB) and HIV/AIDS, or following cancer or other diseases and subsequent disease management that proves contrary to either healthy or successful sperm or egg development.

A WHO evaluation of Demographic and Health Surveys (DHS) data from 2004, estimates that more than 186 million ever-married women of reproductive age in developing countries were maintaining an unfulfilled "child wish", translating into one in every four couples between the of age 15–49. A recent analysis by WHO of internationally published references shows that primary infertility rates are not decreasing (and in some countries are increasing)and secondary infertility continues on an increasing global trend from 1990 to 2008 (unpublished, WHO, 2011). Severe stigmatization, fear, shame and social complications surround vulnerable individuals and couples who are viewed as childless or unable to have children in many developing and transitional countries.

Besides lack of infrastructure and/or high unaffordable costs, limitation to access to care is further complicated by underestimation of the disease magnitude particularly in the low middle income countries (LMIC) and to address this issue, obtaining accurate, country-level estimates of infertility prevalence is essential. Demographic approaches and clinical and epidemiological studies do provide more relevant measure to assess the need for services to enhance fertility. However population based methods for shorter durations are limited and estimations approaches vary. While Time-to-pregnancy (TTP) and current duration (CD) approaches have advantages and disadvantages, their role and application still need to be explored in various settings for accurate estimation of disease prevalence.

Therefore, the aim of the presentation is to evaluate and report preliminary results of the pilot study on estimation of infertility prevalence using current duration approach to estimate TTP to data from Demographic and Health Surveys (DHS).

O-107 The landscape of IVF in lower and middle income countries

T. Chiware[1,2], N. Vermeulen[3], K. Blondeel[2,4], R. Farquharson[3], J. Kiarie[2], K. Lundin[3,5], T. Matsaseng[2], W. Ombelet[3], I. Toskin[2]

[3]European Society of Human Reproduction and Embryology, Central Office, Grimbergen, Belgium

[4]Ghent University, Faculty of Medicine and Health Sciences, Ghent, Belgium

[5]Sahlgrenska University Hospital, Reproductive Medicine, Gothenburg, Sweden

Study question: What are currently available and potential in vitro fertilization (IVF) and other assisted reproductive technologies (ART), and services in low- and middle-income countries (LMIC)?

Summary answer: The ART services available in LMIC vary from conventional ART to low cost ART, depending on the region.

What is known already: Infertility affects 186 million people, 8-12% of couples worldwide, with a prevalence estimated at 3.5-16.7% in LMIC, and 30-40% in Sub-Saharan Africa. High costs of IVF and lack of ART services, in addition to cultural, religious, legal, efficacy and safety concerns, have highlighted the need for affordable, accessible and acceptable ART in LMIC. Infertility and childlessness, particularly in LMIC, have devastating consequences, resulting in considerable interest in developing low cost IVF procedures. However, there is a paucity of evidence on the safety, efficiency and ability to replicate techniques, under different field conditions, and integrate low cost ART into existing infrastructures.

Study design, size, duration: A systematic review was performed by searching several databases for articles on low cost ART in LMIC published from January 2010 to June 2017. Two reviewers independently screened the titles and abstracts, then full texts of selected records were reviewed and data extracted.

Participants/materials, setting, methods: The electronic databases searched included PubMed, Popline, EMBASE and Global Index Medicus (regional WHO online databases). An internet search using 'Google" search engine with the terms 'infertility", 'low and middle income countries" and "in vitro fertilization" or 'assisted reproductive technologies" (limited to results published after 2010) was performed. Similar search terms were used for grey literature databases (worldcat.org, greylit.org). In addition, the reference lists of included studies were checked.

Main results and the role of chance: An extensive search of the proposed databases yielded 3443 citations. After review of the titles and abstracts, 180 studies were included. The full text of 180 articles were reviewed and a further 106 articles were excluded. The grey literature search yielded 419 citations of which 334 were excluded after screening of the title, and a further 85 documents after full text assessment due to duplicate entries, not LMIC, not relevant, or no access to the full document. A final total of 74 citations were included as part of the systematic review and separated into regions. The majority of the studies were qualitative and observation studies. In general, ART services are available and described in several LMIC, ranging from advanced ART in China, to introduction of IUI and ART in some African countries. Efforts for low cost ART treatments have been described in feasibility studies, or efficacy studies, most of low to very low quality or providing indirect evidence from developed countries. We found no studies from LMIC reporting the implementation of low cost ART that is efficient, accessible and affordable to the whole population.

Limitations, reasons for caution: To our knowledge, this is the first systematic review of ART in LMIC. Studies published prior to 2010 were excluded. The available studies were heterogeneous making it difficult to extract findings.

Wider implications of the findings: The WHO is in a unique position to provide much needed guidance for infertility management in LMIC. This systematic review provides insight into the landscape of ART in LMIC in various regions. This will guide efforts to improve availability, quality, accessibility and acceptability of infertility care, including ART in LMIC.

Trial registration number: The protocol developed and registered with PROSPERO International prospective register of systematic reviews, number CRD42017064413.

O-108 Developing ART practice in low and middle income countries

O-109 Closing remarks

INVITED SESSION
SESSION 31: NURSES/MIDWIVES INVITED SESSION
Tuesday 3 July 2018 Room 116 08:30–09:30

O-110 Use of ultrasound at embryo transfer - is it necessary?

O-111 Family planning, knowledge about fertility and lifestyle prior to conception; nurses and midwives as key persons in preconception care

T. Tyden[1], L. Salih[2], J. Hultstrand[2], M. Ekstrand[2]

[1]Department of Women's and Children's Health, Dep. of Women´s and Children´s Health, Uppsala, Sweden
[2]Uppsala University, Women´s and Children´s Health, Uppsala, Sweden

Abstract text

Preconception care and family planning are identified to be of increasing importance for health in a wider sense as recently highlighted in a series of articles in the Lancet. It is relevant for all women of reproductive age. Slightly half of all pregnancies worldwide are unplanned and of these, 50% ends in abortion, 13% in miscarriage, and 38% in unplanned birth.

In low-income countries many women would benefit from delaying and spacing pregnancies. In high-income countries it is the opposite situation as many women postpone childbearing until ages when their fecundity has decreased. These examples highlight the need for preconception care that also should be tailored for each individual. Furthermore, the most critical period for organ development occurs before many women even know they are pregnant and the first contact with antenatal care is often too late for advice about health-promoting changes in life style.

Lifestyle-related factors such as age, obesity and smoking affect fertility and reproductive outcomes. Studies have shown that people underestimate the importance of age on fertility and overestimate the success rate of in vitro fertilization. Smokers have lower odds for clinical pregnancy per cycle, live birth per cycle, and higher odds for miscarriage, ectopic pregnancy, and babies being small for gestational age and for preterm delivery.Obesity is an increasing health problem globally that also impact reproductive health and reproductive outcomes. These examples emphasize the need for educating women and men about lifestyles that are of importance for their reproduction.

A tool called the Reproductive Life Plan (RLP) is recommended by the Centers for Disease Control and Prevention. It consists of a set of questions that can be used by health care providers to guide a conversation about if and when a person wants to become a parent and how to achieve their reproductive goals. The aim with the RLP is to encourage women and men to reflect on their reproductive intentions, to promote a healthy lifestyle prior to conception and to use appropriate contraceptive methods in line with their RLP. Also the RLP aims to give information on lifestyle prior to conception.

In Sweden, midwives working with contraceptive counseling used the RLP-concept in two randomized controlled studies. The midwives asked questions about the RLP with the women who were allotted to the intervention group (IG). They also handed out a specially designed brochure to women in the IG. The brochure contained information about fertility and life styles of importance prior to a pregnancy. Women in the IG increased their knowledge about fertility and the great majority stated that midwives should continue to discuss the RLP in contraceptive counseling. The results and have been reported in two articles in Human Reproduction. Recently we have used the RLP concept among men attending STI- and sexual health clinics.

I will present lessons learned from our experiences with using the RLP in clinical practice. I will also suggest how nurses and midwives can be important persons in preconception care.

For young women and men Internet as an important source of information. We have therefore developed a mobile friendly website about the RLP www.reproduktivlivsplan.selt has been translated into English and also into some other commonly spoken languages in Sweden.

SELECTED ORAL COMMUNICATIONS
SESSION 32: UPDATES IN EMBRYO MORPHOKINETICS
Tuesday 3 July 2018 Forum (Auditorium) 10:00–11:30

O-112 The effect of oocyte vitrification on subsequent embryo developmental morphokinetics and blastocyst formation: a prospective time-lapse sibling oocyte study

S. De Gheselle, V. Muyshond, K. Tilleman, P. De Sutter

Ghent University Hospital, Department for Reproductive Medicine, Ghent, Belgium

Study question: Is there a difference in blastocyst formation between fresh and vitrified warmed sibling oocytes and can this difference be attributed to changes in embryo morphokinetics?

Summary answer: There is a delay in morphokinetic embryo development and blastocyst formation between fresh and vitrified sibling oocytes.

What is known already: Oocyte vitrification is often used in medical assisted reproductive treatments e.g. oocyte-donation programs, fertility-preservation for cancer patients, social-freezing but also in IVF cycles where semen production problems occur. The impact of oocyte vitrification on embryo development remains controversial. Morphokinetic analyses on embryo development from vitrified oocytes are usually based on early morphokinetic parameters (De Munck et al., 2015; Chamayou et al.,2015). A recent report by Cobo et al., 2017, showed delayed morphokinetics from vitrified oocytes up to the blastocyst stage. Although this report included a lot of cycles, the study was not performed on sibling oocytes.

Study design, size, duration: In a prospective study between February 2016 and December 2017, morphokinetic development and blastocyst formation was investigated between fresh (FO) and vitrified sibling donor oocytes (VITO). Blastocyts were scored according to the grading system of Gardner and Schoolcraft(1999) and their developmental morphokinetics were analyzed using time-lapse imaging (EmbryoscopeTM). On the day of oocyte retrieval, and after cumulus-oocyte complex denudation, MII oocytes with normal morphology were randomly allocated to fresh ICSI insemination or to vitrification (Cryotop®).

Participants/materials, setting, methods: MII oocytes (n = 438) from 67 donor cycles (36 fresh / 31 warmed) from 27 different healthy anonymous oocyte donors (age 30.3 ± 3.7) were allocated both to a synchronous FO acceptor (n = 215) and to a VITO acceptor (n = 223). Morphokinetic timings were log-transformed and linear-regression analysis (mixed models) was applied (SPSSv24). Fixed effects were determined by comparing FO and VITO. The variable 'donor' was taken into account for random effects ($p < 0.05$).

Main results and the role of chance: Time-lapse analysis of the 16 different time-points and 6 time-intervals showed that there was an overall delay in the cleavage rate from the time of pronuclei disappearance up to the time of blastulation in the VITO compared to their sibling FO. Twelve morphokinetic parameters were statistically significant between the VITO and FO respectively: tPNf [Geometric mean(GM) 26.18 h versus GM 23.87 h; p = 0.000]; t2 [GM 28.51 h versus GM 26.67 h; p = 0.004]; t3 [GM 38.81 h versus GM 36.05 h; p = 0.004]; t4 [GM 42.36 h versus GM 39.17 h; p = 0.001]; t5 [GM 51.52 h versus GM 47.09 h; p = 0.000]; t6 [GM 56.36 h versus GM 51.28 h; p = 0.000]; t7 [GM 60.12 h versus GM 54.20 h; p = 0.003]; t8 [GM 64.57 h versus GM 57.28 h; p = 0.000]; t9+ [GM 76.73 h versus GM 68.39 h; p = 0.000]; tstart compaction [GM 90.57 h versus GM 86.50 h; p = 0.002}; tcompaction [GM 102.09 h versus GM 96.38 h; p = 0.000]; tstart blastulation [GM 100.92 h versus GM 97.95 h; p = 0.013]. These morphokinetic differences resulted in a similar overall

blastocyst formation (expansion status 1-5) in the FO group compared to the VITO group [51.8% (80/155) versus 41.7% (60/144), P = 0.1043], however, there was a statistically higher full (expansion status 3-5) blastocyst rate in the FO group [46.4% (72/155) versus 31.9% (46/144), P = 0.0128].

Limitations, reasons for caution: Sperm parameters were not included in this prospective sibling oocyte study and could have an effect on embryo development.

Wider implications of the findings: Oocyte vitrification has an impact on morphokinetics parameters and embryo development up to the blastocyst stage. This could be explained by effects of vitrification on ultrastructure or biological processes in the oocytes. Diminished mitochondrial activity could also be responsible for a delay in reactivating the cell division machinery after vitrification.

Trial registration number: EC/2017/0086

O-113 Duration of blastomere movement post first cytokinesis is an effective predictor for the clinical pregnancy after fresh cleaved embryo transfer: in a minimal stimulation program

K. Ohata[1], K. Ezoe[1], A. Yabuuchi[1], S. Ueno[2], K. Uchiyama[2], T. Okimura[2], T. Kobayashi[3], K. Keiichi[3]

[1]Kato ladies clinic, R&D division, Tokyo, Japan
[2]Kato ladies clinic, Embryology Laboratory, Tokyo, Japan
[3]Kato ladies clinic, Department of Gynecology, Tokyo, Japan

Study question: Does the duration of blastomere movement post first cytokinesis correlate with clinical pregnancy after fresh cleavage stage embryo transfer in human?

Summary answer: The clinical pregnancy rate after fresh cleaved embryo transfer was significantly lower when the duration of blastomere movement was persisted.

What is known already: Time-lapse incubator systems allow the evaluation of embryos based on their morphokinetic and morphological assessment. Many studies have shown that timings of human embryo divisions correlate with preimplantation development and subsequent pregnancy outcomes after embryo transfer. During monitoring of embryos in time-lapse system, we observed that blastomere movement occurred after first cytokinesis and that there is a variability among embryos in the duration of the blastomere movement. However, the embryo evaluation based on morphological information obtained from time-lapse imaging is still limited. In addition, it is not known how blastomere movement influences embryonic development and pregnancy outcomes.

Study design, size, duration: A total of 781 embryos from 779 patients, 36.4 ± 0.1 year-old, were cultured in EmbryoScope+® time-lapse system and then transferred into patients at cleavage stage from April to July 2017. The data of morphokinetics and morphology were retrospectively analyzed. Blastomere movement (BMov) was observed after first cytokinesis and the time to end the blastomere movement (tBMovE) was annotated. The correlation between the duration of blastomere movement and clinical pregnancy after fresh cleaved embryo transfer was examined.

Participants/materials, setting, methods: Oocytes were retrieved and inseminated either by conventional in vitro fertilization or intracytoplasmic sperm injection. Fertilized oocytes were cultured in EmbryoScope® and the time from insemination to pronuclear (PN) fading (tPNf), 4-cell stage (t4) and tBMovE was annotated. The duration from first cytokinesis to tBMovE was calculated (dBMovE). The embryo quality was evaluated by Veeck's criteria on Day 2.

Main results and the role of chance: The average dBMovE was 6.56 ± 0.36 h [95% confidential interval (CI): 5.86 – 7.26]. dBMovE was significantly correlated with the developmental rate to 4-cell stage on Day 2 (Odds ratio (OR): 0.937 [95% CI: 0.911–0.965], p < 0.01). dBMovE was also associated with the duration between tPNf and t4 (P < 0.01). Furthermore, dBMovE was statically correlated to the morphological grade evaluated by Veeck's criteria (Grade 1: 2.90 ± 0.79; 2: 5.69 ± 0.69; 3: 8.11 ± 0.47; 4: 18.08 ± 3.98, p < 0.01). Logistic regression analysis demonstrated that clinical pregnancy was correlated with dBMovE (OR: 0.966 [95% CI: 0.943-0.986], P < 0.01). Embryos were stratified into 4 groups according to dBMovE (group A: dBMovE < 1.98, B: 1.98 ≤ dBMovE < 3.64, C: 3.64 ≤ dBMovE < 4.59, D: 4.59 ≤ dBMovE). The clinical pregnancy rates after fresh cleaved embryo transfer were 41.0% (50/122), 34.7% (96/277), 27.9% (41/147) and 15.7% (37/235), respectively. There was a significant trend that the clinical pregnancy rates declined with increasing dBMovE (Cochran-Armitage trend test, P < 0.01).

Limitations, reasons for caution: This study is limited by the small sample size, therefore, large scale studies are required. Furthermore, the effect of blastomere movement on the potential of embryos to develop to the blastocyst stage and subsequent pregnancy outcomes after blastocyst transfer should be investigated.

Wider implications of the findings: This is the first report demonstrating the correlation between blastomere movement and pregnancy outcomes. Embryos with extended blastomere movement after the first cytokinesis have a lower competence to initiate a clinical pregnancy after fresh cleaved embryo transfer. Thus blastomere movement could be an effective predictive parameter for selecting embryos.

Trial registration number: None.

O-114 Time Lapse assessment of the occurrence and clinical outcome of direct cleavage in a population of 10,529 embryos cultured to the blastocyst stage

S. Montgomery[1], C. Nelson[2], N. Davis[3], A. Campbell[1], B. Peterson[4], C. Harlow[2], C. Howles[2]

[1]CARE Manchester, Embryology, Manchester, United Kingdom
[2]University of Edinburgh, Deanery of Clinical Sciences- College of Medicine & Veterinary Science, Edinburgh, United Kingdom
[3]CARE Fertility Northampton, Embryology, Northampton, United Kingdom
[4]BMP Analytics, Biostatistics, Viby, Denmark

Study question: Is the occurrence of direct cleavage (DC) in early stage cleavage embryos associated with a decreased chance of clinical pregnancy?

Summary answer: DC in early cleavage stage embryos is associated with a highly significant decreased chance of clinical pregnancy, particularly at the 2 cell stage.

What is known already: DC has been reported to occur at the 2 cell stage in around 14% of embryos. DC is a generic term for early irregular cell divisions which encompasses both an immediate mulitchotomous mitosis (MM) (a cell cleaves into more than 2 daughter cells), and the relatively rapid division of a cell within a short cell cycle (SCC) (</ = 5 hours). For example, with MM, a cell would divide directly from 1 to 3-cells or more, rather than to 2cells; or spend <5 hours before the next mitotic division (SCC). DC can be identified during cleavage stage embryo development.

Study design, size, duration: Anonymised time lapse data was retrospectively reviewed from two sister clinics between August 2014 and January 2017. 10,529 embryos from 1651 consecutive patients using autologous oocytes, were included. Embryos exhibiting a DC (at the 2, 4 or 8 cell cleavage stages) were analysed for ability to reach blastocyst, and their KID (known implantation data) rate was assessed according to maternal age, insemination method (IVF or ICSI), and stage of embryo transfer (cleavage or blastocyst stage).

Participants/materials, setting, methods: Female age ranged from 19 to 46 years. Embryo development parameters were annotated according to strictly defined guidelines using the EmbryoScope® incubator and software (Vitrolife). The population of embryos not displaying DC at 2, 4 and 8-cell cleavage stages provided the control (non-DC). All data was analysed using Chi-square test, Fisher's Exact test and Kruskal-Wallis test with post-hoc testing – Dunn's multiple comparison test to determine statistical significance.

Main results and the role of chance: Overall, embryos exhibiting DC during cleavage stages had a lower incidence of reaching a blastocyst (56%), compared with non-DC embryos which underwent regular divisions (77%). Embryos displaying DC at the 8-cell stage (DC8) had a higher rate (68%) of reaching blastocyst than DC4 (52%) and DC2 (43%) embryos. Overall KID rate of DC embryos (19.4%) was significantly lower than non-DC embryos (38.4%) (p < 0.0001). DC at the 2-cell stage had the most severe impact with the lowest KID rate (7.8%) compared with 15.9% at DC-4 cell and 35.5% at DC-8.

Women of ≥40 years experienced higher incidences of embryos having DC, with the lowest KID rate (2.8%). No statistical difference was found between IVF (n = 431) and ICSI (n = 1303) KID rates, in both non-DC and DC cases. KID rate was significantly lower ($p < 0.0001$) in DC embryos (7.7%), compared with non-DC (24.6%), for day 2 to 4 transfers. For DC8 embryos, KID rate was 36% vs 50% in non-DC8 embryos (not significant) when transferred at the blastocyst stage.

Limitations, reasons for caution: Live birth information was not fully available for all treatment cycles. The study did not consider all patient factors, which may influence cleavage patterns and embryo viability. The study did not distinguish fully between multichotomous mitosis and short cell cycle.

Wider implications of the findings: DC at 2 cell stage is common and had the most severe impact on embryo viability. The adverse effects of DC highlight the need to select against the transfer of such embryos. Future studies may involve tests for centriole function in contribution to this event, and embryo ploidy assessment.

Trial registration number: Not applicable.

O-115 Is there a relation between embryo early cleavage abnormalities and blastulation or implantation rates? A retrospective time-lapse imaging study

R. Naam Ouarezki[1], X. Ferraretto[1], M. Vigan[2], J. Lousqui[1], M.A. Llabador de Royer[1], M. Peigné[3], S. Tubiana[2], S. Epelboin[3], C. Patrat[1]

[1]*Service de Biologie de la Reproduction, Hôpital Bichat- APHP, Paris, France*
[2]*Département d'Epidémiologie- Biostatistique et Recherche clinique, Hôpital Bichat- APHP, Paris, France*
[3]*Service de Médecine de la Reproduction, Hôpital Bichat- APHP, Paris, France*

Study question: What is the prevalence of atypical dynamic embryo phenotypes identified by time-lapse system and are they associated with poor embryo development and implantation rates?

Summary answer: As abnormal early cleavages are associated with low blastulation and implantation rates, time-lapse and morphokinetic parameters may offer a non-invasive mean for improving embryo selection.

What is known already: Several publications propose morphokinetics as an additional parameter to assist in embryo selection. Most of them demonstrate that embryos exhibiting atypical dynamic phenotypes are highly prevalent in human embryos, and abnormal early cleavages, including Direct cleavage (DC), Rapid cleavage (RaC) or Reverse cleavage (ReC), significantly compromise embryo development. Blastocyst formation rates for these embryos are significantly lower compared with control groups, culminating in poor implantation potential (Rubio and al., 2012; Liu and al., 2014; Wirka and al., 2014; Fan and al., 2016). However, these observations rely on small samples or are not fully explored, especially for ReC.

Study design, size, duration: This research project is a single-center, retrospective cohort study conducted by the Reproductive Department at Bichat hospital (APHP, Paris). We collected the data on all *in vitro fertilization* treatments cycles for which the embryos were observed in the Embryoscope® time-lapse system (Vitrolife Paris, France) from December 2015 to July 2017. The study included 330 consecutive treatment cycles for 256 couples and a total of 1495 embryos. Embryo videos were retrospectively analyzed for dynamic phenotypes.

Participants/materials, setting, methods: Only diploid zygotes were included. Embryo development was evaluated on day 2 (based on cells number, symmetry and percentage of fragmentation) and on day 5-6 (blastocyst formation (Gardner et al., 2000). The data included implantation, issue and clinical factors whether it is factors intrinsic to patients or factors specific to IVF treatment such as: couples' parameters (age, BMI), origin of infertility, type of ovarian stimulation regimen used and insemination method (IVF/ICSI).

Main results and the role of chance: A high prevalence of abnormal early cleavage was observed among embryos: DC 23.5% (349/1486), RaC 25.9% (388/1495) and ReC 7.4% (109/1480). A significant lower percentage of embryos with early atypical dynamic phenotype(s) 5.3% (30/566) had good quality on day 2 (4 or 5 cells, typical character and <30% of fragmentation) as compared to embryos without early cleavage anomalies (42.2% (395/936, $p < 0.001$)). The same observation hold true on good quality on day 5 (≥B3 and ≥BB) (13.8% (65/470) vs 40.6% (197/485) with or without early cleavage defects, respectively <0.001). This significant difference was also observed at day 2 according to the type of anomalies: DC 6.3% (22/349) vs 35.4% (403/1138), RaC 2.6% (10/388) vs 38.3% (415/1083), ReC 9.2% (10/109) vs 30.3% (415/1371), and on day 5: DC 8.2% (24/292) vs 37.1% (240/647), RaC 14.3% (48/336) vs 37.1% (220/593), ReC 9.3% (9/97) vs 30.3% (253/834). Of the 521 embryos that were transferred on day 2 or 5, 104 (19.9%) were identified as abnormal cleavage. Only 14 over 104 affected embryos were known to implant (13.5%) when the implantation rate for embryos with a normal cleavage pattern was 20.1% (84/417) and $p = 0.116$.

Limitations, reasons for caution: The present study is limited by a small sample size of embryos known implantation. Furthermore, we do not know the exact cause of these anomalies. At last, we can question their high prevalence and their impact on the chances of implantation so that many of these embryos can be eliminated?

Wider implications of the findings: The identification of atypical dynamic embryo phenotypes could further refine the process of embryo selection by enabling the deselection of embryos affected, in order to select and transfer the embryo that offers the best chance of pregnancy.

Trial registration number: not applicable.

O-116 Partial embryo compaction: what's behind? Morphokinetic origins and chromosomal status

C. Lagalla[1], R. Sciajno[1], N. Tarozzi[1], F. Pennetta[1], G. Coticchio[1], A. Borini[2]

[1]*9.Baby Family and Fertility Center, IVF Laboratory Unit, Bologna, Italy*
[2]*9.Baby Family and fertility Center, Reproductive Medicine IVF, Bologna, Italy*

Study question: In preimplantation development, how much is partial compaction widespread, does it occur through different morphokinetics mechanisms and is it associated with embryo aneuploidy?

Summary answer: Partial compaction is frequent, is generated by two mechanisms, blastomere exclusion and extrusion, and is associated with embryo characteristics such as maternal age and aneuploidy.

What is known already: Compaction is a well-known developmental stage of the preimplantation embryo, during which blastomeres change dramatically cell shape and establish mutual and extensive cell-to-cell contacts. Overlapping temporally with the specification of the first two embryonic cell lineages and creating a selective barrier between intra- and extra-embryonic environment, compaction is believed to be crucial for further development. Regardless, this stage remains rather obscure and usually is not taken into consideration to assess embryo quality. The Alpha/ESHRE Istanbul consensus on embryo assessment barely mentions that compaction can occur completely or partially, but implications of these two conditions are rather uncertain.

Study design, size, duration: This is a retrospective cohort study using data from 136 PGT-A cycles carried out between May 2013 and July 2017 and whose embryos were cultured in a time-lapse system. Embryos were annotated for morphokinetic characteristics of compaction and analysed at the blastocyst stage for chromosomal constitution. Treatment cycles were divided and analysed comparatively in two age groups, i.e. ≤34 and 35-39 years.

Participants/materials, setting, methods: Three morphokinetic categories of compaction were pre-defined and annotated: i) full compaction, in cases where at the expected time interval all blastomeres appeared with indistinct boundaries and tightly connected; partial compaction in which blastomeres that failed to compact were either ii) excluded from the outset or iii) extruded following an initial involvement in the compaction process. Chromosome analysis was carried out by Array-CGH to determine embryo ploidy status, while statistical analysis with chi-square test.

Main results and the role of chance: Overall, 322 blastocysts were assessed morphokinetically and chromosomally. The total rate of partial compaction was 60.1%. The difference in the rates of partially compacted embryos with excluded or extruded blastomeres was different in the younger age group (68.3% and 31.7%, respectively; $P = 0.00004$), while it was almost identical (50.4% and 49.6%, respectively) in the older age group. Blastomere exclusion was statistically more prevalent in embryos of younger women (68.3% vs.

50.4%, P = 0.02), whereas blastomeres were more frequently extruded in embryos of women aged ≥35 years (31.7% vs. 49.6%, P = 0.02). The overall rate of aneuploidy in blastocysts developed from totally or partially compacted embryos was predictably different in the younger and older age groups (37.8% and 49.7%, respectively; P = 0,037). In both age groups, no differences were observed in the rate of aneuploidy in embryos with excluded or extruded blastomeres. However, even if not statistically significant, partially compacted embryos tend to be less aneuploids compared to totally compacted embryos in younger age group (33,3% vs. 42,9%), whereas this trend was not observed in embryos of older women.

Limitations, reasons for caution: This study is retrospective and based on a data set of limited size. Results should be extended with larger and prospective observations.

Wider implications of the findings: This study sheds novel light on a neglected phase of human preimplantation development. In particular, it indicates that different morphokinetic mechanisms can underlie abnormal compaction. Also, it suggests possible mechanisms of self-correction of aneuploidy that may be compromised in embryos of older women displaying partial compaction.

Trial registration number: Not applicable.

O-117 Time-lapse and NGS evaluation of human embryos cultured in single medium versus sequential media: a prospective randomized pilot study

Z. Yang[1], Y. Kuang[2], X. Zhang[3], Y. Meng[3], L. Tang[4], Q. Lyu[2], L. Su[5], S. Zhang[6], J. Lin[1]

[4]First Affiliating Hospital- Kunming Medical University, Art, Kunming, China
[5]Yunnan Family Planning Institute, Art, Kunming, China
[6]Sir Run Run Shaw Hospital- Zhe Jiang University School of Medicine, Art, Hangzhou, China

Study question: Are there differences in morphokinetics, ploidy and implantation potential of human embryos cultured in single medium versus sequential media?

Summary answer: There were no significant differences in key morphokinetic parameters, percentage of euploid blastocysts and overall clinical outcomes between single medium and sequential media.

What is known already: Clinical studies with time-lapse culture concluded that the most predictive morphokinetic parameters (e.g. t5, cc2 and s2) were highly correlated with implantation potential. Various time-lapse studies were performed to compare morphokinetics of embryos cultured in single medium verses sequential media with controversial results. Nevertheless, ploidy of the cultured embryos was not determined in previous studies. There is very limited information about effects of different culture media on ploidy of human embryos as related to implantation potential. Thus, the objective of this study was to evaluate the morphokinetics, ploidy and clinical outcomes of embryos cultured in single medium versus sequential medium.

Study design, size, duration: With an IRB approval, IVF patients (n = 93) at mean age 32.1 ± 3.4 years seeking single embryo transfer (SET) were enrolled in this prospective randomized pilot study in our IVF clinics from June 2016 to June 2017. Sibling MII oocytes (n = 1205) were randomized into two groups after ICSI: 1) Group A: Embryos (n = 603) were cultured in a single-step culture medium (SSC) and 2) Group B: Embryos (n = 602) were cultured in sequential media (G_1/G_2, Vitrolife).

Participants/materials, setting, methods: For both groups, embryos were cultured to blastocyst stage in a time-lapse system (EmbryoScope, VitroLife). Trophectoderm biopsy was performed on day 5 and the blastocysts were vitrified after biopsy. Whole genomic amplification (WGA) and NGS analysis were performed according to manufacturer's instructions (Yikon Genomics, China; Illumina, USA). Single euploid blastocysts with the most predictive morphokenetic parameters available were transferred to individual patients in FET cycles.The statistical analyses were performed using GraphPad InStat (GraphPad Software, USA).

Main results and the role of chance: Time-lapse evaluation showed that there were no significant differences in key morphokinetic parameters between the single medium and sequential media ($p > 0.05$). The time from insemination to initiation of blastulation (tlB) was slightly faster in Group A compared to Group B (96.3 ± 6.5 hpi vs. 97.1 ± 6.7 hpi, respectively, $p > 0.05$). There was no significant difference in fertilization rate between Group A and Group B (84.9% vs. 85.8%, respectively, $p > 0.05$). There was no significant difference in blastocyst rate between Group A and Group B (48.4% vs. 43.1%, respectively, $p > 0.05$). The percentage of biopsied blastocysts in Group A was similar to that of Group B (93.5% vs. 94.6%, respectively, $p > 0.05$). NGS analysis revealed that there were no significant differences in euploid blastocyst rates (d5) between Group A and Group B (43.5% vs. 42.2% respectively, $p > 0.05$). There was no significant difference in clinical pregnancy rate between Group A and Group B (71.1% vs. 70.7% respectively, $p > 0.05$). The observed ongoing pregnancy rate was comparable between Group A and Group B (68.9% vs. 65.8%, respectively, $p > 0.05$). There was no significant difference in miscarriage rate between Group A and Group B (2.2% vs. 4.9%, respectively, $p > 0.05$).

Limitations, reasons for caution: Data are based on observations with embryos from young patients with a good prognosis and may not fully generalize to all patients, especially those at advanced maternal age and with diminished ovarian reserve. Further randomized clinical trials with a larger number of patients are planed to verify these initial findings.

Wider implications of the findings: Our data demonstrate that the single culture medium supports human embryo development from zygote to blastocyst stage and yields similar clinical and ongoing pregnancy rates compared to sequential media. By minimizing exposure of embryos to the ambient atmosphere, non-disrupted culture with the single medium offers additional advantages over sequential media.

Trial registration number: Not applicable.

SESSION 33: INTRAUTERINE INSEMINATION AND FLUSHING

Tuesday 3 July 2018 Room 211 + 212 10:00–11:30

O-118 The effect of intra-uterine slow-release insemination (SRI) on the pregnancy rate in women designated for standard intra-uterine insemination (IUI) – A multicentre randomized, controlled trial

M. Franz[1], C. Egarter[2], J. Campell[3], E. Vyiska-Binsdorfer[2], J. Ott[2], J. Marschalek[2]

[1]Gyn-Bogenhausen.de, Reproductive Medicine, Munich, Germany
[2]Medical University of Vienna, Dept. for Gynecology and Obstetrics, Vienna, Austria
[3]University of Northampton, Faculty of Health and Society-, Northampton, United Kingdom

Study question: To investigate the effect of intra-uterine slow-release insemination (SRI) on pregnancy rates in women with confirmed sub-/infertility who are eligible for standard intra-uterine insemination (IUI).

Summary answer: In women under 35 years of age the pregnancy rate is improved by SRI compared to standard bolus IUI.

What is known already: Only a few studies have dealt with the actual IUI technique, or have questioned the application method. A modified IUI application technique is slow release insemination (SRI), which was first described in 1992 (Muharib et al, 1992). The authors hypothesized that a persistent low concentration of spermatozoa might prolong the period of potential fertilization and thereby mimic physiological sperm transportation into the fallopian tube. The present authors have recently published data from two pilot randomized, controlled cross-over studies that indicate a statistically significant advantage of SRI over conventional bolus IUI.

Study design, size, duration: Multicentre, randomized, controlled cross-over trial: 82 women were randomized into two treatment arms between 2012

and 2017. A computerised randomisation programme was used to assign women to standard IUI tor SRI. Women who failed to conceive in this first treatment were offered the alternative method in the second course. Sample size was calculated using a minimum clinically significant effect defined as a relative risk of 2.0 in favour of SRI.

Participants/materials, setting, methods: Inclusion criteria: primary or secondary infertility after six months of unprotected sexual intercourse; age 20–40 years; tubal patency; infertility due to anovulation and/or endometriosis and/or male partner with a minimum of >10 million of motile sperm cells per sample and/or unexplained infertility. Women underwent either the standard bolus IUI treatment or the SRI method. For SRI an EVIE device was used for a four-hour continuous slow release injection of spermatozoa into the uterus.

Main results and the role of chance: The overall observed pregnancy rate for SRI was 13.2%, compared to 10.0% for IUI (relative risk [RR] = 1.32); however, this difference was not statistically significant (95% CI 0.69–2.53; p = 0.202). For all women aged under 35 years undergoing SRI, the observed RR for pregnancy was 2.33, with 17% of the SRI procedures resulting in pregnancy compared to just over 7% of the IUI procedures. This difference was statistically significant (p = 0.032). There were no significant differences with respect to female and male characteristics for patients aged under 35 years in the IUI and SRI subgroups. Pregnancy rates were not different with clomiphene citrate, rFSH or progesterone in either group, neither in the whole population nor in the group of patients aged under 35 years. The pregnancy rate in patients aged under 35 years using clomiphene citrate and SRI was, however, exceptionally high (24.1%). There were no significant differences in the use of medications in women who successfully became pregnant after SRI or IUI.

Limitations, reasons for caution: We are aware that the crossover design might be seen as a limitation of this study. Some authors reject the utilization of this study design in infertility trials; however, others claim this an efficient and pragmatic design, particularly as only one cycle of each treatment is given to each woman.

Wider implications of the findings: These data lend support to the hypothesis that the pregnancy rate might be improved by using SRI rather than IUI, especially in women aged under 35 years. Additional, larger, clinical trials are required to fully prove this hypothesis, especially if an economic benefit of SRI is also to be demonstrated.

Trial registration number: Current Controlled Trials Register (registration number NCT02315040).

O-119 What is in unexplained subfertility the impact of gonadotropins or clomiphene citrate on endometrial thickness: a secondary analysis of a trial on intrauterine insemination

M.H. Mochtar[1], N. Danhof[1], R. Van Eekelen[1], B. Mol[2], F. Van der Veen[1], M. Van Wely[1]

[1]*Academical Medical Center Amsterdam, Center for Reproductive Medicine, Amsterdam, The Netherlands*
[2]*Monash Medical Centre, Obstetrics and Gynaecology, Clayton, Australia*

Study question: What is in unexplained subfertility the impact of follicle stimulating hormone (FSH) or clomiphene citrate (CC) in intrauterine insemination (IUI) on endometrial thickness (EMT), and is EMT related to pregnancy?

Summary answer: The mean EMT was significant thicker in women treated with FSH compared to treated with CC. EMT is not independently associated with ongoing pregnancy rate.

What is known already: CC is associated with thinner EMT compared to FSH in ovarian stimulation IUI. Whether a thin EMT has an effect on ongoing pregnancy is unknown. We recently performed a RCT comparing ovarian stimulation with follicle stimulating hormone (FSH) to CC in couples with unexplained subfertility undergoing IUI that showed no significant difference in ongoing pregnancy rates and live birth rates.

Study design, size, duration: This is a pre-planned secondary analysis on the effect of EMT in terms of pregnancy outcome of a multicentre randomised controlled superiority trial; the SUPER study, in which we investigated 738 couples diagnosed with unexplained or mild male subfertility from 24 clinics positioned in the Dutch Consortium for Healthcare Evaluation in Obstetrics and Gynaecology, undergoing ovarian stimulation with FSH or CC in IUI.

Participants/materials, setting, methods: 738 women received 1944 cycles. We used EMT per cycle. We measured changes over consecutive cycles per woman. We determined difference in EMT between women randomised to FSH and CC over all cycles using an independent samples t-test. We subsequently investigated the association between EMT and ongoing pregnancy using logistic regression, with precision measures adjusted for women receiving multiple cycles. Ongoing pregnancy was defined as a positive heartbeat at or beyond 12 weeks of gestation.

Main results and the role of chance: The 1944 IUI cycles resulted in 226 (11.6%) ongoing pregnancies. The mean EMT was 8.9 mm (±2.1) in women treated with FSH and 7.5 mm (±2.2) in women treated with CC (mean difference: 1.4 mm, p < 0.001, 95%CI 1.2-1.6). EMT was not significantly associated with ongoing pregnancy rate (odds ratio: 1.02 per 1 mm thicker, p = 0.59, 95% CI 0.96-1.08). Also after correcting for allocated stimulating agent, or after looking at nonlinear associations between EMT and pregnancy outcome, we found a similar result.

Limitations, reasons for caution: Secondary analyses, commonly used to investigate whether the conclusions are relevant for a particular sub population, are prone to false positive findings. Since this analysis was pre-planned, the risk of reporting bias is low.

Wider implications of the findings: We confirmed that CC result in thinner endometrium compared to FSH. Nonetheless, we found no association between EMT and chances in ongoing pregnancy rate. So EMT should not be used in the decision to continue CC or to switch to FSH in women undergoing IUI with ovarian stimulation.

Trial registration number: SUPER study is registered at NTR 4057

Acknowledgement: SUPER study group.

O-120 A cost-effectiveness analysis of ovarian stimulation with follicle stimulating hormone (FSH) compared with clomiphene citrate (CC) in intra uterine insemination (IUI)

N. Danhof, M. Van Wely, F. Van der Veen, M. Mochtar

AMC, Center for Reproductive Medicine, Amsterdam, The Netherlands

Study question: Is FSH or CC the most cost-effective stimulation regimen in couples with unexplained or mild male subfertility undergoing IUI with adherence to strict cancellation criteria?

Summary answer: The additional costs to achieve one additional ongoing pregnancy with FSH compared with CC were €10556,87. CC is the most cost-effective stimulation regimen in IUI.

What is known already: IUI with ovarian stimulation is the first line treatment in couples with unexplained or mild male subfertility. Almost 176000 IUI cycles are performed in Europe each year. A Cochrane review advises to use FSH for ovarian stimulation in IUI, but we have recently completed a multicentre RCT, in which we found that ovarian stimulation with FSH is not superior to CC in terms of ongoing pregnancies and live births. In using strict cancelation criteria, we found a comparable but low multiple pregnancy rate for FSH and CC.

Study design, size, duration: A cost-effectiveness analysis from a healthcare perspective alongside the multicentre randomised controlled superiority trial; the SUPER study. We investigated 738 couples diagnosed with unexplained or mild male subfertility from 24 clinics positioned in the Dutch Consortium for Healthcare Evaluation in Obstetrics and Gynaecology, undergoing ovarian stimulation with FSH or CC in IUI with adherence to strict cancellation criteria.

Participants/materials, setting, methods: We estimated costs from public sources and published literature. We assessed incremental cost-effectiveness ratios (ICERs) for 75 IE FSH and for 100 mg CC for costs per ongoing pregnancy.

Main results and the role of chance: The mean costs per couple were € 1 472,40 for FSH and € 1 014,65 for CC. The effectiveness of FSH was 4% higher compared with CC. The additional costs to achieve one additional ongoing pregnancy with FSH compared with CC were € 10 556,87. For a willingness-to-pay of € 15 000 for an additional ongoing pregnancy, there is 67% chance that FSH is cost-effective compared with CC. For a willingness-to-pay of € 45 000

for an ongoing pregnancy, there is a 91% chance that FSH is cost-effective compared with CC.

Limitations, reasons for caution: We performed the analysis from a healthcare perspective. We focussed on direct medical costs, but we find it unlikely that including indirect costs of the ovarian stimulation in IUI and indirect costs from a social perspective would change our conclusion, since the impact of these costs is small.

Wider implications of the findings: We could save more than €27 million in Europe on a yearly basis using CC instead of FSH in couples with unexplained or mild male subfertility undergoing IUI with adherence to strict cancellation criteria. Whether FSH should be used depends on society's willingness to pay for an additional ongoing pregnancy.

Trial registration number: Inapplicable.

Acknowledgement: thanks to the SUPER study group.

O-121 Is intrauterine insemination with ovarian stimulation associated with higher chances of ongoing pregnancy compared to expectant management in couples with unexplained subfertility?

Study question: Does starting IUI-OS within 1.5 years after completion of the fertility workup increase ongoing pregnancy rates compared to expectant management in couples with unexplained subfertility?

Summary answer: IUI-OS is associated with higher chances of ongoing pregnancy compared to expectant management in unexplained subfertile couples, especially those with poorer prognoses of natural conception.

What is known already: IUI-OS is often the first-line treatment for couples with unexplained subfertility. Two randomised controlled trials compared IUI-OS to expectant management but found conflicting results. In the absence of a consensus from these trials, a cohort of couples with unexplained subfertility exposed to expectant management and IUI-OS offers an opportunity to determine the chances of conception under both conditions. In addition, a large cohort allows evaluating whether the effect of IUI-OS depends on a couple's prognosis of natural conception, which might explain the discrepancy between trial results.

Study design, size, duration: A prospective cohort study on couples with unexplained or mild male subfertility who could start IUI-OS at any point after completion of the fertility workup in 7 Dutch centres between January 2002 and February 2004. Couples with bilateral tubal occlusion, anovulation, or a total motile sperm count $<1 \times 10^6$ were excluded. Follow up was censored at the start of IVF or at last contact and truncated at a maximum of 1.5 years after the fertility workup.

Participants/materials, setting, methods: The endpoint was time to ongoing pregnancy. We used the sequential Cox approach comparing in each month ongoing pregnancy rates over the next 6 months of couples who started IUI-OS to couples who did not. We calculated the prognosis of natural conception for individual couples and updated this over consecutive failed cycles, then evaluated whether prognosis modified the effect of starting IUI-OS. We corrected for known predictors of conception using inverse probability weighting.

Main results and the role of chance: Data from 1896 couples were available. 800 couples had at least one IUI-OS cycle within 1.5 years post fertility workup of whom 142 couples conceived (rate: 0.50 per couple per year, median follow up 4 months). The median period between fertility workup completion and starting IUI-OS was 6.5 months. Of 1096 couples who remained untreated, 386 conceived naturally (rate: 0.31 per couple per year, median follow up 7 months).

Starting IUI-OS was associated with a higher chance of ongoing pregnancy by a pooled, overall hazard ratio of 1.96 (95%CI: 1.47-2.62) compared to expectant management. The effect of treatment was modified by a couple's prognosis of achieving natural conception ($p = 0.01$), with poorer prognoses or additional failed natural cycles being associated with higher relative chances after starting treatment. The predicted 6-month ongoing pregnancy rate for a couple with a prognosis of 25% over the next 6 cycles (approximately 40% over one year) was 25% (95%CI: 21-28%) for expectant management and 24% (95%CI: 15-31%) when starting IUI-OS right after the fertility workup. For a couple with the cohort-average prognosis of 12% (20% over one year), these predicted rates were 12% (95%CI: 10-14%) for expectant management and 24% (95%CI: 17-30%) for starting IUI-OS.

Limitations, reasons for caution: The effect estimates are based on a prospective cohort. Although we balanced known predictors of pregnancy between treated and untreated couples using inverse probability weighting, observational data may still be subject to residual confounding. The results need to be confirmed by large randomised controlled trials.

Wider implications of the findings: Starting IUI-OS is effective in couples with unexplained subfertility who have a poor prognosis for natural conception and should therefore remain their first-line treatment. Our results may explain the discrepancies between trials that compared IUI-OS to expectant management, but further studies are required to confirm these findings.

Trial registration number: Not applicable.

O-122 Tubal flushing with oil- or water-based contrast medium at hysterosalpingography for infertility: 3-year outcome of a randomized clinical trial

J. Van Rijswijk[1], N. Van Welie[1], K. Dreyer[1], H. Verhoeve[2], A. Hoek[3], J.P. De Bruin[4], A. Nap[5], M. Van Hooff[6], M. Goddijn[7], A. Hooker[8], N. Lambalk[1], P. Hompes[1], H. Zafarmand[7], V. Mijatovic[1], B.W. Mol[9]

[8]Zaans Medical Centre, Department of Obstetrics and Gynaecology, Zaandam, The Netherlands
[9]Monash Medical Centre- Monash Health and Monash University, Department of Obstetrics and Gynaecology, Melbourne, Australia

Study question: What is the impact of the use of oil- or water-based contrast medium at hysterosalpingography (HSG) on fertility outcomes 3 years after randomization?

Summary answer: Women who had their tubes flushed with oil-based contrast had 3-year cumulative ongoing pregnancy rates of 83.2% versus 80.7% after the use of water-based contrast.

What is known already: For decades it has been suggested that tubal flushing with oil-based contrast (Lipiodol) at HSG improved pregnancy

rates (Mohiyiddeen L, et al. 2015). We recently showed in a landmark trial published in the New England Journal of Medicine that in infertile women tubal flushing during HSG with oil-based contrast resulted in more ongoing pregnancies than HSG with the use of water-based contrast at 6 months after randomization(39.7% versus 29.1% (RR 1.37, 95%CI 1.16-1.61, p < 0.001)) (Dreyer et al. 2017). It is unclear whether this difference continues beyond 6 months.

Study design, size, duration: This was a follow-up study of the H2Oil trial, a multi-center randomized controlled trial in the Netherlands in which 1,119 women were included and randomized to hysterosalpingography with oil-based contrast (n = 557) or water-based contrast (n = 562). Here, we present the fertility outcomes at three years after randomization.

Participants/materials, setting, methods: All 1,119 participants were contacted 3-5 years after randomization, and were asked to fill in questionnaires about the fertility treatments and pregnancies. Additionally, we reviewed the medical files to record all pregnancies and fertility treatments. Primary outcome was the first ongoing pregnancy within 36 months after randomization. We also compared naturally conceived pregnancies, pregnancies conceived after IUI and IVF and time to ongoing pregnancy.

Main results and the role of chance: In total, 383 ongoing pregnancies were accomplished in the oil-based contrast group versus 344 ongoing pregnancies in the water-based contrast group. The cumulative ongoing pregnancy rate 3 years after randomization was 83.2% (95%CI:79.3-87.1%) in the oil-based contrast group versus 80.7% (95%CI:76.4-85.0%) in the water-based contrast group. The Kaplan-Meier survival curves for time to ongoing pregnancy were significantly different in favor of the oil-based contrast group (median time to ongoing pregnancy 10.00 versus 14.83 months, p-value log-rank test 0.001).

Of the 383 ongoing pregnancies in the oil-based contrast group, 207 (54.3%) were naturally conceived, 114 (29.8%) after IUI and 60 (15.7%) after IVF/ICSI. Of the 344 ongoing pregnancies in the water-based contrast group, 174 (51.2 %) were naturally conceived, 93 (27.0%) after IUI and 73 (21.2%) after IVF/ICSI. Conception of 2 versus 4 pregnancies was unknown.

When follow-up is censored for starting IVF/ICSI treatment, the cumulative ongoing pregnancy rate was 74.2% (95%CI:68.1-80.3%) in the oil-based contrast group versus 70.1% (95%CI:63.0-77.2%) in the water-based contrast group, with the time to ongoing pregnancy significantly shorter in favor of the oil-based contrast group (median time to ongoing pregnancy 10.16 versus 17.07 months, p-value log-rank test <0.001).

Limitations, reasons for caution: This study was limited to women at low risk for tubal pathology, <39 years and without known endocrinological diseases, the findings should therefore not be generalized. Here, we only report ongoing pregnancies and not live birth.

Wider implications of the findings: Tubal flushing with oil-based contrast does not only result in higher 6-months ongoing pregnancy rates, but also in higher 3-year cumulative ongoing pregnancy rates. Time to ongoing pregnancy was significantly shorter in the oil-based contrast group. In our opinion, tubal flushing with oil-based contrast should be offered to infertile women.

Trial registration number: Dutch Trial Register, NTR 6577.

O-123 Does tubal flushing with oil- versus water-based contrast at hysterosalpingography increase the chance of a second child; long term follow-up of the H2Oil RCT

N. Van Welie[1], J. Van Rijswijk[1], H. Verhoeve[2], H. Annemieke[3], J.P. De Bruin[4], A. Nap[5], M. Van Hooff[6], M. Goddijn[7], A. Hooker[8], N. Lambalk[1], P. Hompes[1], V. Mijatovic[1], H. Zafarmand[7], B.W. Mol[9], K. Dreyer[1]

[7]*Academic Medical Centre Amsterdam, Department of Obstetrics and Gynaecology, Amsterdam, The Netherlands*
[8]*Zaans Medical Centre, Department of Obstetrics and Gynaecology, Zaandam, The Netherlands*
[9]*Monash Medical Centre- Monash Health and Monash University, Department of Obstetrics and Gynaecology, Melbourne, Australia*

Study question: Does tubal flushing with oil- versus water-based contrast at hysterosalpingography (HSG) increase the chance of a second child?

Summary answer: There is no clear effect of a single procedure of tubal flushing with oil- versus water-based contrast on the chance of a second child.

What is known already: For decades it has been suggested that tubal flushing with oil-based contrast(Lipiodol) at HSG improved pregnancy rates (Mohiyiddeen et al. 2015). We recently showed in a landmark trial published in the New England Journal of Medicine that in infertile women undergoing HSG tubal flushing with oil-based contrast resulted in more ongoing pregnancies than with the use of water-based contrast at 6 months after randomisation(39.7% versus 29.1% (RR 1.37, 95%CI 1.16-1.61))(Dreyer et al. 2017). While the effect of oil-flushing on conception of the first child is established, it is unclear whether tubal flushing with oil-based contrast increases the chances of subsequent children.

Study design, size, duration: This was a follow-up study of the H2Oil trial, a multi-center randomized controlled trial in the Netherlands in which 1,119 women were randomized to HSG with oil-based contrast (n = 557) or water-based contrast (n = 562). Participating women were approached 3-5 years after randomization with a questionnaire about their fertility. Additionally, we reviewed the medical files to record all pregnancies and fertility treatments. Here, we present the fertility outcome in terms of a second ongoing pregnancy.

Participants/materials, setting, methods: The outcome of this follow-up study was a second ongoing pregnancy (after the birth of a first child). We also assessed mode of conception and time to pregnancy.

Main results and the role of chance: There were 1,119 women randomized to oil-based contrast(n = 557) or water-based contrast(n = 562). Cumulative ongoing pregnancy rates were 83.2% versus 80.7% after oil and water flushing, respectively. In the oil-based contrast group 142(25.6%) couples had a renewed child wish, versus 129(23.1%) in the water-based contrast group.

In total, 97 women (17.5%) in the oil-based contrast group had a second ongoing pregnancy versus 91(16.3%) women in the water-based contrast group (p-value 0.60).

Of the 97 second ongoing pregnancies in the oil-based contrast group, 67 (69.1%) occurred naturally, 14(14.4%) after IUI and 12(12.4%) after IVF/ICSI. Of the 91 second ongoing pregnancies in the water-based contrast group, 58 (63.7%) were naturally conceived, 9(9.9%) after IUI, and 21(23.1%) after IVF/ICSI. Mode of conception of 4 versus 3 pregnancies was unknown.

The Kaplan-Meier curves for time to ongoing pregnancy showed no statistical difference for the use of oil- or water-based contrast(median time to ongoing pregnancy 50.97 versus 51.37 months respectively, p-value log-rank test 0.693). When time to ongoing pregnancy was censored at the start of IVF/ICSI, the Kaplan-Meier curves for time to ongoing pregnancy showed no statistical difference for the use of oil- or water-based contrast(median time to ongoing pregnancy 46.47 versus 51.37 months respectively, p-value log-rank test 0.717).

Limitations, reasons for caution: This study was limited to women with a low risk of tubal pathology, <39 years and without known endocrinological diseases. Furthermore the time of follow-up is relatively short, despite the large sample size.

Wider implications of the findings: Tubal flushing with oil-based contrast does not increase the chance of a second child. However, in the oil-based

contrast group the need for IVF/ICSI to establish this goal was reduced with almost 50%.

Trial registration number: Dutch Trial Register, NTR 6577

INVITED SESSION

SESSION 34: LAUNCH OF THE INTERNATIONAL EVIDENCE-BASED GUIDELINE FOR THE ASSESSMENT AND MANAGEMENT OF POLYCYSTIC OVARY SYNDROME (PCOS)

Tuesday 3 July 2018 Room 111 + 112 10:00–11:30

O-124 Building an international PCOS guideline: Initiative, process and translation

O-125 International guideline on PCOS: Diagnosis and treatment

Abstract text

PCOS is common and heterogeneous with reproductive, metabolic and psychological features. Diagnosis delays are common internationally, with patient dissatisfaction with care and inadequate provided information and resources. There are gaps in clinician knowledge and inconsistencies in care, underpinned by a lack of quality evidence based guidelines and inadequate translation of evidence into practice. The International Evidence based Guideline for the assessment and treatment of polycystic ovary syndrome (PCOS) addresses health professional and consumer priorities. It integrates the best available evidence with international, multidisciplinary clinical expertise and consumer preferences to provide health professionals, consumers and policy makers with guidance on the assessment and treatment of PCOS. The guideline aims to promote accurate diagnosis, optimal consistent care, prevention of complications and improved patient experience and health outcomes for the one in ten women worldwide with PCOS. Extensive international health professional and patient engagement informed the need, priorities and core outcomes for the guideline. International Society-nominated panels and co-opted experts included women with PCOS, paediatricians, endocrinologists, gynaecologists, primary care physicians, reproductive endocrinologists, psychiatrists, psychologists, dermatologists, dieticians, exercise physiologists, public health experts, researchers, and a project management, evidence synthesis and translation team developed the guideline.

Evidence-based guideline development followed international best practice, involving 60 systematic and narrative reviews and applying the full Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework to reflect quality of evidence, and consider feasibility, acceptability, cost, implementation and ultimately the strength of recommendations. Governance included an international advisory board from six continents, a project board, five guideline development groups with 8-10 members each, advisors and a translation committee. Special Interest groups of world experts were formulated to review and provide feedback on the guidelines. Guideline development groups and special interest groups/ experts were nominated by the partner and collaborator organisations. The Australian Centre for Research Excellence in PCOS, funded by the National Health and Medical Research Council (NHMRC), partnered with the European Society of Human Reproduction and Embryology (ESHRE) and the American Society for Reproductive Medicine (ASRM) to fund and complete the guideline. Four project board and 15 guideline development group face to face meetings occurred across Europe, USA and Australia over 15 months, and enabled training, guideline development and informed translation. Sixty prioritized clinical questions were addressed with 40 systematic and 20 narrative reviews, generating 170 recommendations and practice points. Feedback from our over 40 partner and collaborator special interest groups was sought during consultation to inform the final guideline. The guidelines which cover diagnosis, emotional well-being, lifestyle, medical therapy and infertility treatment will be launched and presented at ESHRE.

O-126 Guideline recommendations: Treatment, emotional wellbeing and pregnancy

[4]Cytocell Ltd, Technopark, Cambridge, United Kingdom

Study question: Is there a specific three-dimensional distribution pattern of chromosomes in the different spermatogenic cells?

Summary answer: Chromosomes are arranged in a specific manner along the different stages of spermatogenesis.

What is known already: In somatic cells, chromosomes occupy specific nuclear regions called chromosome territories (CTs) that are arranged in cell-type specific non-random patterns according to chromosome parameters such as gene density and chromosome size. Moreover, CTs have a functional effect in the regulation of the genome providing additional mechanisms to modulate gene expression. Therefore, it has been suggested that CTs in meiotic cells may be crucial for the proper development of spermatogenesis and early embryo development. Actually, an altered distribution of some CTs has been observed in infertile men. However, the CTs distribution along the spermatogenesis has been poorly explored.

Study design, size, duration: Experiments were performed by using testes from 5 C57BL6/6J mice. The method includes the following steps: i) Optimized cell fixation to preserve the three-dimensionality cell morphology, ii) Fluorescence in situ hybridization of all mouse chromosomes, iii) Three-dimensional image captures of a minimum of 100 nuclei per cell type by confocal microscope, iv) Cell type identification by immunofluorescence, v) Image analysis and data extraction by a numerical computing software, vi) Data analysis by using statistics software's.

Participants/materials, setting, methods: Testicular tissue was disaggregated and cells were spread out on polylysine-coated slides. After cell fixation, three FISH rounds were carried out using the Mice OctoChrome kit. Protein SYCP3 and histone H1T were identified by immunofluorescence to distinguish between spermatogenic cells. Serial optical sections were obtained with a confocal microscope and images were processed by ImageJ. Matlab scripts were used to normalize images and determine chromosome volume and proportion, chromosome radial position and chromosome relative position.

Main results and the role of chance: The application of the developed methodology allowed determining the territoriality of chromosomes in male germ cells. Results showed that there is a specific three-dimensional distribution pattern of chromosomes throughout the different spermatogenic stages. On the one hand, the analysis of the chromosomes radial position revealed that chromosomes are arranged in a specific manner from the center to the periphery of the nucleus. Moreover, it has been observed preference in radial positioning according to some chromosomal parameters such as chromosome size, gene density or the percentage of guanine and cytosine contain. On the other hand, in terms of chromosomes vicinity, results showed that there is a systematic relative position of specific chromosomes pairs, showing preference in proximity or non-proximity.

Limitations, reasons for caution: The methodology applied in this study is complex and time consuming because of requiring three consecutive FISH rounds and one extra round for immunofluorescence.

Wider implications of the findings: Our results will provide the new basis of future studies to find out the relationship between chromosome positioning, genome regulation and male fertility.

Trial registration number: not applicable.

O-128 The altered testicular environment in patients with Klinefelter Syndrome

D. Van Saen[1], V. Vloeberghs[2], I. Gies[3], J. De Schepper[4], H. Tournaye[5], E. Goossens[6]

[1]VUB, Biology of the Testis BITE, Brussel, Belgium

[3]Universitair Ziekenhuis Brussel, Pediatric Endocrinology, Brussel, Belgium
[4]UZ Brussel, Pediatric Endocrinology, Brussel, Belgium
[5]UZ Brussel, Centre for Reproductive Medicine, UZ Brussel, Belgium
[6]Vrije Universiteit Brussel, Biology of the Testis, Brussel, Belgium

Study question: Is testicular fibrosis in Klinefelter syndrome (KS) related to the altered structure of the tubular wall and/or altered vascularization?

Summary answer: An altered expression pattern in adult patients was observed for collagen I and IV. An increase in vessel density was observed in prepubertal KS testis.

What is known already: Patients with KS are infertile due to a massive germ cell loss. By the time of diagnosis, adult KS testes often show extensive fibrosis, hyalinization of the seminiferous tubules and hyperplasia of the interstitium. The architecture of the tubular wall, composed of peritubular myoid cells (PTMCs), extracellular matrix proteins (ECM) and fibroblasts, is altered in men with impaired spermatogenesis and could be related to tubular fibrosis by increased deposits of ECM.

In a mouse model for KS, an altered vascularisation of the KS testes was suggested. Angiogenesis (the formation of new blood vessels) is also related to fibrotic processes.

Study design, size, duration: In this study, we want to characterize the testicular environment in testicular biopsies from adult KS patients and compare it with the testicular environment in testicular tissue from fertile controls and Sertoli Cell Only patients. SCO patients also lack germ cells but do not show the typical fibrotic appearance as seen in testes from KS patients.

Participants/materials, setting, methods: Immunohistochemical analysis of testicular tissue sections from adult control (n = 6), KS (n = 20) and SCO (n = 20) patients was performed using markers for PTMCs (ACTA2), ECM (laminin, fibronectin, collagen I and IV) and blood vessels (VWF). The expression of tubular wall markers was characterized by identifying abnormal staining patterns. The mean blood vessel area and the vessel density was calculated in VWF stained testicular sections from adult (n = 25), pre- (n = 4) and peripubertal (n = 15) KS patients.

Main results and the role of chance: Altered expression for ACTA2 was observed in KS as well as in SCO patients. In SCO patients, the tubular wall often showed two layers of ACTA+ cells interrupted by a negative ring (probably ECM deposits). However, in KS patients, the same pattern was observed but the ring of ACTA2 staining was often interrupted indicating loss of ACTA2 staining. No statistical difference was observed in the expression patterns of fibronectin and laminin between SCO and KS patients. In KS patients, more tubules lacking collagen I expression were observed. An altered expression pattern was also observed for collagen IV. No difference in blood vessel area and vessel density was observed in adult testicular sections from controls, SCO and KS patients and in peripubertal sections from KS patients. However, a higher vessel density was observed in prepubertal KS patients. When vessels were

divided according to their size, more small blood vessels were present in these prepubertal patients.

Limitations, reasons for caution: These data are descriptive. It is not possible to draw causal conclusions from the stainings.

Wider implications of the findings: More research is necessary to identify causes of testicular fibrosis in KS patients. If the mechanism behind this fibrotic process could be identified, this process could be inhibited to increase chances of fertility in KS patients.

Trial registration number: not applicable.

O-129 A heterozygous DNAJB13 mutation induces multiple morphological and structural abnormalities to the sperm flagella (MMSAF) and may be a cause of idiopathic asthenozoospermia

L. Weina[1], Z. Li[2], J. Miaomiao[3], S. Lin[4], L. Guangxiu[4,5], L. Gang[4,6]

[5]*Reproductive & Genetics Hospital CITIC-XIANGYA, Reproductive center, Changsha, China*
[6]*Reproductive & Genetics Hospital CITIC-XIANGYA, Clinical Laboratory, Changsha, China*

Study question: Does a novel heterozygous *DNAJB13* mutation, identified in 9 out of 92 idiopathic asthenozoospermia patients affect multiple male infertility-related genes and cause low sperm activity?

Summary answer: A heterozygous mutation c.106 T>C(p.Ser36Pro) of *DNAJB13*was demonstrated to exhibit defects in sperm motility and affect multiple morphological and structural abnormalities to the sperm flagella (MMSAF).

What is known already: *Dnajb13*, which is upregulated in cryptorchidism mouse models and is highly expressed in the testis, encodes a member of the heat shock protein 40 co-chaperone family (types II). Homozygous mutant mice died before sexual maturation. However, no mutations of *DNAJB13* (NM_153614.2) have been reported in patients with idiopathic asthenozoospermia.

Study design, size, duration: This genetic study used Medical Exome microarrays and Sanger sequencing to discover related-genes mutations, and was followed by a series of studies to investigate mutant protein function. Altogether, 92 idiopathic asthenozoospermia patients and 200 fertile men from the Hunan human sperm bank from 2010-2013 in China were screened for *DNAJB13* mutations.

Participants/materials, setting, methods: Patients and fertile men were recruited from our hospital in China. Genomic DNA samples from the individuals were extracted from peripheral blood. A proband was subjected to Medical Exome microarrays to identify mutations. Mutational analysis in the 92 idiopathic asthenozoospermia patients and 200 fertile men were performed. Identified *DNAJB13* mutations were further investigated using bioinformatics, indirect immunofluorescence assay, papanicolaou staining, CASA, immunoelectron microscopy, Co-IP assays, transmission electron microscopy, iTRAQ, and multiple reaction monitoring studies.

Main results and the role of chance: We identified a heterozygous mutation c.106 T>C, p.Ser36Pro in *DNAJB13* in 9 (10%) idiopathic asthenozoospermia patients. We failed to find this mutation in the 200 fertile control men. Furthermore, using papanicolaou staining, CASA analysis and sperm functional tests, we found that spermatozoa with *DNAJB13* mutations had more deformities, i.e. vacuolus in the head and excessive residual cytoplasm, inflexible midpiece and asymmetric beating flagellum, and abnormal sperm acrosome reaction compared with the control group and patients without the mutation. Immuno-electron microscopy was carried out to observe ultrastructural multiple morphological and structural abnormalities of the sperm flagella (MMSAF) due to *DNAJB13* mutations. iTRAQ and multiple reaction monitoring studies were used to analyze the changes of multiple asthenozoospermia related proteins, spermatozoa structural proteins—NME5, RSPH9, sperm-egg binding and fusion proteins—SPESP1, and energy metabolism proteins—HK1 proteins. These proteins were significantly decreased in spermatozoa of idiopathic asthenozoospermia patients with *DNAJB13* mutations.

This study indicates that *DNAJB13* may be involved in spermatogenesis and sperm motility and a cause of idiopathic asthenozoospermia.

Limitations, reasons for caution: Although our *in vitro* assays demonstrated the effect of the *DNAJB13* mutation on sperm motility in structure and function level, further studies are needed to validate the *in vivo* effects of DNAJB13 mutation.

Wider implications of the findings: This finding further expands the spectrum of known genetic defects associated with asthenozoospermia and provides researchers and clinicians a better understanding of the etiology and molecular mechanism of asthenozoospermia.

Trial registration number: Not applicable.

O-130 Defective H3K9 demethylation of the male genome and abnormal first mitosis observed in mouse oocytes injected with human round spermatids

Y. Kai[1], K. Nakata[2], J. Ito[3], N. Kashiwazaki[3], N. Yamashita[2], Y. Mio[1]

[1]*Mio Fertility Clinic, Fertility Research Centre, Yonago, Japan*
[2]*Yamashita Shonan Yume Clinic, Reproductive Medicine Research Center-, Fujisawa, Japan*
[3]*Azabu University, Department of Animal Science & Biotechnology School of Veterinary Medicine, Sagamihara, Japan*

Study question: Does round spermatid injection (ROSI) contribute to normal embryo development in assisted reproductive technology?

Summary answer: ROSI tended to cause failure of H3K9 demethylation of the male genome, formation of male pronuclei, and chromosome segregation at the first mitosis.

What is known already: ROSI-derived embryos are prone to exhibit abnormal chromosome segregation and epigenetic abnormalities in animals. Indeed, developmental efficiency is significantly lower with ROSI than with intracytoplasmic sperm injection (ICSI), not only in animals, but also in humans. Despite views to the contrary, ROSI is still an option for assisted fertilization in animals and humans.

Study design, size, duration: This study was approved by the ethical committee of JISART (Japanese Institution for Standardizing Assisted Reproductive Technology) and was registered with the Japan Society of Obstetrics and Gynecology. ROSI and ICSI were conducted by injection of human round spermatids or spermatozoa into mouse MII oocytes. DNA/histone methylation status, pronuclear formation and chromosome segregation were analyzed statically and/or dynamically from injection to the first cleavage by immunofluorescence and fluorescence live cell imaging analysis.

Participants/materials, setting, methods: Human male gametes were obtained after donation and ethical approval. Round spermatids were obtained from 13 patients with non-obstructive azoospermia after testicular sperm extraction. MII oocytes were collected from 8-week-old B6D2F1 mice and pre-activated by CZB medium containing 7.5 mM $SrCl_2$ without Ca^{2+} for ROSI. Immunofluorescence was performed using antibodies against 5mC, 5hmC and H3K9me3. Live cell imaging was performed using TagGFP2-H2B mRNA and fluorescent-labeled Fab313, which can react with H3S10ph next to H3K9me3.

Main results and the role of chance: Firstly, immunofluorescence was performed using ROSI- and ICSI-derived two-pronuclear (2PN) zygotes in order to analyze the DNA/histone methylation status. Analysis of DNA methylation status targeting 5mC and 5hmC revealed that all ROSI-derived zygotes (n = 10) showed conversion of 5mC to 5hmC in the male pronucleus, as in ICSI-derived zygotes (n = 5), but analysis of histone methylation status targeting H3K9me3 revealed that all ROSI-derived zygotes (n = 10) retained H3K9me3 in the male pronucleus, unlike ICSI-derived zygotes (n = 7). Fluorescence live cell imaging analysis visualizing histone H2B and H3S10ph also revealed that the male genome was positive for H3K9me3 in oocytes after ROSI (n = 89), but not after

ICSI (n = 17). Failure of male pronucleus formation was observed in 84.3% of oocytes after ROSI. The 2PN fertilization rate of ROSI was low in comparison with ICSI (15.7% vs. 82.4%) and 35.7% of ROSI-derived 2PN zygotes showed distorted male pronuclei not seen with ICSI. Furthermore, half of the ROSI-derived 2PN zygotes showed aberrant chromosome congression at the first mitosis leading to aberrant chromosome segregation.

Limitations, reasons for caution: Our results came from cross-species fertilization and from the limited period until first mitosis, for ethical reasons. Although we have confirmed that oocyte pre-activation does not differ with SrCl2 or phospholipase C-zeta cRNA injection in mouse ROSI, phospholipase C-zeta cRNA injection was not tested in this study.

Wider implications of the findings: Defective demethylation of H3K9 in the male genome and poor developmental ability in ROSI might arise from incomplete protamine-histone replacement. Histone modification could be a key factor to utilize round spermatids in the clinical setting.

Trial registration number: Not applicable.

O-131 SPANX A/D subfamily plays a key role in nuclear organisation, metabolism and flagellar-motility of human spermatozoa

I. Urizar Arenaza[1], N. Osinalde[2], V. Akimov[3], I. Muñoa-Hoyos[1], M. Gianzo[1], T. Ganzabal[4], J. Irazusta[1], N. Subirán*[1], I. Kratchmarova*[3]

[1]*University of the Basque Country UPV/EHU, Physiology, Leioa, Spain*
[2]*University of the Basque Country UPV/EHU, Biochemistry and Molecular Biology, Vitoria-Gasteiz, Spain*
[3]*University of Southern Denmark Syddansk Universitet, Biochemistry and Molecular Biology, Odense, Denmark*
[4]*Unidad de Reproducción Asistida Quirón, Quirón Bilbao, Bilbao, Spain*

Study question: Which is the physiological function of endogenous SPANX A/D subfamily in human spermatozoa?

Summary answer: Quantitative proteomics reveals that SPANX A/D may play a role in nuclear organisation, mitochondrial metabolism and cilium-movement of human spermatozoa by interacting with 307 proteins.

What is known already: SPANX (Sperm Protein Associated with the Nucleus mapped to the X chromosome) multigene protein family is considered a Cancer Testis Antigen (CTA) whose expression is limited to the testis and spermatozoa in normal tissues, but also to a wide variety of tumors in non-gametic cells. This family includes two subfamilies, SPANX N and SPANX A/D. Although, the physiological function of the whole protein family is completely unknown, the low expression of SPANX A/D subfamily is related with asthenozoospermia and globozoospermia, and hence with a lower fertility in human spermatozoa.

Study design, size, duration: We followed a label free quantitative proteomics approach, in quadruplicate, to uncover the interactome of SPANX A/D subfamily in human spermatozoa. Additionally, a number of techniques in molecular biology were used to analyse the expression and subcellular localization of SPANX A/D in human spermatozoa.

Participants/materials, setting, methods: We used human normozoospermic seminal samples coming from the Quirón Bilbao fertility clinic. MS-based interactome study was carried out by immunoprecipitating endogenous SPANX A/D and subsequently, analyzing by a Q Exactive Mass spectrometer at the University of Southern Denmark (Odense, DK). MS raw files were processed with MaxQuant software v1.3.0.7, and output data was analyzed in Perseus bioinformatics analysis program. The same SPANX antibody was used to perform Western Blotting and immunoflurescence experiments.

Main results and the role of chance: We have described the presence of SPANX A/D subfamily in normozoospermic human spermatozoa, in both soluble and insoluble protein fractions, by immunobloting approaches. Immunofluoresce assays also show a strong immunoreactivity of SPANX A/D in the middle section, tail, acrosome and nuclear craters of human spermatozoa. Indeed, label-free proteomics data confirms that SPANX isoforms A, B, C and D are expressed in human male germ cells. Additionally, the MS-based interactome study carried out reveals a list of 307 potential interactors of endogenous SPANX A/D. According to gene ontology analysis, these interacting partners are involved in a wide range of key functions for the human spermatozoa, including the nuclear pore organization, the cilium- or flagellum-dependent motility, the assembly of the axonemal dynein complex, the mitochondrial electron transport and oxidative phosphorylation. This outcome is in line with the data obtained by immunocytochemistry indicating that SPANX is localized in different compartments of the cell.

Limitations, reasons for caution: Further studies are needed to validate the most intense SPANX interactors by accomplishing different molecular techniques. This information could help us to ratify the physiological role of SPANX A-D family in human spermatozoa.

Wider implications of the findings: A better understanding of the physiological function of SPANX in fertility may be useful to detect new therapeutic targets for treating infertility, as well as to develop safer polyvalent sperm contraceptives. Moreover, it could be essential to have a better understanding of the physiopathological mechanisms of this CTA in cancer.

Trial registration number: CEISH/61/2011.

O-132 Copr5is associated with Miwi and modulated the piRNA pathway, a possible mechanism involved in the human teratozoospermia sperm phenotype

C. Innocenti[1], E. Fabbrizio[2], D. Haouzi[3], C. Sardet[2], S. Hamamah[4]

[1]*INSERM U1203, Hôpital St Eloi, MONTPELLIER, France*
[2]*Université Montpellier-Institut de Recherche en Cancérologie de Montpellier, Inserm-U1194- Campus Val d'Aurelle, Montpellier, France*
[3]*Inserm U1203- IRMB, Hôpital St-Eloi- CHU Montpellier, Montpellier, France*
[4]*Service de Biologie de la Reproduction- Hôpital Arnaud de Villeneuve- CHU Montpellier, ART/PGD Department, Montpellier, France*

Study question: Is the Prmt5-associated factor Copr5 involved in the piRNA pathway during spermatogenesis?

Summary answer: Copr5 silencing in mice affects spermatogenesis and low level of Copr5 mRNA correlates with human teratozoospermia sperm.

What is known already: Protein arginine methyl transferase 5 (Prmt5) was implicated in genome defense in primordial germ cells (PGCs) via a PRMT5-dependent methylation of the Piwi protein family that participates within the piRNA pathway in promoting transposon silencing. However, the role of the Prmt-5 and histone-associated protein Copr5 in the regulation of the piRNA pathway remains unknown.

Study design, size, duration: Testes from Copr5 Knock-out (KO) mice and wild type (WT) (n = 3 per group) were used for immunoprecipitation, western blot analyses, immunhistochemistry (IHC) and RTqPCR experiments. Ten human sperm samples were collected from patients with normozoospermia (n = 3) and teratozoospermia (n = 7) for RTqPCR experiments.

Participants/materials, setting, methods: Proteins, total RNA and paraffin-embedded testis sections were extracted and/or prepared from the Copr5 KO and WT mice. 200 µl of each semen were used for total RNA extraction using the miRNeasy serum/plasma kit (Qiagen).

Main results and the role of chance: Prmt5- and histone-associated protein Copr5 is highly expressed intestis and its depletion impacted on the maturation of spermatogonia to spermatids, although Copr5 KO animals were fertile. Extinction of Copr5 in mice testis leads to a down-regulation of the level of Miwi protein, as confirmed by western blot analyses and immunohistochemistry of WT and KO mice testis whole cell extracts and paraffin-embedded testis sections, respectively. In addition, the mRNA level of three pre-pachytene piRNAs, prepiR1, prepiR2 and prepiR3 was decreased in KO Copr5 compared to WTmice, whereas in KO mice the expression level of the LINE1 mRNA, the most abundant retro-transposons that was usedas a read out of deregulation of the piRNA pathway, was increased. Using both human GEO data and patients with teratozoospermia, the present study reports a correlation between a low level of Copr5 mRNA and teratozoospermia, a human pathology characterized by abnormally shaped sperm that can negatively affect fertility.

Limitations, reasons for caution: Further investigation is needed to know whetherthe absence of Copr5 in mice might molecularly impact more strongly

on the piRNA pathway over generation and render mice unfertile, thus phenocopying the human pathology.

Wider implications of the findings: Copr5 KO in mice perturbed some genome surveillance mechanisms in germ cells by an alteration of the expression level of two major components present in the Piwi-interacting RNA (piRNA) pathway, the Miwi and the LINE1.

Trial registration number: Not applicable

Tuesday 3 July 2018 Room 117 10:00–11:30

O-133 A two-step protocol for oocyte In Vitro Maturation in PCO/PCOS patients increases the yield and quality of usable embryos and results in ongoing pregnancies

F. Sanchez[1], S. Romero[1], A.H. Le[2], F. Lolicato[1], H. Van Ranst[1], T.M. Ho[2], J. Smitz[1], L.N. Vuong[2,3]

[1]Vrije Universiteit Brussel, EMGE-FOBI Follicle Biology laboratory, Brussels, Belgium
[2]My Duc Hospital, Ivfmd, Ho Chi Minh City, Vietnam
[3]University of Medicine and Pharmacy at Ho Chi Minh City, Department of Obstetrics and Gynecology, Ho Chi Minh City, Vietnam

Study question: What is the effectiveness of a two-step IVM protocol (CAPA-IVM) involving a pre-maturation culture with C-type natriuretic peptide (CNP) versus Standard IVM in PCO/PCOS patients?

Summary answer: Pre-maturation with CNP followed by IVM (CAPA-IVM) increased the yield and quality of usable embryos resulting in a high ongoing pregnancy rate from first transfer.

What is known already: Oocyte In Vitro Maturation (IVM) is a valuable woman-friendly assisted reproductive technology, especially suited for patients presenting polycystic ovaries or Polycystic ovary syndrome (PCO/PCOS). Since IVM makes use of oocytes obtained from small antral follicles (2-12 mm diameter), embryological and clinical outcomes were proven to be reasonably inferior to conventional stimulated IVF (ICSI) techniques.

A novel two-step IVM system (termed CAPA-IVM) using FSH priming but omitting hCG administration has recently been translated from mouse to human in a pilot study using sibling oocytes, indicating superior results.

This study further explores the embryological and clinical advantages of using CAPA-IVM in PCO/PCOS patients.

Study design, size, duration: This prospective randomised controlled pilot study includes PCO/PCOS patients (Rotterdam criteria, 2004), 24-36 years old, BMI ≤30, without previous history of recurrent failure of ART (including recurrent miscarriages). Enrolments took place between March and June 2017. Patients were randomly allocated to two protocols: CAPA-IVM and Standard IVM, via block randomization with block size of 4. Sample size was 40 (20 each group).

Routine hormonal analyses included AMH, FSH, LH, estradiol and progesterone.

Participants/materials, setting, methods: Patients received 3 doses of rFSH 150IU daily, starting on day 1 or 3 after bleeding. Oocyte retrieval was planned on day 5 to 8 without a prior hCG trigger.

The pre-maturation culture lasted 24 h whereas IVM lasted 30-32 h. The primary outcome was the yield of usable (vitrified) Day 3 embryos, per patient. Secondary outcomes were oocyte maturation, fertilization and good quality embryo rates. A maximum of 2 embryos were transferred in a deferred cycle.

Main results and the role of chance: Mean age (28.9), BMI (21.2) and AMH (10.8 µg/L) were not different among patients allocated to any of the IVM protocols. Baseline values for FSH and LH were 5.82 ± 1.58 IU/L and 12.65 ± 6.12 IU/L, respectively.

The MII (maturation) rate was significantly higher in CAPA-IVM vs Standard IVM (60.4 ± 15.3% vs 50.8 ± 20.8%; $P = 0.0454$). Rates of fertilization per mature oocyte and usable embryos per fertilized oocyte were similar among the groups. However, there was a significant increase (1.8-fold higher) in the mean number of usable embryos (per patient), in CAPA-IVM vs Standard IVM (3.9 ± 2.6 vs 2.2 ± 1; $P = 0.0061$).

Moreover, the rates of good quality embryos (grades 1 and 2) per fertilized oocyte, mature oocyte or cumulus-oocyte-complex (COC), were significantly higher in CAPA-IVM vs Standard IVM (48.9 ± 22.8 vs 36.2 ± 23.2%, $P = 0.0248$; 43.2 ± 23.4% vs 30.8 ± 22.6%, $P = 0.0257$; and 27.2 ± 15.3 vs 15.1 ± 12.9%, $P = 0.002$; respectively).

The ongoing pregnancy rate (per transfer) is currently 52.6% and 36.8% (CAPA-IVM and Standard IVM, respectively). No significant differences have been yet recorded, since ongoing pregnancies are still in follow-up.

Limitations, reasons for caution: Although patients were randomly assigned to either of the IVM protocols, the patient population is still small. Nevertheless, the results with CAPA-IVM in Vietnamese patients are concordant with those previously reported in Belgian patients and published earlier, showing transferability of the CAPA-IVM method.

Wider implications of the findings: This study reports the first pregnancies of CAPA-IVM. The significant increase in oocyte maturation, number of usable embryos and embryo quality by the two-step IVM protocol in this prospective randomized controlled pilot study suggests that IVM could be positioned as one of the routine assisted reproductive techniques for PCOS patients.

Trial registration number: not applicable.

O-134 Assisted oocyte activation significantly increases fertilization and pregnancy rates resulting in healthy live births in patients with oocyte activation deficiencies

D. Bonte, L. Dhaenens, M. Ferrer-Buitrago, S. De Gheselle, I. De Croo, K. Tilleman, P. De Sutter, B. Heindryckx

Ghent University Hospital Ghent Fertility and Stem cell Team, Reproductive Medicine, Gent, Belgium

Study question: To what extent does assisted oocyte activation (AOA) improve fertilization and pregnancy outcome in patients diagnosed with oocyte activation deficiencies (OADs)?

Summary answer: AOA significantly increased fertilization and pregnancy rates and resulted in healthy live births in patients with a history of low or failed fertilization after ICSI.

What is known already: Whether AOA is effective in couples with low or failed fertilization after ICSI remains controversial. This is mainly due to the fact that most clinics applying AOA do not investigate whether the origin of OAD is attributed to sperm- or oocyte-related factors; information that is important for counseling couples about future treatment options. The Mouse Oocyte Activation Test (MOAT) is one diagnostic method to discern the gamete origin of failed fertilization. To date, large-scale studies assessing the efficiency of AOA in patients experiencing failed fertilization after ICSI and undergoing a diagnostic test to reveal the origin of OAD, are lacking.

Study design, size, duration: A retrospective analysis was performed, involving 167 AOA cycles (April 2001 to July 2017) of 105 men with low or failed fertilization after ICSI for whom sperm activation capacity was examined by MOAT prior to the subsequent AOA cycle(s). The AOA efficiency in terms of fertilization and pregnancy rate and neonatal outcome was investigated according to the MOAT result and compared to 207 previous conventional ICSI cycles of these couples.

Participants/materials, setting, methods: For MOAT, mature mouse oocytes (B6D2F1, 7-12 weeks) were injected with patients' spermatozoa. Depending on the percentage of activated oocytes next day, patients were categorized in MOAT group 1 (0-20% activation), 2 (21-84% activation) or 3 (85-100% activation) and compared to a positive fertile control. For AOA treatment, mature patients' oocytes were injected with patients' spermatozoa along with $CaCl_2$ (0.1 M), followed by a two-fold exposure to ionomycin (10 µM, 10 min) with a 30 minute time interval.

Main results and the role of chance: MOAT revealed 18 patients with a sperm-related OAD (MOAT group 1), 49 patients with a diminished oocyte

activation capacity of the sperm (MOAT group 2) and 38 patients with a presumably oocyte-related OAD (MOAT group 3). AOA treatment significantly improved fertilization rates: MOAT group 1: 69.69% for 34 AOA cycles versus 10.53% in 19 prior ICSI cycles, MOAT group 2: 62.54% (76 cycles) versus 14.21% (123 cycles), MOAT group 3: 58.26% (57 cycles) versus 17.18% (65 cycles) ($p < 0.001$). Moreover, significantly higher pregnancy rates were observed after AOA treatment compared to previous ICSI cycles, in MOAT group 1 (46.94% versus 0.00%), 2 (34.88% versus 6.35%), and 3 (29.03% versus 6.25%) patients ($p < 0.05$). Interestingly, AOA results for MOAT group 1 tended to be better than for MOAT group 3 in terms of fertilization rates (69.69% versus 58.26% respectively, $p < 0.05$) and pregnancy rates (46.94% versus 29.03% respectively, $p = 0.05$). In total, 52 healthy children were born (28 boys and 24 girls): 19 singletons in MOAT group 1, 13 singletons and 3 twins in MOAT group 2, and 12 singletons and 1 twin in MOAT group 3.

Limitations, reasons for caution: As AOA technology is still considered experimental, its application is thus best reserved for those cases where there is a clear indication of an OAD. To date, our results demonstrate that AOA seems to be a safe and effective technique. However, further follow-up of children born after AOA is warranted.

Wider implications of the findings: Our large cohort study shows that in cases with OAD, AOA restores fertilization and pregnancy rates to a satisfactory level. More sensitive tests (e.g. calcium pattern analysis) will aid to further distinguish those cases that are likely to benefit from AOA, and additionally guide further clinical management of these patients.

Trial registration number: not applicable.

O-135 Three babies born after pronuclear transplantation in young women with unexplained infertility and repeated implantation failure of euploid embryos

P. Mazur[1], V. Veselovsky[2], Y. Masliy[2], M. Borisov[2], D. Mykytenko[3], V. Zukin[4]

[1]*Clinic of Reproductive Medicine 'NADIYA', Embryology, Kyiv, Ukraine*
[2]*Clinic of Reproductive Medicine 'NADIYA', Obstetrics and gynaecology, Kyiv, Ukraine*
[3]*Clinic of Reproductive Medicine 'NADIYA', Genetics, Kyiv, Ukraine*
[4]*Clinic of Reproductive Medicine 'NADIYA', Management, Kyiv, Ukraine*

Study question: Can pronuclear transplantation (PNT) be applied to women with unexplained infertility and repeated implantation failure?

Summary answer: Three healthy babies born after PNT in a group of five women <37 years old, who were unable to conceive using repeated cycles of ART.

What is known already: Using nuclear transplantation or whole cytoplasm replacement in humans is an experimental approach which avoids transmission of mitochondrial disease. Concerns have been raised about these procedures and particularly about later expression of potentially affected mitochondria and the potential of nuclear-cytoplasmic incompatibility. PNT resulted in a single ongoing twin pregnancy in 2003 for a patient with recurrent embryo arrest, but this did not result in live birth. Maternal spindle transfer for prevention of Leigh syndrome resulted in the first delivery of a healthy boy in 2016.

Study design, size, duration: The study period was from September 2015 to January 2018. Patients were informed and consent to possible risks and the experimental protocol was approved by ethics committee of Ukrainian association of reproductive medicine. Inclusion criteria were: (1) no less than two failed previous IVF attempts with embryo arrest, (2) low blastulation rates, (3) recurrent implantation failure of euploid embryos; (4) age ≤ 37 years, normal ovarian reserve, absence of endometrial or uterus factor of infertility.

Participants/materials, setting, methods: Oocyte retrievals for five infertile women (from 29 to 34 years of age) were synchronized with donors; thawed donor oocytes were used in a case of patient's oocytes excess. ICSI with patient's partner's sperm had been performed simultaneously for all oocytes. PNT, assisted by HVJ-E cell fusion kit, was applied at ~12 h after fertilization. Reconstituted zygotes were cultured until blastocyst stage in time-lapse incubator and biopsied for aCGH or NGS analysis.

Main results and the role of chance: Overall, 36 zygotes from 43 patient's zygotes (84%) were successfully reconstituted, that resulted in 19 blastocysts (53%); 14 were euploid (74%). Elective single embryo transfer (eSET) of thawed embryos was done for each patient. Positive hCG levels (> 100 mIU/mL) were confirmed in 4/5 patients after the first try. In two patients amniocentesis was performed at 17 weeks of gestation to confirm successful cytoplasm replacement by an independent laboratory. The third patient refused amniocentesis; however, donated umbilical cord blood after she gave birth. For two cases the result was: "None of the variants of the biological mother and all mitochondrial variants of the donor were detected in the fetus" and for the third one it was: "The majority of mitochondrial variants detected in the child are shared with the mitochondrial donor and not with its biological mother". First baby girl was born on 5th of January 2017 through vaginal delivery and a second baby boy was born on 19th of February 2017; third baby boy was born on 15th of October 2017 by Caesarean section. The three children performed well in pediatric analyses. The fourth case was at an early stage of development at the moment of abstract submission.

Limitations, reasons for caution: Since, nuclear transplantation in human is still experimental and highly controversial; further investigations and long term follow up of children is required. The number of patients included into study is low; any broad conclusions may be premature. Patients above 37 years of age may not benefit from PNT.

Wider implications of the findings: Not only mitochondrial diseases, but a rare condition named preimplantation embryonic lethality (embryo arrest) could possibly be overcome by pronuclear transplantation. This experimental technique may be used as an assessment tool to study nuclear-cytoplasmic interactions.

Trial registration number: Not applicable.

O-136 Blastocysts collapse as an embryo marker of low implantation potential a time-lapse study

R. Herrer Saura[1], R. Sciorio[2], M. Esbert[3], S.J. Pickering[2], J.K. Thong[2], M. Meseguer[4]

[1]*IVI Zaragoza, IVF laboratory, Zaragoza, Spain*
[2]*Edinburgh Fertility Reproductive Center- Royal Infirmary Edinburgh., IVF laboratory, Edinburgh, United Kingdom*
[3]*IVI Barcelona, IVF laboratory, Barcelona, Spain*
[4]*IVI Valencia, IVF Laboratory, Valencia, Spain*

Study question: To validate the relationship between blastocyst collapse and implantation potential in *in vitro* human embryo culture using Time-Lapse technology.

Summary answer: Blastocysts showing a severe collapse during development are less likely to implant and generate a viable pregnancy compared with embryos which do not show collapse.

What is known already: The process of hatching in mammalian embryo, involving the escape of the blastocyst from the zona pellucida (ZP) was first observed by Lewis and Gregory in 1929. Whether blastocyst collapse could be a novel marker of embryo quality, and correlated with outcome of ICSI/IVF cycles, should be demonstrated in an independent dataset of embryos. This study investigated the correlation between blastocyst collapse and pregnancy and implantation rates following elective single transfer at blastocyst stage (eSET).

Study design, size, duration: This is a retrospective multicenter analysis, carried out between January 2016 and February 2017. Four IVF units participate to the study: EFREC, RIE, Edinburgh, UK, IVI Valencia, IVI Barcelona and IVI Zaragoza in Spain. Blastocyst were analysed by measuring the maximum volume reduction during development and defined as having collapsed if there was ≥50% of the surface of the TE was separated from the ZP.

Participants/materials, setting, methods: The study included 1297 ICSI/IVF cycles having an eSET on day 5. Embryos were cultured individually in an EmbryoSlide™, using an EmbryoScope™ imaging system in 6% CO2, 5% O2, 89% N2. Morphological assessment was made by examining a video of development using the associated EmbryoViewer software. Following embryo transfer, blastocyst was retrospectively allocated to one of two groups (collapsed or not collapsed). Pregnancy and implantation rates were analysed.

Main results and the role of chance: A total of 1297 cycles were analyzed. 259 blastocysts collapsed once or more during development (19.9%) and the

remaining 1038 either contracted minimally or neither contracted nor collapsed during development (80.1%). A significantly higher ongoing pregnancy rate of 51.9% (CI95% 48.9%-59.9%) was observed when blastocysts which had not collapsed during development were replaced compared to cycles in which collapsed blastocysts were transferred 37.5% (CI95% 31.6%-43.4%). A multivariable logistic regression analysis revealed an ongoing pregnancy 1.78 (1.33-2.40) OR, and the stratified study demonstrated that blastocyst collapse is mainly affecting implantation potential on good quality embryos.

Limitations, reasons for caution: Live birth rates should also be investigated to see if there is a difference in final outcome between the groups.

Wider implications of the findings: The pattern of blastocyst collapse could improve IVF/ICSI outcome following eSET at blastocyst stage. Therefore, it could be used as a negative marker for embryo selection.

Trial registration number: not applicable.

O-137 The impact of dry incubation on osmolality of media in time-lapse culture dishes

G. Carpenter, E. Hammond, J. Peek, D.E. Morbeck

Fertility Associates, Embryology, Auckland, New Zealand

Study question: Does continuous culture in a dry incubator lead to an increase in culture medium osmolality that is affected by the type of time-lapse dish used?

Summary answer: Osmolality increased for all tested time-lapse dishes, with a greater effect for Primovision, Miri-TL and standard microdrop culture compared to Embryoscope dishes.

What is known already: Osmolality of culture media is critical for optimal embryo development with high osmolality having adverse effects. Osmolality of culture media is affected by factors such as humidity, temperature, dish preparation method and media droplet volume. Compared to humidified incubation, negative effects of dry incubation on human embryo development have been observed. However, the use of dry incubators is becoming increasingly common due to advantages of time-lapse continuous culture. Different time-lapse systems use different dishes with various media to oil surface ratios, which may alter the effect of dry incubation on osmolality.

Study design, size, duration: Changes in osmolality were measured in four culture dishes over 7 days in a dry incubator (Miri-TL). The cultures dishes were: Miri-TL culture coin (MTL), Vitrolife EmbryoSlide (ES), and Primovision dish (PV), with a Vitrolife Micro-Droplet dish (MD) as the control. The study was repeated three times. Osmolality was determined in duplicate at days 0, 3, 5 and 7 of culture. The impact of oil depth on osmolality was also studied for standard MD dishes.

Participants/materials, setting, methods: Dishes were prepared with protein supplemented media and oil. For MD dishes, the impact of 3, 5 or 7 mL oil overlay was determined over 5 days. The time-lapse dishes were prepared as per manufacturer. MD dishes had 20 uL microdroplets under 5 mL of oil. For each condition, osmolality was tested on a 10 uL sample using a VAPRO osmometer. Relative changes in osmolality were assessed (ANOVA) and means were compared using Tukey's HSD.

Main results and the role of chance: Culture media osmolality was affected by oil depth, with a 3 mL oil overlay resulting in the highest osmolality compared to either 5 or 7 mL. For time-lapse dishes, osmolality increased as the culture continued over 7 days in the dry incubator. From a starting osmolality of 258 mOsm, media osmolality in MD, MTL and PV increased similarly over 7 days of culture, but for ES dishes, the increase in osmolality occurred to a lesser extent, showing that the ES condition was less prone to increasing osmolality during a 7 day dry incubation. For MD, MTL, PV and ES dishes, osmolality increased, respectively, by 26.9, 23.7, 20.3 and 12.2 mOsm on day 3, 42.3, 42.5, 38.5 and 27.7 mOsm on day 5, and 53.5, 50.4, 57.3 and 33.2 mOsm on day 7. ES osmolality was lower than the control MD dish on day 3 ($p < 0.05$), both MD and MTL on day 5 ($p < 0.05$) and all dishes on day 7 ($p < 0.01$), showing that the ES condition had the greatest ability to prevent media evaporation, resulting in slower osmolality rise over 7 days of culture during dry incubation.

Limitations, reasons for caution: This study was performed using a MiriTL bench top incubator; therefore the results may not be applicable to other dry incubators. Osmolality increased in all dishes and the impact of these increases on human embryo development is unknown.

Wider implications of the findings: The osmolality of culture media increased with dry incubation despite oil overlay in various dishes, an increase that was dish dependent. The ES dish, which uses deep culture wells that results in the lowest ratio of culture medium surface area to oil, had the lowest amount of media evaporation.

Trial registration number: Not applicable.

O-138 Utility of the Vienna consensus on ART Laboratory Performance Indicators for managing multiple IVF laboratories performance

G.H. Trew[1], S. Nelson[2]

[1]*The Fertility Partnership, IVF, London, United Kingdom*
[2]*University of Glasgow, School of Medicine, Glasgow, United Kingdom*

Study question: Is the Vienna consensus on Laboratory Performance Indicators useful in standardising performance and setting benchmarks across a commercial group of IVF clinics?

Summary answer: The Vienna consensus facilitates a uniform reporting platform, however, with the focus on extended embryo culture Day 2 embryo development rates are less relevant.

What is known already: Laboratory performance indicators are critical for managing laboratory quality control. Ensuring reproducible laboratory outcomes across a growing commercial group of IVF clinics is essential, with agreed outcomes and benchmarks conventionally set in house. The Vienna consensus, sets 19 indicators including 12 key performance indicators (KPIs), five performance indicators (PIs) and two reference indicators (RIs) with internationally agreed definitions, competence levels and aspirational benchmark values.

Study design, size, duration: Prospective cohort study of seven IVF clinic performing 2418 fresh and 1300 frozen cycles between 1 January to 30 June and nine IVF clinics performing 1799 fresh cycles and 1005 frozen transfer from 1 July to 31 October 2017.

Participants/materials, setting, methods: Nine IVF clinics in the United Kingdom and Poland. Comprehensive data collection using IDEAS software platform, with centralised analysis of clinic performance in accordance with the 19 laboratory indicators and associated competence and aspirational benchmark values described in the Vienna consensus.

Main results and the role of chance: Of the 19 indicators, 18 were routinely recorded with day 2 embryo development rate not collected by any centre due to extended embryo culture systems. For the 18 different measures, different laboratories were able to achieve each of the predetermined competence values with only blastocyst survival (competence >90%) attained by all laboratories (range 91.2 to 100%). However, no laboratory achieved all competency values. Despite overall high clinical pregnancy rates exceeding national averages (47.2% per embryo transfer for fresh and 58.2% for frozen), the highest performing laboratory only achieved 12 of the 18 competency values. The clinic with the lowest compliance attained only four competencies, despite achieving clinical pregnancy and live birth rates in accordance with the Human Fertilisation and Embryology Authority limits. The aspirational benchmarks for ICSI fertilisation rate (≥80%), IVF fertilisation rate (≥75%) and blastocyst development rates (≥35%) were not achieved by any clinics with the highest observed rates being 78.0%, 73.7% and 59.5% respectively.

Limitations, reasons for caution: Patient characteristics were not taken into account with summary data used for each clinic, adjustment for confounders is likely to enable more accurate identification of clinical and laboratory issues. The aspirational benchmarks may not be achievable using summary data for a broad patient population.

Wider implications of the findings: The Vienna consensus provides an agreed standard for clinical and laboratory reporting, with each competency value potentially attainable by every clinic. UK regulator data on clinic outcomes potentially provides false reassurance, with external benchmarking and group performance providing a more accurate estimate of achievable performance.

Study question:: Does endometrial scratching delivered by an endometrial pipelle biopsy, increase the probability of live-birth in women undergoing IVF/embryo transfer?

Summary answer: Endometrial scratching was not associated with any improvement in live birth rate.

What is known already: Endometrial scratching has been suggested to improve the probability of embryo implantation, and therefore pregnancy, in women undergoing IVF. It is proposed that the mechanical disruption to the endometrium results in a favourable inflammatory response, increasing the endometrial receptivity. Pooled results from randomised trials suggest benefit from endometrial scratching prior to an IVF cycle, especially in women with previous implantation failure. However, many of the studies had a high risk of bias secondary to study design, such as exposure of controls to endometrial disruption and lack of allocation concealment. Therefore, there is uncertainty about the validity of a beneficial effect.

Study design, size, duration: A pragmatic, multi-centre, open-label, randomised trial was conducted between June 2014 and June 2017 in 13 centres across five countries. Women were randomised 1:1 to either endometrial scratching or no procedure, using an online trial-specific database which ensured allocation concealment. Sample-size was calculated separately in women with recurrent implantation failure (≥2 unsuccessful embryo transfers, 15% increase live-birth rate anticipated) and without (8% increase). At 80% power and a 5% significance level, 1300 women were required.

Participants/materials, setting, methods: Eligible women were undergoing embryo transfer (fresh or frozen) using their own oocytes, with no recent exposure to disruptive intrauterine instrumentation. Women in the endometrial scratching arm underwent a pipelle biopsy between day 3 of the preceding cycle and day 3 of the IVF/embryo transfer cycle. The primary outcome was live-birth using an intention-to-treat approach. Risk ratio and 95% confidence intervals were calculated, and logistic regression was used to test for subgroup differences.

Main results and the role of chance: A total of 1364 women were randomised: 690 to endometrial scratching and 674 to control. Baseline and cycle characteristics were similar between the two groups. Endometrial scratching was not associated with any improvement in live birth rate 26.1% (180/690) vs 26.1% (176/674), odds ratio =1.00 (0.78 to 1.27). The effect remained similar after adjusting for protocol deviations and the observation that fewer women in the control arm underwent an embryo transfer. There was no difference in the rate of biochemical pregnancy, ectopic pregnancy, ongoing pregnancy, clinical pregnancy or multiple pregnancy between the two groups. Subgroup analysis did not identify any subpopulations that may benefit from endometrial scratching; there was no evidence of a benefit in women: with recurrent implantation failure, undergoing fresh or frozen cycles, or depending on the timing of the scratch in relation to the embryo transfer. The median pain score from endometrial scratching was 3.5/10 (IQR 1.9–6.0). There were 14 adverse events related to endometrial scratching: 7 vasovagal reactions, 2 excessive bleeding and 5 excessive pain.

Limitations, reasons for caution: Although a higher proportion of women in the endometrial scratching arm underwent embryo transfer, this did not impact the results. The definition of recurrent implantation failure was two or more previous unsuccessful embryo transfers, with no consideration for the stage or quality of the previously transferred embryos.

Wider implications of the findings: This was a large trial and the pragmatic design increases the generalisability of the results. As the beneficial effects reported previously were not confirmed by this trial, and the procedure caused a moderate amount of pain and bleeding, the current use of endometrial scratching in fertility clinics should be abandoned.

Study funding/competing interest(s) Research grants were provided by (New Zealand): A+ Trust, Auckland District Health Board; The Nurture Foundation for Reproductive Research; and Maurice & Phyllis Paykel Trust. There are no competing interests.

Trial registration number: ACTRN12614000626662

O-140 The impact of non-cavity distorting intramural fibroids on IVF outcomes: A systematic review and meta- analysis

M. Hamdan, M.N. Nuzaim

University of Malaya, Obstetrics and Gynaecology, Kuala Lumpur, Malaysia

Study question: To identify the impact of non- cavity distorting uterine fibroid on IVF outcomes.

Summary answer: Presence of non-cavity distorting IM fibroids with or without subserosal fibroids will reduce LBR CPR, and MR but not IR.

What is known already: Uterine fibroids (UF) including. those non-cavity distorting variant can cause infertility. When these women require IVF treatment, controversies whether its presence will negatively impact on their IVF outcomes has been continually debated. The heterogenous nature of UF has given inconsistence result in many published studies. Available meta analysis on this subject however is dated and has significant heterogeneity. Moreover, IVF techniques and protocol have also been rapidly evolved since the last review. An updated review and Meta-Analysis is needed to give informed choice to patient and IVF practitioner.

Study design, size, duration: Systematic review and meta-analysis.

Participants/materials, setting, methods: We performed a systematic review and meta-analysis on extracted data according to PRISMA. Relevant articles were selected from literature search carried out using Medline, Embase, and Web-of-science. Randomised and non-randomised controlled studies were included. Primary outcomes are live birth rate (LBR) and clinical pregnancy rate (CPR) and secondary outcomes are implantation rate (IR) and miscarriage rate (MR). Qualities of included studies were scored using Newcastle-Ottawa Quality Assessment Scales and meta-analysis conducted by using RevMan 5.3.

Main results and the role of chance: We found 2482 articles but only included 26 articles that satisfy our inclusion and exclusion criteria. All are non-randomised studies with a total of 7733 IVF cycles. Most (26/27) are high qulity studies. Fourteen (n = 14/27) studies included IM with SS and only (n = 12/26) reported IM only. Our meta-analysis revealed non-cavity distorting IM fibroids with or without subserosal fibroids, significantly reduced CPR (RR = 0.83, 95% CI = 0.63–0.99, P < 0.000, I^2 = 42%, 2955 IVF cycles, 23 studies), LBR (RR = 0.80, 95% CI = 0.73-0.87, P = 0.000, I^2 = 40%, 1815 cycles, 16 studies) and MR (RR = 1.26, 95% CI = 1.06-1.50, P = 0.009, I^2 = 21%, 509 cycles, 16 studies). Where as IR (RR = 0.79, 95% CI = 0.81–1.01, P = 0.07, I^2 = 33%, 1379 IVF cycles, 10 studies) is not significanltly

affected. Our subgroup analysis on non cavity distorting IM only, revealed significantly reduced CPR (RR = 0.84, 95% CI = 0.77-0.92, P = 0.000, I^2 = 18%, 1871 IVF cycles, 12 studies), LBR (RR = 0.83, 95% CI = 0.73–0.94, P = 0.005, I^2 = 32%, 799 IVF cycles, 6 studies) and MR (RR = 0.84, 95% CI = 0.77-0.92, P = 0.000, I^2 = 18%, 1871 IVF cycles, 12 studies). However, IR (RR = 0.71, 95% CI = 0.49 – 1.02, P = 0.07, I^2 = 81%, 1511 IVF cycles, 5 studies).

Limitations, reasons for caution: included studies are non-randomised studies. The result of this study is still subjected to confounders relating to clinical heterogeneity.

Wider implications of the findings: This finding will facilitate clinician on the decision of need for performing myomectomy in non cavity distorting uterine fibroid.

Trial registration number: NA.

O-141 Supplementation in adolescent girls with endometriosis (SAGE): A double blind, randomized, placebo-controlled trial

J. Nodler[1], A. DiVasta[2], A. Vitonis[3], S. Karevicius[4], M. Malsch[5], V. Sarda[2], A. Fadayomi[3], S. Missmer[6]

[1]*Houston IVF, REI, Houston, U.S.A.*

[3]*Brigham and Women's Hospital and Harvard Medical School, Department of Obstetrics- Gynecology- and Reproductive Biology, Boston, U.S.A.*
[4]*Boston Children's Hospital and Brigham and Women's Hospital, Boston Center for Endometriosis, Boston, U.S.A.*
[5]*Boston Children's Hospital, Institutional Centers for Clinical and Translational Research, Boston, U.S.A.*
[6]*College of Human Medicine- Michigan State University, Department of Obstetrics-Gynecology- and Reproductive Biology, Grand Rapidsd, U.S.A.*

Study question: Does adjuvant supplementation with omega-3 fatty acids or vitamin D remediate pain and improve quality of life in adolescents with surgically-confirmed endometriosis?

Summary answer: All groups–vitamin D, omega-3 fatty acids, and placebo improved at three and six months in pelvic pain and mental and physical quality of life.

What is known already: Adolescents with endometriosis are an underserved population who struggle with chronic pain, missed school, poor social relationships, and concerns about future infertility. Endometriosis is a pro-inflammatory condition characterized by elevated levels of cytokines and growth factors, decreased cell apoptosis, and increased angiogenesis. Vitamin D and omega-3 fatty acids may decrease inflammatory factor proliferation, which could reduce progression of endometriosis and endometriosis-associated pain. Several articles and books exist in the lay press regarding the use of diet and supplementation to manage endometriosis, but there are no published data demonstrating an association between nutritional supplementation and modification of endometriosis symptoms.

Study design, size, duration: Double blind, randomized, placebo-controlled trial in which 69 adolescent girls and young women were randomized to receive vitamin D3 (2000 IU), fish oil (1000 mg), or placebo daily for 6 months – administered as identical white capsules. An independent biostatistician developed a permuted blocks randomization schema that the research pharmacy implemented to allocate the blinded study medications. No member of the study team nor the participants were privy to treatment assignment.

Participants/materials, setting, methods: 59 girls and young women (age 12-25) recruited from a pediatric gynecology clinic completed all study visits. 19 were allocated to placebo, 23 to vitamin D, and 17 to fish oil. All participants had surgically-confirmed endometriosis and a minimum visual analog scale (VAS) pain score ≥ 3 out of 10 for their worst pain in the month preceding study enrollment. There were no differences in severity of endometriosis or pelvic pain at baseline.

Main results and the role of chance: 59 participants completed all study visits; there were no differences in characteristics between completers and non-completers. The majority of participants had rASRM stage 1 endometriosis at surgical diagnosis. From baseline to 6-months, a significant increase in serum 25(OH)D was observed only in the vitamin D arm; likewise, an increase in total omega-3 fatty acids, eicosapentaenoic acid(EPA) and docosahexaenoic acid (DHA) was observed only among those randomized to fish oil. Participants in all 3 arms demonstrated improvement in VAS pain; mean(SD) worst pain in the past month improved from baseline to 6 months in placebo [6.0 (1.9) to 4.4 (3.2), P_{trend} = 0.06], vitamin D [7.0 (2.2) to 5.5 (3.0), P_{trend} = 0.04], and fish oil [5.9 (2.9) to 5.3 (3.5), P_{trend} = 0.40] arms ($P_{heterogeneity}$ = 0.64). The mean number of hours that pelvic pain usually lasted improved similarly from baseline to 6-months among participants in all 3 arms. Three participants from each arm required a clinical visit for pain at the 6-month time point, which was similar to baseline. Average use of non-narcotic pain medication did not change from baseline in any study group. Quality of life similarly improved among the 3 arms for both mean SF-12 mental component and physical component scores ($P_{heterogeneity}$ = 0.38 and 0.60 respectively).

Limitations, reasons for caution: The small sample size was powered to detect a minimum difference in change of 1.6 in VAS pain, requiring 19 subjects per arm, assuming standard deviation = 1.7, 80% power, and alpha-error = 0.05. Enrolled from one clinic, the experience of this population of adolescents may not generalize to all young women.

Wider implications of the findings: The strong placebo effect evident in multiple outcome measures demonstrates the possibility that enhanced clinical interaction and active study involvement improves pain associated with endometriosis. Vitamin D and omega-3 fatty acids may not reduce pelvic pain, pain medication usage, or improve quality of life independent of this effect.

Trial registration number: NCT02387931

O-142 The Endometriosis Fertility Index (EFI) can be estimated accurately prior to surgical treatment of endometriosis

C. Tomassetti[1], C. Bafort[1], C. Meuleman[1,2], S. Fieuws[3], M. Welkenhuysen[1], T. D'Hooghe[2]

[1]*University Hospitals Leuven, OBGYN/Leuven University Fertility Center, Leuven, Belgium*
[2]*KU Leuven, Organ System- Dept Development and Regeneration, Leuven, Belgium*
[3]*KU Leuven, L-Biostat, Leuven, Belgium*

Study question: Can the final EFI-score be estimated before surgical endometriosis treatment, from pre-operative non-surgical findings only (type-A estimation) or pre-operative plus diagnostic laparoscopy data (type-B estimation)?

Summary answer: The final EFI can be estimated well before completion of operative laparoscopy for endometriosis, based on non-surgical data with or without surgical diagnostic laparoscopic data.

What is known already: The EFI is a thoroughly validated clinical instrument to predict non-ART clinical pregnancy rate after endometriosis surgery, but as the EFI-score is calculated at the end of an operative laparoscopy – i.e. after all endometriosis lesions have been removed – it currently is not clear if this score can be also estimated prior to surgical treatment. If this would be possible, then such estimated EFI-score could be used to triage patients with endometriosis-associated infertility to treatment with surgery or with ART (assisted reproductive technologies).

Study design, size, duration: Prospective single center cohort study on 82 patients, undergoing laparoscopic endometriosis surgery between June and December 2016. Although the study was exploratory, the sample size (minimum 71) was appropriate to confirm an agreement of minimally 95% between estimated and final EFI (one-sided test, alpha 0.05, beta 0.8). Two definitions were used for agreement: clinical (scores within the same EFI-score range: 0-4, 5-6, 7-10) and numerical agreement (maximally allowed difference of 1 EFI-point, irrespective of range).

Participants/materials, setting, methods: All patients underwent complete CO_2-laser-laparoscopic excision of any rASRM-stage endometriosis in a tertiary referral center. A coded clinical research file (CRF) consisted of 3 parts: type-A contained only pre-surgical information, type-B contained type-A information plus information of the diagnostic phase of laparoscopy, and type-C included all pre-, intra- and post-operative information. An algorithm was created to translate pre-surgical clinical/imaging information for EFI type-A calculation. Scoring was done by one person, with an appropriate time interval.

Main results and the role of chance: For the comparison between the estimated EFI type-A and the final EFI, the rate of agreement was high, with narrow

95% confidence intervals (CI): 91.5% (95%CI 83.2%-96.5%) for clinical agreement, and 87.8 (95%CI 78.7%-94.0%) for numerical agreement. For the comparison between estimated EFI type-B and the final EFI, agreement rates were even higher: 98.8% (95%CI 93.4%-100%) and 96.3% (95%CI 89.7%-99.2%) for clinical and numerical agreement respectively. Taken together, these results confirm that the final EFI-score (calculated after operative laparoscopy) can be accurately estimated by pre-operative non-surgical findings only (EFI type-A estimation), and the accuracy of estimation is increased when the information from the diagnostic phase of the laparoscopy was added to the pre-operative non-surgical findings (EFI type-B estimation). It is also noteworthy that estimation of the rASRM stage was far less accurate, especially when based on pre-operative non-surgical findings only (agreement between type-A and final rASRM stage 68.3% (95%CI 57.1%-78.1%) and type-B and final 90.2% (81.7%-95.7%).

Limitations, reasons for caution: Rating was done by one person, so it remains to be confirmed whether others can repeat the estimations with similar accuracy. The high quality of the ultrasound (and report) performed by experts - to calculate EFI-type-A –, may render implementation in general clinical practice outside endometriosis referral centers less feasible.

Wider implications of the findings: If other groups confirm our accurate pre-surgical estimation of the final EFI, this will revolutionize the possibilities of individualizing the management of endometriosis-associated infertility. Choice of first-line treatment with laparoscopic surgery or medically assisted reproduction could be based on the estimated EFI, while taking pain symptoms into account.

Trial registration number: Institutional study registration number: S59221.

O-143 The effect of different IVF protocols for women with endometriosis on their IVF outcomes: A Systematic review and Meta-Analysis

K.K. Lwin, M. Hamdan, S.Z. Omar

University of Malaya, Obstetrics and Gynaecology Department- Faculty of Medicine, Kuala Lumpur, Malaysia

Study question: What is optimal IVF protocol for women with endometriosis and the effects of different protocols on the outcomes of Live Birth (LBR), Clinical Pregnancy (CPR), oocyte retrieval (MOR) and miscarriage.

Summary answer: The ultra-long protocol should be the recommended protocol for women with endometriosis and/or endometrioma. The antagonist protocol has given non-inferiority effect to the protocol.

What is known already: Infertile women with endometriosis may require IVF/ICSI to conceive. Women with endometrioma during IVF treatment yield fewer oocytes during oocyte retrieval procedure despite requiring more stimulation drugs. It is also established that the embryos from women with endometriosis and/or endometrioma is poorer compared to women with no endometriosis, and the exact mechanism is still left unexplained. Various treatment strategies have been investigated to improve the outcomes. Several protocols are utilised including long protocol, ultra-long protocol and antagonist protocol intended to improve the IVF outcomes, but to date, a suitable protocol exclusive to women with endometrioma is yet to be found.

Study design, size, duration: This is a Meta-Analysis and systematic review. Electronic search through various Databases including Pubmed, ScienceDirect, OVID, Cochrane, Medline and Google Scholar was performed to search for both published and unpublished data.

Randomized Controlled Trials (RCT), cohort studies, retrospective studies as well as prospective studies from 1980 up to 2017 were reviewed.

Participants/materials, setting, methods: A total of 2667 papers were identified through electronic search and after screening, 15 studies were eligible to be included for data synthesis. The quality of each paper was assessed and scored according to Newcastle-Ottawa Assessment scale. All suitable data were extracted and analysed using Review Manager 5 software.

Main results and the role of chance: We retrieved 2667 articles looking into these protocols however after careful scrutiny we found several studies comparing ultralong vs. long protocol (n = 9), long vs. antagonist (n = 4) Short vs. antagonist (n = 1), ultralong vs. short agonists (n = 2). From the meta-analysed data, there are significantly higher CBR in women with ultralong protocol (OR CI 95% (1.23, 4.10) 853 cycles, 9 studies, I2 = 70%) as reported by the previous meta-analysis.

There was no significant difference in the miscarriage rate [OR CI 95% 1.19 (0.55,2.58) 361 cycles, 4 studies] and little difference in the meiosis II oocyte retrieval rate [OR CI 95% -0.30 (-0.48,-0.12)].

Limitations, reasons for caution: Due to the observational nature of the included studies, the result of this study is subjected to confounders relating to clinical heterogeneity.

The relatively small number of studies and sample population within each study may increase the risk of bias.

Wider implications of the findings: The ultra-long protocol is thought to render the endometrioma dormant, thus improving the chance of retrieving high-quality oocytes and embryos. However due to potential side effects, patients can be pretreated with Dienogest (Visanne) which has been proven to reduce symptoms and prevent recurrence, and may reduce the size of endometrioma.

Trial registration number: not applicable.

O-144 Nationwide cohort study of the risk of major adverse cerebrovascular and cardiovascular events in the Asian women with endometriosis

H.J. Chiang[1], K.C. Lan[1], Y.H. Yang[2], P.H. Sung[3]

[1]Kaohsiung Chang Gung Memorial Hospital- Kaohsiung- Taiwan, Department of Obstetrics and Gynecology, Kaohsiung, Taiwan R.O.C.
[2]Chang Gung Memorial Hospital- Chiayi- Taiwan, Department for Traditional Chinese Medicine- Health Information and Epidemiology Laboratory, Chiayi, Taiwan R.O.C.
[3]Kaohsiung Chang Gung Memorial Hospital- Kaohsiung- Taiwan, Division of Cardiology- Department of Internal Medicine, Kaohsiung, Taiwan R.O.C.

Study question: Based upon positive correlation of anti-mullerian hormone (AMH) to cardiovascular disease in recent studies, we investigated the association between endometriosis and major adverse cerebro-/cardio-vascular events (MACCE) in an Asian population.

Summary answer: The risk of MACCE including major CVD or CVA increases in the Asian women with endometriosis at reproductive age.

What is known already: Endometriosis has a negative impact on ovarian reserve. AMH, an ovarian reserve marker, declines with increasing cardiovascular risk in women.

Study design, size, duration: Taiwan National Health Insurance Research Database (NHIRD) was utilized to answer the question. A retrospective population-based cohort study was held through 1997 to 2013.

Participants/materials, setting, methods: A total of 17,543 patients with endometriosis and age between 18 and 50 years were identified from 1,000,000 general populations after excluding initially concomitant diagnoses of MACCE. The MACCE was defined as major cardiovascular disease and cerebrovascular accident. The comparison group (n = 70,172) without endometriosis was selected matching in a 1:4 ratio. We compared the demographic data, frequency of comorbidities, incidence of and risk of MACCE between the disease and non-disease groups.

Main results and the role of chance: With a median follow-up of 9.2 years, the endometriosis patients had significantly higher frequency and cumulative incidence of MACCE than non-endometriosis counterparts (2.76% vs. 2.18%, $p < 0.0001$). After adjusting with multivariate analysis, the patients with endometriosis had 1.17-fold greater risk for future development of MACCE (95% CI 1.05-1.29, $p = 0.0053$). In further, the adjusted hazard ratios of endometriosis for major CVD and CVA were 1.19 and 1.16, respectively (all $p < 0.04$). Apart from endometriosis, older age, lower urbanization level, hypertension and diabetes were identified as risk factors for MACCE occurrence as well.

Limitations, reasons for caution: This is a retrospective study to analyze the diagnosis of endometriosis and MACCE in a nationwide population data.

Further investigation will be needed to clarify the trajectories of serum AMH and associated incidence of MACCE in endometriosis patients.

Wider implications of the findings: Early awareness of deteriorating ovarian reserve via checking serum AMH is important to prevent following MACCE in endometriosis patients. Early interventions, such as surgery or medication, would be helpful to break the vicious circle among endometriosis, deteriorating ovarian reserve, and MACCE.

Trial registration number: not applicable.

International Committee for Monitoring Assisted Reproductive Technologies (ICMART) World Report on ART, 2014 and The International Glossary on Infertility and Fertility Care, 2017.

Study question: In 2014 what was global utilization, effectiveness and safety of ART, and what is status of The International Glossary on Infertility and Fertility Care, 2017.

Summary answer: Globally, ART utilization and data collection continue to increase but with wide variations in utilization, effectiveness and safety. The significantly expanded, revised Glossary was published.

What is known already: ICMART began ART global data collection in 1991. Utilization, effectiveness and safety have continuously improved with more cycles, higher pregnancy rates and lower multiple birth rates, the latter coupled with an increase of frozen embryo transfer (FET) cycles; however, wide variations exist globally. Over 7 million ART babies have been born. ICMART has helped develop African registries in association with the African Network and Registry for Assisted Reproductive Technology (ANARA). Data collection and quality remain challenging. The Glossary is an important document created through ICMART's leadership with a partnership of all the major global reproductive medicine organizations and other stakeholders.

Study design, size, duration: Countries and regions annually collect ART data, some prospectively and others retrospectively. ICMART retrospectively requested these data from all known global sources for 2014, analyzed them collaborating with Uppsala Clinical Research (UCR) at the University of Uppsala, Sweden, and presents preliminary results. The Glossary was created through a global partnership of major professional organizations and other stakeholders. ICMART's Data Collection System (DCS) first used for 2014 data represents years of collaboration between ICMART and UCR.

Participants/materials, setting, methods: The European IVF Monitoring Consortium (EIM), Society for Assisted Reproductive Technology (SART), Latin American Network of Assisted Reproduction (REDLARA), Australian/ New Zealand Registry, ANARA and other countries, totaling 70, contributed national data through standardized formats to the DCS. Data were reviewed, corrected, analyzed and summarized by ICMART working with UCR using standard statistics. ICMART led a partnership of international stakeholders who revised the ICMART/WHO 2009 Glossary. ICMART and UCR collaborated to create the ICMART DCS.

Main results and the role of chance: Data collection and analysis are ongoing. Preliminary results are presented at ESHRE. The number of ART cycles continues to increase, but utilization is still very influenced by affordable access to ART which is related to insurance or public funding. Regional differences persist in the age of the population treated, number of embryos transferred, rate of multiple births, and other factors.

The International Glossary on Infertility and Fertility Care, 2017, is significantly expanded and has revised many commonly used terms. The new ICMART DCS is functional.

The role of chance is minimal. Actual global ART results are limited to reporting countries and clinics representing approximately 2/3 of global cycles. However, this is a very large sample size from which imputation of total global results is performed. Many countries have limited data validation and ICMART can perform only minimal verification of submitted data.

Limitations, reasons for caution: Actual reported data represent 2/3 of total performed cycles. Data validation is not universal or standardized. Routine use of Glossary terms takes time and translation into multiple languages. The ICMART DCS needs to have its functionality continuously assessed and improved so that data quality can continue to expand and improve.

Wider implications of the findings: ICMART World Reports standardize data, track trends, enable comparisons, stimulate questions and improve ART quality. Better understanding of ART increases societal acceptance and support for ART research and clinical access. The International Glossary on Infertility and Fertility Care, 2017 represents a unique stakeholder partnership that harmonizes ART terminology globally.

O-147 Gender inequality and utilisation of assisted reproductive technology: an international analysis

G. Chambers[1], O. Fitzgerald[1], S. Dyer[2], F. Zegers-Hochschild[3], G.D. Adamson[4]

[1]University of New South Wales, National Perinatal Epidemiology and Statistics Unit, Sydney, Australia
[2]University of Cape Town, Department of Obstetrics & Gynecology- Groote Schuur Hospital and Faculty of Health Sciences, Cape Town, South Africa
[3]University Diego Portales, Program of Ethics and Public Policies in Human Reproduction- Clinica las Condes- Unit of Reproductive Medicine-, Santiago, Chile
[4]Fertility Physicians of Northern California, Palo Alto Medical Foundation, Palo Alto-California, U.S.A.

Study question: Is there an association between gender inequality and utilisation of assisted reproductive technology (ART) treatment globally?

Summary answer: Countries with less gender inequality have higher rates of ART utilisation, regardless of the country's level of economic and human development.

What is already known: ART utilisation varies enormously worldwide. Previous research has indicated that consumer affordability, access to clinics, and normative cultural acceptance are important factors in ART utilisation.

Study design, size, duration: A longitudinal cross-national analysis of ART utilisation in 69 countries, with the outcome defined as the total number of ART cycles per million population. The Gender Inequality Index (GII), Human Development Index (HDI), and Education Index (EI) developed by the United

Nations Development Programme (UNDP), were used as composites measures of gender inequality, human development and education respectively. Data is drawn from several sources (ICMART, UNDP, World Bank).

Participants/materials, setting, methods: Our sample includes data from 69 countries for the years 2002–2012. Following a descriptive graphical and bivariate correlation analysis, mixed and fixed effect regression methods served to establish the cross-sectional and longitudinal relationship between the predictor variables and the number of ART treatments per million population in a country.

Main results and the role of chance: A one standard deviation movement in the GII towards greater gender equality is associated with an increase in ART utilisation by a factor of 2.8 (95% CI: 1.5–5.2), when controlling for a country's level of economic and human development. There were differences in the strengths of association of different components of gender equality and human development with ART utilisation. Increases in a country's female parliamentary representation, level of male and female education and wealth had the strongest longitudinal relationships with ART utilisation. Preliminary findings indicate the following: an increase of 10% in female parliamentary representation saw a county's ART utilisation increase by a factor of 1.3 (95% CI: 1.1–1.6). A one standard-deviation increase in the EI (equivalent to 2.5 additional mean years of schooling) was associated with ART utilisation increasing by a factor of 1.9 (95% CI: 1.0–3.5). A one-unit increase in log gross national income per capita (2011 PPP US$) was associated with ART utilisation increasing by a factor of 2.6 (95% CI: 1.5–4.3).

Limitations, reasons for caution: Multiple imputation was used to impute missing covariate data for 13% of observations. Countries, predominantly in the Middle East and North Africa, with low ART clinic reporting rates were excluded from the analysis. As the analysis was cross-national, inferences to the individual level are not possible.

Wider implications of the findings: Access to infertility care is central to women's sexual and reproductive health, to women's rights, and to human rights. Our analysis demonstrates that as gender equality improves, so does utilisation of assisted reproductive technologies. Progress towards global, equitable access to infertility care can hence be expected with global improvement of women's status within societies.

Study funding/competing interest(s): None.

SESSION 39: NEW ASPECTS IN POLYCYSTIC OVARY SYNDROME

Tuesday 3 July 2018 Room 111 + 112 11:45–12:45

O-148 First line treatment in PCOS: what to do?

F. Van der Veen[1]

Academic Medical Centre, Centre for Reproductive Medicine, Amsterdam, The Netherlands

Abstract text

There are several guidelines on first line treatment in PCOS. The most relevant one's are the ESHRE/ASRM consensus, the NICE guideline and the WHO's global guideline which is under development. (1,2,3) The common denominator of these guidelines is that they all -broadly speaking- recommend lifestyle modification, followed by or combined with medical ovulation. With respect to the latter there are some variations: ESHRE/ASRM recommend Clomiphene Citrate (CC) as first line treatment, while NICE recommends CC, metformin or a combination of the two, while WHO advises CC or Letrozole. The explanation for these differences is probably the accumulation of evidence which has taken place in between the dates of publication of the various guidelines.

The evidence on the commonly used drugs has been summarized in conventional but authoritative Cochrane reviews, which provide the data on pairwise meta analysis. (4,5,6) On clomiphene citrate the evidence suggests that it improves the chance of a clinical pregnancy compared with placebo without any differences between different anti-oestrogens (low quality evidence) On aromatase inhibitors, specifically Letrozole, the evidence suggests that Letrozole improves live birth and pregnancy rates compared with CC. (low quality evidence) On insulin sensitisers, specifically metformin, the evidence is complex, but suggests that metformin alone may be beneficial over placebo for live birth, and that any superiority of metformin over CC and vice versa is inconclusive, although there may be interaction with body mass index. (very low to low quality evidence) Combined therapy with metformin and clomiphene citrate improved clinical pregnancy compared with clomiphene citrate alone it is at present unknown whether this translates into increased live births and gastrointestinal side effects are considerable (low to moderate quality evidence).

This traditional pairwise meta-analyses only allow the comparison of two interventions for ovulation induction. Since many of these medications have not been compared directly it is still not clear what the most effective treatment option would be. A recent network meta-analysis has studied all possible combinations and has provided interesting data, which can be summarized as follows: all interventions are effective, Letrozole improves live birthrate compared to CC. Combined therapy with CC and metformin is superior to CC and to metformin in terms of pregnancy rates.

The conclusion, taking all available evidence into account, is that at present letrozole and combined treatment with CC and metformin are the drugs of first choice.

O-149 Does race and ethnicity matter for metabolic risks in PCOS?

Norman RJ[1], **Moran L**[2], **Teede H**[2]

[1]*Robinson Research Institute and Fertility SA, University of Adelaide SA 5005.*
[2]*MCHRI, Monash University, Clayton VIC 3800.*

Abstract Text

The phenotypic appearance of polycystic ovary syndrome (PCOS) varies across geography, ethnicity and race. The genotypic variation is not as marked comparing Asian and Caucasian populations, suggesting that environmental factors may play a major role in the presentation of PCOS.

Over the past few decades, it has been recognised that hyperinsulinism, insulin resistance, diabetes mellitus and hyperlipdemias are more common in people with PCOS when compared to controls of the same body mass index. Early studies indicated marked differences in metabolic profiles between immigrants in their recently arrived country, people of the same ethnicity who remained in their original country and other population groups of different races.

Significant differences are found in the metabolism in PCOS between Hispanics, African Americans and those of European decent in North America.

These have been compared with Europeans residing in Europe with the same ethnic background. There are also marked differences between Asians, depending on whether they are East Asian or South Western Asian, with major discrepancies in body mass index, diabetes mellitus and insulin resistance.

Recent studies in the Indigenous Australian population have shown the marked change that diet and lifestyle has induced over the past thirty years as people moved from a high exercise and traditional diet lifestyle to more western food and sedentary practices.

The increasing recognition of metabolic dysfunction in patients with PCOS makes the diagnosis, investigation and management of the condition even more important, affirming the importance of international guidelines for PCOS. Awareness of individual group risks will also lead to superior treatment for metabolic and fertility dysfunction.

INVITED SESSION

SESSION 40: ERRORS IN IVF: DO THEY OCCUR AND HOW MANY?

Tuesday 3 July 2018 Room 113 + 114 + 115 11:45–12:45

O-150 To err is human: even in IVF

D. De Ziegler[1], P. Pirtea[2], M. Poulain[3], R. Fanchin[3], J.M. Ayoubi[3]

[1]*Hopital Foch - Universite Paris Ouest, Obstetrics and Gynaecology, Suresnes, France*
[2]*Foch Medical Center - University de Paris Ouest, Obstetrics and Gynecology, Suresnes, France*
[3]*Foch Medical Center - University Paris Ouest, Obstetrics and Gynecology, Suresnes, France*

The seminal publication of Kohn et al. (To Err is Human: Building a Safer Health System. Kohn LT, Corrigan JM, Donaldson MS, editors. Washington (DC): National Academies Press (US); 2000.), has made us aware of the fact that safety systems need to acknowledge that we, humans, make and will continue to make mistakes. IVF is no exception. Considering that IVF is performed in basically healthy people, avoiding errors of possible catastrophic consequences is of paramount importance.

The first step for minimizing the consequences of our errors is to understand the context in which they occur. Two distinct factors that define this context need to be clearly apprehended. First, there are the existing hazards, which are potential sources danger inherent to any procedure. In mountain climbing for example, one typical hazard is height. Second, there are the prevailing risks which are defined as the possibility that something unpleasant happens – an adverse event. Risks are inherently affected by existing hazards. In our mountain climbing example, slipping on top of a mountain can obviously have more dreadful consequences than if the same happens in low land. While hazards cannot be altered – height is inherently linked to mountains – risks can be mitigated. In mountain climbing, roping will prevent the possibility of dreadful consequences from slipping. In medicine – in ART in particular – we need to develop safety systems that adequately prevent adverse events from occurring in spite of the hazards and risk existing and errors occurring.

For being effective, safety systems imply an in-depth knowledge and understanding of the existing risks and possible consequences or adverse events. For this, we commonly plot adverse events emanating from prevailing risks on a frequency vs. severity diagram. Certain minor adverse events are frequent and of menial consequences, which can be considered as acceptable. Other adverse events may have serious – possibly fatal – consequences and are therefore unacceptable. Only a proper understanding of the dynamic of each risk can permit to develop and efficient risk averting system.

In order to avert adverse events from occurring as a result existing risks, one needs to develop protective measures or defenses. The choice of defenses must result from a careful assessment of the risks existing and root cause analyses of the possible adverse events that can emanate from these risks. Improper and poorly designed and/or too-complex defenses that impede proper functioning will not properly avert risks and may actually constitute a risk factor of its own. One should beware of the too often encountered 'let's write another procedure attitude' instead of conducting a proper root cause analysis of any encountered adverse event.

Accepting that errors are made is a crucial step in the design of any safe operation, and ART is no exception. A safety system that acknowledges that it is human to err – in IVF included – will bank on enacting a no-blame safety culture that integrates and share incident reports for averting the occurrence of more severe adverse events. Return on experience of 'near misses' in a positive no-blame culture is a crucial step for enacting safety systems that correct procedure based on minor deviations before these result in catastrophes when left unheeded.

O-151 This is how many errors occur in the IVF lab: a true analysis

M. J. De Los Santos

IVI Valencia, IVF Laboratory, Valencia, Spain

In ART as in the rest of areas of application of tissues and cells there are situations that may trigger the incidence of adverse reactions (harm to a donor, harm to a recipient, harm to a foetus or offspring) and adverse events (risk of harm despite no harm actually occur).

Many IVF laboratories are very complex in terms of not only the technology and equipment being used but in the introduction of overprocesses adding many steps during procurement, processing and distribution. These and other factors, all contribute in creating the perfect culture media facilitating the errors to happen, and despite hazards can be prevented from causing serious unwanted effect by the implementation of barriers, incidents still may occurs due to the inadvertent weakness of each barrier.

This talk focuses on identifying the steps where errors may take place, analyzing the root causes in the IVF laboratory and how implement tools to measure the error rate, decrease it and control it.

There are different strategic policies for risk management that help in assessing and prioritizing the possible existing hazards, so the probability of an adverse event occurring will be kept to a minimum. Strategies such as "Failure mode, effects and critical analysis" (FMECA) are very useful of tools in ART. Such approaches help to create lists of relevant steps or processes under risk, make an estimation of any identified hazard to happen based on the severity of the error, its frequency as well as its probability of detection. All together will create a risk priority index which helps in ranking the risks and prioritize the actions to take.

As some of the causes leading to error in the IVF laboratory are due to human mistakes, the reasons of human errors will be also addressed. Among the factors to blame on, are: complexity of the activity, lack of education and training, perception that the procedures were not appropriate or efficient or just lack of attention to well-defined procedures. A list of key factors that facilitate the incidence of human errors has been compiled by Toft and coworkers. Some of them can be conscious automaticity, involuntary automaticity, ambiguous accountability and stress. All of them are considered especially relevant when considering aspect in IVF related to loosing traceability leading to sample

mismatch that are undesirable reaction that can occur in an IVF laboratory with important consequences for both patients and healthcare professionals.

SESSION 41: FOCUS ON BLASTOCYST STAGE
Tuesday 3 July 2018 Room 117 11:45–12:45

O-152 Predicting blastocyst formation rate using a hierarchical and data mining-based statistical model

J. Yao Serna[1], R. Milewski[2], D. Bodri[1], T. Sugimoto[1], R. Kato[1], T. Matsumoto[1], S. Kawachiya[1]

[1]Kobe Motomachi Yume Clinic, Assisted Reproduction, Kobe, Japan
[2]Medical University of Bialystok, Department of Statistics and Medical Informatics, Bialystok, Poland

Study question: Is it possible to establish equally efficient predictive algorithms for blastocyst (BT) formation using two different statistical methodologies?

Summary answer: Combining several cleavage-stage morphokinetic variables through data mining-based statistical algorithm achieved higher predictive power than the hierarchical model which included only the two strongest predictors.

What is known already: In recent years increasing number of time-lapse monitoring (TLM) studies focused on finding morphokinetic variables that could be predictors of blastocyst formation, successfully identifying several (early) cleavage-stage variables that were consistently associated with it. However, only a recent study (Motato et al, 2016) has managed to establish a four-category hierarchical score (including tM=time to morula and s3=t8-t5) predicting blastocyst development which showed a good discrimination ability (AUC: 0.849). It is arguable however, whether including tM is really useful if a blastocyst prediction model would be used in a clinical setting to select day-3 embryos for prolonged culture.

Study design, size, duration: All consecutive infertile patients from a single centre whose cleavage-stage embryos were submitted to prolonged culture (n = 1133) in a TLM incubator (EmbryoScope, Vitrolife) between 2012 and 2014 were included in this retrospective analysis. Patients (38.2 ± 3.9 years) underwent minimal ovarian stimulation, prolonged embryo culture and elective vitrification of expanded blastocysts. Cleavage-stage, static (tPNf, t2-t8), and interval morphokinetic parameters (cc2a-b, s2-3) were scored according to recently published consensus criteria and standardized to time of pronuclear fading (tPNf).

Participants/materials, setting, methods: A first, hierarchical model - including the two strongest BT formation predictors selected by multivariate analysis - and a second, more robust one - based on combination of principal component analysis (PCA) and logistic regression methods - were created. The PCA technique is a data-mining method that relies on transformation of an initial correlated set of features into new uncorrelated variables called principal components. For both models the area-under-the-curve values (AUC) with 95%CI were calculated.

Main results and the role of chance: The average rate of expanded blastocyst formation was 44% (501/1133). The examination of detailed histograms revealed that areas with a high, medium and low BT formation rates existed for all, eleven cleavage-stage morphokinetic variables thus permitting their conversion from continuous (hours) to categorical ones. Following multivariate analysis combining the two strongest morphokinetic predictors (t2 and s3) resulted in a simple, five-category (from 'E" to 'A") hierarchical model, representing 9, 15, 23, 34, and 19% of the entire cohort of cultured embryos, respectively. The model effectively distinguished between embryos of increasing BT development potential (18, 22, 40, 60 and 70% from category 'E" through 'A", $p < 0.0001$). For the second model quartiles of the created Sc parameter (Q1-Q4) had increasing BT formation rates (Q1: 14%, 'Q2": 39%, 'Q3": 61%, 'Q4": 81%, $p < 0.0001$). The AUC value of the data mining-based model was significantly higher compared to the hierarchical one (0.794, 95CI%: 0.77-0.82 versus 0.702, 95CI%: 0.67-0.73).

Limitations, reasons for caution: Our unselected cohort was biased towards advanced-aged, poor-prognosis patients undergoing mild IVF treatment coupled with single vitrified-warmed blastocyst transfer. This might limit generalizability to other less infertile populations or to centres that use different treatment protocols.

Wider implications of the findings: Both models were similarly successful in stratifying cleavage-stage embryos of different BT formation potential and could be further tested in everyday clinical practice. However, the more robust PCA-based methodology originally was developed in a fundamentally different setting from ours with similarly high predictive capabilities (Milewski, 2015) suggesting wider between-center applicability.

Trial registration number: not applicable.

O-153 Blastocyst morphology grading: what is the most important predictor of live birth when accounting for endometrial receptivity? A multicentre analysis of 2477 single blastocyst transfers

A. Storr[1], E. Bilir[2], S. Cooke[3], D. Garrett[4], C. Venetis[5]

[1]Flinders Fertility, Embryology, Adelaide, Australia
[2]Koç University, School of Medicine, Istanbul, Turkey
[3]IVFAustralia, Embryology, Sydney, Australia
[4]IVFAustralia, Work Health & Safety, Sydney, Australia
[5]University of New South Wales, School of Women and Children's Health, Sydney, Australia

Study question: What is the most important embryo morphology parameter associated with live birth (LB) rate after controlling for female age and endometrial receptivity?

Summary answer: Developmental stage (DevSt) of an embryo, followed by trophectoderm (TE) grading are the most important morphology parameters independently associated with LB rate.

What is known already: It is well known that transferring better quality embryos results in a higher chance of achieving a pregnancy. The move towards single blastocyst transfers (SBT) has placed more importance on the ability to select an embryo with the highest implantation potential, yet it remains unclear which morphology parameters should be prioritised. Previous studies investigating the impact of embryo morphology parameters on pregnancy outcome in SBT cycles have shown conflicting results. Most importantly, none of these studies have controlled for differences in endometrial receptivity, which plays a critical role in the establishment of a successful pregnancy and is a major confounder.

Study design, size, duration: This was a retrospective study (n = 2477 fresh SBTs from 2183 couples) of cycles performed between January 2012 and April 2015 at three different clinics. The embryo morphology parameters that were assessed on day of embryo transfer (day 5/6) by experienced embryologists included DevSt (morula (M), early blastocyst (EB), full blastocyst (BL), expanded blastocyst (XBL), hatching blastocyst (HgBL)), inner cell mass (ICM: A, B, C) and TE (A, B, C).

Participants/materials, setting, methods: Fresh IVF/ICSI SBT cycles where the value of serum progesterone on the day of human chorionic gonadotrophin (P4dhCG) was available were included. P4dhCG was used as it is considered one of the best markers of endometrial receptivity after ovarian stimulation. Generalized estimating equation regression models were used to evaluate the independent effect of DevSt, ICM grade and TE grade on LB rates, while controlling for female age, P4dhCG and the non-independence of data.

Main results and the role of chance: The mean age of the population was 36.0 years (95% CI: 35.8-36.2) and the mean P4dhCG was 2.95 (95% CI: 2.89-3.00). In most cycles XBL (27.5%) were transferred, followed by BL (22.2%) and HgBL (14.2%). DevStage was strongly associated with the probability of live birth ($p < 0.001$) independently of female age (OR: 0.92, 95% CI: 0.90-0.94) and P4dhCG (OR: 0.80, 95% CI: 0.74-0.87), both of which were also strong predictors of LB. The predicted LB according to the DevStage was a) M: 5.3% b) EB: 13.5% c) BL: 22.8% d) XBL: 31.1% e) HgBL: 35.2%. In BL, XBL and HgBL, the addition of ICM and TE grading in the multivariable analysis suggested that besides female age (OR: 0.92, 95% CI: 0.90-0.94) and P4dhCG (OR: 0.80, 95% CI: 0.73-0.88), only DevStage ($p = 0.003$) and TE quality ($p = 0.020$) were independent predictors of LB while the predictive capacity of ICM was no longer significant ($p = 0.296$). The mean probability of LB was higher for AA

embryos (34.8%, 95% CI: 31.6-38.0), followed by BA embryos (30.3%, 95% CI: 25.1-35.6), AB embryos (27.9%, 95% CI: 23.7-32.1) and BB embryos (23.9%, 95% CI: 19.3-28.6). This order of implantation potential persisted regardless of developmental stage (BL vs XBL vs HgBL).

Limitations, reasons for caution: This study is limited by its retrospective nature as well as the subjective nature of embryo scoring. Furthermore, limited numbers of embryos with poor quality ICM or TE (C grade) were transferred and hence the estimates around their predictive role are not as robust.

Wider implications of the findings: This is a large study analysing for the first time the independent role of blastocyst morphology in predicting LB after SBTs while controlling for both female age and P4dhCG. Its findings suggest that DevStage and then TE grade should be prioritised over ICM grade when selecting an embryo for transfer.

Trial registration number: N/A.

O-154 Predicting live birth by combining cleavage- and blastocyst-stage time-lapse variables using a hierarchical and a data mining-based statistical model

S. Kawachiya[1], D. Bodri[1], R. Milewski[2], T. Sugimoto[1], J. Yao Serna[1], M. Kondo[1], T. Matsumoto[1]

[1]Kobe Motomachi Yume Clinic, Assisted Reproduction Unit, Kobe, Japan
[2]Medical University of Bialystok, Department of Statistics and Medical Informatics, Bialystok, Poland

Study question: Is it possible to establish highly predictive algorithms for live birth (LB) by combining cleavage- and blastocyst-stage morphokinetic variables using two different, robust statistical models?

Summary answer: The combination of cleavage- and blastocyst-stage morphokinetic variables through hierarchical or data mining-based statistical algorithms could be successfully used to predict live birth.

What is known already: Most of published predictive algorithms focused on cleavage-stage morphokinetic variables only, despite the fact the prolonged embryo culture is increasingly used as a way of improving pregnancy rates, especially in the context of single embryo transfer. So far, only a handful of studies examined the relation between implantation potential and blastocyst-stage morphokinetic parameters (Kirkegaard 2013, Campbell 2013, Motato 2016). Despite these efforts time-lapse parameters extracted from later stages of embryo development (morula, early and expanded blastocyst) are still under investigation, although it was suggested that adding these variables to existing cleavage-stage models could significantly improve their predictive potential.

Study design, size, duration: All 326 single blastocyst transfers (SBT) from all consecutive patients whose embryos were submitted to time-lapse monitoring (TLM) between 2012 and 2014 were retrospectively analysed. Patients (38.2 ± 3.9 years) underwent minimal ovarian stimulation, prolonged embryo culture in TLM incubator, elective vitrification and vitrified-warmed SBT. All pregnancies were followed-up until live birth. Early (PNf, t2-t9), late (tM, tearlyB, tfullB, texpB_{1-2}) and interval morphokinetic parameters (cc2a-b, s2-3) were scored according to published consensus criteria and standardized to tPNf.

Participants/materials, setting, methods: A first, hierarchical model - including the two strongest LB predictors (t2 and texpB_2) - and a second, more robust one - based on combination of principal component analysis (PCA) and logistic regression methods - were created. The PCA technique is a data-mining method that relies on transformation of an initial correlated set of features into new uncorrelated variables called principal components. For both models the area-under-the-curve values (AUC) with 95% confidence intervals were calculated.

Main results and the role of chance: The overall LB rate per SBT was 30% (97/326). The examination of detailed histograms revealed that areas with a significantly higher proportion of LBs ('optimal LB ranges") existed for six cleavage-stage (t2, t3, t4, t6, cc2a, and cc2b) and four blastocyst-stage variables (tearlyB, tBfull, texpB_1 and texpB_2) thus permitting the conversion of these morphokinetic variables from continuous (hours) to categorical ones. Combining two of the strongest variables (t2 and texpB_2) resulted in a simple, four-category ('A" to 'D") hierarchical model. The model effectively distinguished between blastocysts with increasing live birth potential (categories 'D": 9%, 'C": 27%, 'B": 39%, 'A": 54%, $p < 0.0001$). For the second model quartiles of the created Sc parameter (Q1-Q4) had increasing LB rates (Q1: 9%, 'Q2": 15%, 'Q3": 34%, 'Q4": 42%, $p < 0.0001$). AUC values for both models were equally high (0.722, 95CI%: 0.66-0.78 versus 0.723, 95CI%: 0.67-0.78 for the data mining-based and hierarchical models, respectively).

Limitations, reasons for caution: Our unselected patient cohort was biased towards advanced-aged, poor-prognosis patients who undergone mild IVF treatment coupled with single vitrified-warmed blastocyst transfer exclusively. This might limit generalizability to other less infertile populations or to centres which use different treatment protocols.

Wider implications of the findings: Although we have created two different statistical models their predictive power was similar and higher than most previously published algorithms. The more robust, PCA-based model was originally developed in a fundamentally different setting from ours, yet its predictive power was similarly high in both datasets suggesting a wider, between-center applicability.

Trial registration number: not applicable.

O-155 Day 5 versus Day 6 fresh and frozen blastocyst transfer cycle outcomes: a systematic review and meta-analysis

A. Finet[1], M. Bourdon[2], V. Grzegorczyk-Martin[1], M. Poulain[3], A. Amar-Hoffet[4], E. Arbo[5], K. Pocate-Cheriet[6], P. Santulli[2]

[6]Université Paris Descartes- Sorbonne Paris Cité- Faculté de Médecine- Assistance Publique – Hôpitaux de Paris AP-HP- Hôpital Universitaire Paris Centre HUPC- Centre Hospitalier Universitaire CHU Cochin, Department of Reproductive Biology, Paris, France

Study question: Is there a difference in clinical pregnancy and live birth rates between day 5 and day 6 blastocysts following fresh and frozen transfers?

Summary answer: Day 5 (D5) blastocyst transfers present higher clinical pregnancy and live birth rates than day 6 (D6) in both fresh and frozen transfers.

What is known already: Blastocyst transfer (BT) is increasingly popular in assisted reproductive technology (ART) centers today. Numerous studies described conflicting results in clinical outcomes following D5 and D6 BT. To our knowledge, no meta-analysis has focused on clinical outcomes in both fresh and frozen BT. Concerning frozen blastocysts, one meta-analysis found no significant difference in pregnancy outcomes between D5 and D6 blastocysts (Sunkara *et al.*, 2010). Yet since 2010, more articles comparing D5 and D6 frozen embryo transfer cycles have been published, and ART practices have evolved particularly with the wide use of vitrification.

Study design, size, duration: Systematic review and meta-analysis of published controlled studies. Searches were conducted on MEDLINE, EMBASE, Cochrane Library, Eudract and clinicaltrials.gov from 2005 to May 2017 using the following search terms: Blastocyst; Day 5; Day 6; Pregnancy; Implantation; live birth; embryo transfer.

Participants/materials, setting, methods: Forty-seven full-text articles were preselected from 808 references, based on title and abstract and assessed utilizing the Newcastle-Ottowa Quality Assessment Scales. Study selection and data extraction were carried out by 2 independent reviewers according to Cochrane methods. Random-effect meta-analysis was performed using Review Manager software on all data (overall analysis) followed by subgroup analysis (fresh, vitrified/warmed, slow frozen/thawed). Risk ratio (RR) and 95% confidence interval (CI) were estimated using Mantel-Haenszel method. Sensitivity analyses were performed.

Main results and the role of chance: Data from 28 relevant articles were extracted and integrated in the meta-analysis totaling 12,932 transfers involving fresh and frozen D5 or D6 embryos. Meta-analysis of all transfers showed overall significantly higher clinical pregnancy rates (CPR) following D5 BT (overall RR = 1.26, 95% CI:1.14-1.40, $p < 0.001$), and remained unchanged after adjustment for subgroups (RR = 1.27, 95% CI:1.15-1.40).

For CPR, calculated subgroup RRs were: 2.29, 95% CI:1.69-3.09, $p < 0.001$ for fresh BT; 1.27, 95% CI:1.16-1.40, $p < 0.001$ for vitrified/warmed BT and 1.15, 95% CI: 0.93-1.41, p = 0.2 for slow frozen/thawed BT.

Live birth rate (LBR) was also significantly higher after D5 BT (overall RR = 1.46, 95% CI:1.25-1.70, $p < 0.001$), and remained unchanged after adjustment for subgroups. The LBR calculated RRs for subgroups were: 1.65, 95% CI:1.23-2.21, $p < 0.001$ for fresh BT; 1.37, 95% CI:1.19-1.59, $p < 0.001$ for vitrified/warmed BT and 1.44, 95% CI: 0.70-2.96, p = 0.32 for slow frozen/thawed BT.

Sensitivity analysis led to similar results and conclusions: CPR and LBR were significantly higher following D5 compared to D6 BT.

Limitations, reasons for caution: The validity of meta-analysis results depends mainly on the quality and the number of the published studies available. Indeed, this meta-analysis included no randomized controlled trial (RCT). Slow frozen/thawed subgroups showed substantial heterogeneity.

Wider implications of the findings: In regards to results of this original meta-analysis, ART practitioners should preferably transfer D5 rather than D6 blastocysts in both fresh and frozen cycles. Further RCTs are needed to address the question of whether D6 embryos should be transferred in a fresh or a frozen cycle.

Trial registration number: Prospero CRD42018080151

SELECTED ORAL COMMUNICATIONS
SESSION 42: NURSING AND MIDWIFERY
Tuesday 3 July 2018 Room 116 11:45–12:45

O-156 Facilitators and barriers affecting help seeking of infertile women in the United States: A systematic review

M. Cebert

Duke University, Duke University School of Nursing, Durham, U.S.A.

Study question: What are facilitators and barriers contributing to help seeking behaviors in women who experience infertility?

Summary answer: After conducting a systematic review, the literature does not provide a clear understanding of facilitators and barriers due to limitations in study designs.

What is known already: In the United States it is estimated that 7.4 million women in childbearing ages 15-44 have used some type of infertility services for family building, however this value may not reflect all women who experience infertility. It is estimated that upwards to 50% of women who meet criteria for infertility do not seek treatment.

Study design, size, duration: A systematic review was conducted and reported using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guide.

Participants/materials, setting, methods: A systematic review of studies published between 2000 and 2017 was undertaken using the following databases: PubMed, SocIndex, CINAHL, PsychInfo, ScienceDirect, and Google Scholar. Primary search terms were infertility, subfertility, female, patient acceptance of health care, help-seeking, health seeking, fertility awareness, social support, culture, and treatment-seeking behaviors. The studies were organized using the matrix method and critiqued using Chrisman's Health Seeking Model.

Main results and the role of chance: A total of 12 articles examined facilitators and barriers that contributed to help seeking behaviors in women who experienced infertility. In studies that reported race/ethnicity, samples were majority Caucasian American women. Nearly half of the studies were secondary analyses of self-reported data from national surveys. There were 29 unique measurement tools used among the articles. Positive help seeking facilitators were perceived symptom salience, positive self-esteem, life satisfaction, and increased importance of parenthood, and fertility awareness. The most noted barrier was lifetime diagnosis of depression and depressive symptoms. Findings from these studies suggest there are multi-factorial barriers and facilitators for help seeking. There were inconsistencies in reporting common demographic factors especially race and ethnicity. A more uniform tool is needed to comprehensively assess mediating factors affecting help seeking.

Limitations, reasons for caution: Search, abstraction, and analysis were all conducted by one author. Varying use of help seeking, treatment seeking, and health seeking may have limited results. However, all 12 studies are highly reflective of the main aim of this review to understand the facilitators and barriers of women who sought fertility treatment.

Wider implications of the findings: Further exploration is needed to understand these factors in other ethnicities. The use of theoretically guided frameworks of help seeking may limit variations in measurement tool selection. More understanding could lead to practice guidelines that encourage facilitators and remove barriers to allow earlier and more consistent access to available care.

Trial registration number: not applicable.

O-157 A feasibility and acceptability study of a novel self-help coping intervention for recurrent miscarriage

S. Bailey[1], C. Bailey[2], E. Kitson-Reynolds[3], Y. Cheong[4], J. Boivin[5], N. Macklon[6]

[1]*University Hospitals Southampton NHS Foundation Trust, Women and Newborn, Southampton, United Kingdom*
[2]*University of Nottingham, Faculty of Health Sciences, Nottingham, United Kingdom*
[3]*University of Southampton, Faculty of Health Sciences, Southampton, United Kingdom*
[4]*University of Southampton, Human Development and Health- Faculty of Medicine, Southampton, United Kingdom*
[5]*University of Cardiff, School of Psychology, Cardiff, United Kingdom*
[6]*London Women's Clinic, London Women's Clinic, London, United Kingdom*

Study question: Is a multi-centre RCT to test the effectiveness of the Positive Reappraisal Coping Intervention (PRCI) in women who have experienced recurrent miscarriage, viable?

Summary answer: Feasibility findings ascertained that study design was successful, there was a sizeable population willing to participate who engaged with the intervention and found it acceptable.

What is known already: The early waiting period of a new pregnancy following recurrent miscarriage (RM) is associated with high levels of uncertainty and anxiety for the affected woman, yet there is limited support available and many women are left to cope alone with managing these distressing emotions. The PRCI, a self-administered supportive technique is effective at promoting positive feelings and sustaining ability to cope in fertility patients awaiting the outcome of in vitro fertilisation and seen as helpful in the first three weeks of pregnancy following RM, suggesting the PRCI benefits could be sustained for the waiting period before the twelve week scan.

Study design, size, duration: A two-centre RCT feasibility study established the viability of conducting a multi-centre definitive RCT to test the hypothesis that the PRCI can improve psychological wellbeing of women during the initial experience of pregnancy following recurrent miscarriage. Nested within the RCT was a qualitative process evaluation that explored participant's subjective experience of study methods and the intervention.

Recruitment (n = 75 feasibility RCT, n = 14 qualitative process evaluation) took place over a two-year period.

Participants/materials, setting, methods: Participants were recruited from Recurrent Miscarriage Clinics in two major hospitals in the United Kingdom.

Participants were randomised, received the intervention and weekly questionnaires to assess psychological wellbeing up until twelve weeks of pregnancy, or to simply complete the same weekly questionnaires. Descriptive statistics

explored the feasibility of study procedures and were utilised to make an informal assessment of any impact of the intervention.

Study participants accepted an invitation to participate in qualitative process evaluation.

Main results and the role of chance: This study successfully gathered knowledge about the feasibility aspects of conducting a future multi-centre definitive study to determine the effects of the PRCI on the psychological well-being of women with RM during the challenging waiting period of a new pregnancy.

Main themes identified included:

- The components of the protocol worked well together.
- There was a sizeable and appropriate population willing to participate in the study.
- Participants engaged with the PRCI and found it an acceptable intervention to use.
- The PRCI appeared to convey benefits to participants with an indication anxiety levels were lower in intervention group.

Results showed that an effectiveness RCT of the PRCI is possible but with modifications to take in to account some specific issues. These included the need to:

- Introduce strategies to ensure more robust estimates of potential participants in study sites.
- Pay careful consideration to potential barriers and facilitators to recruitment.
- Introduce additional measures to aid monitoring of use of the intervention.
- Introduce additional measurements of coping.
- Address the reactivity to one of the study questionnaires.

Importantly, study data provided conclusive evidence of the need for an intervention such as the PRCI to address the psychological needs of women during this time.

Limitations, reasons for caution: While every effort was made to support the recruitment of a diverse sample to the feasibility study, the UK setting may limit extrapolation to other national and cultural contexts.

Wider implications of the findings: If a future, definitive study of the PRCI proves it to be an effective intervention, then this model of care has the potential to be made more widely available as a safe, low cost, convenient and easily deliverable intervention to provide much needed support to a vulnerable patient group.

Trial registration number: This study is funded by the National Institute of Health Research, UK (Award reference number CDRF-2012-03-004).

It is registered with the ISCTRN registry, registration number: ISRCTN43571276

O-158 A retrospective observational study to compare the success rate of embryo transfer between Doctors and Nurse Practitioners in a nurse-led fertility centre

J. Mutch[1], A. Drakeley[1], R. Gregoire[1], R. Wheeler[1], L. Briscoe[2]

[1]*Liverpool Women's Hospital, Hewitt Fertility Centre, Liverpool, United Kingdom*
[2]*Edge Hill University, Health and social care, Lancashire, United Kingdom*

Study question: Is the success rate of embryo transfer between Doctors and Nurse Practitioners comparable?

Summary answer: The rate of success of embryo transfer was significantly better from the Nurse Practitioner group, indicating that professional role does have an impact on success.

What is known already: The number of embryos transferred in the UK in 2015 was 85,134 and according to HFEA data the average clinical pregnancy rate in the same year for a couple undergoing IVF/ICSI using the woman's own eggs was 31%. In the North West of England alone, 3979 embryo transfers took place in 6 different centres between July 2015 and June 2016, resulting in a clinical pregnancy rate ranging from 13-36%. Due to the variation in treatment outcomes between UK centres and the fact that there are very few nurse-led fertility units, it was important to identify if professional role influences success.

Study design, size, duration: This was a retrospective observational study based on data collected between 1st October 2015 and 31st October 2017 (25 months). Data were collected from 5,182 embryo transfers facilitated by 11 nurses and 14 doctors. The study focused around couples undergoing IVF/ICSI using the woman's own eggs and excluded fertility preservation, PGS, egg sharing, surrogacy and donated gamete or embryo cycles.

Participants/materials, setting, methods: The study focused on the results per embryo transfer of 11 nurses with experience ranging from 6 months to 12 years and 14 doctors with experience ranging from 6 months to 16 years, working within a large NHS fertility centre in the UK. The data were collected from the electronic fertility database (IDEAS). Outcomes were measured for IVF/ICSI cycles using the woman's own eggs by positive pregnancy test and clinical pregnancy rate.

Main results and the role of chance: The cumulative success rates for positive pregnancy determination test (PPDT) and clinical pregnancy (CPR) within the nursing group were PPDT 48.93%, CPR 37.23% respectively, and within the doctors group were PPDT 43.24%, CPR 31.35% respectively. The nurse practitioner group were significantly better in both categories ($P = 0.001/0.001$ respectively). The significant difference in PPDT and CPR following embryo transfer by a Nurse Practitioner as compared with a doctor from these data was achieved from a large number of cycles (>5000), indicating that the higher PPDT and CPR achieved following transfer with a Nurse Practitioner were not chance findings.

These findings conclude that success rates following embryo transfer by Nurse Practitioners are not only comparable but significantly improved on those achieved by their medical colleagues, demonstrating that Nurse Practitioners can positively and significantly influence success. Experienced nurses can be trained and with sufficient exposure to embryo transfers can become an essential part of a successful fertility team. Fertility healthcare providers may wish to consider the findings of this study when planning future workforce requirements as the use of Nurse Practitioners can provide a sustainable and cost effective option to a medically dominated service in which experienced fertility doctors are often in short supply.

Limitations, reasons for caution: Quality of embryos was not included in this data analysis.

Quality of the endometrial environment was not assessed.

Frozen versus fresh embryo transfer was not measured.

Number of embryo transfers per practitioner varied.

The degree of difficulty of individual cases was not taken into consideration.

Wider implications of the findings: Nurses can be trained to successfully transfer embryos.

Trained nurses performing embryo transfer can positively influence the chance of a successful pregnancy. A larger scale, matched cohort study would help to measure the cost/benefit and help to identify if this model should underpin workforce development.

Trial registration number: N/A.

O-159 The importance of a genetic link between siblings after oocyte donation

S. Somers[1], V. Provoost[2], H. Van Parys[3], I. Stuyver[1], A. Buysse[3], G. Pennings[2], P. De Sutter[1]

[1]*Ghent University Hospital, Department of Reproductive Medicine, Gent, Belgium*
[2]*Ghent University, Bioethics Institute Ghent - BIG. Department of Philosophy and Moral Sciences, Gent, Belgium*
[3]*Ghent University, Department of Experimental-Clinical and Health Psychology, Gent, Belgium*

Study question: How do (aspiring) parents perceive and experience the importance of a genetic link between siblings born after oocyte donation?

Summary answer: Because other factors co-determined the fulfilment of the child wish, being able to use the same donor over time was less prominent throughout the interviews.

What is known already: In case of sperm donation, we know that the opportunity to use the same donor for subsequent conceptions seems important for (aspiring) parents (Somers et al., in preparation). In case of oocyte donation, we see at the clinic that couples starting treatment focus

less on this topic. Scarce literature is available on the importance of a genetic link between siblings after oocyte donation (Stuart-Smith et al., 2012). The strength of this study is that we carried out couple interviews instead of individual interviews and that we address both anonymous and known oocyte donation.

Study design, size, duration: For this study, 19 heterosexual couples were recruited at the Department of Reproductive Medicine of a University Hospital. They consented for an in-depth, semi-structured couple interview. One couple was interviewed separately, for two couples only the woman participated. The interviews were conducted between June 2013 and May 2014. Data were analysed through step-by-step inductive thematic analysis. Approval of the clinic's Ethics Committee was obtained.

Participants/materials, setting, methods: 6 couples became parents after known sister-to-sister oocyte donation and 8 couples opted for anonymous oocyte donation. Nine of them gave birth to one child or twins, 3 couples had consecutive children from a different donor and 2 couples had children from the same donor. We also included aspiring parents (5 couples) who were either already in treatment with anonymous oocyte donation or about to start.

Main results and the role of chance: When the heterosexual couples in our study talked about their (future) family, being able to use the same oocyte donor over time did not seem very important. The number of children in the family depended on several external or uncontrollable factors such as: (1) the number of oocytes retrieved per donation: a child wish could remain unfulfilled because no more oocytes were left, (2) whether the recipients wanted to go through the uncertain and intense treatment phase again, (3) the donor: if she wanted to donate again and/or if the recipients dared to ask her to donate again or the quest for a new donor and (4) practical reasons such as financial situation, professional career and housing.

Four couples talked about their preference of using the same oocyte donor. This was perceived as positive because the children would be full siblings. However, they mentioned that they could not decide on the same donor when they opted for anonymous donation. Most aspiring parents focussed on having a first child. They also talked about other options to give meaning to their life such as completing an adoption procedure and childlessness.

Limitations, reasons for caution: A specific question about being able to use the same oocyte donor over time could not always be asked because the participants co-determined the flow of the interview. Future research could focus on lesbian parents and aspiring parents in the trajectory of intra-partner oocyte donation.

Wider implications of the findings: Similar to the counselling of couples starting treatment with sperm donation, couples considering oocyte donation should be asked how they see their future family. The number of desired children should be discussed as it can influence the type of requested oocyte donation.

Trial registration number: NA.

O-160 Replication of Cytomegalovirus and Zika virus in first-trimester human placentas, mechanisms of viral pathogenesis and host cell defense

L. Pereira

UCSF School of Dentistry, Cell and Tissue Biology, San Francisco CA, U.S.A.

Abstract text

Human cytomegalovirus (CMV), a *Herpesvirus*, is a leading viral cause of congenital infection and birth defects, including microcephaly, neuromotor deficits, and hearing and vision loss. Likewise, Zika virus (ZIKV), a *Flavivirus*, responsible for the recent American pandemic, causes a spectrum of congenital malformations rarely seen with other neurotropic viruses. How these viruses disseminate from maternal circulation to the fetus is poorly understood. For almost two decades, we have investigated the biology of CMV infection in developing human placentas and deciphered mechanisms that result in pathology observed in placentas from newborns with congenital disease. We recently completed studies of ZIKV infection in cells isolated from human placentas and amniochorionic membranes and reported patterns of viral proteins in explants of chorionic villi from first-trimester placentas (Tabata, *et al.* Cell Host & Microbe, 2016; Tabata, *et. al.* Journal of Infectious Diseases, 2017). Comparisons of CMV and ZIKV infection and between prototype and pathogenic strains revealed impaired replication and functional defects in infected cells. Host cell factors were identified that modulate viral replication and prolong viremia *ex vivo*. Our studies suggest novel strategies to strengthen natural protection and reduce virus transmission at the uterine-placental interface.

O-161 Cell-free fetal hemoglobin as a biomarker of impaired place

S. Hansson

Institute of Clinical Science Lund- Lund university, Department of Obstetrics and Gynecology-, Lund, Sweden

Abstract text

Preeclampsia (PE) is a severe pregnancy-related syndrome that annually affects at least 8.5 million women worldwide. It is a leading cause of maternal and perinatal morbidity and mortality, responsible for about 18% of all maternal deaths and up to 40% of neonatal deaths. With its aetiology still largely unknown, diagnosis of PE is based on maternal clinical symptoms; high blood pressure (BP) and proteinuria manifesting after 20 weeks of gestation. Currently, delivery is the only known cure. In addition, early disease diagnosis is challenging and there are still no reliable biomarkers for clinical prediction or diagnosis.

We have shown elevated levels of ***free fetal hemoglobin*** (HbF) in the maternal blood circulation in PE as early as the first trimester and we have shown the levels to correlate with the BP, i.e. the severity of the disease in late pregnancy. Extracellular haemoglobin and its hydrophobic metabolite heme are highly toxic with pro-inflammatory, pro-oxidative, tissue damaging as well as vasoconstrictive effects.

By using the well-established dual-placenta perfusion model to study the human placenta *ex vivo*, we have shown that free HbF causes damage to the placenta barrier and endothelial cells by inducing oxidative stress and inflammation. Furthermore, cell-free HbF has also been shown to increased the microcirculatory resistance. In different animal models, cell-free HbF has been shown to cause kidney and placental damage similar to that seen in PE, i.e. glomerular endotheliosis and reduction of the podocyte-specific protein, nephrin.

To prevent toxicity of cell-free hemoglobin as well as its degradation metabolites heme and free iron, several scavenger proteins and degradation enzymes protect the body. ***Haptoglobin*** (Hp) binds free hemoglobin and transports it to macrophages and hepatocytes where the uptake is facilitated by CD163 receptor-mediated endocytosis. Hemoglobin is degraded to heme and then further catabolized by the rate limiting enzyme ***heme oxygenase 1*** (HO-1). ***Alpha-1-microglobulin*** (A1M), a lipocalin protein, that in addition to heme also binds radicals and has enzymatic reducing capacity. We have recently shown that A1M is up regulated in early and late onset PE. ***Hemopexin*** (Hx) is a circulating plasma glycoprotein, mainly synthesized in the liver, that binds free heme with high affinity. Hemopexin also has enzyme activity, which has been suggested to regulate the vascular responsiveness to angiotensin II.

In a series of studies we have deciphered how maternal plasma HbF and heme impact the scavenger enzyme systems Hx and HO-1 in patients with PE and studied how these proteins can be used as biomarkers for PE. Logistic regression analysis with ROC-curve analysis was performed to evaluate them as biomarkers. In PE plasma, significantly higher levels of HbF and heme in combination with significantly lower Hx activity, Hx and HO-1 levels was shown compared to normal pregnancies. The Hx activity was inversely correlated to the diastolic blood pressure and the HO-1 concentration was inversely correlated to both the systolic and diastolic blood pressure. The ROC-curve analysis showed a combined detection rate for these biomarkers of 84% at 10% false positive rate in late pregnancy.

Studies on ***fetal growth restriction*** (FGR) have shown increased levels of cell-free HbF, whilst elevation of its ratio with HO-1 suggests failure of the catabolic compensation. Placental endothelial cells, primed with cell-free HbF,

developed a pro-inflammatory phenotype and disruption of endothelial cell flow-alignment.

Conclusions: There is an important aetiological role for cell-free HbF in both fetal growth restrictions and in preeclampsia.

By measuring components in the HbF metabolism as potential biomarkers, they can be clinically useful to support the PE diagnosis. Future studies are needed to evaluate the role of these biomarkers as first trimester predictive biomarkers for PE, particularly in late-onset PE and neonatal outcome.

O-162 Nuclear reprogramming and chromatin functions in oocytes and preimplantation embryos

K. E. Latham

Michigan State University, Animal Science, East Lansing, U.S.A.

Nuclear Reprogramming and Chromatin Functions in Oocytes and Preimplantation Embryos.

Reprogramming of the genome is an essential part of creating each new life. The genomes of two highly differentiated gamete genomes must be reprogrammed to create an embryonic genome capable of development. This process begins with reprogramming the genome for meiosis, continues in the early cleaving embryo, and continues throughout preimplantation development until the earliest lineages are established. Meiotic reprogramming, including transcriptional silencing, histone deacetylation, and chromatin condensation, is essential to create a chromatin state that is compatible with correct spindle formation and faithful chromosome segregation. Further reprogramming is associated with preparing and activating the embryonic genome, first creating transcriptional competence, and then creating a repressive chromatin environment that allows gene regulation. As the embryo cleaves, further reprogramming occurs, culminating in the creation of cells with different identities, destined to give rise to inner cell mass and embryo proper, trophectoderm, and extraembryonic endoderm. Recent studies reveal that developmental pluripotency remains dependent on early embryonic chromatin states, establishing one potential connection between early events and later progeny health. Artificial reprogramming methods, achieved by somatic cell nuclear transfer, induced pluripotency, and application of epigenetic drugs, display significant limitations. These limitations attest to the unique dialog between ooplasm and gamete/embryonic genomes, the continuously shifting demands of the embryonic system, the opposing needs that must be satisfied at key points in the process, and the potential points at which exogenous factors may intervene to compromise development. The factors responsible for the different phases of this unique and ongoing reprogramming dialog are still being discovered. A deeper understanding of the nature of these factors and the underlying chromatin states upon which they act should be beneficial in basic and applied arenas.

O-163 Mitochondrial stress in preimplantation development and opportunities for treatment

R. Robker

University of Adelaide, School of Medicine- Robinson Research Institute, Adelaide, Australia

Abstract text

Oocytes contain all of the cellular building blocks required to support embryogenesis until the blastocyst stage of development. However the quality, quantity and composition of these cellular building blocks is determined by physiological signals influenced by the maternal environment; which in turn have dramatic effects on the progression of embryogenesis. In particular oocytes are lipid-rich cells and oocyte lipid content is influenced by maternal nutrition. Similarly, oocyte mitochondria are highly sensitive to environmental signals which can change their capacity for energy production and biogenesis and thereby influence embryo development and mitochondrial inheritance. Using a number of approaches in mice we have sought to determine how these key aspects of oocyte quality, namely lipid content and mitochondrial activity, regulate embryo developmental kinetics during pre-implantation development to the blastocyst stage. This information is needed because accumulating evidence demonstrates that discrete changes to oocyte quality influence the timely formation of the inner cell mass as well as distinct aspects of offspring phenotypes into adulthood.

To examine the effects of relevant physiological and in vitro conditions of oocytes on subsequent developmental competence, oocytes were isolated from female mice that were either obese or aged or that were manipulated in vitro in order to deplete cholesterol lipid or induce oxidative stress. Embryo morphokinetics were then assessed by continuous time-lapse monitoring, and cell lineage allocation to the inner cell mass (Oct4+) or trophectoderm (Cdx2+) was identified by immunohistochemistry. The results show that exposing oocytes to different environmental conditions in vivo or in vitro causes distinct changes to cell cycle kinetics following fertilization and deficiencies in either inner cell mass or trophectoderm cell number by the blastocyst stage. In addition, embryos fertilized in vitro exhibit altered development compared to those fertilized in vivo, even from the 2 cell stage. These results further demonstrate that even subtle insults to oocytes during maturation and fertilization change zygote cell cycle kinetics, and identify differential effects on embryos in response to distinct physiological and in vitro environments. Most importantly, we are able to restore the developmental competence of poor quality oocytes, damaged by obesity, aging or in vitro stress, using specific pharmaceuticals.

O-164 Surrogacy in Portugal - from struggle to accomplishment

A. Galhardo

Instituto Superior Miguel Torga- CINEICC-Faculty of Psychology and Educational Sciences of the University of Coimbra- Associação Portuguesa de Fertilidade, Psychology, Coimbra, Portugal

Abstract text

Relevant medical advances in the field of reproductive medicine now allow people previously unable to become genetic parents due to medical factors (e.g., women without a uterus, uterine abnormalities or medical conditions that contraindicate pregnancy) or social motives (e.g., gay men or couples) to accomplish this usually valued objective. Gestational surrogacy policy in Europe varies by country and it remains a controversial topic due to ethical and legal concerns. This third-party reproductive technique is a complex subject involving the commissioning parents, the gestational surrogate and the child to be. Recently in Portugal, July 2017, the legal context changed and gestational surrogacy is currently possible. This was an important achievement from the patients' perspective and one of the last steps of a long journey of struggle. In 2012 a parliament working group was formed with the aim of revising the medically assisted reproductive legal framework. Two years later a group of Portuguese Fertility Association (APFertilidade) members wrote to all political parties in the parliament, to the Health Commission and the National Council for Medically Assisted Reproduction, asking for the

inclusion of surrogacy in their agenda. On 22nd April 2016 the first law project addressing gestational surrogacy was rejected and APFertilidade requested the main right wing party to vote for. A week later a left wing party proposed the text to be voted in a plenary session in the same date the revised version of the law would be presented (May 13th). At the same time, APFertilidade launched a video containing real testimonies of women without a uterus who needed the law change to accomplish their dream of becoming mothers and it was sent to all deputies. This was an interesting piece of campaign encompassing several messages such as exclusion and stigma as well as the idea of not being heard and being pushed to illegal and cross-board scenarios. On 13th May the new law was approved by the parliament and access to assisted reproductive technologies (ART) was extended to all women independently from their marital status or sexual orientation. Furthermore, gestational surrogacy was also approved but in June the President considered there were queries, mainly concerning the interest of the child and the surrogate, and these should be clarified before promulgation. In June 2017 the law received the approval of the Ministries Council. Finally, in July 2017, the President promulgated the law regulation. The approved framework states that women facing medical conditions such as not having a uterus or uterus malformations or other medical conditions that clearly contraindicate pregnancy are the ones who can benefit from this treatment approach. Within this regulation it is also worth noting that besides medical criteria, it is mandatory to include psychological support for the parties involved and this suggests that psychological and social implications were considered by the legislator. By the end of 2017 the National Council for Medically Assisted Reproduction approved the first application. Although this was a demanding and challenging process, a study conducted in 2015 (before the law change) with 518 participants to whom it was asked to state their opinion about surrogacy, 69% agreed with legalization, 19% did not agree and 12% were non-respondents. Moreover 38% stated that they would support a friend in need of a gestational surrogate and 32% would support a female friend who decided to act as a gestational carrier. Nevertheless, when the question was whether they would pursue such a treatment option in case they needed, 50% answered "no" and 37% would consider surrogacy if all other possibilities were to be excluded.

O-165 Surrogacy and stratified kinship

A. Pande

University of Cape Town, Department of Sociology, Cape Town, South Africa

Abstract text

Commercial surrogacy is a multi billion-dollar industry across the world, with India being one of the world leaders. Although often couched in dystopic terms, the topic of surrogacy is not restricted to medical or scientific circles and has been generating feminist, ethical, legal and social debates for over three decades now. Despite this rich and growing literature, the common perception of surrogacy is one of intense anxiety – with dystopic images of baby farms, breeding factories and women as cows and guinea pigs flooding the media. When intended parents travel from countries in the global north to access services in the global south, there is an additional anxiety that such travel reifies global inequalities by making the bodies of people in resource-poor countries easily rentable by others. In my previous works I have argued that while these images are justifiable, they do not get to the complexity of the industry, the way it is unfolding in India. Commercial surrogacy in India is a rapidly growing informal labour market, one that needs to be understood empirically and not as an ethical dilemma (Pande 2014, 2015, 2016). Once we start unpacking these empirical realities, we realize that much of the structural inequalities are inherent to commercial surrogacy. In fact this industry reflects the global trend of "stratified motherhood" – "the hierarchical organization of reproductive fecundity and birth experiences that supports and rewards the maternity of some women while despising or outlawing the mother-work of others" (Rapp 1991). In this paper I use my recent ethnographic findings from my field to expand on this notion of stratification by highlighting a fundamentally unequal aspect of this practice – what I label "stratified kinship" – whereby there is legal and social acknowledgement and celebration of only genetic parenting while making birth mothering invisible.

O-166 What is it like to be a wombless woman in the age of ART's? Patients' perspectives on gestational surrogacy in Finland

K. Kivipuro

University of Helsinki, Department of Social Research, Helsinki, Finland

Abstract text

Each year in Finland, a number of fertile age women encounter an involuntary hysterectomy or find out they have never had a uterus. In my presentation, I examine how Finnish wombless women of fertile age cope with their condition and tackle their life between the imperative of procreation and the restrictions of reproduction. Based on my ongoing sociological study, I discuss what it means to be a wombless woman in Finland, where gestational surrogacy is forbidden, adoption is heavily regulated, and uterus transplants are still only a promise for the future.

Lack of uterus is always dramatic, because the indication for involuntary hysterectomy can be, for instance, a gynecological cancer, a life threatening complication during delivery, or it involves a teenage girl with congenital absence of a uterus (Mayer-Rokitansky-Küster-Hauser syndrome). Involuntary womblessness is a relatively rare incident, but it has a major effect on these women's lives and the possibilities to have a child. The situation forces to redefine the frames of reproduction and makes the woman to think strategically how founding a family would be possible. Furthermore, the lack of uterus does not only have a profound effect on the woman but also on her partner and immediate family.

Since 2007, the Assisted Fertility Treatment Act has prohibited gestational surrogacy in Finland. Based on research data, which includes 25 semi-structured in-depth interviews conducted with wombless women during 2017 and collaboration with two patient organizations for involuntary childlessness, I show that the prohibition of gestational surrogacy induces deep sorrow and resentment for majority of those affected by the condition. In practice, the legislative limitations are unable to prevent people from seeking and obtaining reproductive services elsewhere. In Finland, proximity to Russia prompts the intended parents with their Finnish surrogate to obtain the IVF from Russia, while giving birth to the baby in Finland. Intended parents are placed in highly contradictory situations, as they need to consider if they are willing to circumvent the legislation, invest a great amount of mental and financial resources, and leave their home country to seek the fertility services. Without regulatory support, evaluation of ethicality and riskiness of reproductive travel is left to individuals.

INVITED SESSION

SESSION 47: HOW TO INCREASE PEOPLE'S FERTILITY AWARENESS?

Tuesday 3 July 2018 Room 116 14:00–15:00

O-167 Development and impact of fertility campaigns

L. Schmidt

University of Copenhagen, Department of Public Health- Section of Social Medicine, Copenhagen K, Denmark

Introduction: Considerable gaps have been identified in men and women's knowledge of fertility. Fertility education and increasing the population's fertility awareness has been suggested as intervention strategies to contribute to prevention of infertility and to also reduce other negative consequences of delayed childbearing.

In response to this call, a small number of studies have measured the impact of fertility knowledge interventions. These studies show that these interventions are successful in increasing fertility knowledge in the short term. However, these interventions have often been developed for research and are not widely available to the public as in a widespread fertility campaign.

Results: A review of PubMed and searching keywords via Google showed that several fertility campaigns have been developed and launched across the globe. The campaigns are generally driven by one or both of the following goals:

(1) To increase men and women's fertility knowledge in order to promote informed and satisfying fertility/childbearing decision-making
(2) To increase knowledge and awareness of fertility in order to increase falling birth rates.

Content generally includes information about the fertility lifespan and risks to fertility.

The media plays a significant role in how the campaigns are understood and interpreted by the public and can facilitate or hinder the campaign goals. In some cases, the media provides a wider dissemination of the fertility campaign on a larger platform (e.g., ASRM).

In other cases, the media's portrayal of the campaign can result in the intended messaging being lost or misconstrued. For example, the media in Denmark linked the increased birth rate to fertility campaigns suggesting increasing the birth rate was the primary intention. In many cases, more coverage can be focused on the backlash rather than the content. The most common criticisms of fertility campaigns include blaming women for waiting too long and/or not being aware of their fertility, encouraging women and men to have children before they are ready, reducing women to their biological potential and presenting a one-sided story that does not acknowledge the structural and societal barriers and restrictions to younger parenthood.

A common problem across fertility campaigns is how to determine their impact. In the case of online campaigns, page views, social media hits and downloads can be tracked and provide some sense of the reach (example of YourFertility.org.au). The fertility campaigns have largely been unevaluated empirically so we do not know how or if they are impacting fertility knowledge and behaviour.

Conclusions: It is of importance that fertility campaigns are developed together with the many different stakeholders regarding fertility and family building; e.g., national health authorities, different groups of health professionals (medical doctors, midwives, nurses), NGO's on family building and sexual education as well as the target groups in the population. Further, evaluation is a necessary next step in fertility campaigns to gain a better sense of their impact and reach.

O-168 Preconceptional personalised mHealth lifestyle coaching: \rFirst results of a randomized controlled trial in couples undergoing IVF/ICSI treatment

R.P.M. Steegers-Theunissen

Erasmus MC, Dept of Obstetrics and Gynaecology Room Ee 22.71a, Rotterdam, The Netherlands

Abstract text

Mounting evidence demonstrates that healthy maternal lifestyles, including nutrition, significantly improve pregnancy chances as well as maternal pregnancy- and neonatal outcomes, with implications for health and disease risks across the lifecourse. Although the impact of paternal lifestyles has been largely neglected, more data are now available showing also their influence on semen quality and embryonic growth trajectories, with potential health consequences for the offspring. Again, this data very much illustrate the importance of the critical periconceptional window, defined as 3 months before up to 3 months after conception, during which most adverse reproductive outcomes originate. Therefore, in the first part of this presentation new evidence on the impact of periconceptional maternal and paternal lifestyles on the gametes and (pre) implantation embryo quality and growth trajectories will be demonstrated using questionnaire data and (non) invasive biomarkers using for example 3-dimensional ultrasound, time-lapse and offline virtual reality techniques.

As researchers we also have the responsibility to implement evidence-based data in patient care. Indeed more couples with a child wish and planning pregnancy, especially subfertile couples and health care professionals, are aware of the impact of lifestyle on reproduction. However, adopting healthy behaviors remains a big challenge for everyone. Therefore, following the implementation of a preconceptional clinic on lifestyle coaching (2007-2012) at the Erasmus MC, University Medical Center in Rotterdam, The Netherlands, we have developed the successful mHealth coaching programme 'Smarter Pregnancy'. This mHealth programme with CE certification is available in the Dutch (www.slimmerzwangeronderzoek.nl and www.slimmerzwanger.nl) and English language (www.smarterpregnancy.co.uk/research) and aims to empower couples of adopting healthy lifestyles before and during pregnancy. Between 2012 and 2014 a large survey was performed using 'Smarter pregnancy' as intervention which showed significantly positive results on compliance, feasibility, usability and first effectiveness. From 2014 onwards also a multicenter randomized controlled trial is conducted in 6 IVF clinics in the Netherlands using this mHealth programme. In the second part of this presentation the first results will be presented of this trial that demonstrate an even higher compliance than was revealed from the survey. Moreover, the significant effectiveness of this mHealth programme is conformed with regard to adopting short- and long-term healthy lifestyles in couples undergoing IVF treatment. Subgroup analysis also shows the beneficial effects in overweight and obese women. Since mHealth has the potential to reach and empower a large population, our next ambition is the development in co-creation with multiple stakeholders of a digital life course platform for implementation of lifestyle care in routine patient care from the preconceptional period onwards. This is a societal challenge which can also be a great opportunity for Big data collection to further improve (cost)effectiveness of health care.

SELECTED ORAL COMMUNICATIONS

SESSION 48: EFFECTS ON TESTICULAR DEVELOPMENT AND GERM CELL DIFFERENTIATION

Tuesday 3 July 2018 Forum (Auditorium) 15:15–16:30

O-169 Exposure to acetaminophen and ibuprofen affects fetal germ cell development in both sexes in rodent and human

P. Hurtado-Gonzalez[1], J. MacDonald[1], K. Kilcoyne[1], S. Van den Driesche[1], A. Jorgensen[2], R. Anderson[1], R. Sharpe[1], R. Mitchell[1]

[1]*University of Edinburgh, MRC Centre for Reproductive Health, Edinburgh, United Kingdom*

[2]*Copenhagen University Hospital Rigshospitalet, Department of Growth & Reproduction, Copenhagen, Denmark*

Study question: We determined whether therapeutic doses of analgesics affect germ cell development in the human (and rodent) fetal testis and ovary using in-vitro, in-vivo and xenograft approaches.

Summary answer: Germ cell number was significantly reduced (28-49%) in human fetal testes and ovaries exposed to acetaminophen or ibuprofen, whilst rodent studies revealed altered epigenetic regulation.

What is known already: The majority of women use an analgesic (acetaminophen or ibuprofen) at least once during pregnancy. Whilst some epidemiological studies have reported associations between analgesic use during pregnancy and cryptorchidism in sons, the findings are inconsistent within and between the different study populations. A recent study which utilised a xenograft model of human fetal testis tissue showed that prolonged acetaminophen exposure at human-relevant dosing reduced plasma testosterone levels, whilst rodent studies have indicated potential for germ cell effects following acetaminophen exposure. However, whether germ cell effects occur in analgesic-

exposed human fetal gonads and the mechanisms involved have not been determined.

Study design, size, duration: First trimester human fetal testes and ovaries (n = 8) were cultured exposed to acetaminophen and ibuprofen for 7 days. Second trimester human fetal testes (n = 10) were xenografted into immunocompromised mice and exposed to vehicle, acetaminophen (60 mg/kg/day; 1 or 7 days) or ibuprofen (30 mg/kg/day; 7 days). To determine mechanism of action, a human GC tumor-derived cell line (NT2) was used (acetaminophen or ibuprofen +/- PGE2 agonists) as well as an in-vitro and in-vivo (n = 13-30) rat model.

Participants/materials, setting, methods: Fetal testis sections were double/triple immunostained for SOX9 (Sertoli cells), TFAP2C (gonocytes) and MAGEA4 (pre-spermatogonia). mRNA Expression of epigenetic regulators in human (TET1, EZH2, DNMT3a, DNMT3b) and rat (Tet1, Ezh2, Dnmt3a and Dnmt3b), in addition to germ cell pluripotency (POU5F1, TFAP2C and NANOG) genes were determined. Results were analyzed by two-factor ANOVA with replication. Statistical significance was indicated where $p < 0.05$

Main results and the role of chance: Gonocyte ($TFAP2C^+$) number was decreased in 1st trimester human fetal testes exposed in-vitro to acetaminophen (28% reduction; p = 0.008) or ibuprofen (22% reduction; p = 0.001) and in ovaries exposed to acetaminophen (43% reduction; p = 0.016) or ibuprofen (49% reduction; p = 0.005), compared with controls. Acetaminophen exposure decreased gonocyte number in xenografted 2nd trimester human fetal testes by 17% (p = 0.044) and 30% (p = 0.014) after treatment of host mice for 1 or 7 days respectively. NT2 cell number was decreased after exposure to acetaminophen (19% reduction, p = 0.0002), ibuprofen (18 %reduction, p = 0.006) or to prostaglandin E2 (PGE_2) antagonists (27% reduction; p = 0.0001), and PGE_2 agonists prevented acetaminophen-induced reduction in NT2 cell number (p = 0.029). Gene expression of regulators of DNA and histone methylation and of GC pluripotency genes, differed from controls following analgesic and PGE2 antagonist exposures. Gene expression changes also occurred in rat fetal testis/ovary cultures and following in vivo acetaminophen exposure of pregnant rats. One such example was expression of the epigenetic regulator TET1, which was significantly increased after exposure to acetaminophen in several model systems (human NT2 cells, rat fetal testis/ovary cultures, and fetal testes and ovaries after in vivo exposure of pregnant rats), demonstrating robust translatability across experimental models and species.

Limitations, reasons for caution: Although the xenograft/culture models can mimic many aspects of normal human fetal gonad development, they cannot recreate in vivo human conditions. Despite these limitations, the consistency of analgesic effects and concordance between humans and rats (including in-vivo), suggest that mechanisms for fetal GC effects are conserved between rodents and humans.

Wider implications of the findings: These findings provide novel evidence for potential adverse effects of analgesics during pregnancy. They suggest that exposure of human fetal gonads to therapeutically-relevant concentrations of acetaminophen and ibuprofen may impact fetal germ cell number and, potentially, epigenetic modifications. This could affect future fertility of the individual and/or future generations.

Study question: How can AML affect mouse male fertility?

Summary answer: AML impaired the seminiferous tubules (STs) histology, reduced the number of spermatogenic cells, increased apoptosis in the STs and reduced production of testicular growth factors.

What is known already: It is known that some types of cancer can affect semen quality even before anti-cancer treatment. Some studies reported significant reductions in semen parameters (motility, concentration and morphology) in Leukemia patients before chemotherapy. In addition, a significant reduction in semen quality of thawed cryopreserved semen from leukemia patients compared to control patients was reported. Also, a reduction in some hormones was reported in cancer patients compared to control. However, the mechanisms behind these impairments parameters are not yet fully understood.

Study design, size, duration: Six-week-old males C57/BLACK mice were used. 1. Control group – injected with saline. 2. AML group – injected (intraperitoneal; i.p) with 1×10^5 AML cells (murine C-1498 AML cell line). Mice were sacrificed (4-6 mice in each time point) after 1,2,3,4 weeks of AML injection.

Participants/materials, setting, methods: Testes were removed and fixed in Bouin's solution for histological evaluation, or kept at -70^0 C for RNA extraction. The presence of premeiotic (SALL4,PLZF), meiotic (CREM-1) and postmeiotic (ACROSIN) cells were examined by immunofluorescence staining. Apoptosis was examined by tunel assay. The expression of growth factors in the testes was examined by qPCR analysis. Sperm cells were extracted from the epididymis. The fertility capacity of the mice was examined by mating with normal C57/BLACK females.

Main results and the role of chance: Mice were still alive 4 weeks after AML injection. A significant decrease in the number of cell layers and a significant increase in the size of the lumen of the STs were demonstrated in AML mice compared to control. The number of premeiotic (SALL4, PLZF) cells/ST and the percentage of STs with meiotic (CREM-1) or postmeiotic (ACROSIN) cells were significantly lower in AML mice compared to control. The percentage of STs with apoptotic cells significantly increased in AML mice compared to control. The expression of growth factors in testicular tissue [macrophage-colony stimulating factor (MCSF), glial cell-derived neurotrophic factor (GDNF), leukemia inhibitory factor (LIF)] was significantly lower in AML mice compared to control group. Sperm concentration, motility and morphology were significantly lower in AML mice compared to control. The fertility capacity of the AML mice was 50% of the control after 3 weeks of AML injection compared to control.

Limitations, reasons for caution: Animal model of leukemia may behave different from human model.

Wider implications of the findings: This study deepens our understanding of mechanism behind reduced fertility and infertility in AML male patients. Understanding these mechanisms may assist in the development of future therapeutic strategies for male fertility preservation.

Trial registration number: NA.

O-171 CRISPR/cas9 mediated HSD17B3 gene mutation on mouse Leydig cells: Effectivity of CRISPR/cas9 on testosterone synthesis pathway

N. Karahan[1], S. Karahuseyinoglu[2]

[1]*Koc University, Graduate School of Health Sciences- Reproductive Biology, Istanbul, Turkey*

[2]*Koc University, School of Medicine- Department of Histology and Embryology, Istanbul, Turkey*

Study question: Can CRISPR/cas9 method be used for gene editing to interfere testosterone synthesis in mouse Leydig cells?

Summary answer: HSD17B3 gene knock-out via CRISPR/cas9 gene editing technology can be accomplished in mouse Leydig cells successfully to interfere and decrease secretion of testosterone.

What is known already: CRISPR/cas9 gene editing technology comprises programmable endonucleases that facilitate making models with precise genetic changes to study the progress and treatment of diseases, some of which are related to faulty testosterone production. Testosterone synthesis involves a highly complicated cascade of sequential reactions that precise regulations are not usually possible, since non-specific interventions affect the other steroid-related products in the cascade, as well. CRISPR/Cas 9 has made it possible to accomplish cell targeted interventions, which are widely used in a variety of cells in the body in order to obtain genome based therapies.

Study design, size, duration: This study involved the knock-out of HSD17B3 gene of Leydig cells isolated from adult CD1 mouse (n = 36) testis via the use of CRISPR/cas9, followed by evaluation of changes in secretion of testosterone within control group and experimental group throughout 15 days under the effect of 100 ng/ml human chorionic gonadotropin. Quantitative analysis was performed by qRTPCR, WB and ELISA in triplicates compared by student's t-test. The semiquantitative analysis was accomplished by superresolution microscopy.

Participants/materials, setting, methods: Leydig cells isolated from adult CD1 mice were cultured 2 days with human chorionic gonadotropin to induce maturity and secretion of testosterone before CRISPR/cas9 gene editing procedure. HSD17B3 gene was knocked-out with a specific guide-RNA specially designed for that mouse gene. Triplicate experiments for Western Blot, qRT-PCR, and super-resolution confocal microscopy were performed to show the reduction in this gene expression, with altered cell morphology, as ELISA was used to detect changes in testosterone levels.

Main results and the role of chance: This project was undertaken to design testosterone deficiency model in vitro and evaluate the effect along with the efficiency of CRISPR/cas9 method for Leydig cells.

The first set of experiments was set to confirm the isolation of Leydig cells and the effect of CRISPR/Cas9 gene edition on isolated cells. Leydig cells of mouse testis were isolated with high purity (>95%) in adequate amounts to carry out culture and gene edition experiments. The efficiency of CRISPR/cas9 for the edition of HSD17B3 gene was >85% in with no suspected off-target performance. The second set of experiments were designed to search for the efficacy of gene edition. Expression of HSD17B3 was significantly decreased in the gene edited group compared to control group as depicted by qRT-PCR, that was designed with triplicate controls, and Western Blotting ($p < 0.05$). Testosterone production of gene-edited Leydig cells in significantly lower ($p < 0.05$), as recorded by ELISA of the culture medium samples. Super-resolution microscopy revealed that morphological appearance of gene-edited cells which showed a less round cell structure with fewer steroid granules. 3BHSD stainings were found to be critically decreased in gene edited group compared to the normal group.

Limitations, reasons for caution: As this study is based on gene edition of primary mouse Leydig cells, **various outcomes can be expected for human** Leydig cells. This study design is very useful to create effective and simpler in vitro models; however, knocking out of HSD17B3 gene can be **lethal for in vivo studies.**

Wider implications of the findings: The limited number of *in vitro* models for testosterone deficiency limits research on this topic. Additionally; the literature on the effectiveness of CRISPR/cas9, which is very up-to-date knock-out and gene editing method, is insufficient regarding Leydig cells. This study releases an effective, feasible method to interfere testosterone production in vitro.

Trial registration number: not applicable

O-172 Busulfan distinctly affected Sertoli cell activity in immature mice

M. Huleihel[1], A. AbuMadigem[2], R. Solomon[2], E. Lunenfeld[3]

[1]*Ben-Gurion University of the Negev, The Shraga Segal Dept. of Microbiology & Immunology, Beer - Sheva, Israel*

[2]*The Center of Advanced Research and Education in Reproduction CARER- Faculty of Health Sciences- Ben-Gurion University of the Negev- Beer-Sheva- Israel., The Shraga Segal Dep. of Microbiology- Immunology and Genetics, Beer-Sheva, Israel*

[3]*The Center of Advanced Research and Education in Reproduction CARER- Faculty of Health Sciences- Soroka Medical Center and Ben-Gurion University of the Negev- Beer-Sheva- Israel., Dep. OB/GYN, Beer-Sheva, Israel*

Study question: What are the effects of busulfan on Sertoli cells from immature-treated mice?

Summary answer: Busulfan did not affect the number of Sertoli cells, but it significantly and distinctly affected their function to produce different growth factors.

What is known already: Busulfan (BU) is an aggressive chemotherapy, which may lead to male infertility. Sertoli cells (SCs) communicate directly with germ cells (GC) and thus regulate their development in the seminiferous tubules (STs) to sperm. Sertoli cells produce different factors that affect proliferation and differentiation of spermatogonial cells such as GDNF, LIF, SCF, transferrin, ABP and others. Busulfan was shown to increase some testicular growth factors such as GDNF and hormones such as AMH, but also to destroy vimentin filaments and ICAM-1 adhesion molecules that affect development of spermatogonial cells.

Study design, size, duration: Seven-day-old mice (immature) were injected intraperitoneal with BU (45 mg/kg) and sacrificed after 10 days [a time demonstrated by our group to severely affect spermatogenesis compared to control (DMSO)]. Twenty-twenty five mice were used in each experiment. Experiments were repeated at least 3 times.

Participants/materials, setting, methods: Cells from STs were enzymatically isolated and double immunofluorescence stained for SCs and growth factors was performed. Also, RNA expression of SCs marker and growth factors were evaluated by qPCR analysis.

Main results and the role of chance: A significant increase ($p < 0.001$) in the percentage of vimentin-positive cells (a SCs marker) and RNA expression, with no change in the overall number of SCs were demonstrated in BU-treated mice compared to the control group. Also, a significant increase ($p < 0.001$) in the percentage of SCs that produce CSF1 with no change in other growth factors (GDNF, SCF, LIF) was demonstrated compared to the controls. In addition, a significant increase in the expression of FSHR, androgen-receptor, inhibin B and transferrin, with a significant decrease in androgen binding protein was demonstrated in the BU-treated mice compared to controls.

Limitations, reasons for caution: Limitations, reasons for caution: Animal model treated with chemotherapy may behave different from human model.

Wider implications of the findings: We showed for the first time that BU treatment of immature mice doesn't affect SCs number, but increases their percentage in the testes. BU treatment distinctly affected regulatory molecules produce by SCs and play a key role in spermatogenesis. These results may partially explain testicular response to BU.

Trial registration number: NA

O-173 The nuclear envelope: an unknown actor of human spermiogenesis

C. Metzler-Guillemain[1], R. Elkhatib[2], G. Longepied[2], P. Bourgeois[2], N. Levy[2], M. Paci[1], M. Mitchell[2]

[1]*AP-HM La Conception, Biologie de la Reproduction-CECOS, Marseille, France*

[2]*Aix Marseille Univ- MMG, Marseille Medical Genetics, Marseille, France*

Study question: What roles do the nuclear envelope proteins play during normal human spermiogenesis?

Summary answer: In humans, B-type lamins, LEM-domain and BAF proteins are involved in the specific spermatid nucleus remodelling, SUN5 is required for solid sperm head-tail junction.

What is known already: The nuclear envelope (NE), composed by the nuclear membrane, the nuclear pore complexes and the nuclear lamina, is interposed between nuclear and cytoplasmic compartments.

In mouse, emerging evidence supports the involvement of many proteins of the nuclear membrane, the nuclear lamina (NL), and some of their partners, in the specific remodelling of the mammalian spermatid nucleus.

Recent studies in human, during normal spermiogenesis or in patients with abnormal sperm phenotypes, show a strong involvement of the NE, the NL

proteins and their associated proteins in the control of specific spermatid nucleus remodelling and formation of the sperm head-tail junction.

Study design, size, duration: A prospective qualitative and functional analysis of NE proteins and some partners, in human testis and ejaculated spermatozoa, supported by functional experiments in HeLa cells.

Participants/materials, setting, methods: Testicular samples and ejaculated spermatozoa from the Germetheque biobank, Hela cells, RNA extraction, RT-PCR, cell transfection, western blotting, immunofluorescence.

Main results and the role of chance: B-type lamins are present at the nuclear periphery, except in the region covered by the acrosome, and that as the spermatid matures the B-type lamins recede towards the posterior pole. We determine that, human lamin B3, but not lamin B2, induces strong nuclear deformation, when ectopically expressed in HeLa cells. LEMD1, LEMD2, ANKLE2, LAP2β, BAF and BAF-L, are present and Emerin, LBR and LEMD3 are absent. In spermatids, no LEM-domain protein localised to the nuclear periphery, but five were nucleoplasmic, receding towards the posterior nuclear pole as spermatids matured. The NL appears immature in globozoospermic spermatozoa. SUN5 is required for the formation of the sperm head-tail junction. Our work therefore establishes that the lamina-chromatin interface in human spermatids is radically distinct from that defined in somatic cells. Our results in human highlight the importance of the NE proteins in mammalian spermiogenesis and male fertility.

Limitations, reasons for caution: The number of samples and patients tested for rare phenotypes should be increased.

Wider implications of the findings: In general, our results illustrate the importance of spermatid NE components and partners in the coordination of the cellular events, between the nuclear and cytoplasmic compartments, that lead to the formation of functional spermatozoa. In human, spermiogenesis represents a new model of nuclear plasticity.

O-174 High resolution array comparative genomic hybridization contribution to uncover genetic etiologies of idiopathic premature insufficiency: a cohort study

A. Sassi[1], J. Désir[2], B. Alvaro-Mercadal[3], C. Hans[2], A. Delbaere[1]

[1]*Erasme Hospital-Université Libre de Bruxelles, Department of Obstetrics, Gynecology and Human Reproduction*

[2]*Erasme Hospital-Université Libre de Bruxelles, Department of Human Genetics, Brussels, Belgium*

[3]*Dexeus Hospital, Department of Obstetrics, Gynecology and Human Reproduction*

Study question: Can high-resolution array comparative genomic hybridization (CGH) contribute to uncover genetic etiologies of idiopathic premature ovarian insufficiency (POI)?

Summary answer: High resolution CGH array analysis can identify new candidate genes in the pathophysiology of POI as well as previously reported ones.

What is known already: Premature ovarian insufficiency (POI) is a heterogeneous disorder affecting 1% of women and remains idiopathic in the large majority of cases. It is defined by the presence of primary or secondary amenorrhea and hypergonadotropic hypogonadism, occurring before the age of 40. Familial history of POI is reported in up to 31% suggesting a significant genetic contribution, which remains largely unknown. Different genomic tools have been used to elucidate the genetic etiology of POI including array-CGH. However, different types of array platforms with various levels of resolution were used leading to heterogeneous results generally not replicated between studies.

Study design, size, duration: High resolution array CGH analysis was performed on DNA samples from 110 patients with idiopathic POI recruited prospectively from June 2016 to June 2017 in order to identify Copy number variants (CNVs). Data were compared to Database of Genomic Variants (DGV)

Participants/materials, setting, methods: Women were included if they experienced POI, as defined by the ESHRE guidelines. All patients had a normal karyotype. Patients with aneuploidies, fragile X premutation, adrenal/ovarian antibodies and iatrogenic POI were excluded from the study. Oligonucleotide array-CGH analysis was performed using the CytoSure™ Constitutional v3 Arrays (4×180k) from OGT and analyzed with CytoSure Interpret Software. The mean spatial resolution was approximately of 200 kb for the whole genome and higher for 502 highly-targeted developmental delay genes.

Main results and the role of chance: Thrirty-six patients (32.7%) presented CNVs of unknown significance (class III CNV) and one patient presented a pathogenic CNV (class V). As 9 of these patients presented 2 different class III CNVs, a total of 45 class III CNVs (23 microdeletions and 22 microduplications) were identified. These 45 CNVs were located in 32 genomic segments, 9 of them being involved in at least 2 patients (2p16.3, 4p15.32, 7q11.22, 10q21.1, 11q14.1, 17q11.2, 20p12.1, Xp22.11, Xp22.33). Three among those have been previously associated with POI (2p16.3, 17q11.2, Xp22.11). Different genes were included or interrupted by these CNVs, 16 of them being potentially relevant in the development of POI. Two of these genes were previously suggested as candidate genes for POI (CPEB1, DIAPH2), while the remaining ones could be considered as new candidate genes in POI as they were reported to be either implicated in the development of the stock of primordial follicles and the prevention of its depletion in non-human species, or in molecular pathways known to be associated with POI, or located in critical region of X chromosome or next to genes important for folliculogenesis.

Limitations, reasons for caution: This is a descriptive analysis: neither functional studies nor comparison to CNVs of patient's family members were performed. We have not considered benign CNVs for this study, which should be considered with caution as information from DGV is related to CNVs detected in healthy individuals without information concerning their fertility.

Wider implications of the findings: High resolution array CGH can uncover potential genetic etiologies of POI. This analysis should be integrated in POI assessment especially in idiopathic cases and in complement to a normal karyotype as long as whole genome sequencing is not used routinely.

O-175 ACTH-stimulation in women with low functional ovarian reserve (LFOR) confirms adrenal origin of hypo-androgenism

V. Kushnir[1], S. Darmon[2], D. Albertini[2], D. Barad[2], N. Gleicher[2]

[1]*The Center for Human Reproduction, n/a, New York- NY, U.S.A.*

[2]*Center for Human Reproduction, n/a, New York- NY, U.S.A.*

Study question: Is the reported hypo-androgenism in women with LFOR adrenal or ovarian in origin?

Summary answer: Insufficiency in androgen-production by the adrenal zona reticularis is a characteristic feature of LFOR, profoundly contributing to hypo-androgenism.

What is known already: LFOR, whether due to age or premature ovarian aging (POA), also called occult primary insufficiency (oPOI), has been previously associated with hypo-androgenism (Gleicher et al., Hum Reprod 2013;28 (4):1084-1091).

Study design, size, duration: Prospective cohort study involving 62 women.

Participants/materials, setting, methods: 43 LFOR and 19 normal ovarian reserve (NOR) patients underwent 250 µg Cosyntropin (ACTH) stimulation in AM after overnight fast. Based on levels <95% CI, 12/43 LFOR patients were low-DHEAS. LFOR was defined as FSH > 95%CI for age and/or AMH < 95%CI for age for CHR's patient population (Barad et al., Reprod Biomed Online 2011;22(3):284-291; Barad et al., Obstet Gynecol 2007;109(6):1404-1410). Serum cortisol, 17-hydroxy-progesterone, DHEA, DHEAS, androstenedione and total testosterone (T) were evaluated at baseline and 30 mins.

Main results and the role of chance: Age did not vary between groups. As expected, FSH ($P = 0.0003$) and AMH ($P < 0.0001$) did. At baseline, with and

without LFOR, whether DHEAS was normal or low, all androgens, DHEA ($P < 0.0001$), DHEA ($P = 0.0002$), androstenedione ($P = 0.0005$), and T ($P = 0.0033$) differed significantly. At 30 minutes after ACTH infusion, however, only Δ DHEAS, the only exclusively adrenal androgen, was still significantly lower in LFOR than NOR patients ($P = 0.0265$), suggesting relatively insufficiency of adrenals.

Limitations, reasons for caution: To better understand adrenal control of ovaries via androgen production, further elucidation of endocrine signaling between adrenals and ovaries is required, including detection of yet unknown likely feedback loops.

Wider implications of the findings: It is becoming increasingly clear that adrenals, through diminished androgen production, may inhibit follicular function, producing a form of secondary ovarian insufficiency (SOI), like POI characterized by low estradiol and elevated FSH but, in contrast to POI, potentially treatable through androgen supplementation.

Trial registration number: Not applicable.

O-176 Are serum LH levels at the initiation of ovarian stimulation associated with oocyte retrieval yield after GnRH agonist triggering?

B. Popovic - Todorovic[1], S. Santos-Ribeiro[1], M. De Vos[1], A. Racca[1], P. Drakopoulos[1], Y. Thorez[2], H. Tournaye[1], C. Blockeel[1]

[1]UZ Brussel, Centre for Reproductive Medicine, Jette- Brussels, Belgium
[2]UZ Brussel, Department of Informatics, Jette- Brussels, Belgium

Study question: To evaluate the relationship between basal serum LH levels and oocyte retrieval yield in GnRH antagonist cycles triggered with a GnRH agonist.

Summary answer: LH levels at the start of ovarian stimulation can identify patients with suboptimal oocyte retrieval yield following GnRH agonist triggering.

What is known already: GnRH agonist trigger may result in an inadequate oocyte yield in a small subset of patients. This failure can range from empty follicle syndrome to a retrieval of much fewer oocytes than expected. Suboptimal response has been defined as the presence of circulating LH values < 15 IU/l 12 h after triggering. It has been shown that patients with immeasurable LH levels on trigger day have an up to 25% risk of suboptimal response. However, it would be far more clinically relevant if one could identify these patients at the start of ovarian stimulation, namely by assessing basal LH levels.

Study design, size, duration: A retrospective cohort study of all patients from 2011 until 2017 who performed GnRH agonist triggering for final oocyte maturation (n = 3334) in GnRH antagonist cycles. Patients with known diagnosis of hypothalamic amenorrhoea were excluded from this treatment. Our primary outcome was oocyte yield, defined as the ratio between the total number of collected oocytes and the number of follicles with a mean diameter > 10 mm prior to GnRH agonist trigger.

Participants/materials, setting, methods: Final maturation triggering was performed using 0.2 mg of triptorelin. In order to evaluate whether LH levels at the start of ovarian stimulation predicted oocyte yield, we performed multivariable regression analysis adjusting for the following confounding factors: female age, body mass index, oral contraceptive pretreatment, basal and trigger day estradiol levels, starting FSH and LH levels and total gonadotropin dose. Suboptimal response to GnRH agonist trigger was defined as $<10^{th}$ percentile of oocyte yield.

Main results and the role of chance: The average age was 31.9 years and the mean oocyte yield was 89%. The suboptimal response to GnRH agonist trigger was 45% ($<10^{th}$ percentile) which was exhibited by 340 patients (10.2%).

Suboptimal responders had lower mean starting FSH, LH and estradiol levels compared to optimal responders 6.1 vs. 6.4 IU/l ($p = 0.04$); 4.74 vs. 5.9 IU/l ($p < 0.001$); and 33.3 vs. 36.4 ng/L ($p < 0.001$) respectively. They also had lower estradiol levels at trigger: 2277.5 vs. 2796.2 ng/L ($p < 0.001$), respectively. Pretreatment with oral contraceptive pill significantly affected the oocyte yield. In the suboptimal response group, 8.6% patients were pretreated with the pill compared with 4.4% ($p < 0.001$) in the optimal responders. Inadequate response was associated with longer stimulation 11.5 vs. 10.6 days ($p < 0.001$) and higher gonadotropin consumption 2086.4 vs. 1838.1 IU ($p < 0.001$).

Following confounder adjustment, multivariable regression analysis showed that LH levels at the initiation of ovarian stimulation remained a significant predictor of oocyte yield.

Patients with immeasurable LH levels at the start of stimulation (<0.11IU/l) had a risk of 45.2% of suboptimal response, while the risk decreased with increasing basal LH levels: < 0.5 IU/L, < 2 IU/L and <5 IU/L were associated with a 39.1%, 25.2% and 13.2% risk respectively.

Limitations, reasons for caution: The main limitation of the study is its retrospective design.

Wider implications of the findings: This is the largest study in GnRH agonist trigger cycles only, since most of the previous research on the predictive value of basal LH levels was performed in dual trigger cycles. LH levels at the start of ovarian stimulation are associated with suboptimal oocyte retrieval yield following GnRH agonist trigger.

Trial registration number: None.

O-177 Luteal phase stimulation compared with conventional follicular phase stimulation in poor ovarian responders: Results of a randomized control trial

J. Llacer, B. Moliner, L. Luque, A. Bernabeu, E. Fernandez, J.A. Ortiz, J.C. Castillo, J. Ten, R. Bernabeu

Instituto Bernabeu, Reproductive Medicine, Alicante, Spain

Study question: Does luteal phase stimulation (LPS) result in comparable efficiency to conventional follicular phase stimulation (FPS) in young bologna poor responders (POR)?

Summary answer: LPS results in similar outcomes than FPS in terms of the number of oocytes retrieved and gonadotropin consumption in a population of young Bologna POR.

What is known already: POR remains one of the main therapeutic challenges in women undergoing ovarian stimulation. In the last years, LPS emerged as a feasible way to obtain good quality oocytes. In POR, the use of LPS has been proposed within a strategy of double stimulation starting the gonadotropin administration immediately after the egg retrieval of a conventional stimulation. However, to date, the efficiency of LPS hasn't been tested in a population of POR. Therefore, the study was designed to explore benefits and pitfalls of LPS in POR.

Study design, size, duration: This is a pilot, prospective, single center, randomized controlled trial in a parallel two-arm design. The study included 60 patients < 40 years fulfilling the "Bologna" criteria who underwent ovarian stimulation to accumulate vitrified eggs for immediate IVF treatment. The randomization sequence was performed using a computer-generated randomization list.

Participants/materials, setting, methods: Patients were randomized to be stimulated with rFSH(300IU) + rLH(150IU) (Pergoveris® 2 ampoules per day). FPS arm started stimulation on the 3rd day of the cycle while patients in the group of LPS initiated the gonadotropin administration 4 days after an LH positive test. Both groups started antagonist administration in a flexible protocol. The primary outcome was the number of vitrified oocytes. Secondary outcomes included the duration of stimulation, gonadotropin consume and cancellation rate.

Main results and the role of chance: Using an intention to treat analysis the number of vitrified oocytes per patient did not differ significantly between LPS group 2,1 and FPS group 2,6 ($p = 0,31$). Other parameters of the ovarian stimulation were also comparable: number of cumulus-oocyte complex (COC) 2,7 in LPS and 3,1 in FPS ($p = 0,44$); duration of the stimulation 7,5 days in LPS and 8,0 in FPS ($p = 0,69$); gonadotropin consumption 16,7 ampoules in LPS and 16,3 in FPS ($p = 0,0,76$); maturation rate 77,5% in LPS and 84,0% in FPS ($p = 0,47$) and cancellation rate 20% in LPS and 3,3% in FPS ($p = 0,08$). However, a post-hoc analysis was necessary taking into account that ovarian reserve parameters were not comparable between groups. AMH in the 3rd day of the cycle was lower in the LPS group (4,65 pmol LPS vs 7,30 FPS $p = 0,021$). Other parameters as age, weight, BMI, AFC and number of previous stimulation attempts were not different. Creating a new variable to evaluate the ovarian response in function of the ovarian reserve (COC/AMH) resulted in a higher sensitivity in the LPS group 0,96 eggs per AMH pmol than in the FPS group 0,58 ($p = 0,037$)

Limitations, reasons for caution: This is a pilot study and the sample size was not calculated. The two arms of the study were different in terms of ovarian reserve.

Wider implications of the findings: Data show LPS comparable with FPS in terms of efficiency in POR patients. Therefore, this way of stimulation can be used in this group of patients when planning to accumulate eggs or embryos. Some data suggest a higher ovarian sensitivity so more trials will be necessary to explore this possibility.

Trial registration number: EudraCT: 2015-003856-31

[4]Kulakov-s National Medical Research Centre of Obstetrics- Gynaecology and Perinatology of the Russian Ministry of Healthcare, Molecular-Genetic Methods Laboratory, Moscow, Russia C.I.S.

Study question: Does double stimulation (DuoStim) improve the embryological outcome and increase pregnancy rate in patients with reduced ovarian reserve?

Summary answer: DuoStim results in retrieving more good quality oocytes in a single menstrual cycle which leads to a higher clinical pregnancy rate.

What is known already: Multiple follicular waves during the menstrual cycle make it feasible to start ovarian stimulation in luteal phase (LF). LF stimulation and DuoStim have been suggested with the aim of fertility preservation in cancer patients. Previous studies showed that this approach could be a good opportunity for poor-responder patients because it results in more oocytes and embryos. To predict oocyte competence, cumulus cell (CC) gene expression could be used. There are several genes which have a positive correlation with fertilization and embryo development. However, there is limited data about CC gene expression after LF stimulation and IVF treatment success after DuoStim.

Study design, size, duration: This prospective randomized (Microsoft Office Excel 2007) study included 148 patients with reduced ovarian reserve. Group 1 (n = 72) received stimulation on day 2 follicular phase. Group 2 (n = 76) received the DuoStim (stimulation started on day 2, then, on 4 day after the first oocyte retrieval (OR), stimulation repeated during LF. Plasma samples were obtained on stimulation starter day, 6 days after, on triggering and OR day. 40 patients were chosen to study CC gene expression.

Participants/materials, setting, methods: Inclusion criteria: age < 43 years; AMH <1,2 ng/ml; AFC < 6; basal FSH > 11 IU/ml. Exclusion criteria: uterine fibroids, deep endometriosis, cancer. Concentrations of LH, estradiol and progesterone in serum were evaluated with immunochemiluminometric assay. The CC gene expression was evaluated with Real-time PCR.

Main results and the role of chance: Age (36,0 ± 4,5vs.36,7 ± 3,8 in group 1 and 2, respectively) and antimullerian hormone concentrations (0,89 ± 0,3vs.0,94 ± 0,3) were similar in both groups. Comparisons of embryological outcomes showed significant difference between the number of retrieved oocytes (4,4 ± 2,1vs.8,8 ± 4,2, $p < 0,001$), MII (3,9 ± 2,0vs.7,4 ± 3,6, $p < 0,001$) and blastocysts (1,8 ± 1,5vs.2,7 ± 2,7, $p = 0,039$) with values being greater in group 2. The genes HAS2, COX2, GREM1, ALCAM, CD166, VCAN, SDC4, TP53I3, SPSB2, CALM2 expression in cumulus cells after LF group 2 (n = 17) were similar compared to group 1 (n = 23). After embryo transfer in cryo cycle, clinical pregnancy rate in group 2 was higher compared to group 1 (41.7% (30/72) vs. 51,3% (39/76), in group 1 and 2, respectively $p > 0.034$), but no significant differences were observed in the rate of early reproductive loss (16.7% (5/30) vs. 7.7% (3/39), $p = 0.06$). Progesterone (0,9 ± 1,67vs.16,7 ± 13,27) and estradiol (150,94 ± 83,41vs. 384,27 ± 334,44) levels on stimulation starter day were higher in LF group 2 compared to group 1, however, their concentrations on triggering day were similar in both groups (progesterone:3,49 ± 3,62vs.5,65 ± 4,58; estradiol:4630,17 ± 2469,52vs.3697,73 ± 2231,34 in group 1 and LF group 2, respectively).

Limitations, reasons for caution: Our study was carried out in a relatively small subset of patients whose CC gene expression was studied. Therefore, obtained results can not be extrapolated on other groups of patients and need to be confirmed in larger trials.

Wider implications of the findings: This study opens new possibilities for ovarian stimulation in the management of patients with impaired ovarian response.

O-179 Increased heteroplasmic load of coding mitochondrial DNA variants in tissues from ART children

J. Mertens[1], F. Zambelli[1], F. Belva[2], A. Van Montfoort[3], M. Bonduelle[2], S. Seneca[2], K. Sermon[1], C. Spits[1]

[1]Vrije Universiteit Brussel, Reproduction and Genetics, Brussels, Belgium
[2]UZ Brussels, Center for Medical Genetics, Brussels, Belgium
[3]Maastricht University, Medical Centre, Maastricht, The Netherlands

Study question: Is there an increase in heteroplasmic mitochondrial DNA variants in children born after ART?

Summary answer: We have found a statistically significant increase in mean variant load in individuals born after ART as compared to their naturally conceived peers.

What is known already: Children born after ART have an increased risk of a lower birthweight and a slightly abnormal cardio-metabolic profile later in life. Despite much research into epigenetic factors, the molecular cause of these differences remains unknown. Mitochondrial dysfunction is associated with lower birthweight, cardio-metabolic disease and it has been repeatedly suggested to play a role in infertility. Therefore, we hypothesized that an increase in variants in the mitochondrial genome (mtDNA) of ART individuals might explain the observed differences.

Study design, size, duration: We deep-sequenced the full mtDNA of 163 ART and 98 spontaneously conceived individuals, extracted from blood (58 ART, 65 control), saliva (77 ART, 6 control) and placental tissue (28 ART, 27 control). The samples were collected at the Center for Medical Genetics of the UZ Brussel and the Maastricht University Medical Center.

Participants/materials, setting, methods: The full mitochondrial genome was amplified using long-range PCR, sequenced on an Illumina platform and aligned to the reference genome (NC_012920.1) using BWA-MEM. mtDNA server was used to call single nucleotide variants, while insertions and deletions were detected using MuTect, with a lower threshold of 1.5%. Variants in the non-coding regions were excluded from the analysis. We calculated the cumulative heteroplasmic variant load as the sum of the loads of all variants in one individual.

Main results and the role of chance: We found that the three DNA sources followed similar differential distributions in cumulative mtDNA variant load in the ART and control groups. In blood, ART individuals carried a mean load of 9.1%±19.3, while in controls this was 5.4%±12.8. In the placental tissue, the ART carried a mean load of 12.6%±31.4, control samples of 5.7%±12.7. The saliva samples from ART carried a mean load of 8.5%±18.4. When all the

data from the different tissues were pooled per mode of conception, we observed a statistically significant higher mean load in the ART group (ART 9.4%±21.3, control 5.3%±12.4, p = 0.042 with one-tailed t-test). This difference is mainly due to the presence of more individuals in the ART group with higher loads. For instance,12.5% of ART individuals have cumulative loads >30%, while this is 5.1% for the controls (2.4 fold change, p = 0.04, one-tailed Fisher exact). We found no obvious correlation to maternal age and birthweight, although our current sample size is still too small to reliably test this.

Limitations, reasons for caution: The study is currently only able to show an increase in variant load, but not to correlate these to factors such as birthweight, maternal age or ART procedure. For this, we require a larger sample size; the study is still ongoing and we are currently sequencing control samples.

Wider implications of the findings: It is unclear what effect this type of mtDNA variants can have on an individuals' health, but studies in mouse have shown a significant impact of low load heteroplasmies on infertility, birthweight and premature aging. Further research is needed to clarify this and to identify the source of these mutations.

Trial registration number: NA.

O-180 Hypomethylation of imprinted genes in term placenta samples conceived by IVF/ICSI is associated with concomitant changes in post-translational histones modifications

C. CHOUX[1], P. Petazzi[2], M. Sanchez-Delgado[2], J. Hernandez-Mora[2], A. Monteagudo[2], P. Sagot[1], D. Monk[2], P. Fauque[3]

[1]CHU Dijon Bourgogne, Service de Gynécologie-Obstétrique, 21000 Dijon, France
[2]Bellvitge Biomedical Research Institute, Imprinting and Cancer group- Cancer Epigenetic and Biology Program, 08908 L'Hospitalet de Llobregat- Barcelona, Spain
[3]CHU Dijon Bourgogne, Laboratoire de Biologie de la Reproduction, 21000 Dijon, France

Study question: Is variability in DNA methylation at imprinted genes (IGs) differentially methylated regions (DMRs) following Assisted Reproductive Technologies (ART) associated with changes in post-translational histones modifications?

Summary answer: After IVF/ICSI, the histones marks at IGs' DMRs displayed enrichment of "active" and simultaneous loss of "repressive" modifications, consistently with the previously observed DNA hypomethylation.

What is known already: ART has been associated with an increased risk of placenta-related adverse pregnancy and perinatal outcomes, major malformations and imprinting disorders. Altogether, these data raise the concern of the potential epigenetic vulnerability associated with ART.

We previously demonstrated that DNA methylation in the placenta was significantly lower after IVF/ICSI than following natural conception at two IGs' DMRs: *H19/IGF2* and *KCNQ1OT1* (Choux *et al.*, *Human Reproduction* 2017). The aim of this original study was to profile active and repressive histones marks in placenta biopsies to reveal a better understanding of the epigenetic modifications in the context of ART.

Study design, size, duration: Patients were prospectively included from January 1st 2013 to April 30th 2015 in the Department of Obstetrics, Gynaecology and Reproductive Biology at Dijon University Hospital, France. Controls were singleton pregnancies of women that had conceived spontaneously within 1 year after stopping contraception. IVF/ICSI patients were singleton pregnancies achieved following fresh embryo transfer after two days of *in vitro* culture.

Participants/materials, setting, methods: In our previous study, we compared the placental DNA methylation by pyrosequencing in 51 IVF/ICSI *vs.* 48 control placentas for three IGs DMRs: *H19/IGF2*, *KCNQ1OT1* and *SNURF*. In the present study, we analysed histones marks abundance by Chromatin ImmunoPrecipitation (ChIP) in 16 patients who presented with below the 5th percentile of DNA methylation for at least one of these DMRs and compared with 16 controls matched for parity, new-born's sex, and gestational age at delivery.

Main results and the role of chance: DNA methylation of *H19/IGF2*, *KCNQ1OT1* and *SNURF* DMRs was significantly lower in the IVF/ICSI group (45.1 [43.2-48.9]; 32.8 [31.7-35.7] and 38.3 [35.5-40.5], respectively) than in the natural conception group (53.5 [49.6-59.3], P = 0.004; 39.4 [34.8-41.9], P = 0.001 and 41.2 [38.4-42.1], P = 0.036, respectively). Quantitative PCR targeting *H19/IGF2* and *KCNQ1OT1* DMRs in ChIP material precipitated with H3K4me2, a permissive modification, revealed significantly higher quantity of H3K4me2 in the IVF/ICSI group than in the natural conception group (P = 0.016 and 0.003, respectively). There was no significant difference for H3K4me2 for *SNURF*, or for the others permissive marks (H3K4me3, H3K9ac). The quantity of the repressive marks H3K9me3 and H3K9me2 at *H19/IGF2* and *SNURF* DMRs was significantly lower in the IVF/ICSI group than in the natural conception group (P = 0.011 and 0.027 for *H19/IGF2*, respectively; and P = 0.010 and 0.035 for *SNURF*, respectively) but there was no significant difference for *KCNQ1OT1*.

Limitations, reasons for caution: These data were assessed on a limited number of IGs DMRs. Therefore, it would be interesting to extend analyses to others DMRs.

Wider implications of the findings: These novel findings highlight that DNA hypomethylation at IGs' DMRs after ART is linked with increased active/decreased repressive histones marks, altogether promoting an "active" conformation of the chromatin. This concomitant change in epigenetic state at IGs at birth might be an important developmental event as a consequence of ART manipulations.

Trial registration number: not applicable.

O-181 Ovarian stimulation for IVF and risk of primary breast cancer in BRCA1/2 mutation carriers

I. Derks-Smeets[1], L. Schrijver[2], C. De Die-Smulders[1,3], V. Tjan-Heijnen[3,4], R. Van Golde[3,5], B. Caanen[1], M. Rookus[2], F. Van Leeuwen[2], E. Gómez-Garcia[1,3]

[1]Maastricht University Medical Center, Clinical Genetics, Maastricht, The Netherlands
[2]Netherlands Cancer Institute, Department of Epidemiology, Amsterdam, The Netherlands
[3]Maastricht University, GROW - School for Oncology and Developmental Biology, Maastricht, The Netherlands
[4]Maastricht University Medical Center, Internal Medicine - division of Medical Oncology, Maastricht, The Netherlands
[5]Maastricht University Medical Center, Obstetrics and Gynecology, Maastricht, The Netherlands

Study question: Does exposure to ovarian stimulation for IVF increase the risk of primary breast cancer for *BRCA1/2* mutation carriers?

Summary answer: No increased risk for breast cancer was found after ovarian stimulation for IVF in *BRCA1/2* mutation carriers.

What is known already: Female carriers of a pathogenic mutation in the *BRCA1* or *BRCA2* gene have a high risk of breast cancer. Their breast cancer risk rises from age 25 onwards and is particularly increased at reproductive age. In the general population no association between exposure to ovarian stimulation for IVF and breast cancer risk was found. However, a potential effect is rarely examined in *BRCA1/2* mutation carriers. This matter is of particular interest since *BRCA1/2* mutation carriers not only undergo IVF for infertility or fertility preservation, but also and in an increasing extent for preimplantation genetic diagnosis (PGD).

Study design, size, duration: 1,550 *BRCA1* and 964 *BRCA2* carriers were derived from (1) the nationwide HEBON study, a retrospective cohort with prospective follow-up among *BRCA1/2* mutation families, and (2) the national PGD registry. Observation time started at birth and ended at first invasive breast cancer diagnosis (event of interest), other cancer diagnosis or bilateral prophylactic mastectomy, whichever occurred first. In case these events did not occur, observation time ended at the age of questionnaire or last PGD contact.

Participants/materials, setting, methods: Eligible women were 18 years or older and had a pathogenic mutation in the *BRCA1* or *BRCA2* gene. Questionnaires were used to collect data on IVF exposure. Information on risk-reducing surgeries and cancer diagnoses was derived from clinical records and linkages with the Netherlands Cancer Registry, respectively. A time-dependent IVF exposure variable was used in Cox regression analyses, stratified for birth cohort and adjusted for infertility.

Main results and the role of chance: IVF exposure was not associated with risk of breast cancer for *BRCA1/2* mutation carriers (hazard ratio (HR) 0.79, 95%CI 0.46-1.36). Similar results were found for the subgroups of infertile women (n = 232; HR 0.73, 95%CI 0.39-1.37) and *BRCA1* mutation carriers

(HR 1.12; 95%CI 0.60-2.09). In addition, age at first IVF treatment and recency of IVF treatment were not associated with breast cancer risk.

Limitations, reasons for caution: Despite the availability of a nationwide cohort, power is still limited due to the low portion of women exposed to IVF. The subgroup *BRCA2* mutation carriers was too small for separate analysis. Hazard ratios were slightly biased to zero due to the oversampling of breast cancer cases.

Wider implications of the findings: Based on the current data, there is no reason to exclude *BRCA1/2* mutation carriers from IVF for fertility treatment, fertility preservation or PGD. Obviously, ruling out pre-existing lesions before IVF remains important because of the high *a priori* breast cancer risk in these women.

Trial registration number: Not applicable.

O-182 Higher gonadotropin dosage and longer ovarian hyperstimulation do not influence aneuploidy rates

C. Canon[1], M. Irani[2], N. Zaninovic[2], K. Xu[2], Z. Rosenwaks[2]

[1]*New York Presbyterian - Weill Cornell, Obstetrics and Gynecology, New York, U.S.A.*
[2]*Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.*

Study question: Does the gonadotropin dosage, duration of ovarian hyperstimulation, peak estradiol levels, or number of oocytes retrieved affect aneuploidy rates?

Summary answer: Aneuploidy rates are not affected by higher gonadotropin dosage, longer stimulation, higher estradiol levels, or larger number of oocytes harvested, regardless of a woman's age.

What is known already: Aneuploidy rates increase steadily with age, reaching >80% in women >42 years old. Preimplantation genetic screening (PGS) has been used along with blastocyst morphology to enhance embryo selection. The goal of controlled ovarian hyperstimulation (COH) is to overcome this high aneuploidy rate through the recruitment of several follicles, which increases the chances of obtaining a euploid embryo that results in a healthy conceptus. However, a recent study reported a significant difference in the aneuploidy rates (range: 39.5%–82.5%) between young oocyte donors who underwent stimulation at different fertility centers. These findings suggest that various methods of stimulation might affect aneuploidy rates.

Study design, size, duration: A retrospective cohort study including PGS data was conducted to compare aneuploidy rates. A total of 1,463 IVF/PGS cycles between January 2013 and December 2016 were included. PGS was performed using array comparative genomic hybridization. χ^2 test was used for categorical variables.

Participants/materials, setting, methods: A total of 7,980 embryos were analyzed for ploidy status. Cycles were divided into five age groups (<35, 35–37, 37–39, 40–42, and >42 years old), and aneuploidy rates were compared between different total gonadotropin dosages (<5,000 and ≥5,000 IU), duration of stimulation (<10, 10–13, and ≥14 days), number of oocytes harvested (<10, 10–19, and ≥20 oocytes), and peak estradiol (E2) levels (<1,500, 1,500–3,000, and >3,000 pg/mL).

Main results and the role of chance: Within the same age group, aneuploidy rates were not significantly different between cycles with different total gonadotropin dosages, duration of stimulation, number of oocytes retrieved, or peak estradiol levels. In the youngest group (<35 years, n = 2,366 embryos), aneuploidy rates were comparable between cycles of various total gonadotropin dosages (44.1% for <5,000 IU and 45.8% for ≥5,000 IU; $P = 0.7$), duration of stimulation (44.4% for <10 days, 44.2% for 10–13 days, and 40.4% for ≥14 days; $P = 0.8$), number of oocytes harvested (38.5% for <10 oocytes, 44% for 10–19 oocytes, and 45.8% for ≥20 oocytes; $P = 0.1$), and peak estradiol levels (45.7% for E2<1,500 pg/mL, 45.4% for E2 1,500–3,000 pg/mL, and 43.8% for E2>3,000 pg/mL; $P = 0.7$). Similarly, in the oldest group (>42 years, n = 741 embryos), aneuploidy rates ranged from 90.5% for gonadotropins <5,000 IU to 90.6% for gonadotropins ≥5,000 IU ($P = 1$), from 87.8% for <10 days of stimulation to 94.0% for ≥14 days of stimulation ($P = 0.3$), from 93.1% for <10 oocytes to 91.3% for ≥20 oocytes ($P = 0.1$), and from 88.6% for E2<1,500 pg/mL to 91.3% for E2>3,000 pg/mL ($P = 0.6$).

Limitations, reasons for caution: Although this large study (1,463 IVF/PGS cycles and 7,980 embryos) demonstrates the safety of COH in terms of aneuploidy, it would also be interesting to determine whether gonadotropin dosage affects the implantation potential of euploid embryos. Furthermore, a multicenter study may help to prove the generalizability of our single-center data.

Wider implications of the findings: The findings of this study reassure providers and patients that the total gonadotropin dosage, duration of ovarian hyperstimulation, estradiol levels, and number of oocytes retrieved do not influence aneuploidy rates, regardless of a woman's age.

Trial registration number: N/A.

O-183 Correlation between Embryo Ploidy Status and ovarian response after controlled ovarian Stimulation in ART cycles

S. Seshadri[1], X. Gonzalez Vinals[1], R. Odia[2], A. Alchami[1], W. Saab[3], P. Serhal[1]

[1]*Centre for Reproductive & Genetic Health CRGH- London, Reproductive Medicine, London, United Kingdom*
[2]*Centre for Reproductive & Genetic Health CRGH- London, Embryology, London, United Kingdom*
[3]*CRGH, Reproductive medicine, London, United Kingdom*

Study question: Is there a relationship between ovarian response and number of euploid embryos and aneuploidy rate in preimplantation genetic testing for aneuploidy (PGT-A)?

Summary answer: Ovarian response (OR) after conventional IVF stimulation is positively correlated with number of euploid embryos. Euploidy rate in younger patients decreases when OR is exacerbated.

What is known already: A positive relationship between ovarian response and the embryo aneuploidy rate has been described when mild controlled ovarian stimulation (COS) is performed in infertile patients, but this trend is not observed in patients who undergo conventional COS treatments with higher doses. It has been recently suggested by a published study that a threshold level for gonadotropin doses may exist and that no more competent oocytes can be obtained if it is exceeded. It has been shown in a retrospective study that high ovarian response to conventional ovarian stimulation does not increase embryo aneuploidy rates in aCGH-PGS cycles.

Study design, size, duration: 1560 blastocysts generated after ICSI between January 2016 to January 2017, derived from 210 patients (mean age 37.4 (SD 3.5) years), were included in study. This single centre retrospective cohort study was conducted at the Centre for Reproductive and Genetic health (CRGH), UK. Cycles were classified according to OR: poor (<4 oocytes collected), suboptimal (4-9), normal (10-14) and hyperresponse (>15). Embryo biopsy was performed at the blastocyst stage and PGT-A performed with Next Generation Sequencing.

Participants/materials, setting, methods: Female age was used to group the sample according to the Human Fertilisation and Embryology Authority (HFEA) categories into: <35 years (49/210), 35-37 years (43/210), 38-39 years (38/210), 40-42 years (40/210) and >42 (40/210). Number of euploid embryos, euploidy rate and relevant cycle parameters (i.e oocytes collected, embryos biopsied) was annotated for each of the categories. Statistical analysis was done using SPSS version 23.

Main results and the role of chance: Mean age for all patients in cohort 37.4+/-3.5 years. Analysis of euploid rate (number of euploid embryos/blastocysts biopsied) negatively corelates with an increase in ovarian response. This association is evident especially for young patients (<35 years) where euploidy rate for normal OR is 48% and drops to 32% in hyperresponse. Euploidy rate shows the same trend with a higher OR, but is not statistically significant in all age groups. Spearman's rank-order correlation was performed to determine the relationship between oocytes retrieved and euploidy rate in the same cycle (all ages). Analysis concluded a strong, negative correlation between both variables ($rs = 0.-062$, $p = 0.035$). The Poseidon group defined a "suboptimal response," (4-9 oocytes), which is associated, at any given age, with a significantly lower live birth rate compared with normal responders i.e., those with 10–15 oocytes. The euploidy rate in the "Poseidon" group was 28.1%. This rate is 0% in patients above 38 years of age when 4-9 oocytes are retrieved. Euploidy rate per oocyte collected decreases significantly for all age categories when number of oocytes retrieved is + 12. Maximum euploidy is obtained

when 8-10 oocytes are retrieved for patients (<35), 10-12 oocytes for ages 35-39 and 9-11 oocytes for patients above 40.

Limitations, reasons for caution: Larger studies (well-designed trials) with an increased number of biopsied embryos are needed to confirm our findings with analysis. The trials designed should also standardise the PGT-A technique being used as different laboratories have different reported sensitivity assays.

Wider implications of the findings: The first study that analysed the correlation between ovarian response and euploidy rate where PGT-A was performed using NGS technique on blastocysts. The degree of ovarian stimulation should be tailored to individual patient's ovarian reserve to optimise number of eggs retrieved thus resulting in a better yield of euploid embryos.

Trial registration number: Not applicable

SESSION 51: IMMUNOLOGIC AND OTHER TREATMENT OPTIONS IN RM/RIF

Tuesday 3 July 2018 Room 117 15:15–16:30

O-184 Effect of Administration of Intravenous intralipid on implantation rate in women with implantation failure after IVF/ICSI: A randomized controlled trial

N. Singh[1], A. Davis[2], A. Kriplani[3], S. Kumar[2]

[1]All India Institute Of Medical Sciences AIIMS, Department of Obstetrics & Gynaecology, New Delhi, India
[2]All India Institute of Medical sciences, Obstetrics & Gynaecology, New delhi, India
[3]All India Institute Of medical Sciences-, Obstetrics & Gynaecology, New delhi, India

Study question: To measure and compare the clinical pregnancy rate in women who receive intravenous intralipid versus placebo with previous implantation failure after fresh non donor IVF/ICSI.

Summary answer: Administration of intravenous intralipid in women with previous implantation failure after fresh non donor oocyte IVF/ICSI leads to a significant increase in clinical pregnancy rate.

What is known already: Proposed mechanisms for recurrent implantation failure is immunological abnormalities which reduce maternal endometrial receptivity, with focus on uterine natural killer (NK) cells and cytotoxic cytokines. Intravenous intralipid, a sterile fat emulsion containing soy oil, egg yolk, glycerin, and water, has traditionally been used in patients requiring total parenteral nutrition and has found to reduce the incidence of sepsis by regulating immune dysfunction. It is hypothesized that the fatty acids in the intralipid serve as ligands to activate peroxisome proliferators activated receptors (PPARs) expressed by the NK cells which decreases NK cytotoxic activity, which can enhance implantation and maintain pregnancy.

Study design, size, duration: Randomized controlled trial of 102 subjects with previous failed IVF undergoing IVF/ICSI from June 2016 to January 2018. Subjects were randomized after oocyte pickup into two arms.

Women with anatomical defects by diagnostic hysteroscopy, genital tuberculosis by endometrial aspiration for acid fast bacilli, acquired thrombophilias, and immunological co-morbidities were excluded.

Participants/materials, setting, methods: Women in the intervention arm(n = 52) received 2 doses of 20% intravenous intralipid (Fresenius Kabi), 4 mL diluted in 100 mL normal saline by slow infusion. The first dose was given immediately after oocyte recovery, second dose given one hour prior to transfer. The control group (= 50) received normal saline. All the women received routine luteal phase support. Outcomes measured were implantation rate and clinical pregnancy rate. No adverse effects of intralipid were observed.

Main results and the role of chance: The mean age of the participants was (31.6+/-4) in the intervention group and (32.1+/-3.5) years in control group (P = 0.47). The mean BMI was (24.1+/-3.1) in intervention and (24.6+/-3.3) kg/m2 (P = 0.394) in control group. The average number of attempts of IVF was (2.33+/-0.5) in both the groups, with minimum and maximum of 1 and 3 previous failed IVF.

The implantation rate (Beta HCG >/- 100 IU 14 days after embryo transfer) was 38.5% and 14% in intervention and control groups (P = 0.005). Clinical pregnancy rate as determined by sonographic fetal cardiac activity was 34.6% and 14% in intervention and control groups (P = 0.016). Ongoing pregnancy rate as defined as pregnancy continuing beyond 16 weeks gestation was 34.6% and 14% in intervention and control groups (P = 0.016). No adverse effects of intralipid were observed.

Limitations, reasons for caution: None

Wider implications of the findings: This study shows a statistically significant increase in implantation rate and clinical pregnancy rate in women who receive intravenous intralipid with prior implantation failure after IVF/ICSI, with no adverse effects.

Trial registration number: CTRI/2017/01/017206

O-185 Recombinant Human Granulocyte - Colony Stimulating Factor (rhG-CSF) in women with unexplained Recurrent Pregnancy Losses (RESPONSE Study): randomised, double-blind, multicentre, placebo controlled trial

A. Eapen[1], M. Joing[2], D. Lissauer[3], A. Coomarasamy[3]

[1]University of Iowa Carver College of Medicine, Obstetrics and Gynecology REI Division, Iowa City, U.S.A.
[2]Nora Therapeutics, Nora Therapeutics Inc, Palo Alto, U.S.A.
[3]Institute of Metabolism and Systems Research- University of Birmingham, Tommy's National Centre for Miscarriage Research, Birmingham, United Kingdom

Study question: Does administration of recombinant human granulocyte - colony stimulating factor in the first trimester of pregnancy improve outcomes in women with a history of unexplained recurrent pregnancy losses?

Summary answer: There is no evidence that administration of rhG-CSF in the first trimester of pregnancy improves outcomes, among women with history of unexplained recurrent pregnancy losses.

What is known already: rhG-CSF is shown to improve pregnancy outcomes by immunomodulation. The evidence prior to this study is only one RCT which was a smaller single centre study and another 4 observational study which suggested statistically significant increase in pregnancy rates and live birth rates.

Study design, size, duration: Women between the age of 18 to 37 years with a BMI of 19-35 (at the time of consent) and actively trying to conceive naturally after being diagnosed with a history of unexplained recurrent pregnancy losses were eligible. 340 women were screened into the study of which 150 were randsomised between June 2014 and June 2016. This was a double bind, placebo controlled randomised trial.

Participants/materials, setting, methods: The participants were recruited from 21 hospitals with established recurrent pregnancy loss clinics from across the United Kingdom. Eligible participants were randomised to receive rhG-CSF 130 mcg or placebo in a 1:1 ratio. Stratified permuted block randomisation was used with number of prior miscarriages (3, >3), and age (<35, 35-37 years)as the stratification factors. An online computerised system was used for randomisation. The primary outcome was ongoing clinical pregnancy at 20 weeks of gestation.

Main results and the role of chance: A total of 340 participants were screened for eligibility, of whom 150 women were randomised. 76 were randomised to rhG-CSF and 74 were randomised to placebo. All women were followed-up to primary outcome, and beyond to live birth. The clinical pregnancy rate at 20 weeks, as well as the live birth rate, was 59.2% (45/76) in the rhG-CSF group, and 64.9% (48/74) in the placebo group, giving a relative risk of 0.9 (95% CI: 0.7 to 1.2; p = 0.48). There was no evidence of a significant difference between the groups for any of the secondary outcomes.

Limitations, reasons for caution: The limitation of this study was that participants were not screened prior to inclusion to demonstrate immune dysfunction as the reason for their pregnancy losses. This is because there is no accepted test(s) for immune dysfunction in reproductive immunology. This trial was therefore exclusively for women with unexplained recurrent miscarriages.

Wider implications of the findings: G-CSF is widely used in reproductive medicine to treat recurrent miscarriages. Observational studies suggested

statistically significant improvements in clinical pregnancy rates after administration of G-CSF. However, we now have high quality evidence suggesting that G-CSF is not an effective treatment for patients with unexplained recurrent miscarriages.

Trial registration number: Eudract Number –2014-000084-40.

O-186 A reduction in uterine Natural Killer (uNK) cell density in response to luteal-phase endometrial scratch (ES) is associated with improved pregnancy outcome

M. Lokman[1,2], K. Fishwick[1], J. Brosens[1], S. Quenby[1,2]

[1]University of Warwick, Biomedical Research Unit, Coventry, United Kingdom
[2]UHCW NHS Trust, Obstetrics and Gynaecology, Coventry, United Kingdom

Study question: Does a change in uNK cell density following endometrial tissue injury relate to subsequent pregnancy outcome in women with recurrent reproductive failure?

Summary answer: A reduction in uNK cell density in response to endometrial scratch is associated with higher rates of ongoing pregnancies (≥12 weeks) and live births (P = 0.007).

What is known already: Work from our laboratory demonstrated an important role for uNK cells in maintaining tissue haemostasis in cycling endometrium. Specifically, IL-15 activated uNK cells target and clear acute senescent decidual cells during the window of implantation. Some but not all clinical trials have suggested that endometrial injury from scratch improves pregnancy outcome. This conflicting evidence could be explained by an inter-patient variation in response to injury. We hypothesised that changes in uNK cell density normalised to the day of biopsy relative to the LH surge, could be a marker of endometrial plasticity and by extension, subsequent pregnancy outcome.

Study design, size, duration: This is a 3 year prospective cohort study of 60 women with recurrent reproductive failure (2014-2017). Participants had either a history of recurrent miscarriage or implantation failure following IVF/ICSI. All participants had two LH-timed, mid-luteal endometrial biopsies at 1 to 6 months apart and a pregnancy or embryo transfer within one year of the second biopsy (2015-2017).

Participants/materials, setting, methods: Women were recruited from a dedicated Implantation Research Clinic for couples with recurrent reproductive failure. Participants had two pre-conceptual, mid-luteal endometrial biopsies. Each biopsy was subjected to immunohistochemistry staining for CD56 (uNK cell marker). uNK cell density was calculated using image analysis and normalised for day of biopsy relative to LH-surge, using a published centile chart based on 1900 samples. Inter-cycle variation was defined as the difference between uNK cell centiles of the two biopsies.

Main results and the role of chance: There was a significant variation in the inter-cycle difference in normalised uNK cell densities between participants with some patients showing minimal or no inter-cycle variability whereas the response was marked in others. In order to assess the clinical importance of this variance, we analysed uNK cell variance in two clinical groups according to subsequent pregnancy outcome following the second biopsy. Group 1 included women who achieved a subsequent ongoing pregnancy beyond 12 weeks gestation or live birth (n = 29) and Group 2 consisted of women who experienced a further first trimester miscarriage or IVF/ICSI implantation failure (n = 31). Group 1 had a significant reduction in uNK cell density [P = 0.007, median difference: -13% (CI -4 to -26.7)]. In comparison, Group 2 showed no significant inter-cycle variation [P = 0.58, median difference: -1.5% (CI -16.6 to 10.8)].

Limitations, reasons for caution: Linking endometrial factors to pregnancy outcome is hindered by the fact a proportion of miscarriages and implantation failures will be due to chromosomally abnormal embryos. The findings in this study are not yet robust and confidence intervals are large. To confirm or refute these findings, a larger cohort is required.

Wider implications of the findings: Our findings support the emerging concept of endometrial plasticity, i.e. the ability of the endometrium to adapt from cycle to cycle in response to stress signals. In addition, the patient-specific response to tissue injury likely determines the clinical benefit, or lack thereof, of the scratch procedure in clinical practice.

Trial registration number: N/A.

O-187 Combinatorial use of Endometrial Receptivity Array (ERA) and PGT-A can improve the clinical outcome in cases with previous ART failures

N. Findikli[1], M. Gultomruk[2], K. Boynukalin[3], M. Kavrut[3], E. Oral[4], M. Bahceci[3]

[1]Bahceci Fulya IVF Centre, IVF Laboratory, Istanbul, Turkey
[2]Bahceci Fulya IVF Centre, R&D Laboratory, Istanbul, Turkey
[3]Bahceci Fulya IVF Centre, Infertility Clinic, Istanbul, Turkey
[4]Istanbul University Cerrahpasa Faculty of Medicine, Obstetrics and Gyneocology, Istanbul, Turkey

Study question: This study investigates whether ERA and PGT-A approaches can be properly integrated in order to improve the clinical outcome in cases with previous ART failures.

Summary answer: Endometrial receptivity assessment by ERA and euploidy assessment by PGT-A can be effectively coupled in order to maximize the clinical outcome in recurrent ART failures.

What is known already: It has been shown that ERA test, which is based on the transcriptomic signature of 236 genes of a given endometrial sample, can successfully and objectively assess the endometrial receptivity in patients undergoing ART. By using this tool, recent reports indicate that in around 30-35% of the implantation failures can be due to pre- or post-receptive state of the endometrium and subsequent pET can rescue this defect. It is also well-accepted that majority of implantation failures can be of embryonic origin and by transferring euploid embryos high pregnancy rates can be obtained after PGT-A by comprehensive chromosomal screening (CCS).

Study design, size, duration: This retrospective clinical study includes clinical data of 632 patients with previous ART failures, whose endometrial receptivity were assessed by ERA between November 2013 – August 2017. During the study period, based on the ERA results, embryo availability as well as the clinical treatment protocol, patients were subsequently scheduled for either frozen embryo transfers (With embryos of unknown or known euploidy status), a freeze-all cycle or a PGT-A cycle.

Participants/materials, setting, methods: All endometrial biopsies were performed by a pipelle under general anesthesia after a hormone replacement therapy cycle (HRT) adjusted for expected window of implantation (WOI; at P + 5). Same HRT approach was also used in the subsequent frozen embryo replacements in patients with receptive results. In patients with displaced receptivity, embryo warming and transfer was personalized according to producer's recommendations. All PGT-A cycles involved Day5/6 trophectoderm biopsy, embryo cryopreservation and CCS analysis by aCGH or NGS.

Main results and the role of chance: Of these 632 patients, mean female age and number of previous ART trials were 35.8 ± 4.7 and 2.2 ± 2.3 respectively. Out of 684 endometrial biopsy samples obtained, 657 (96.1%) were successfully diagnosed as receptive (n = 432; 65.8%), pre-receptive (n = 160; 24.3%) and post-receptive (n = 65; 9.9%). In 27 (4.1%) of the samples, results were not informative. Based on the test results and clinical conditions, a total of 516 frozen embryo transfer cycles were performed either by embryos with unknown euploidy status (not screened by PGT-A; n = 171; Group I) or by euploid embryos obtained from a previous PGT-A (n = 345; Group II) cycle. Sixtyfour cycles (37.4%) in Group I and 108 cycles (31.3%) in Group II were performed as pET (p = 0.35). Biochemical pregnancy, clinical pregnancy, implantation as well as missed abortion rates were 47.4%, 43.2%, 31.8% and 20.3% for Group I and 75.9%, 70.4%, 65.8% and 16.4% for Group II respectively and these rates were found to be significantly higher in the latter (p < 0.01). At the time of data collection, the percentage of ongoing pregnancy/live birth cases in Group II was also significantly higher (58.2%) than the one in Group I (34.5%; p < 0.001).

Limitations, reasons for caution: Implantation is a complex process, involving synchronization of a variety of known as well as yet unknown embryonic & maternal factors. This study aimed at analyzing the possible impact of embryonic euploidy and endometrial receptivity assessment in patients with previous ART failures.

Wider implications of the findings: Results indicate that around 30% of patients with history of ART failures in this study show displaced endometrial receptivity. Personalization of FET cycles by the integration of ERA test in

conjunction with PGT-A can significantly improve the clinical outcome in these cases.

Trial registration number: None.

Study question: Do immune therapies improve live birth rate in women with a history of recurrent implantation failures (RIF), who are undergoing another cycle of assisted reproduction?

Summary answer: There is some evidence that intralipid may improve live birth rate with PBMC,GCSF treatment conferring potential benefit with regards to clinical pregnancy rate. However, the safety profile of these agents needs further investigation.

What is known already: RIF remains a clinically and emotionally challenging diagnosis for most patients undergoing IVF. Currently, there is lack of evidence to support specific screening tests and therapeutic measures. This has led to an offering of "empirical" treatment with immuno-suppressive agents to patients who experience RIF. However, this approach has been based on very little clinical evidence and treatment is offered to patients, without fully assessing the risks and benefits.

Study design, size, duration: The Cochrane Gynaecology and Fertility Group Specialised Register, the Cochrane Central Register of Studies Online (CRSO), MEDLINE, Embase, CINAHL and PsyINFO were searched from inception to September 2017. Randomised controlled trials (RCTs), where immunotherapy was given to women with a history of unexplained RIF who were undergoing assisted reproduction, were included for data analysis. The primary outcomes were live birth and miscarriage rates below 24 weeks of gestation. Secondary outcomes included clinical pregnancy rate and adverse events such as preterm delivery, multiple pregnancy and drug side effects. All outcomes were reported per woman randomised.

Participants/materials, setting, methods: The systematic review included 19 studies with a total of 1748 patients. G-CSF was used in 8 studies, heparin in 4, intralipid in 2 and leukocyte inhibitory factor (LIF) in 2 studies.

Risk ratios (RRs) with 95% confidence intervals (CIs) were calculated for each study and the data were synthesized using a fixed-effect model. The quality of the evidence was assessed using the GRADE method.

Main results and the role of chance: The evidence showed that intralipid probably improves the live birth rate compared to no treatment (RR 2.13, 95% CI 1.35 to 3.36; participants = 303; studies = 2; I2 = 6%, moderate certainty evidence)). Similarly heparin may slightly improve the live birth rate compared to aspirin, however the evidence for this was graded as low certainty evidence (RR 2.56, 95% CI 1.17 to 5.58; participants = 126; studies = 1; I2 = 0, low certainty evidence).

The evidence for miscarriage rate for intralipid, PBMC and LIF was insufficient or not reported for heparin and GCSF.

There was moderate evidence that PBMC, GCSF and Heparin treatment may improve the clinical pregnancy rate.

The data on adverse effects, either during the IVF procedure or pregnancy were either sparse or missing. The majority of studies had no means of blinding and were at high risk of performance and detection bias.

Limitations, reasons for caution: The use of intralipid is still under investigation and should be used with caution; PBMC is still at the experimental stage. Therefore, these results should only be applied to the research setting; further work is needed before it is offered in the clinical context.

Wider implications of the findings: Once the pathophysiology of RIF is understood, and its definition is agreed upon, targeted immune therapies may be proved effective in increasing pregnancy and live birth rates.

Trial registration number: N/A

SELECTED ORAL COMMUNICATIONS

SESSION 52: REPRODUCTIVE EPIDEMIOLOGY, SOCIO-CULTURAL ASPECTS AND HEALTH ECONOMY

Tuesday 3 July 2018 Room 116 15:15–16:30

O-189 The DOD (Distance Oocytes Donation) strategy: A safe, efficient and "patient friendly" way to overcome lack of egg's donors in different countries

F. Moffa[1], F. Bongioanni[2], I. Cino[3], C. Garello[2], A. Farreras[1], L. Delle Piane[2], G.L. Gennarelli[2], V. Biasoni[3], M. Benigna[3], A. Revelli[2], M. Lopez-Teijon[1]

[1]*Institut Marques, Reproductive Medicine Service, Barcelona, Spain*
[2]*LIVET, IVF Unit, Turin, Italy*
[3]*Institut Marques, Reproductive Medicine Service, Milan, Italy*

Study question: DOD (Distance Oocyte Donation) as fresh IVF-eggs donor's cycles with individual blastocyst vitrification and subsequent shipping to the recipient's country for thawed embryo transfers: a good alternative to reproductive tourism?

Summary answer: As a "patient friendly" strategy with good success rates, DOD cycles are a valid alternative to reproductive tourism in countries with lack of egg's donors.

What is known already: In some countries, legal statements as well as ethical, cultural and social aspects generate a huge discrepancy between the need for egg donation treatments and the availability of egg donors. Therefore, many recipient patients will travel to a different country to seek for egg donation treatments: it is not astonishing that in Europe more than 1/3 of all egg donor's cycles is performed in Spain (European registers 2013 by ESHRE). The cost of reproductive tourism is very high for patients: physical and psychological distress, difficulties in the medical follow-up during and after treatment, travel expenses, loss of working days, etc.

Study design, size, duration: This is a retrospective study of 215 DOD cycles preformed during a two years time period (may 2015 - may 2017) between two IVF clinics, based in two different European countries, as Spain (Barcelona) and Italy (Turin).

Participants/materials, setting, methods: For 195 couples, a frozen sample of husband's sperm was shipped from the Italian clinic to the Spanish clinic. In 20 cases, we used donor's sperm samples proceeding from a Spanish sperm bank (Barcelona, Spain). At the Spanish clinic, a total of 215 fresh IVF-eggs donor's cycles were completed and blastocyst stage embryos individually vitrified. Frozen embryos were shipped back to the Italian clinic in liquid nitrogen and 215 recipients underwent thawing transfer cycles.

Main results and the role of chance: When comparing DOD cycles with standard fresh egg-donor's cycles completed in the same time-period at the Spanish clinic in Barcelona, no statistically significant differences were observed in the mean number of good morphology blastocysts/cycle obtained (3.4 vs 3.4), mean age of recipients (41.7 years vs 42.1 years) and donors (26 years vs 26 years). A mean number of 1.58 (1-4) thawed transfers/DOD cycle was

performed. A single blastocyst transfer was performed in 90.9% of the DOD thawed transfers, being 1.09 the mean number of transferred embryos in each transfer. Clinical pregnancy rate was 64.6% (139/215) miscarriage rate was 12.6% (27/215), live birth rate was 52% (112/215), and twins rate was 0.9% (2/215).

Limitations, reasons for caution: Efficiency and safety of the DOD strategy depends on a strong and consistent blastocyst freezing/thawing method. Moreover strong partnership and shared IVF protocols between clinics, are needed to ensure a good outcome. Strict shipping rules are applied when frozen gametes and embryos are shipped between different countries.

Wider implications of the findings: The DOD strategy seems to be a safe and efficient alternative to the reproductive tourism in those countries where - for different reasons - there is a lack of eggs donors. DOD cycles are "patient friendly" treatments, allowing patients to receive reproductive care in their own country.

Trial registration number: Not applicable.

O-190 You did not turn up… I did not realise I was invited…: Understanding male attitudes towards fertility awareness and poor engagement

B. Grace[1], J. Shawe[2], S. Johnson[3], J. Stephenson[4]

[1]*University College London, Institute for Women's Health, London, United Kingdom*
[2]*University of Plymouth, Director of The Institute of Health and Community, Plymouth, United Kingdom*
[3]*Swiss Precsion Diagnostics, Scientific and Medical Affairs, Bedford, United Kingdom*
[4]*University College London, Insitute for Women's Health, London, United Kingdom*

Study question: What are the underlying reasons of poor male involvement in fertility awareness and reproductive health?

Summary answer: Improving male involvement in fertility awareness reproductive health will require more male focused initiatives in order to engage men better.

What is known already: Involvement of men in fertility and reproductive health is important for healthy pregnancies and positive outcomes for mother, father and child. However in research studies in these areas, there is a dearth of information on men's perspective. Whilst many studies have postulated the numerous reasons for lack of inclusion of men in reproductive health research, few studies have actually included men. Poor engagement by men is often cited as reason for this. In our study, we interviewed different groups, including men, to understand the underlying reasons for the lack of engagement.

Study design, size, duration: The study was a qualitative component of a wider mixed methods study. We carried out 35 qualitative in-depth interviews on 3 population groups: 13 women, 13 men and 9 healthcare professionals. Interviews were conducted between October 2016 and February 2017. Interviewees were purposively sampled to include men and women from the reproductive age range (18-45 years) and of varying ethnic and educational backgrounds.

Participants/materials, setting, methods: Participants were sampled from a UK cross-sectional survey on Fertility Awareness with 1080 participants who agreed to a follow-up interview. Survey participants were recruited nationwide via online newspaper and social media adverts. Healthcare professionals (HCPs) included doctors and nurses. Healthcare professionals were recruited from professional bodies such as RCN, RCGP, RCP, doctors.org.uk. Data was transcribed and analysed via framework analysis. Favourable ethical opinion was given by UCL.

Main results and the role of chance: The difficultly experienced recruiting the required samplesize of men highlighted a disconnect between men and reproductive health issues. We assessed this issue from the men's, women's and HCPs' perspectives. The reasons different groups gave for lack of male involvement were varied and reflected a need to evaluate different approaches for improving male involvement.

We found recurring themes towards men's reluctance to engage in fertility discussions. Women expressed that this was due to stereotypical male and female roles. They discussed the impact of societal norms and the perception that fertility is the 'woman's territory'. HCPs supported this view but also highlighted that poor male involvement was across healthcare needs; not just unique to fertility.

Contrary to expectations, we found that men wanted to be involved in family building discussions and wanted to improve their knowledge. However, men felt they did not have a voice on the topic because discussions have traditionally focused on women. The notion that men were not expected to be interested and engaged thus becomes a self-fulfilling prophecy.

To encourage male involvement, services, education programmes and researchstudies should widen scope to include men. Additionally, typical methods for attracting and incentivising women in studies will not necessarily work for men.

Limitations, reasons for caution: Although we gathered rich data, interviewees were self-selected and results principally reflect views of those who we willing to participate. Due to the online recruitment method, there is a bias towards more educated respondents with online internet access.

Wider implications of the findings: To encourage male involvement, the current female-oriented services and education programmes on fertility and reproductive health should be reviewed and revised to involve men. Additionally, educational programs on sexual and reproductive health should be engaging and structured to include boys and adolescents from a young age.

Trial registration number: Not applicable.

O-191 Risk of prostate cancer in ICSI treated men

Y. Al-Jebari[1], A. Elenkov[2], A. Giwercman[1], E. Wirestrand[1], I. Schütz[1], Y. Lundberg Giwercman[1]

[1]*Lund University, Department of Translational Medicine, Lund, Sweden*
[2]*Medical University Sofia, Department of Urology, Sofia, Bulgaria*

Study question: At what risk for prostate cancer are clinically sub-fertile men who have undergone ICSI as compared to men conceiving naturally?

Summary answer: Men who had undergone ICSI had a statistically significant increased risk of prostate cancer, in particular, early-onset prostate cancer, compared to men conceiving naturally.

What is known already: Register-studies have reported lower risk of incident prostate cancer for childless men than biological fathers. Other studies have indicated that men with impaired fertility are at higher risk for prostate cancer than fertile men. The majority of the men undergoing ICSI treatment are subfertile and since they are in contact with the health care system, these men are well suited as target for preventive measures.

Study design, size, duration: This register-based study sourced data from the Swedish Medical Birth Register, the Swedish Cancer Registry, and the Swedish Quality Register for Assisted Reproduction. All fathers and their first child born 1994-2014 were identified. ICSI fathers were compared to those who had become fathers by natural conception (controls) and IVF fathers regarding incident prostate cancer during a follow up of total 51990101 person-years until 2016. Sensitivity analysis stratified upon age at diagnosis of prostate cancer.

Participants/materials, setting, methods: Among all fathers (n = 1 181 490), 20 618 and 14 882 had undergone IVF and ICSI, respectively; and 3 211 were diagnosed with prostate cancer. Associations between mode of conception (ICSI/IVF/natural) and subsequent prostate cancer were investigated using Cox regression models with their date of birth as start of follow-up and adjusted for education level. Early and late-onset prostate cancer was defined according to age at diagnosis: ≤50 and >50 years.

Main results and the role of chance: Fathers who had undergone ICSI had a higher risk of prostate cancer (at any age) as compared to controls (HR = 1.47, CI 95% 1.15-1.89; p = 0.002). Conversely, IVF-men did not have an increase in prostate cancer risk when compared to controls (HR = 1.14, CI 95% 0.91-1.43; p = 0.25).

When stratified into age groups at cancer, the fathers who had conceived through ICSI had higher risk for early-onset prostate cancer (HR = 2.94, 95% CI = 1.84–4.71; p < 0.001) i.e. diagnosed before 50 years of age. However, ICSI-men did not have an increased risk for late-onset prostate cancer compared to controls. No increased risk of early onset PCa was detected for IVF-fathers (HR = 1.06, 95% CI = 0.57–1.98; p = 0.86).

In sensitivity analysis excluding fathers who were diagnosed with cancer prior to their offspring conception date, ICSI-fathers still had a statistically significant increased risk of PCa (HR = 1.32, 95% CI = 1.01–1.72; p = 0.045) and of early onset PCa (HR = 2.54, 95% CI = 1.52–4.24; p < 0.001).

Limitations, reasons for caution: Even with a cohort of this size, the prostate cancer cases within the ICSI group were quite limited (n = 63). The study design did not allow inclusion of the heterogeneous group men who had never fathered children.

Wider implications of the findings: The results show immense risk for early-onset prostate cancer, generally considered more aggressive, in men referred for ICSI. These men may already have a latent tumor at the time of ICSI, why the possible benefits of targeted screening could be considered.

Trial registration number: N/A.

O-192 The Canadian Assisted Reproductive Technologies Register (CARTR) Plus database: A validation study

V. Bacal[1,2,3], D.B. Fell[2,4], H. Shapiro[5,6], A. Lanes[3,7], A. Sprague[4,7], M. Johnson[7], H. Wang[7], M. Walker[1,2,3,7], L.M. Gaudet[1,2,3]

[1]University of Ottawa, Obstetrics and Gynecology, Ottawa, Canada
[2]University of Ottawa, School of Epidemiology and Public Health SEPH/ École d'épidémiologie et de santé publique EESP, Ottawa, Canada
[3]The Ottawa Hospital, Ottawa Hospital Research Institute, Ottawa, Canada
[4]Children's Hospital of Eastern Ontario, Children's Hospital of Eastern Ontario Research Institute, Ottawa, Canada
[5]University of Toronto, Department of Obstetrics and Gynecology, Toronto, Canada
[6]Mount Sinai Hospital, Mount Sinai Fertility, Toronto, Canada
[7]Children's Hospital of Eastern Ontario, Better Outcomes Registry & Network Ontario, Ottawa, Canada

Study question: Are data in the Canadian Assisted Reproductive Technologies Register (CARTR) Plus database valid and reliable?

Summary answer: Markers of validity were strong for the majority of variables evaluated. Those with moderate agreement were FSH levels, oocyte origin and elective single embryo transfer.

What is known already: Health databases and registries are excellent sources of data. However, as these databases are typically not established for the primary purpose of performing research, they should be validated prior to utilization for research both to inform the study design and to determine the extent to which key study variables are accurately documented in the database. CARTR Plus is Canada's national register for collecting information on in vitro fertilization (IVF) and corresponding pregnancy outcomes, and it has yet to be validated.

Study design, size, duration: This validation study of the CARTR Plus database examined IVF cycles performed in 2015 using patient chart reabstraction. Six clinics across Canada were recruited to participate using a purposive sampling strategy. Fixed random sampling was employed to select 146 patient cycles at each clinic, representing unique patients.

Participants/materials, setting, methods: Twenty-five data elements were reabstracted from patient charts, which was declared the reference standard. Data were reabstracted by two independent auditors with relevant clinical knowledge after confirming inter-rater reliability. Data from the chart were then compared to those in CARTR Plus. We calculated kappa coefficients, sensitivity, specificity, positive predictive value, and negative predictive value with 95% confidence intervals (CI) for categorical variables, and mean differences, paired t-tests and intraclass coefficients for continuous variables.

Main results and the role of chance: Six clinics agreed to participate in this study representing 5 Canadian provinces. The mean age of patients was 35.5 years, which was similar between the two data sources, resulting in a near perfect level of agreement (ICC = 0.99; 95% CI: 0.99, 0.99). The agreement for FSH was moderate, ICC = 0.68 (95% CI: 0.64, 0.72). There was nearly perfect agreement for cycle type, kappa = 0.99 (95% CI: 0.98, 1.00). Over 90% of the cycles in the reabstracted charts used autologous oocytes; however, data on oocyte source was missing for 13% of cycles in CARTR Plus, resulting in a moderate degree of agreement, kappa = 0.45 (95% CI: 0.37, 0.52). Embryo transfer and number of embryos transferred had nearly perfect agreement with kappa coefficients greater than 0.90, whereas that for elective single or double embryo transfer was much lower (kappa = 0.55; 95% CI: 0.49, 0.61). Validity markers for pregnancy type, number of fetal sacs, and number of fetal hearts on ultrasound were nearly perfect, with kappa coefficients greater than 0.90.

Limitations, reasons for caution: CARTR Plus contains over 200 variables, of which only 25 were selected for this study. This study, therefore, represents the first step in the validation process for the national database. This foundational validation work should be extended to other database variables in future studies.

Wider implications of the findings: This study provides the first assessment of the quality of the CARTR Plus database and we found very high data quality for the majority of the variables that were analyzed. The rigorous methodology used can serve as a guide for future validation projects.

Trial registration number: Not applicable.

O-193 Assisted reproductive technology (ART) treatment and risk of ovarian cancer

D. Vassard[1], C.H. Glazer[2], J. Lyng Forman[3], M. Kamper-Jørgensen[4], A. Pinborg[5], L. Schmidt[1]

[1]University of Copenhagen, Department of Public Health- Section of Social Medicine, 1014 Copenhagen K, Denmark
[2]Bispebjerg University Hospital, Department of Occupational and Environmental Medicine, 2400 Copenhagen NV, Denmark
[3]University of Copenhagen, Department of Public Health- Section of Biostatistics, 1014 Copenhagen K, Denmark
[4]University of Copenhagen, Department of Public Health- Section of Epidemiology, 1014 Copenhagen K, Denmark
[5]Hvidovre Hospital- Copenhagen University Hospital, Fertility Clinic- Department of Obstetrics/Gynaecology, 2650 Hvidovre, Denmark

Study question: Is ART treatment associated with risk of ovarian cancer?

Summary answer: An increased risk of ovarian cancer after ART treatment was mainly apparent during 12 years after treatment initiation and is likely influenced by detection bias.

What is known already: Ovarian stimulation in ART treatment has been suggested to increase the risk of ovarian cancer. Previous findings are inconsistent and often based on few diagnosed cases, and it has proven difficult to assess potential confounders such as endometriosis in large-scale studies. Nulliparity has been shown to be associated with ovarian cancer, although the causal relation is not clear. Ovarian cancer is often detected at an advanced stage due to a lack of symptoms during the early stages of disease. Latency time from initiated cancer until diagnosis has been estimated to be 30-40 years.

Study design, size, duration: The Danish National ART-Couple II (DANAC II) cohort includes all women treated with ART at Danish fertility clinics in 1994-2015. Each woman in ART treatment was age-matched with ten women from the background population without a history of ART treatment. The women were followed until first cancer diagnosis, death, migration or end of study December 31st 2015. The cohort consisted of 58,472 women treated with ART and 549,210 women without a history of ART treatment.

Participants/materials, setting, methods: Multivariable analyses were conducted using cox proportional hazards regression. Having a primary cancer diagnosis other than ovarian cancer was incorporated as a competing risk. Adjustment for confounders included baseline nulliparity, educational level, partnership status, endometriosis and PCOS and time-dependent adjustment for age and treatment year. Analyses were stratified on baseline nulliparity and on cause of infertility. Further, the risk of being diagnosed with ovarian cancer was observed over time in order to detect potential patterns.

Main results and the role of chance: During follow-up 393 (0.06%) women were diagnosed with ovarian cancer, 64 (0.11%) among ART-treated women and 329 (0.06%) among non-ART women. Women undergoing ART treatment had a higher risk of ovarian cancer than non-ART women (HR 1.20, 95% CI 1.10-1.31). ART treatment was associated with an increased risk of ovarian cancer among parous women (HR 1.34, 95% CI 1.11-1.62) and among nulliparous women (HR 2.38, 95% CI 2.17-2.60) versus (HR 2.03, 95% CI 1.89-2.19). ART treatment due to female factor infertility was associated with an increased risk of ovarian cancer (HR 1.36, 95% CI 1.25-1.48), while ART treatment due to male factor/unexplained infertility was associated with a lower risk (HR

0.87, 95% CI 0.76-1.00). ART treatment was not associated with a long-term increased risk of ovarian cancer which would be expected if caused by ovarian stimulating hormones. The excess risk of ovarian cancer among ART-treated women was highest during the first two years after ART treatment initiation (HR 1.24, 95% CI 1.06-1.45). The excess risk gradually declined and 12 years after ART treatment initiation the risk was similar to the background population (HR 1.05, 95% CI 0.87-1.27). This pattern suggests an influence of detection bias while undergoing ART treatment.

Limitations, reasons for caution: Although we did not find any indications of harmful effects of ovarian stimulating hormones, it is uncertain to what extent detection bias explains the higher risk among ART-treated women. ART treatment without female factor infertility was not associated with an increased risk of ovarian cancer.

Wider implications of the findings: Disentangling between the effect of underlying causes of infertility and the ovarian stimulation on the risk of ovarian cancer is a challenge. Further, detection bias should be thoroughly considered prior to drawing conclusions.

Trial registration number: Not relevant.

O-194 A pre-treatment counselling tool for predicting the cumulative probability of live birth

N. Balachandren, M. Salman, N.L. Diu, D. Mavrelos

UCLH, Womens Health, London, United Kingdom

Study question: Can we predict the chance of live birth after a single cycle of ovarian stimulation and transfer of all resulting embryos using only pre-treatment variables?

Summary answer: Using ovarian reserve and age, our model achieved a positive predictive value of 80% and AUC of 0.776 (95%CI 0.71 – 0.83).

What is known already: Published IVF prediction models calculate the probability of live birth per embryo transfer. More recently the cumulative probability of live birth (CPLB) has been predicted based on number of eggs collected after ovarian stimulation (Drakopoulos et al. 2016). While this information is useful, couples often want to know what their CPLB would be before they make the decision to engage with IVF. A model based on pre-treatment variables to calculate CPLB after one stimulated cycle of IVF and transfer of all frozen embryos would be helpful. To our knowledge there is no such model in current published work.

Study design, size, duration: This was a retrospective cohort study of patients who underwent their first ovarian stimulation between January 2014 and December 2015 in a tertiary referral hospital in central London. We reviewed all electronic and paper based records for each couple. 551 cycles were reviewed of which 335 complete cycles of IVF were included in the study.

Participants/materials, setting, methods: To estimate the CPLB we only included couples who had used all embryos from their initial stimulation or achieved a live birth. We excluded: (i) cycles that involved oocyte or sperm donation or in vitro maturation; (ii) unstimulated cycles; (iii) cycles that resulted in neither fresh nor frozen–thawed embryo transfer; and (iv) patients who did not have a live birth and had frozen embryos left or had discarded or transferred out their frozen embryos.

Main results and the role of chance: The cumulative live birth rate was 80% (268/335, [95% CI 76.0-84.0]). Women with a live birth had significantly lower median age (34 [IQR 6] vs. 36 [IQR 5], p = 0.005) and median FSH 6.6 [IQR 2] vs. 7.7 [IQR 2], p = 0.001). They had significantly higher median AMH (22.0 pmol/L [IQR 19] vs. 9.98 [IQR 6], p = 0.001) and AFC (18 [IQR 12] vs. 11 [IQR 8], p = 0.001). There were no significant differences in BMI, cause of infertility, previous pregnancy and duration of infertility.

We constructed a logistic regression model using live birth as the dependent variable and then used a backward elimination method to create the best fitting regression model to predict the probability of a cumulative live birth without removing age as this is a known predictor of live birth. Our model has a positive predictive power of 80% and the area under the curve (AUC) was 0.74 (95% CI 0.71 – 0.83).

The model was internally validated using 72 couples who had their first IVF cycle between January 2016 and December 2016. This model was able to correctly predict 96% of couples who had a live birth.

Limitations, reasons for caution: This was a small study and requires external geographical validation. The study population were only those eligible for NHS funded IVF treatment which had strict ovarian reserve criteria. The low specificity of this model could be a result of exclusion of women with very low ovarian reserve.

Wider implications of the findings: This model is a useful tool for couples considering whether to undergo ovarian stimulation allowing them to appreciate the full potential benefit of ovarian stimulation and embryo freezing. Couples with low probability can have realistic expectation on how many cycles of ovarian stimulation may be needed to achieve live birth.

Trial registration number: N/A.

O-195 Development and validation of an artificial intelligence based algorithm for the selection of an optimal stimulation protocols in IVF patients

N. Correa[1], S. Brazal[2], D. García[2], M. Brassesco[1], R. Vassena[2]

[1]*Centro de Infertilidad y Reproducción Humana CIRH, Assisted Reproduction, Barcelona, Spain*

[2]*Clínica EUGIN, Research Department, Barcelona, Spain*

Study question: Are artificial intelligence (AI) algorithms able to reliably predict ovarian response in patients undergoing their first IVF treatment according to different proposed ovarian stimulation protocols?

Summary answer: AI can predict with high reliability both the number of cumulus oocyte complexes (COCs) and of MII obtained in patients undergoing their first IVF cycle.

What is known already: Patients accessing IVF treatment for the first time are prescribed a stimulation protocol based on their reproductive characteristics and clinical history. Nevertheless, such initial treatment might not optimize their ovarian response, and the objective of averting non optimal outcomes (i.e. low response or hyperstimulation) might not be met. The analysis of large databases by machine learning algorithms should allow predicting with great accuracy the results of ovarian stimulation with different stimulation protocols, thus assisting the clinician in selecting the most appropriate treatment course since the first IVF cycle.

Study design, size, duration: Cohort database of 6952 first IVF cycles. Predictor variable included: patient age, BMI, blood type, smoking habit, reason for treatment, ethnicity, antral follicular count, FSH, estrogen and LH levels, age at menarche. 80% of the cycles in the database were used to train the algorithm, and the remaining 20% were used to validate the best model. As control in the training process we used a 5 times repeated 10-fold cross validation technique.

Participants/materials, setting, methods: Algorithm tested included Random Forest (RF), and two types of black box algorithms such as Support Vector Machine (SVM, linear kernel), and Artificial Neural Network (ANN). All of them capable of regression prediction, as the response variables that the algorithms were trained to predict were: number of COCs and of MII retrieved after stimulation.

Main results and the role of chance: Women in the database analyzed were on average 37.6 ± 4.7 years old (range 18-45), and had a BMI was 24.2 ± 2.8, mean number of COCs and MII obtained was 10 ± 7.1, and 7.2 ± 5.3, respectively. The best results were obtained using the RF algorithm (mtry = 51) and the response variable number of OCCs (correlation = 0.829, R squared = 0.676, mean absolute error = 2.405). Nevertheless, the difference with the RF model (mrty = 34) using as response the number of MII is

minimum (correlation = 0.816, R squared = 0.632, mean absolute error = 2.079), and it is better to be able to predict MII as the presence of these determine the success possibilities of the cycle. In other word, the AI algorithm could predict with 81% accuracy the number of MII obtained by a patient only considering pre-treatment characteristics and comparing them to a large database of known cycles' characteristics, stimulation protocols and stimulation outcomes.

Limitations, reasons for caution: Although the dimension of the database and the presence of both a training and a validation sample population should ensure the robustness of the model developed, AI based applications should be tested prospectively before release.

Wider implications of the findings: AI and machine learning algorithms can offer the opportunity to model the outcome of the first IVF cycle under different stimulation protocols, and therefore help clinicians in selecting the most appropriate treatment for first time patients.

Trial registration number: Not applicable.

O-196 Optimization of prediction models for live birth and miscarriage rate in intrauterine insemination between homologous and frozen donor semen

M.J. Soriano[1], I. Molina[2], J.V. Martínez[2], A. Palomar[2], S. Balasch[3], J.M. Rubio[2]

[1]Instituto de Investigación Sanitaria La Fe, Reproductive Medicine, Valencia, Spain
[2]Hospital Universitari i Politècnic La Fe, Reproducción Humana Asistida, Valencia, Spain
[3]Universitat Politècnica de València, Estadística e Investigación Operativa Aplicadas y Calidad, Valencia, Spain

Study question: Can we identify the factors predicting a positive and negative clinical outcome in the homologous and donor intrauterine insemination?

Summary answer: It is possible to establish a prognostic model of live birth and miscarriage rate before the intrauterine insemination (IUI) depending on female and male factors.

What is known already: Although IUI is a commonly used treatment, it is difficult to predict the chances of gestation. The overall success rate of IUI remains controversial and depends on several factors. Determinants of IUI success can be classified into three categories: female infertility factors (age, weight, hormones on the third day of the cycle, follicle development and aetiology), male infertility factors (semen analysis and preparation technique), and technique-dependent factors (type of insemination, number of cycles, type of stimulation received, and total dose administered). There is a controversy between researchers if pregnancy rates are influenced or not by these factors among others.

Study design, size, duration: A retrospective cohort study. A total of 7582 subfertile couples undergoing IUI between April 1997 and December 2017 were analysed. 5491 couples underwent IUI with homologous semen (IUI-H) and 2091 couples underwent IUI with frozen donor semen (IUI-D).

Participants/materials, setting, methods: All the infertile couples that underwent IUI cycles in the last ten years. Predictive factors evaluated were female infertility diagnosis, female age, body mass index (BMI), number of preovulatory follicles, number of the IUI cycle, endometrial thickness and sperm quality (total motile sperm count, TMSC). Binary and ordinal multinomial logistic regression analysis by the stepwise procedure were used to selecting the potential variables related to the live birth rate and miscarriage rate.

Main results and the role of chance: The overall pregnancy rate (PR) in IUI-H was 10.4% and 20.5% in IUI-D. Ordinal PR was 0.5% and 1.6%, respectively. The overall live birth (LB) rate was 8.3% in IUI-H and 17.5% in IUI-D, and the overall miscarriage rate (MR) was 2.1% in IUI-H and 3.0% in IUI-D. Binary and ordinal multinomial logistic regression analysis identified number of follicles ($p = 0.03$), number of IUI cycle ($p = 0.02$), female infertility diagnosis ($p = 0.00$) and TMSC ($p = 0.00$) as significant predictive factors of LB in IUI-H cycles. Number of follicles ($p = 0.01$), female age ($p = 0.00$) and NTSM ($p = 0.00$) were significant predictive factors in IUI-D cycles. IUI-H achieves the best results with two or three follicles, carrying out a maximum of 5 cycles, a high TMSC number and in cases of female infertility from ovulation disorders or a normal ovarian reserve. Moreover, patients under 30 years would significantly increase the LB rate in the IUI-D. A single preovulatory follicle ($p = 0.04$) and patients with genital malformation ($p = 0.00$) would be considered as prognostic miscarriage factors in IUI-H cycles. The risk of abortion would also be greater as the age increases in IUI-D cycles ($p = 0.01$).

Limitations, reasons for caution: The limitations of our study include lack of a prospective design, instead relying on a retrospective analysis.

Wider implications of the findings: There are not studies analysing the predictive factors of live birth between homologous and donor IUI, under the same conditions. This study will allow defining which couples will obtain a greater benefit with the IUI technique for more effective counselling and assisted reproduction treatment planning.

Trial registration number: This is not a clinical trial.

O-197 Comparison of machine learning models for the prediction of live birth following IVF treatment: an analysis of 463,669 cycles from a national database

I. Sfontouris[1], A. Patelakis[2], G. Panitsa[2], S. Theodoratos[2], N. Raine-Fenning[1]

[1]University of Nottingham, Child Health- Obstetrics and Gynaecology, Nottingham, United Kingdom
[2]Business Insight Co, Business Insight Co, Cambridge, United Kingdom

Study question: What is the comparative ability of different machine learning models in predicting live birth following IVF based on the analysis of a large national database?

Summary answer: Deep neural networks were associated with the highest accuracy and specificity for live birth prediction compared to other machine learning models.

What is known already: The increasing wealth of IVF-treatment data has presented the opportunity, but also the challenge, to develop models for accurate and personalized outcome prediction facilitating optimal treatment design and patient counseling. Machine learning allows the construction of algorithms that can 'learn' from data and make predictions. It is a powerful way to analyze large and complex datasets, which may not be effectively interpreted by the use of conventional statistics. Machine learning has been applied in several fields of healthcare and may prove to be a useful tool in developing accurate personalized predictions in fertility treatment.

Study design, size, duration: This population-based cohort study used anonymous data obtained from the register of the Human Fertilization and Embryology Authority (HFEA), the ART statutory regulator in the UK. A total 463,669 fresh autologous IVF/ICSI, non-PGD cycles, with a full set of data, performed between 1991 and 2012 were analysed to predict live birth per cycle started.

Participants/materials, setting, methods: A predictive model of live birth constructed using latest-technology deep neural networks (DNN) was compared with random forest (RF), decision trees (DT) and Naive Bayes (NB) machine learning models. Cycles were randomly divided into a training and testing set at a 80:20 ratio. The training set was used to develop the prediction model and the testing set to validate model performance. Comparisons were performed using McNemar's test.

Main results and the role of chance: After exclusions, a total 463,669 cycles were included, of which 99,537 [(21.5% (95% CI: 21.4-21.6%)] resulted in a live birth. 370,935 and 92,734 cycles were assigned to the training and testing sets, respectively. Variables up to and including the day of embryo transfer were included in the analysis.

The DNN model was associated with significantly higher accuracy, specificity, positive predictive value (PPV), positive and negative likelihood ratios compared to other machine learning models. Conversely, sensitivity and negative predictive value (NPV) were lower in DNN compared to other models. All differences compared to DNN were statistically significant ($p < 0.0001$).

Details of predictive parameters for all machine learning models are shown in Table 1. ratios and 95/ratios and 95% confidence intervals.

Table I

	Deep neural networks	Random forest	Decision trees	Naive Bayes
Accuracy %	76.83 76.59-77.08	74.94 74.66-75.22	72.90 72.61-73.18	35.91 35.61-36.22
Specificity %	94.86 94.72-95.01	91.16 90.95-91.36	87.07 86.82-87.31	18.30 18.02-18.58
Sensitivity %	11.09 10.71-11.49	16.16 15.65-16.67	21.53 20.96-22.11	99.76 99.68-99.82
Positive Likelihood Ratio	2.16 2.07-2.26	1.83 1.76-1.90	1.67 1.61-1.72	1.22 1.22-1.23
Negative Likelihood Ratio	0.94 0.93-0.94	0.92 0.91-0.93	0.90 0.89-0.91	0.01 0.01-0.02
PPV %	37.20 36.16-38.25	33.52 32.65-34.40	31.48 30.79-32.19	25.20 25.13-25.27
NPV %	79.55 79.48-79.63	79.76 79.65-79.86	80.09 79.96-80.21	99.63 99.51-99.72

Limitations, reasons for caution: The anonymised HFEA database holds no information on the number of cycles performed per patient. Therefore, necessary adjustments and calculation of cumulative live birth were not possible. Furthermore, availability of features related to patient demographics, ovarian reserve, baseline and stimulation characteristics, would likely improve the models' predictive ability.

Wider implications of the findings: The DNN model offered the highest specificity and accuracy, efficiently predicting cycles not leading to live birth. Prediction of unsuccessful treatment may be of value for counseling and patient assessment by clinics and funding bodies. Ongoing research using large datasets will attempt further improvements of the model's overall predictive performance.

Trial registration number: Not applicable

[4]*University "Alfonso X el Sabio, Research Department, Madrid, Spain*
[5]*Hospital Virgen de la Luz, Reproduction, Cuenca, Spain*
[6]*Clinica Tambre, Reproduction Unit, Madrid, Spain*

Study question: Are afamin levels and single nucleotide polymorphisms in the 5'-untranslated region of the afamin gene associated with male infertility?

Summary answer: Our results show increased afamin levels in the patient group when compared to controls. Also, suggest that afamin genetic variations might be associated with infertility.

What is known already: The plasma glycoprotein afamin has been previously identified and described as an alternative carrier protein for vitamin E in extravascular fluids such as plasma, ovarian follicular and seminal fluids. The role of afamin in male fertility was discovered by the afamin knockout mouse model. These results from a gene-deleted mouse model indicate a central role of afamin in fertility possibly due to its vitamin E-binding properties. However, so far, we have not observed any study which was able to establish a relationship in-between the levels of the protein, polymorphisms and expression of afamin genes with male and female infertility.

Study design, size, duration: This observational prospective study evaluates afamin levels in serum and seminal fluids from infertile men and compares them with healthy controls Plus, it also studies the association in-between single nucleotide polymorphisms (SNPs) in the 5'-untranslated region (5'-UTR) of the afamin gene with infertility. The study was performed from samples collected during the period from May to September 2017.

Participants/materials, setting, methods: Semen samples from 20 oligoasthenoteratozoospermic patients attending the Andrology Laboratory were included in the study. The control was formed by 39 men with normal semen parameters. Concentration of afamin was quantified by sandwich-type ELISA. Peripheral blood samples were analysed to examine the presence of specific sequences from the afamin gene (AFM) by PCR amplification followed by direct sequencing. T-Student test was applied to verify normality distribution of the variables.

Main results and the role of chance: Subjects with low sperm motility or/and sperm concentration had higher median sperm afamin (18,9 ± 2,9 ng/mg of proteins) and serum afamin concentrations (24,1 ± 4,0 ng/mg of proteins) than those without sperm alterations (10,6 ± 1,4 ng/mg of proteins) ($p < 0,02$); (15,6 ± 1,4 ng/mg of proteins) ($p < 0,002$).

A total of five different polymorphisms have been found, these include one deletion and the remaining four considered as single nucleotide polymorphisms (SNP).

A new transversion (A/T) (position 4:73481093) was identified in an OATz patient and was associated with high levels of afamin in plasma and seminal fluids. The prevalence of this variant in our study in the case homozygous for TT is 0.985 (98.5%), whereas in the case heterozygous for TA is 0.015 (1.5%).

5'Upstream single nucleotide polymorphisms rs115041046, rs371710441, rs35680917, rs72856618 of AFM were polymorphic in both patient and control groups. However, our data showed that the AG genotype (rs115041046) was higher among patients compared with controls, and that the TA genotype (rs371710441) was predominant in the group of male patients.

Limitations, reasons for caution: The main limitation of our study is the small number of replicates. The results observed in this study should be further confirmed with a larger sample number.

Wider implications of the findings: Afamin concentration is higher in the patient group, potentially due to a compensatory mechanism caused by a possible decrease in vitamin E levels. Accordingly, these patients could benefit from an antioxidant therapy. Moreover, these findings could significantly enhance our understanding of the molecular-genetic causes of infertility.

[5]Department of Poultry Sciences-, Faculty of Agriculture- Tarbiat Modares University-, Tehran-, Iran
[6]Tehran university of medical sciences, Anatomy department, Tehran, Iran

Study question: What is stress tolerance pathways and changes in the level of proteome and transcriptome in cryopreserved human sperm exposed to sublethal stress?

Summary answer: Sub lethal stress induced by nitric oxide(NO) increased sperm cryoservival by induce expression and modifications of proteins but, did not effect on transcriptome level.

What is known already: Stress preconditioning of sperm before cryopreservation is a novel approach for increase sperm cryosurvival. Beneficial effects of sublethal stress may attributed to the protein response and biosynthesis of stress-related proteins such as heat shock proteins (HSP) and cellular antioxidant enzymes. These proteins could reduce activation of the apoptotic cascade and maintain the quality of sperm after freeze. This response may be regulated at translational or posttranslational levels. Understanding the cellular and molecular modifications involved in the offensive controllable strategy by whole genome sequencing and proteomics could yield valuable information on the mechanism of cryotolerance in sperm.

Study design, size, duration: This was a control versus treatment study. We selected 60 semen samples from normozoospermic men, 28-35 years old. Basic semen analysis performed according to the WHO guidelines, samples which had not the oxidative stress (ROS-TAC score ≤ 50) were processed by density gradient centrifugation. Each sample was divided into the following three subsamples: fresh, freezing without treatment and group exposed to 0.01 µM NO for 1 h at 37°C and 5% CO2 before cryopreservation.

Participants/materials, setting, methods: Sperm suspensions were cryopreserved according to the rapid freezing method and stored for one week. The post-thaw sperm was evaluated for motility parameters (CASA), percentage of apoptosis rate (flow cytometry) and fertilizing ability (heterologous piezo-ICSI). Protein and transcript profiles were investigated between groups by TMT technology coupled to LC-MS/MS and RNA-seq respectively. Bioinformatics analyses were performed using DAVID. Candidate proteins and mRNA were further validated by western blot and Quantitative RT-PCR analysis respectively.

Main results and the role of chance: Data were analyzed using SPSS software and one-way ANOVA. Chi-Square analysis was used for fertilization data, Level of $p < 0.05$ was considered statistically significant. NO-0.01 group significantly increased total motility and progressive motility compared to the cryopreserved group. The lowest percentage of apoptotic rate observed in the NO-0.01 group in compared to the freezing group. In the fertilization trial, the rate of 2- cell formation was higher in fresh and NO-0.01 groups when compared with the control freezing group. In proteomic analysis,out of 2,912 proteins identified, 428 proteins were differentially expressed in the fresh, freeze and NO-0.01 groups. Gene ontology analysis of differentially proteins showed that the gluconeogenesis pathways, and fertility related proteins such as PLCz significantly down-regulated under cryopreservation condition. whereas in the NO-0.01 group, HSP70 and redox proteins such as thioredoxin were up-regulated in compared to cryopreserved group. Using RNA sequencing, Alignment mapped to the human reference genome (hg19).We determined that 368 transcripts were differentially expressed ($p < 0.05$) between fresh and freeze groups. The main down-regulated genes were PRM1 and PIK3R2, whereas SPATA family was up-regulated in cryopreserved sperm. We did not find a significant differentially in transcript level between NO-0.01 and freeze groups.

Limitations, reasons for caution: Due to lack of an adequate amount of protein and RNA for proteomics and RNA-seq analysis,extracted proteins and RNAs were pooled in each experimental group. Ethical committee not allowed using human oocytes for research, therefore, for evaluate oocyte activation capacity,we used mouse oocytes.

Wider implications of the findings: Cryopreservation effects on the proteome and transcriptome of sperm which may ultimately impair the sperm function. Stress precondition human sperm before cryopreservation could induce expression and modifications of proteins that can increase resistance to cryostress. understand mechanisms of stress-induced stress tolerance might improve sperm conservation protocols in assisted reproductive techniques.

Trial registration number: not applicable.

O-200 Attenuation of peroxiredoxin activity induce apoptosis in seminal plasma of men with idiopathic male infertility: striking the chord for evaluation of a novel biomarker

S. Kanta Goswami[1], R. Chattopadhyay[2], S. Ghosh[2], P. Chakraborty[3], M. Chakraborty[2], B. Chakravarty[2]

[1]Institute of Reproductive Medicine, ART, Calcutta, India
[2]Institute of Reproductive Medicine, Assisted Reproductive Technology, Calcutta, India
[3]Institute of Reproductive Medicine, Infertility, Calcutta, India

Study question: Is expression of the antioxidant gene panel is altered in seminal plasma of patients with idiopathic male infertility (IMI) compared to normozoospermic men?

Summary answer: Our results show that expression of peroxiredoxin and glutathione peroxidase was lower in IMI suggesting them as critical oxidative-stress regulators for fertilization and embryonic development.

What is known already: Most spermatozoa experience DNA repair, additional reactive oxygen species (ROS) being the main cause for DNA injury. High concentrations of ROS can alter biosynthesis kinetics of stress-related proteins(Heat Shock Protein, intracellular antioxidants etc.). Peroxiredoxin (PRDX), glutathione peroxidase 6 (GPX6), thioredoxin reductase 1 (TXNRD1) are chief antioxidant genes present in semen and are associated with various biological processes such as protection against DNA damage, detoxification, oxidative stress and cell apoptosis. Our previous studies have shown that combination of antioxidants may reduce pregnancy loss by correcting DNA abnormality induced by OS. However, the molecular mechanism responsible is yet to be explored.

Study design, size, duration: Prospective study; 147 men with IMI served as study cohort. Normozoospermic men (WHO criteria 2010) were treated as control ($n = 156$). The study was carried out from October 2014 to September 2017and was approved by Institutional Ethics Committee of Institute of Reproductive Medicine, Kolkata. All participants signed written informed consent form.

Participants/materials, setting, methods: Sperm parameters (velocity, motility), apoptosis status, DNA fragmentation, intracellular ROS was evaluated by Makler's chamber, flow cytometry, HaloTech DNA assay, and H2DCF-DA (2',7'-dichlorofluorescein diacetate) fluorescent probe respectively after freezing-thawing of ~200 spermatozoa. mRNA expression of PRDX, GPX6, TXNRD1and controls was measured by qRT-PCR using TaqMan probes. Relative changes in gene expression were calculated using the 2-ΔΔCT method. Statistical significance was set at $p < 0.05$ as evaluated by Pearson's correlation test and student's T-test.

Main results and the role of chance: In comparison with normozoospermic spermatozoa, there was a significant decrease ($P < 0.03$) in motility and velocity parameters and increase in Caspase+/propidium iodide- (PI-) cells ($P < 0.04$) in cryopreserved spermatozoa. As expected, small halo producing dispersed DNA loops in IMI cohort showed good correlation ($r = 1.39$; $p < 0.001$) with high DNA fragmentation index (DFI) and were significantly higher ($P < 0.01$) than control. Intracellular ROS levels were significantly higher in samples with increased caspase+ cells compared to normozoospermic men ($p \leq 0.02$) (57 ± 5.5 vs. 16 ± 7.8). We found that increased expression of PRDX2, PRDX5 and PRDX6 was associated with a significant reduction ($r=-0.69$, $p < 0.02$; $r=-0.61$, $p < 0.02$; $r = 0.55$, $p < 0.01$) in sperm motility parameters, and viability whereas ROS levels, DNA fragmentation, and loss of mitochondrial membrane potential as measured by rhodamine 123 were increased. qRT-PCR analysis revealed that the mean relative levels of mRNA coding for PRDX2, PRDX5, and PRDX6 were significantly decreased in seminal plasma of men with IMI (PRDX2 $p < 0.02$; PRDX5 $p < 0.05$; PRDX6 $p < 0.01$). TXNRD1 showed no differential regulation. Attenuation in GPX6 expression,

although lower than PRDX family, was comparable when correlated with ROS levels ($r = 0.87$, $p < 0.04$).

Limitations, reasons for caution: The results observed in this study should be confirmed on a larger sample number.

Wider implications of the findings: The cellular antioxidant defense is compromised by the attenuation of PRDXs and GPX6 leading to an increase in oxidative damage thus affecting the fertility potency of patients with IMI. Thus, current findings provide a strong platform for new therapeutic strategies through targeting PRDXs.

Trial registration number: Not applicable.

O-201 Seminal plasma cell-free mitochondrial DNA copy number is associated with human semen quality

Y. Chen[1], T. Liao[2], X. Lin[1], R. Wu[1], L. Jin[3]

[1]*Reproductive Medicine Center, Zhongshan Boai Hospital, Southern Medical University*
[2]*Reproductive Medicine Center, Affiliated Hospital of Guangdong Medical University, Zhanjiang, China*
[3]*Reproductive Medicine Center, Tongji Hospital, Tongji Medical College*

Study question: Whether is there association between seminal cell-free mitochondrial DNA (mtDNA) copy number and human semen parameters.

Summary answer: Seminal cell-free mtDNA copy number is associated with semen parameters, which may serve as a novel diagnostic marker of semen quality.

What is known already: Mitochondria are the major source of ATP through the electron transport chain and play important roles in sperm function and spermatogenesis. Recently, it has been suggested that abnormal sperm mitochondrial DNA copy number has been associated with defective sperm function. Despite that the cell-free mtDNA in body fluids has ignited great interest in exploiting its diagnostic value, there have no report about seminal plasma cell-free mtDNA and its probable clinical implications.

Study design, size, duration: Semen samples were collected from 205 men who were undergoing fertility assessment because of idiopathic inability to conceive. The population included men with normal and abnormal semen parameters.

Participants/materials, setting, methods: Seminal cell-free mtDNA copy number was measured using Real-time PCR. Seminal reactive oxygen species (ROS) level was analysed by using the in vitro OxiselectTM assay kit. Sperm quality was assessed using World Health Organization criteria, while sperm motility parameters were determined by computer-aided sperm analysis.

Main results and the role of chance: We applied PCR to detect seminal cell-free mtDNA from infertile men. All seminal plasma samples had mitochondrial MTF3212/R3319 gene expression. Average cell-free mtDNA copy numbers were 310.3, 199.4, 44.6 and 23.1 in the group of Normal, Oligozoospermia, Asthenozoospermia and Oligoasthenozoospermia. There were significant differences in mtDNA copy number among the groups of infertile men ($P < 0.05$). Comparing with the Normal group, seminal cell-free mtDNA copy numbers were decreased significantly in the Asthenozoospermia group ($P < 0.05$) and Oligoasthenozoospermia group ($P < 0.05$). In contrast with the Normal group, ROS levels were increased significantly in the Asthenozoospermia group ($P < 0.05$) and Oligoasthenozoospermia group ($P < 0.05$). Cell-free mtDNA copy number positively correlated with sperm concentration ($r = 0.345$; $P < 0.05$), motility ($r = 0.673$; $P < 0.05$), morphology ($r = 0.291$; $P < 0.05$), curvilinear velocity ($r = 0.263$; $P < 0.05$), straight-line velocity ($r = 0.247$; $P < 0.05$), and average path velocity ($r = 0.271$; $P < 0.05$). ROS level negatively correlated with sperm concentration ($r = -0.455$; $P < 0.05$), motility ($r = -0.676$; $P < 0.05$), curvilinear velocity ($r = -0.273$; $P < 0.05$), straight-line velocity ($r = -0.261$; $P < 0.05$), and average path velocity ($r = -0.264$; $P < 0.05$). There was negative correlation between seminal cell-free mtDNA copy number and ROS level ($r = -0.753$; $P < 0.05$).

Limitations, reasons for caution: The results need to be confirmed in more samples.

Wider implications of the findings: The strong positive correlation between cell-free mtDNA and conventional semen parameters suggest seminal cell-free mtDNA copy number could be used as a novel biomarker in the study and diagnosis of male infertility.

Trial registration number: N/A.

SESSION 55: FEMALE AND MALE FERTILITY PRESERVATION

Tuesday 3 July 2018 Room 113 + 114 + 115 17:00–18:00

O-202 Freezing ovarian tissue and simultaneously obtaining an average of 8 mature oocytes without ovarian stimulation - is it a reality?

D. Nikiforov[1], C. Junping[1], S.E. Pors[1], J. Gruhn[2], S.G. Kristensen[1], C.Y. Andersen[1]

[1]*University Hospital of Copenhagen- Rigshospitalet, Laboratory of Reproductive Biology, Copenhagen, Denmark*
[2]*University of Copenhagen, Centre for Chromosome Stability- Department of Cellular and Molecular Medicine- Faculty of Health Sciences, Copenhagen, Denmark*

Study question: Can immature oocytes found in the medium after cortical tissue preparation for fertility preservation, constitute a reliable source of mature eggs?

Summary answer: GV oocytes released during cortical tissue preparation, mature to MII stage with an average 23% success rate, resulting in average 8 MII oocytes per patient.

What is known already: Cryopreservation of ovarian tissue by slow freezing has become a reliable method of fertility preservation for many groups of the patients. During the procedure of cortical tissue preparation, many small antral follicles within the tissue are cut open resulting in release of immature oocytes into the medium. These oocytes have the potential to develop into mature oocytes that may be used for fertility purposes. The aim of present study was to improve the IVM protocol for oocytes deriving from small follicles which was previously rarely used in the context of fertility utilization.

Study design, size, duration: Oocyte-cumulus complexes (COCs) were collected into HEPES-buffered medium supplemented with 10 mg/mL of human serum albumin and cultured following an IVM protocol established in our laboratory (315 oocytes). After 48 hours oocytes were denudated and their maturation stage was determined.

Participants/materials, setting, methods: A total of 9 patients aged 21-36 years (mean age 29) who had one ovary excised for fertility preservation were included. After collection GV oocytes were divided into one of three groups: COCs with large amount of cumulus cells, small amount of cumulus cells and naked oocytes. After maturation measurements of oocyte diameter, diameter of egg's cytoplasm and zona pellucida thickness were taken and related to the maturation status of the oocyte.

Main results and the role of chance: On average, 35 immature oocytes per patient from one ovary were collected with the range of 13-60 oocytes. 23% ($N = 74$) of all oocytes matured to the MII stage within 48 hours. On average each patient had 8,2 mature oocytes. Maturation rate for the oocytes from large COCs was 37,5%, small COCs matured with the rate of 22,7%, while success rate for the naked ones was only 6,3% ($p < 0,001$). Our morphometric observations showed how diverse the pool of immature oocytes was. All found oocytes were within the range of 114-167 µm in diameter (including zona pellucida - ZP). Oocytes matured to MII had a significantly larger diameter than MI and GV ones ($p < 0,001$). No differences were found in relation between zona pellucida thickness and different stages. No significant relationship was observed between the number of collected oocytes and the age of patients.

Limitations, reasons for caution: More patients are needed to evaluate the developmental potential of oocytes obtained by the described method.

Wider implications of the findings: The unexpected developmental capacity of immature oocytes from small antral follicles is likely to augment chances for conception in this group of patients in addition to the cortical tissue. The

use of IVM oocytes collected from small antral follicles during normal IVF treatment may be of interest in the future.

Trial registration number: n/a.

O-203 Recovery of ovarian function after chemotherapy for Hodgkin lymphoma is limited by age, not pretreatment ovarian reserve

R. Anderson[1], A.M. Kirkwood[2], L.A. Clifton-Hadley[2], L.I. Stevens[2], P.E. Johnson[3]

[1]*University of Edinburgh, MRC Centre for Reproductive Health, Edinburgh, United Kingdom*
[2]*University College, Cancer Research UK & UCL Cancer Trials Centre, London, United Kingdom*
[3]*Southampton General Hospital, CRUK Centre, Southampton, United Kingdom*

Study question: How much do age and pretreatment ovarian reserve impact on ovarian function recovery after low toxicity chemotherapy with A(B)VD (doxorubicin, (bleomycin), vinblastine, dacarbazine) for Hodgkin lymphoma?

Summary answer: Anti-mullerian hormone (AMH) showed complete recovery after A(B)VD in women aged <35 but not in those ≥35, whereas recovery was similar across pretreatment AMH levels.

What is known already: Chemotherapy can be very damaging to the ovarian reserve, reflected in post-treatment amenorrhoea of variable duration, and reduced AMH levels in those without overt POI. Chemotherapy regimen and dose, age and pretreatment ovarian reserve have all been implicated in determining recovery of ovarian function after treatment, but previous studies have often included women with a range of diagnoses and treatment regimens, precluding clear interpretation. We have investigated recovery from A(B)VD treatment, regarded as having low gonadotoxicity, in a relatively young adult population as a more standardised model to investigate the relative contributions of age and pretreatment ovarian reserve.

Study design, size, duration: Women were recruited from the RATHL trial of treatment for newly diagnosed advanced Hodgkin lymphoma. Blood samples from 57 women treated with ABVD or AVD chemotherapy (grouped as A(B)VD) were taken pretreatment, at the end of treatment and at 1, 2 and 3 years later and serum stored.

Participants/materials, setting, methods: Women were aged 27.4 ± 0.9 years (range 18-44). Samples were analysed in a single batch for AMH using the Roche Elecsys automated assay. AMH recovery was calculated as concentration at 2 years/pretreatment. Spearman correlation coefficients were calculated and multiple linear regression used to analyse age and pretreatment AMH against AMH recovery. Groups were compared by Mann-Whitney U test.

Main results and the role of chance: AMH levels fell markedly in all women during chemotherapy, 13.8 ± 1.8 to 3.5 ± 0.7 pmol/L at end of treatment then recovered to pre-treatment levels by 1 year (13.1 ± 1.9 pmol/L) with no decline over the following 2 years. FSH showed opposite changes. There was a very good correlation between AMH pretreatment and at 2 years (Spearman $r = 0.71$, $p = 0.0002$) but not with AMH recovery ($r=-0.02$, $p = 0.9$). There was no significant correlation between age and pretreatment AMH ($r=-0.2$, $p = 0.1$) but there were significant negative correlations between age and 2 year levels ($r=-0.53$, $p < 0.0001$) and with AMH recovery ($r=-0.48$, $p = 0.001$). This negative impact of age on recovery was supported by mean AMH recovery in women <35 yrs being complete at 1.27 ± 0.12, whereas it was markedly reduced at 0.37 ± 0.10 in those ≥35 ($p < 0.0001$). Analysis by pretreatment AMH below/above the median value (9.77 pmol/L) showed that recovery was similar in the 2 groups (low group 1.23 ± 0.21 vs high group 1.03 ± 0.09, ($p = 0.8$). Multiple linear regression analysis also confirmed a significant impact of age (beta -0.43, $p = 0.004$) but not pretreatment AMH (beta -0.15, $p = 0.3$) on AMH recovery.

Limitations, reasons for caution: This analysis may be relevant only to women treated with this chemotherapy regimen, for Hodgkin lymphoma. It is unclear whether this impact of age on ovarian recovery can be generalized to other diagnoses/treatments. The mechanisms through which ageing impacts on recovery from chemotherapy are unknown.

Wider implications of the findings: The limiting effect of age on recovery of growing follicle populations requires further study to more fully understand the effects of age and chemotherapy on the ovary. This is likely to involve effects on both on the stroma and vasculature, in addition to depletion of the ovarian reserve.

Trial registration number: NCT00678327

O-204 Recombinant AMH prevents primordial follicle loss and long term fertility alteration in cyclophosphamide treated mice

C. Sonigo[1], I. Beau[1], M. Grynberg[2], N. Binart[1]

[1]*Inserm U1185, Université Paris Sud, Le Kremlin Bicetre, France*
[2]*Hopital Antoine Béclère, Reproductive Medicine and Fertility Preservation, Clamart, France*

Study question: What is the effect of concomitant recombinant Anti-Müllerian Hormone (rAMH) and cyclophosphamide (Cy) administration on ovarian reserve and fertility in a mouse model?

Summary answer: Co-treatment of rAMH with Cy preserves primordial follicle (PMF) loss induced by Cy and might improve fertility outcome after treatment.

What is known already: An endowment of oocytes is established during fetal development in women. The majority of oocytes are present within non-growing PMF. This PMF stockpile may decline as a result of age or in some pathological conditions. Mechanisms controlling the activation of PMF imply a balance between factors activating the initiation of follicular growth, mainly actors of the phosphatidyl-inositol-3-kinase (PI3K) signaling pathway, and inhibiting factors, such as AMH. Cy induces both the initiation of dormant follicle growth via an activation of PI3K pathway and the apoptosis of growing follicles leading to a major depletion of the follicular reserve.

Study design, size, duration: Forty-eight pubertal Swiss female mice received one intra-peritoneal injection of either vehicle, Cy (150 mg/kg), rAMH (100 µg) or Cy + rAMH and were sacrificed 24 hours or 8 days after treatment. To assess fertility outcome, a subgroup of pubertal mice was treated with one weekly intra-peritoneal injection of either vehicle, Cy (75 mg/kg), AMH (10 µg) or Cy + AMH through 4 weeks and then mated with proven fertile male along 14 weeks. Four weeks after male removing, ovulation tests were performed.

Participants/materials, setting, methods: Ovaries were removed one week after treatment, serially cut into 4 µm sections and stained with hematoxylin eosin. One out of five sections was analyzed and all follicles were counted. Western blot analysis of whole ovaries was performed to study PI3K pathway signaling. Fertility assessment included estrous cycles monitored by daily vaginal smears, mating experiment, and counting of cumulative pups. At last the number of ovulated oocytes after superovulation was evaluated.

Main results and the role of chance: The number of PMF into Cy-treated mice ovaries was significantly decreased as compared to controls (597.7 ± 35.9 vs 813.4 ± 68.7 follicles, $p = 0.010$) and was similar to normal range in Cy +rAMH mouse ovaries (875.5 ± 83.9 follicles). In addition, the number of early growing follicles was higher after a single injection of Cy as compared to control (802.4 ± 64.8 vs 507.7 ± 55.4 follicles $p = 0.02$). Western blot of ovary homogenates analysis showed that Cy increased significantly the phosphorylation of PI3K-pathway key proteins (P70S6K and FOXO3a). Co-administration of rAMH does not impact PI3K signaling pathway. Nevertheless, phosphorylation of the transcription factor FOXO3a was significantly decreased in ovaries of mice treated with rAMH alone as compared to control mice suggesting that AMH via FOXO3a blocks the PMF activation.

Cy-treated mice exhibited a significantly reduced number of estrous cycles when compared to controls (6.5 ± 0.4 vs 9.2 ± 0.3 cycles, $p = 0.006$). Co-treatment with AMH did not modify this alteration of cyclicity. The number of pups was slightly decreased in Cy-group as compared to controls or Cy+ rAMH mice. At last, the mean number of ovulated oocytes was decreased in the Cy-group as compared to controls and significantly increased after AMH co-administration.

Limitations, reasons for caution: This original study using a mouse model supports a potential protective role of rAMH against Cy-induced follicular loss. Further research and clinical studies are needed to confirm these results.

Wider implications of the findings: PMF activation has been recently reported as mechanisms for Cy-induced gonadotoxicity. This follicular activation might not be specific of Cy and has been described for other drugs.

Therefore rAMH could become a new option in the therapeutic arsenal of fertility preservation for young women having to undergo chemotherapy.

Trial registration number: not applicable.

O-205 Organotypic culture of fresh and cryopreserved-thawed human prepubertal and pubertal testis

J. Portela, C.M. De Winter-Korver, S.K. Van Daalen, A. Meißner, A.A. De Melker, S. Repping, A.M. Van Pelt

Academic Medical Center, Center for Reproductive Medicine, Amsterdam, The Netherlands

Study question: Can organotypic culture of fresh and cryopreserved-thawed human (pre)pubertal testicular tissue equally maintain spermatogenesis?

Summary answer: Though spermatogonia could be maintained *in vitro* for 5 weeks, the percentage of tubules containing MAGEA4+ cells decreased independently of tissue status and culture condition.

What is known already: Cryopreservation of testicular tissue is increasingly offered as a fertility preservation method for (pre)pubertal patients prior to gonadotoxic treatment, whereas strategies for fertility restoration still remain under development. One of the proposed experimental approaches is to differentiate germ cells *in vitro*. In fact, this has already been accomplished in mouse using an organ culture method to both fresh and cryopreserved-thawed testicular fragments. Despite these encouraging results, the spermatogenic yield is yet relatively low and could not be successfully applied to cryopreserved human testis tissue.

Study design, size, duration: Testicular tissue was collected from nine (pre)pubertal boys (6-14 years) admitted for fertility preservation procedure prior to gonadotoxic treatment. In all cases, ethical approval was obtained and informed consent was received from the boys' parents in order to use a portion of the testicular biopsy for research purposes.

Biopsies were either immediately processed or cryopreserved-thawed before organotypic cultured in two different media for a maximum period of 5 weeks, depending on the initial biopsy size.

Participants/materials, setting, methods: Fresh or cryopreserved-thawed testis fragments (1-2 mm^3 pieces) were cultured at a gas-liquid interphase (34°C, 5% CO_2) in weekly refreshed α-MEM + 10% KSR media containing 10^{-7} M melatonin and 10^{-6} M retinoic acid, with or without 3IU/L FSH/LH supplementation. A minimum of 3 cultured pieces were weekly fixed for further histological and immunohistochemical assessment of spermatogonial survival and proliferation (MAGEA4/PCNA). Percentage of tubules with MAGEA4 positive spermatogonia was determined in 25-100 tubular cross sections from each fragment.

Main results and the role of chance: Our data shows that, under the described conditions, organ culture of human (pre)pubertal tissue supported spermatogonial maintenance, but no further germ cell differentiation was detected over a period of 5 weeks. Quantitative analysis revealed a progressive decrease in the percentage of testicular tubules containing MAGEA4 positive cells during culture. Nevertheless, spermatogonial survival was comparable between fresh and cryopreserved-thawed cultured fragments and independent on culture media (without or supplemented with FSH/LH). Only in a single case (14 years patient), when elongating spermatids were already present in the testicular biopsy before culture, the percentage of tubules with MAGEA4 positive cells increased in fresh cultured tissue.

Depending on patients' age, spermatogonia remained proliferative active in the first weeks of culture and Sertoli cells regained proliferative ability *in vitro*.

Limitations, reasons for caution: These results should be interpreted considering that it is necessary to further optimize the organ culture method for human testicular tissue, ensuring better spermatogonial survival as well as differentiation potential. Additionally, investigations comprising the supporting somatic environment should be performed.

Wider implications of the findings: Our data suggests that fresh and cryopreserved-thawed testicular fragments are maintained similarly *in vitro*. Therefore, although the culture conditions need to be further optimized, these results support the concept that cryopreserved testis fragments from (pre) pubertal cancer survivors could be used for fertility restoration in the future.

Trial registration number: Not applicable.

SESSION 56: BIOLOGY OF OOCYTE AND CUMULUS COMPLEX

Tuesday 3 July 2018 Room 117 17:00–18:00

O-206 Mitochondrial DNA sequence variation in human oocytes by single-cell mtDNA sequencing

Q. Zeng[1], S. Cao[2], L. Cai[1], Z. Xue[3], J. Liu[1]

[1]*First Affiliated Hospital- Nanjing Medical University, The Center of Reproductive Medicine, Nanjing Jiangsu, China*

[2]*Nanjing Maternity and Child Health Hospital, The Center of Reproductive Medicine, Nanjing, China*

[3]*Tongji University, School of medcine, Shanghai, China*

Study question: Using single-cell mtDNA sequence to explicit variation of mitochondrial DNA in human oocytes during maturation.

Summary answer: All of the oocytes mtDNA were heteroplasmy. Most of mtDNA sequence variations were de novo distict to cumulus and located in MT-RNR1 and MT-RNR2 locus.

What is known already: Mitochondria's quantity and quality are essential to oocytes development, fertilization and early embryo development. mtDNA is unique from the nuclear genome, and mitochondrial inheritance is solely maternally inherited (non-mendelian patterning). And mtDNA shows a higher rate of mutation than nuclear DNA. It is assumed that most *de novo* mutations accumulate through the process of heteroplasmy. However, it is unknown whether mutations initiated, occur and accumulate early in the oocytes.

Study design, size, duration: Human oocytes were obtained from 8 patients at our Centers for Clinical Reproductive Medicine through written informed consent and institutional approval. 36 oocytes and its cumulus: Germinal vesicle (GV) (13), MI (4), and MII (19). After digestion them, oocytes or cumulus were used to construct mtDNA library and sequence. The whole mitochondrial genome was sequenced on the Illumina HiSeq platform and haplogroups and mtDNA variants were identified through mapping to reference mitochondrial genomes.

Participants/materials, setting, methods: After controlled ovarian hyperstimulation, oocytes were collected after 34–36 hours of hCG injection. Oocytes were treated with Tyrode's acidic solution to remove zona pellucida then were used to construct mtDNA library using VariantPro™ PCR reaction. The libraries were sequenced on the Illumina HiSeq 4000 platform. After removing low quality reads, clean data were analyzed and mapped to the reference human mitochondrial genomes using MtoolBox toolkit, BWA, GATK HaplotypeCaller, UnifiedGenotyper and so on tools.

Main results and the role of chance: It revealed the crucial mtDNA variations in different stages of oocytes. All samples showed different degree of mtDNA heterogeneity, and the proportion of heterogeneity and homogeneity (Het/Hom Ratio) was 0.03 to 0.46. The mitochondrial heteroplasmies were different among different stages of oocytes from the same patient, and mitochondrial heterogeneities were slightly different between the same stages of oocytes in the same individual.

A total of 196 mitochondrial variations or mutants were detected, and about 30% of them distributed in the non encoding region of (D-loop), e.g. MT-RNR1 and MT-RNR2 locus, which had high mutation rates. All of oocytes had different number of 25-50 mutants, and most of them were single nucleotide polymorphism (SNP). The types of SNP were different between individuals. It was found that most of the SNP (75.5%) was common to the oocytes and granulosa cells, and which was a genetic marker for the patients. But there are also oocytes and granulosa cells specific for the SNP, of which there were 22 SNP in oocytes included 9 missense mutations, and there were 26 SNP mutations in granulosa cells included 6 missense mutations and 2 synonymous, but most of the missense mutations with low frequency.

Limitations, reasons for caution: In the study, every stage of human oocytes was not achieved in natural cycles but induced using a GnRH agonist

and GnRH antagonist. And extremely-low-level variations were not anaylzed in this paper.

Wider implications of the findings: The results provide a valuable resource to comprehend for mtDNA duplication regulatory mechanisms underlying progressive development of human oocytes, and our study provides new insight into mitochondrial genetic disease occurrence and therapy.

Trial registration number: not applicable.

O-207 Transcriptional profile of tubulin post translational modification (PTM) enzymes throughout human oocyte meiotic progression in vivo and in vitro

P. Karamtzioti[1], G. Tiscornia[1], M. Barragán[1], I. Vernos[2], R. Vassena[1]

[1]*Clínica EUGIN, Assisted Reproduction, Barcelona, Spain*
[2]*Center for Genomic Regulation CRG, Cell and Developmental Biology Programme, Barcelona, Spain*

Study question: How do PTM enzyme transcripts in human germinal vesicles (GVs) change during the process of meiotic progression to the MII stage of maturation?

Summary answer: 17 PTME transcripts are detectable in GVs, MII oocytes and GVs cultured *in vitro* to the MII stage; only 3 PTMEs vary between maturation stages.

What is known already: Oocyte maturation requires the formation of the meiotic spindle, mainly composed of tubulin heterodimers (microtubules). Tubulin PTMs alter microtubule properties, making PTM enzymes potential regulators of spindle formation and chromosome segregation. Tubulin acetylation, glutamylation, formation of Δ2- tubulin, and tyrosination have been described in the meiotic spindle. In mice, increased acetylation impairs spindle migration to the subcortical region. Deacetylase overexpression can compensate for altered spindle formation and chromosome alignment in aged mouse oocytes. A role for glutamylation and tyrosination has not yet been defined in oocyte meiosis. Importantly, PTM and PTM enzymes have not been systematically characterized in human oocytes.

Study design, size, duration: This is a basic research study. GVs or MII stage oocytes were retrieved from hormonally stimulated oocyte donors aged 20-35 years old. Three experimental groups were defined: GVs (n = 6), *in vivo* matured MII oocytes (n = 8) and GVs cultured *in vitro* (without cumulus cells) until the MII stage (n = 6). Expression levels of 22 PTM enzymes responsible for all known tubulin PTMs were determined by single–cell real time quantitative PCR (qPCR) in the each oocyte.

Participants/materials, setting, methods: All women were stimulated by GnRH antagonist protocol, with GnRH agonist trigger. Trigger criterion was 2 or more follicles >18 mm, and OPU was carried out strictly 36 h later. Total RNA was isolated from each oocyte independently, cDNA generated by random hexamer priming and amplified for 24 cycles. qPCR for PTME transcript detection was performed in triplicate and expression levels were normalized to ACTB, RPLP1, DNMT1, GADPH, SDHA and UBC, using the $\Delta\Delta C_t$ method.

Main results and the role of chance: Out of 22 transcripts measured, 17 transcripts were detected. 14 transcripts out of 17 detected showed no variation between GVs and *in vivo* matured MII stage oocytes. NAA50 (acetylation), TTLL4 (monoglutamylation) and TTLL6 (polyglutamylation) showed the highest overall expression between both groups. In contrast, CCP2 (involved in deglutamylation) had low expression in both groups. In particular, expression levels of TTLL3 and TTLL10 (responsible for glycylation) were remarkably low, consistent with the presence of this modification only in exceptionally stable microtubules, such as in cilia and flagella. All other PTME had intermediate levels of expression. Notably, CCP2, TTLL4 and TTLL12 (unkown function) were significantly lower (Mann-Whitney test, $p < 0.05$) in MII oocytes as compared to GVs. PTME expression levels in MII stage oocytes obtained by culturing GVs in G2-plus medium did not show significant differences when compared to MII oocytes, except in the case of TTLL12 and TTLL5 (involved in monoglutamylation), which showed significantly higher expression levels than those observed in MII oocytes matured *in vivo* (Mann-Whitney test, $p < 0.05$). SIRT2 (involved in deacetylation) showed a similar tendency but did not reach statistical significance.

Limitations, reasons for caution: Variability may be underestimated by the relatively low number of samples per group. mRNA and protein expression levels of PTM enzymes may not be correlated, as transcripts may be stored in the oocytes in an inactive state, or be left-over from translation during oocyte growth.

Wider implications of the findings: This is the first characterization of tubulin PTM enzyme during human oocyte meiosis. Overall, expression levels of PTM enzymes did not change, with the exception of TTLL4, TTLL12 and CCP2, which decrease significantly during meiotic progression. We hypothesize that these PTM enzymes may play a role in meiotic spindle regulation.

Trial registration number: Not applicable.

O-208 Dual trigger vs. hCG for final oocyte maturation. A prospective randomized controlled, double blinded study: preliminary results

J. Haas[1], R. Bassil[2], R. Casper[2]

[1]*TRIO fertility clinic, IVF unit, Toronto, Canada*
[2]*TRIO fertility partners, IVF unit, Toronto, Canada*

Study question: Does co-administration of GnRH agonist and hCG in IVF cycles improve the number of oocytes and oocyte quality compared to hCG alone.

Summary answer: The dual trigger increases the number of mature oocytes, and number of top quality blastocysts compared to triggering with hCG alone in normal responder patients.

What is known already: Human chorionic gonadotropin (hCG) is usually used at the end of controlled ovarian hyperstimulation as a surrogate LH surge to induce final oocyte maturation. Recently, based on retrospective studies, the co-administration of GnRH agonist and hCG for final oocyte maturation (dual trigger) has been suggested to improve IVF outcome and pregnancy rates.

Study design, size, duration: A single center, prospective, randomized controlled, double-blinded clinical trial between July 2016 and January 2018.

Participants/materials, setting, methods: Normal responder patients were randomized either to receive hCG or dual trigger for final oocyte maturation. Data on patients age, BMI, AMH, number of follicles >10 mm and >15 mm on day of hCG administration, number of oocytes retrieved, MII, zygotes and blastocysts were assessed and compared between the dual trigger group and the hCG group.

Main results and the role of chance: One hundred and forty six patients were included in the study, 73 patients in each arm. The age (35.9 vs. 35.7 p = NS), BMI (23.7 kg/m^2 vs. 24 kg/m^2, p = NS), AMH (20.7 pmol/l vs. 19.5 pmol/l P = NS) and FSH (6.5 vs. 5.8 p = NS) were comparable between the two groups. The total amount of gonadotropins, the length of the stimulation and the number of follicles >10 mm and >15 mm in diameter on day of hCG administration were also similar in the two groups. The number of eggs retrieved (12.9 vs. 10.6, p = 0.02), the number of MII (10.1 vs. 8.6, p = 0.03) and the number of zygotes (7.9 vs. 6.3, p = 0.04) were significantly higher in the dual trigger group compared to the hCG group. The oocyte recovery rate (oocytes/follicles≥11 mm) was significantly higher in the dual trigger group compared to the hCG group (97% vs. 78% p = 0.001). The number of top quality blastocysts (2.8 vs. 1.8 P = 0.005) was significantly higher in the dual trigger group. The clinical pregnancy rate and the ongoing pregnancy rate were similar in both groups.

Limitations, reasons for caution: None.

Wider implications of the findings: The co-administration of hCG and GnRH agonist increases the number of oocytes, and the number of top quality embryos compared to triggering with hCG alone in normal responder patients. This increase may improve the outcome of the IVF cycle but a larger study powered by pregnancy outcome is needed.

Trial registration number: NCT02703584

O-209 Anti-Müllerian hormone promotes granulosa cell proliferation in the preantral-to-early antral follicles, but induces granulosa cell apoptosis during the subsequent follicular development, in the primate ovary

J. Xu[1,2], M. Lawson[1], L. Liang[1,3], C. Bishop[1]

[1]*Oregon National Primate Research Center Oregon Health & Science University, Division of Reproductive Sciences, Beaverton- Oregon, U.S.A.*
[2]*Oregon Health & Science University, Department of Obstetrics and Gynecology-School of Medicine, Portland- Oregon, U.S.A.*

[3]Henan Provincial People's Hospital, Reproductive Medical Center, Zhengzhou-Henan, China

Study question: Do granulosa cells in follicles at the different stages of folliculogenesis respond differently to anti-Müllerian hormone (AMH) in vivo in the primate ovary?

Summary answer: AMH may enhance preantral and early antral follicle growth by promoting granulosa cell proliferation, and prevent subsequent antral follicle maturation by inducing granulosa cell apoptosis.

What is known already: AMH action in the primate ovary is stage-dependent, directly promoting preantral follicle survival and growth while inhibiting antral follicle maturation in vitro. Blocking AMH actions in vivo interferes with dominant follicle selection process in nonhuman primates.

Study design, size, duration: Hemi-ovariectomized animals (n = 9) served as their own controls and were assigned randomly to 6 treatment sequences in a crossover design. Intraovarian treatments were administered during the follicular phase (cycle day -2 to mid-cycle estradiol, or E2, surge) of menstrual cycles 1, 3, 5 and 7, with 1 recuperation cycle between treatment cycles. Treatments included (a) control vehicle, (b) recombinant human AMH (rhAMH; 25 ng/hr), and (c) neutralizing anti-human AMH antibody (AMH-Ab; 1000 ng/hr).

Participants/materials, setting, methods: Female rhesus macaques (6-10 years) received intraovarian infusions via an osmotic pump. The menstrual cycle length was recorded. Blood samples were measured daily during treatment cycles for E2 and progesterone (P4) levels by immunochemiluminescence assays. Ultrasonography was performed at mid-cycle to assess antral follicle cohorts. One hour before the ovariectomy at the mid-cycle of the last treatment, animals received 20 mg bromodeoxyuridine (BrdU; iv). Ovaries were evaluated by hematoxylin/eosin staining, BrdU immunostaining, and TUNEL assay.

Main results and the role of chance: In the control cycles, only one large (5-9 mm) antral follicle was observed at the mid-cycle E2 surge. However, 3 rhAMH-treated ovaries displayed multiple medium-sized (2-4 mm) antral follicles, while the other 6 developed a single medium-to-large antral follicle with diameters less than those of controls (6.1 versus 7.0 mm; $P < 0.05$). Seven AMH-Ab-treated ovaries developed multiple medium-to-large (3-10 mm) antral follicles. The average serum E2 levels during the follicular phase decreased following rhAMH infusion, but increased following AMH-Ab infusion, relative to those of the control cycles (109.9/167.6 versus 136.1 pg/ml; $P < 0.05$). There were no differences in the menstrual cycle length, overall ovarian size at the mid-cycle E2 surge, peak E2 levels, or average P4 levels during the luteal phase between the control and rhAMH/AMH-Ab treatment cycles. While the preantral and early antral follicles of the control and rhAMH-treated ovaries appeared to be healthy, with the rhAMH-treated follicles containing abundant BrdU-positive granulosa cells, those in AMH-Ab-treated ovaries exhibited abnormal morphology with TUNEL-positive granulosa cells. In contrast, healthy medium-to-large antral follicles containing BrdU-positive granulosa cells were identified in the control and AMH-Ab-treated ovaries, whereas those in the rhAMH-treated ovaries contained abundant TUNEL-positive granulosa cells or became atretic.

Limitations, reasons for caution: The current study was performed in vivo with follicle cohorts from different developmental stages co-existing in the macaque ovary. Therefore, effects of the follicle-follicle interactions could not be ruled out. Hematoxylin/eosin, BrdU and TUNEL staining was descriptive, but could be quantified in future studies using cell and follicle counting methods.

Wider implications of the findings: The findings are consistent with previous in vitro data on the stage-specific actions of AMH in follicle cohorts. The study provides valuable information relevant to understanding and/or treating ovarian dysfunction. For example, elevated serum AMH in patients with polycystic ovary syndrome may contribute to the pathology of this endocrine disorder.

Trial registration number: Not applicable.

SELECTED ORAL COMMUNICATIONS

SESSION 57: APPROACHING THE CLINIC: STEM CELLS TREATMENTS FOR INFERTILITY

Tuesday 3 July 2018 Room 116 17:00–18:00

O-210 Autologous mitochondrial transfer as a complementary technique to ICSI to improve oocyte and embryo quality in IVF patients. A Randomized Pilot Study

E. Labarta Demur[1], S. Herraiz[2], M.J. De los Santos[3], A. Marzal[1], M.J. Escribá[3], A. Buigues[2], A. Pellicer[4]

[1]IVI RMA Valencia, Human Reproduction, Valencia, Spain
[2]IVI RMa, IVI Foundation, Valencia, Spain
[3]IVI RMA Valencia, IVF Laboratory, Valencia, Spain
[4]IVI RMA Rome, Human Reproduction, Rome, Italy

Study question: Does Autologous mitochondrial transfer (AUGMENT® treatment) improve oocyte/embryo quality and pregnancy rates in patients with previously failed IVF treatments?

Summary answer: AUGMENT does not seem to improve oocyte/embryo quality in this poor prognosis patients. No differences regarding live birth rates per embryo cohort were observed.

What is known already: AUGMENT is a proprietary new technology launched in 2014 by OvaScience℠. Previous clinical use suggested that the addition of autologous mitochondria during IVF is safe, improves embryo quality, increases the success of IVF and avoids concerns associated to heteroplasmy. Many studies described the existence of egg precursor cells (EPCs) in the outer lining of the ovarian cortex, however others have failed to find them. OvaScience reports that mitochondria isolated from EPCs are of high quality and morphologically like oocyte mitochondria.

Study design, size, duration: Triple blind, randomized, single-center, controlled experimental pilot study.

Study period: October 2015- June 2017.

A biopsy of the ovarian cortex was performed to isolate the EPCs to obtain their mitochondria. Sibling MII oocytes obtained after stimulation were allocated though computerized randomization to two groups: AUGMENT protocol (experimental) and Conventional ICSI (control).

Sample size was calculated to detect a 20% difference (15-35%) in the OPR between both groups. An interim analysis was performed in 59 patients.

Participants/materials, setting, methods: Infertile patients undergoing an IVF-PGT-A cycle, aged ≤42, BMI < 30, AMH ≥4 pmol/mL, >5 million/mL motile sperm, ≥1 unsuccessful previous IVF cycle with ≥5 MII eggs collected and extremely low embryo quality.

Primary endpoint was ongoing pregnancy rate (>12w).

In the experimental group, ≈1-2 picoliters of mitochondrial suspension were injected along with the sperm during ICSI. Viable blastocysts from both groups were biopsied and cryopreserved. The genetic content of the embryos was evaluated through CGH arrays.

Main results and the role of chance: Two of 59 enrolled patients spontaneously conceived (one ended in miscarriage). A total of 57 ovarian cortex biopsies were performed. In one case, a suboptimal number of EPCs were isolated; a second biopsy was performed yielding sufficient EPCs for inclusion in the study. Twenty-six patients did not undergo embryo transfer for the following reasons: no blastocysts available for biopsy (n = 16); all aneuploid (n = 8); no fertilization (n = 1); no survival after thawing (n = 1). A total of 253 MII were inseminated in the AUGMENT and 250 in the Control group, with a fertilization rate of 64.0 % and 70.8%, respectively ($p = 0.11$).

Day 5 blastocyst formation rates were significantly reduced in the AUGMENT group (27.2%) compared to the Control group (43.5%), $p = 0.002$. The number of euploid blastocysts/biopsied blastocysts was 42.2% (19/45) in the AUGMENT and 50% (37/74) in the Control group ($p = 0.42$). Statistical differences in euploidy rate/MII oocytes between both groups (7.5% vs. 14.8%, $p = 0.01$) were observed.

No differences were observed regarding mtDNA content in euploid embryos, $p = 0.56$.

The live birth rate per transferred embryo was 41.2% (7/17) in the AUGMENT and 39.1% (9/23) in the Control group ($p = 0.90$).

Limitations, reasons for caution: The technique requires a laparoscopy. Isolation of EPCs and mitochondrial extraction was performed in a separated laboratory set up from OvaScience. Data regarding final mitochondrial quantity and quality was not available for this analysis.

Wider implications of the findings: In this difficult to treat patient population, the ratio of euploid embryos obtained per MII was significantly lower with

AUGMENT compared to the Control group. No differences regarding live birth rates per embryo cohort were seen. Therefore, the study is no longer been continued.

Trial registration number: The www.clinicaltrials.gov registration number is NCT02586298

O-211 3D Architecture of endometrial glands in relation to stem cell organisation

N. Tempest[1], A.M. Baker[2], M. Jensen[3], N. Wright[2], D. Hapangama[4]

[1]Liverpool Women's Hospital, Department of Women's and Children's Health, Liverpool, United Kingdom
[2]Bart's Cancer Institute, Epithelial Stem Cell Biology group, London, United Kingdom
[3]Bart's Cancer Institute, University College London, London, United Kingdom
[4]Liverpool Women's Hospital, Women's and Children's Health, Liverpool, United Kingdom

Study question: Is there an epithelial stem cell(s) in the human endometrium that can regenerate all epithelial cell subtypes and what is the 3D architecture of endometrial glands?

Summary answer: Epithelial stem cells producing luminal, functional and basal epithelial subtypes exist in human endometrium; 3D glandular architecture demonstrates region-specific, horizontal branching and vertical singular arrangement.

What is known already: Menstrual shedding and repair of the endometrial functionalis is unique to humans and higher-order primates. The current dogma is that endometrial epithelium regenerates from endometrial epithelial stem cells residing in the base of the glands; this theory presumes endometrial glands to have a single tubular architecture with a blunt end. The precise 3D organisation of the human endometrial glandular epithelium is unknown. The existence of a human endometrial epithelial stem cell(s) that can produce the 3 epithelial regions (luminal, functionalis and basalis) is yet to be directly confirmed.

Study design, size, duration: Prospective observational study examining full thickness human endometrial samples from 50 normal pre (menstrual/proliferative/secretory) and postmenopausal women undergoing hysterectomy for benign gynaecological conditions without endometrial pathology.

Participants/materials, setting, methods: The gold standard method, in vivo cell lineage tracing, detecting unique mitochondrial DNA mutations (mtDNAm) in laser captured micro-dissected single epithelial cells, was used to confirm the existence of endometrial epithelial stem cells. 100 consecutive paraffin sections stained with H&E / cytochrome *c* oxidase (CCO) were used for 3D reconstruction. Manual drawing of gland boundaries in 2D images were connected along the third dimension. Epithelial subtypes were examined with 10 stains in consecutive endometrial sections.

Main results and the role of chance: CCO deficient patches exist in human endometrium, first appearing in a 27 year old. A unique CCO-mtDNAm, in a partially mutated gland within a CCO deficient area confirmed a clonal population evidently with its origin in a stem cell and suggesting there may be more than one stem cell responsible for regenerating that gland. Basalis glands interconnect (branch) and take a horizontal course along the myometrium; whilst non-branching single functionalis glands appear to germinate perpendicularly from these horizontal basal glands. mtDNAm occur in the basalis glands, and the vertical tracking of such mutations along the functionalis glands, confirmed that at least one population of endometrial epithelial stem cells resides in the basalis glands, responsible for endometrial epithelial regeneration. The sequential tissue sections stained for ten known epithelial cell markers also demonstrated the existence of all these cell types in a CCO negative clonal patch, confirming their common origin.

(I have 3D reconstruction videos that look great in a presentation)

Limitations, reasons for caution: Since the different epithelial cell subpopulations with phenotypical and functional differences are not fully characterised in the human endometrium, the ability of the potential stem cells to produce all different epithelial cells cannot be conclusively demonstrated.

Wider implications of the findings: More than one endometrial epithelial stem cell contributes to the monthly glandular regeneration. The complex 3-dimentional histo-architectural arrangement, highlights endometrial epithelium cannot be treated as a single entity. The existence of multiple endometrial epithelial stem cells with possible functional diversity warrants further interrogation, essential for understanding endometrial pathology.

Trial registration number: NA.

O-212 Human pluripotent stem cell-derived cells expressing functional follicle-stimulating hormone receptor (FSHR) - a tool for functional studies and disease modeling

K. Lundin, P. Väyrynen, K. Sepponen, K. Luiro, T. Tuuri, J.S. Tapanainen

University of Helsinki and Helsinki University Central Hospital, Department of Obstetrics and Gynecology, Helsinki, Finland

Study question: Can human pluripotent stem cells (hPSCs) be utilized in modeling FSHR function during early human development, and to study *FSHR* expression and function in FSH resistant patients?

Summary answer: hPSC-derived cells expressing human *FSHR* were derived. These cells responded normally to FSH while cells from patients with inactivating *FSHR* mutation failed normal responses.

What is known already: FSH regulates follicular growth and spermatogenesis. FSH bioactivity is exerted through binding to FSHR, where upon intracellular cAMP synthesis and other downstream signaling pathways are activated. Besides ovaries and testes, *FSHR* expression has been reported in extragonadal tissues including developing placenta and endothelial cells of female reproductive tract. We have previously shown that the inactivating *FSHR* mutation (A189V) leads to arrest of follicular development and infertility in females. Affected males have reduced sperm counts but are able to father children. Thus far, the expression or function of the mutated FSHR has not been studied in cells endogenously expressing the receptor.

Study design, size, duration: The study was conducted in a control human embryonic stem cell line (hESC H9, 46, XX) and two patient derived human induced pluripotent stem cell lines (hiPSC HEL127.6 and HEL128.5, 46, XX). The patient lines contained a A189V mutation in the *FSHR* gene, known to inactivate normal receptor function. Generation of patient lines was approved by Ethics Committee.

Participants/materials, setting, methods: Cells were differentiated with Activin A, CHIR-99021 and Y-27632 (1d), BMP7 and CHIR-99021 (1d), CHIR-99021 and dorsomorphin (2d), and B27 supplemented media (4d). Cells at different stages of differentiation were studied by qPCR. At d6 or d8, cells were stimulated with FSH for flow cytometry, localization, western blotting and qPCR studies and for cAMP assay. Single-cell sequencing was performed on control cells. Experiments were repeated at least three times for each cell line.

Main results and the role of chance: hPSCs differentiated by our protocol endogenously expressed functional FSHR. These cells responded dose-dependently to FSH stimulation by increasing cAMP production, downregulation of *FSHR* and inhibin βA (*INHBA)* mRNA expression and upregulation of inhibin α (*INHA*) expression. Patient derived iPSCs carrying A189V mutation also expressed *FSHR*, but the receptors did not respond to FSH stimulation by cAMP production or regulation of *FSHR* or inhibin gene expressions. Preliminary qPCR and single cell sequencing results indicate that the cells resemble extraembryonic cell types. Interestingly, hPSCs differentiated into trophoblast-like cells with another protocol also expressed *FSHR* at mRNA level but did not respond to FSH stimulation. Hence, we have established a method for differentiating human cells endogenously expressing *FSHR* that can be used for studying wild type and mutant receptors. However, the true identity of these cells is yet to be confirmed.

Limitations, reasons for caution: The cells express functional FSHR and can thus be used for studying the FSHR biology, but the biological role of these cells have to be further evaluated. So far, the localization of the receptor on the cell has not been elucidated due to lack of functional FSHR antibodies.

Wider implications of the findings: This study presents novel information about *FSHR* gene expression patterns during differentiation. The model generated here provides an efficient method to study the regulation and function of cells endogenously expressing FSHR obtained from both healthy subjects and subjects with abnormal FSHR function.

Trial registration number: Translational research, no trial.

O-213 A novel two-step transplantation procedure using adipose tissue-derived stem cells increases follicle survival by boosting angiogenesis in xenografted frozen-thawed human ovarian tissue

D.D. Manavella I.[1], L. Cacciottola[1], J. Donnez[2], C.A. Amorim[1], M.M. Dolmans[1]

[1]*Institute de Recherche Expérimentale et Clinique- Université Catholique de Louvain, Gynecology Research Unit, Brussels, Belgium*
[2]*Society for Research into Infertility, Fertility Preservation, Brussels, Belgium*

Study question: Do adipose tissue-derived stem cells (ASCs) increase follicle survival by enhancing oxygenation and vascularization in xenografted ovarian tissue using a two-step transplantation approach?

Summary answer: Higher rates of oxygenation and vascularization of ovarian tissue, as well as increased follicle survival rates, were detected in the early post-grafting period.

What is known already: ASCs have multilineage differentiation potential, proangiogenic properties and enhance vascularization in a peritoneal grafting site. Some studies suggest that using ASCs may improve quality of grafted ovarian tissue by enhancing graft angiogenesis.

Study design, size, duration: In vivo experimental model. A total of 15 severe combined immunodeficient (SCID) mice were intraperitoneally grafted with frozen-thawed human ovarian tissue from 5 different patients for a short-term period (7 days). A peritoneal transplantation site had been previously prepared in a first step using either empty fibrin (Fi + OT group [n = 5]) or ASC-loaded fibrin (Fi/ASCs+OT group [n = 5]) 14 days prior to grafting. Five mice underwent the standard one-step transplantation procedure and served as controls (OT group).

Participants/materials, setting, methods: Prospective experimental study conducted at the Gynecology Research Unit, Université Catholique de Louvain. Lithium phthalocyanine (LiPc) crystals were inserted into all grafted human ovarian tissue before transplantation. On days 3 and 7: pO_2 measurements (EPR oximetry); on day 7: mice were euthanized and samples were collected for histological (H-E and Masson's trichrome staining), IHC (anti-mouse and human double CD34 and anti-human Ki-67) and TUNEL analyses.

Main results and the role of chance: A significant increase in pO_2 was observed in all groups between day 3 and 7 ($p < 0.001$). A significantly higher pO_2 level was observed in the Fi/ASCs+OT group compared to the OT group on day 7 ($p = 0.028$). Total CD34-positive vessel area on day 7 was greater in the Fi/ASCs+OT group than in any other group (vs non-grafted group: $p = 0.0014$; vs OT group: $p = 0.013$; vs Fi + OT group: $p = 0.018$). Follicle survival rates after grafting were also higher in the Fi/ASCs+OT group compared to all the rest (vs OT group: $p = 0.0059$; vs Fi + OT group: $p = 0.0138$). TUNEL-positive follicle percentages after grafting were significantly lower in the Fi/ASCs+OT group than in any other grafted tissue (vs OT group: $p = 0.045$; vs Fi + OT group: $p = 0.0268$). Percentages of Ki-67-positive primordial follicles were significantly higher in all grafted groups compared to non-grafted tissue controls ($p < 0.01$). No differences in were observed fibrotic areas.

Limitations, reasons for caution: As demonstrated by our results, the proposed two-step ovarian tissue transplantation procedure using ASCs enhances vascularization in the early post-grafting period, leading to increased follicle survival rates and decreased apoptosis. However, mechanisms involved in the proangiogenic behavior of ASCs remain to be elucidated.

Wider implications of the findings: Our results suggest that the proposed transplantation procedure with ASCs is a promising step towards potentially solving the problem of massive follicle loss after ovarian tissue grafting.

Trial registration number: N/A.

INVITED SESSION

SESSION 58: COCHRANE SESSION: INDUSTRY AND EVIDENCE IN REPRODUCTIVE MEDICINE: MANAGING THE CONFLICTS

Wednesday 4 July 2018 Room 211 + 212 08:30–09:30

O-214 Conflict of interest and bias: not your problem or is it?

L. Bero

The University of Sydney, D17- The Hub- 6th Floor- Charles Perkins Centre, Sydney NSW, Australia

Abstract text

Bias in research is a problem that concerns researchers, consumers, policy makers and other users of evidence. Researchers strive to reduce bias in their research and make it transparent. A variety of methods have been used to identify "bias"—the systematic error or deviation from the true results or inferences of a study—in clinical pharmaceutical research. Bias related to funding sources or investigator conflicts of interest can be introduced throughout the entire research process (questions asked, design, conduct or publication). Global transparency initiatives have enabled the detection of previously hidden financial ties between researchers and pharmaceutical companies. I will discuss a number of ongoing efforts aimed at identifying and reducing bias in clinical research and practice.

O-215 We need some sunshine - making gifts from industry Transparent

P. Vercellini

Università degli Studi and Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico- Milan- Italy, Department of Clinical Sciences and Community Health, Milano, Italy

Abstract text

The collaboration between academic investigators and industry is invaluable for the advancement of medical knowledge and improvement of health care. However, whereas the main objective of medicine is to develop increasingly clinically effective and cost-effective therapeutic options, that of pharmaceutical industries and medical device manufacturers is to generate profit. Physicians are accountable to their patients and, more in general, to society. Industry CEOs and senior executives are accountable to their board of directors and, more in general, to shareholders. In spite of different main aims, a "convergence of interests" may arise between medicine and industry when crossing the boundaries of science and accepting the weight of financial dynamics. Physicians may desire money for themselves, but also for their research programmes, scientific societies, conferences, and medical journals. In an era of scarce public funding, industry becomes an attractive and abundant source of money for the entire medical community. In this condition, the risk for medicine would be to favour the interest of industry to the detriment of that of patients, thus derailing from its mission, whereas industry can continue to pursue its main interest (i.e., profit) without mission distortion. According to entrepreneurial logic, any industry financial investment should generate revenues, in this case through modification of prescribing patterns. In this regard, scientific information is crucial to increase sales of drugs and devices. The way scientific information is generated, selected, disseminated, and conveyed to patients is precisely the process that industry may be tempted to influence. To accumulate funds for their research programmes, academicians could accept to conduct trials expressly designed to systematically favour the experimental drug. The reports of these trials may appear in prestigious journals that would gain from selling advertisement and reprints. The publication of these results could influence the drafting of guidelines issued by scientific societies, especially when members of the panel of experts received industry funds. Annual conferences, which are indispensable for the financial survival of many professional organisations, could be supported by drug and device manufacturers, provided sponsored symposia including selected key opinion leaders are strategically positioned within the scientific programme. Industry may focus not only on investigators tempted to facilitate their career and increase their visibility, but also on patient associations, generally considered by citizens as honest and reliable sources of information. Awareness campaigns can be organized by façade committees behind which industries operate. Several stakeholders would profit from this "convergence of interests", except patients, their families, and public health services that eventually would pay the bill. If influenced scientific information is the cornerstone of this ambiguous compromise, then medicine appears much guiltier than industry, because no distortion of evidence would ever be possible without the active role of academia. The validity of the shared decision-making process, i.e. the

currently accepted paradigm of care in chronic medical conditions, is based on a properly conveyed, complete and truthful information. In case the professional contract is breached to the benefit of industry, who is more to blame: the individual physician who accepted meals, gifts, and travels to conferences, or those academicians with vested interests who, playing several different roles, generated and disseminated distorted information used to influence the end-prescriber? With the objective of limiting the "convergence of interests", an open peer-review system could be readily implemented by major journals for those manuscripts dealing with novel medical interventions with a potential impact on prescribing patterns. If names of editors and reviewers, as well as their reports, were publicly accessible, probably the gatekeepers of scientific information would be less indulgent toward industry interests.

INVITED SESSION

SESSION 59: NON-GENETIC FACTORS INFLUENCING EMBRYO VIABILITY

Wednesday 4 July 2018 Room 111 + 112 08:30–09:30

O-216 Influence of maternal diet on preimplantation embryo development and long-term potential

T. Fleming

Southampton General Hospital, School of Biological Science\rMailpoint 840- Level D Lab & Path Block, Southampton, United Kingdom

Abstract text

Epigenetic and physiological mechanisms permit embryos at the onset of development to adapt to environmental conditions such as maternal dietary quality, leading to altered phenotype of both extra-embryonic (placental) and embryonic (fetal) cell lineages. Thus, poor maternal diet around the time of conception in mouse models induces compensatory responses in extra-embryonic lineages that collectively enhance the capacity for nutrient delivery from the mother. Peri-conceptional poor diet also causes fetal tissues to coordinate growth with nutrient availability through control of ribosome biogenesis, mediated by DNA methylation level of the rDNA promoter. Such adaptations to peri-conceptional maternal diet appear mediated through nutrient sensing, particularly levels of select amino acids and insulin, at the blastocyst stage and modulation of mTOR signalling. Whilst this maternal-embryonic 'dialogue' supports embryo survival, if environmental conditions change, adaptations can become maladaptive and associate with long-term risk of cardiometabolic and neurological disease in adult offspring. Evidence of related environmental programming of early embryos has been forthcoming across mammalian species including the human, and can occur in response to diverse conditions, not only maternal diet but also in vitro embryo techniques as used in assisted conception. Funding: BBSRC, MRC, EU, NIH, Rosetrees Trust, Kerkut Trust.

O-217 Extrinsic factors disrupting embryo physiology in vivo and vitro

Y. Menezo[1], B. Dale[2]

[1]*Laboratoire CLEMENT, Paris, France*
[2]*CFA centro fecondazione assistita, Assisted reproduction, Napoli, Italy*

Abstract text

Hypo fertility or delay/failure to conceive is an increasing multifactorial problem in western populations. Increasing parental age due to delaying the decision to have a baby is one problem, while a decrease in sperm quality and premature ovarian failure (POF) and diminished ovarian reserve (DOR) are today observed with increasing frequency. Obesity and diabetes are on the increase and now affect 30% of the population. The link between these chronic pathologies, oxidative stress (OS) and epigenetics and their impact on embryo quality is now clear. Endocrine disruptors (EDCs) are strong effectors in the contribution to hypofertility. Pesticides, xenoestrogens, endocrine disrupting chemicals involved in plastic technology such as polychlorinated bisphenols (PCB), bisphenols (BP), phthalates, alkyl phenols are now present in the environment, food and even in cosmetics. They induce OS that affects DNA (but not only) quality via the estrogen (ER) and androgen (AR) receptors leading to hormonal anomalies. Via the peroxisome proliferator-activated receptors (PPARs), they perturb metabolic signaling and induce endocrine pathologies (obesity). Recent research suggests that they negatively affect correct DNA methylation in offspring tissue and thus epigenesis and imprinting. Epigenetic mechanisms modify the expression of specific genes without changing the underlying DNA sequence: they are involved in important cellular processes: chromosome stability (and inactivation), transcription and cellular growth and differentiation; all major effectors for a correct embryonic development. Fetal male and female gametes are submitted first to a methylation/imprinting erasure and then a full reset of a complete profile. EDCS may affect this resetting as these chemicals are found in urine of children and adults; they induce ovarian resistance during pre-implantation development, there is a strong methylation maintenance driven by the DNA methyltransferase 1 highly expressed in oocytes and early embryos (Menezo et al. 2011). This maintenance may be affected in vitro as well as the majority of culture media do not contain methyl donors; these compounds are the only molecules able to counteract the negative effects of the EDCs. Recent publications have demonstrated that IVF babies have different DNA methylation profiles compared to babies obtained by natural conception (Katari et al. 2009, Song et al. 2015). All these negative features may be increased by the endogenous backgrounds affecting methylation process such as mutations affecting the one carbon cycle (1-CC), such as MTHFR (methylene tetrahydrofolate reductase) and MS (Methionine synthase) mutations.

In conclusion, many aspects of modern day life have increased the difficulty to conceive. Nutritional backups that support the 1-CC, and therefore methylation processes, and endogenous protection against oxidative stress are strongly recommended for men and women before trying to conceive since avoiding negative factors from environmental pollution now seems impossible.

INVITED SESSION

SESSION 60: NURSES/MIDWIVES INVITED SESSION: TOWARDS PARENTHOOD

Wednesday 4 July 2018 Room 113 + 114 + 115 08:30–09:30

O-218 Antenatal care in transition from fertility treatment to parenthood

C. Warmelink, M. Boekhout, E. Tros, L. Kool

Midwifery Academy Amsterdam-Groningen, Midwifery Academy Groningen, Groningen, The Netherlands

Study question: What are the antenatal maternity care needs of MAC-parents in the transition from fertility treatment to parenthood?

Summary answer: The study will be ready in July 2018

What is known already: Nearly five percent of newborns in the Netherlands are now born following fertility treatment, Medically Assisted Conception (MAC), a steadily increasing number. Pregnancies conceived through MAC are associated with higher risks of complications, such as small for gestational age, preterm birth, low birth weight, perinatal death and delivery complications. Next to the medical impact, the fertility treatment and the pregnancy after MAC can have psychological and social impact for the MAC-parents, such as higher levels of anxiety in early pregnancy and perception of the pregnancy as being more risky and demanding.

Little is known about the antenatal care needs of MAC-parents in transition from fertility treatment to parenthood. There is a lack of awareness and training for midwives and other maternity care providers on the impact of MAC on the pregnancy.

Study design, size, duration: Mixed Methods Review – a systematic review of qualitative, quantitative, and mixed method studies guided by the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) checklist and methodological quality appraised in accordance with the Mixed Method Appraisal Tool (MMTA). Data sources such as Medline/PubMed, Cochrane library, Cumulative Index to Nursing and Allied Health (Cinahl) and Psychology and behavioral science were searched to find eligible studies.

Participants/materials, setting, methods: Two student-midwives researchers conducted the searches and selected the studies together and abstracted the data independently in Winter and Spring 2018. Two researchers (psychologist and educational scientist) supervised the study.

A PRISMA flowchart present the screening process and results of the bibliographic search.

Main results and the role of chance: In progress.

Limitations reasons for caution: As with all research, the value of this systematic review depends on what was done, what was found, and the clarity of reporting. As with other publications, the reporting quality of systematic reviews varies, limiting readers' ability to assess the strengths and weaknesses of those reviews. Even though systematic review and meta-analysis are considered the best evidence for getting a definitive answer to a research question, there are certain inherent flaws associated with it, such as the location and selection of studies, heterogeneity, loss of information on important outcomes, inappropriate subgroup analyses, and duplication of publication.

Wider implications of the findings: The number of women treated with and babies born after fertility treatments is mounting. Also, there is clear empirical evidence of the postponement of the first child in Western societies, which has implications on the (dis)ability of women to conceive and parents to produce additional offspring. Subfertility and fertility treatment can be a potential medical, social and psychologist burden. This places additional and changed demands on the competence and knowledge of professionals working in maternity care.

The study output can lead to the implementation of innovative interventions, care models and methods and guidelines for midwives, gynaecologists and other maternity care takers.

Study funding/competing interests: This work is not funded. All authors declare s.

O-219 Focussing on infertile men's needs

R. Sylvest

Copenhagen University Hospital Hvidovre, Department of Obstetrics/Gynaecology, Hvidovre, Denmark

Infertile men and their needs

Abstract text

Childlessness concerns both partners in the couple; however until now only limited focus has been on men's needs regarding their fertility treatment. Men with low sperm count are frequently a complex group to treat at the fertility clinic. Women undergo the majority of the physical aspects of treatment, thus the focus of the information and physical care is generally directed toward the women. Even in couples with male factor infertility, men's role in treatment is generally limited to providing a semen sample. Research has shown that men wish to talk about the psychosocial topics and be included more.

Approximately one third of men in heterosexual couples in fertility treatment have low sperm count. For the individual man this often means that he will consider why his sperm count is low, try to find explanations and consequences of this. Male infertility is a potential severe low-control stressor, and research has shown that many men with low sperm quality would like to talk about it more widely. Men, unlike women, rarely express their problems and needs in the health service or are more reluctant to do so. Mikkelsen et al. found that 72% of 210 Danish men undergoing fertility care lacked information about the psychological consequences of male infertility.

Previous studies on male fertility patients' satisfaction with treatment differ in results. A study among Australian men has shown that the contentment with the fertility treatment was not influenced by the outcome of the treatment. A Danish study among 909 male fertility patients treated in four public clinics and initiating treatment in 2000-2001 showed higher satisfaction ratings of medical care and patient-centered care with decreasing social class and if the couple had achieved a pregnancy after treatment. A Danish qualitative interview study showed that infertile couples preferred that their treatment took place in a separate clinic, with few employees, short waiting list and in a setting where the plan of treatment was known by the doctor and the couple. The patients saw the fertility treatments as a psychological and emotional strain and they did not feel that these problems acknowledged by the staff. Further, that the patients who disclosed their fertility problems to others were the patients who expected most of the health professionals. These participants wanted detailed technical assessments along with psychosocial and sexual advice.

We conducted a qualitative study among infertile men who initiated ART with ICSI-treatment to explore their expectations and needs in order to optimize the treatment and handling of this patient group. The results showed that men experienced the process of going from diagnosis to treatment like 'being in a maze', which affected their personal life. The men were ready to become fathers and felt impatient because they needed medical assistance to achieve this life goal. The men felt like they were placed on the sideline but they expressed a desire to have information about the treatment plan from medical professionals and they wanted to discuss the psychological consequences of their low semen quality.

Fertility care and treatment needs to be considered as a couple issue and not only as a woman issue. Fertility staff needs to focus on involving both the man and the woman in the treatment, and more focus is needed on the men and their psychosocial needs.

INVITED SESSION

SESSION 61: ARTHIQS SESSION: THE EVOLVING ROLES OF COMPETENT AUTHORITIES, PROFESSIONAL ORGANISATIONS AND THE EUROPEAN COMMISSION IN ART

Wednesday 4 July 2018 Room 117 08:30–09:30

O-220 Introduction: The roots and findings of ARTHIQS

O-221 Competent authorities: From inspectorates to support structures

N. Jones

Human Fertilisation and Embryology Authority HFEA, London, United Kingdom

Abstract text

The session will introduce examples of how competent authorities can undertake their mission. Firstly, by carrying out efficient and effective 'core' work in setting standards and inspecting ART tissue establishments to maintain and improve standards, doing so in an environment of mutual respect where dialogue about practise is engendered; and secondly building on this environment so policy discussion takes place openly. As such, this may create an opportunity to ensure that innovation is introduced carefully, together with practices that would not ordinarily have been introduced – given the country's context, culture and history. For example, consultation and discourse on, the treatment of same sex couples; single woman; pre-implantation genetic diagnosis and other ethically controversial areas. The two approaches are not mutually exclusive to a Competent Authority.

O-222 The relationship between competent authorities and the European Commission

W.N. Strang

Agence de la biomedecine, DPEGH, Saint Denis La Plaine Cedex, France

Abstract text

During and since the preparatory phases of the 2004 EU Tissue and Cells Directive that created Competent Authorities in all European Union Member

States, the European Union has worked closely with these Member States and emerging Competent Authorities in order to align community legislation as closely as possible to the needs of the different situations found in the different Member States.

This cooperation occurs within the formal consultations of the advisory groups, but also via more informal stakeholder consultations and in particular, through Joint Actions, such as ARTHIQS, where the Commission and its executive Agency CHAFEA establish frameworks within which the Member State Competent Authorities can work together, but also with Commission Services and external organisations such as ESHRE, to share and develop expertise amongst themselves.

For the European Commission, ARTHIQS was an important Action allowing the increase of shared knowledge and know-how in the EU-28 Member States in the fields of reproductive medicine and haematopoietic stem cell transplantation. These fields are increasingly important for a large number of EU citizens in need of treatment for infertility problems on the one hand, and for blood cancers on the other.

Both these areas are characterised by rapid development. It is therefore of utmost importance that the national Competent Authorities which oversee these activities in the 28 EU Member States, keep pace with these developments and have a minimum and common understanding of how to ensure safety and quality in these therapies. ARTHIQS built on our European model of collaboration, bringing together the best expertise in these fields and making it available to authorities in all Member States of the European Union.

In domains as complex as reproductive medicine it is essential to create conditions of mutually beneficial synergy whilst defining and developing legislative and good practice frameworks. As such, the relationships between the Commission and the Competent Authorities and Professional Societies have evolved into a quasi-partnership over the last decade. The relationships between CAs, tissue establishments and professional societies are also developing and are, overall, positive and constructive. The missions of all these organisations are aligned with the need to protect donors and patients affected by assisted reproduction.

O-223 The role of medical societies in promoting good practice and the scope for reprovigilance

R.G. Farquharson

Liverpool Women's Hospital, Department of Gynaecolog, Liverpool, United Kingdom

Abstract text

The role of specialist medical societies was historically confined to research, education and training for the benefit of its membership. A more modern approach has enlarged that sphere of interest to include core behaviour standards and patient safeguarding in the belief that collaboration is the gateway to the future. The European Society of Human Reproduction and Embryology (ESHRE) has become more involved with relevant competent authorities (CA), patient organisations and European funded projects in helping to frame policy making and act as a focus for direction of travel.

With ART specifically in mind, the journey from gamete to child via pregnancy and the newborn requires safety assurance and dialogue with regulatory agencies to protect patients from harm and to optimise patient outcomes in achieving a family. Reprovigilance is a term coined by ESHRE that involves monitoring of treatment activity and intervention profiling that mirrors the ethos of our core values.

O-224 Closure: Future perspectives for competent authorities' Cooperation

C. Plancha[1,2,3]

[1]*CNPMA, Conselho Nacional de Procriação Medicamente Assistida, Lisboa, Portugal*
[2]*Instituto de Histologia e Biologia do Desenvolvimento, Faculdade de Medicina - Universidade de Lisboa, 1649–028 Lisboa, Portugal*
[3]*CEMEARE, Centro Médico de Assistência à Reprodução, Lisboa, Portugal*

Abstract text

The ARTHIQS Joint Action brought clarity to the diversity of practice and legislation in the field of Assisted Reproductive Technologies (ART) within and between European Union (EU) Member States (MS). It highlighted the specific aspects of ART and how ART dedicated Competent Authorities (CA) might implement regulation in the field.

The ARTHIQS Joint Action provided several opportunities of interaction between different regulators regarding ART, and of these with the professionals, all recognized as beneficial for the advancement of quality and safety measures in this sector. The ART dedicated CA have much to learn from each other, given their different experience in several MS, and need also to work closely with the healthcare professionals, their representatives and the general public, given the sensitive and exceptional nature of ART.

How to maintain a close cooperation between CA following the ARTHIQS Joint Action, emerges as a major organizational challenge. However, this may also become an opportunity for ART dedicated CA to fertile exchange of experience and expertise, adoption of shared policies, and to facilitate harmonization of practices among the different MS, maintaining and enhancing national and European registers, namely those regarding the safety of patients, donors and recipients.

We defend that a network of ART CA, could conveniently follow the ARTHIQS Joint Action, in order to provide a forum to bring this experience together improving quality and safety for the patients, donors and children born of ART. This could involve proposing joint initiatives, working closely with the European Commission to analyse amendments to policy and legislation and resolving difficulties encountered in the complex evolving field of ART. The tissues and cells CA could provide the basis for the creation of such a network, which might be constituted as a specific working group, with the support of DG Sante, with transparent declarations of conflicts of interest and adhesion to the EU institutions guidelines. The ART CA network or working group should call upon the experience of and cooperate with professional and patient's organisations, in particular ESHRE. Professional societies play a fundamental role in the complex and evolving field of ART which continues to be driven by rapid scientific progress.

SESSION 62: FROM OOCYTE MATURATION IN VIVO TO BABY BIRTH

Wednesday 4 July 2018 Forum (Auditorium) 10:00–11:45

O-225 Immature oocyte incidence: Contributing factors and effects on intracytoplasmic sperm injection cycles

B.F. Zanetti[1], **D.P.A.F. Braga**[2], **R.C.S. Figueira**[3], **A. Iaconelli Jr.**[4], **E. Borges Jr.**[4]

[1]*Instituto Sapientiae - Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific Department, Sao Paulo, Brazil*
[2]*Fertility Medical Group, Scientific Department, Sao Paulo, Brazil*
[3]*Fertility Medical Group, IVF Laboratory, Sao Paulo, Brazil*
[4]*Fertility Medical Group, Clinical Department, Sao Paulo, Brazil*

Study question: Which factors contribute to the incidence of immature oocytes and how this impacts the outcomes of intracytoplasmic sperm injection (ICSI) cycles?

Summary answer: The immature oocyte incidence is affected by pituitary blockage regime,gonadotrophin type and dose, and negatively impacts on fertilization rate, embryo quality, implantation and pregnancy outcomes.

What is known already: Oocyte maturation is defined as the restart and completion of the first meiotic division with accompanying cytoplasmic maturation, which includes storage of enzymes, mRNAs, organelles, and substrates that are necessary for fertilization and early embryo development. Controlled ovarian stimulation (COS) for IVF apply supra-physiologic gonadotropin doses to induce coordinately multiple follicular growth and maturation, however up to 30% of the retrieved oocytes are still immature. The ovarian asynchrony can be indicative of less responsiveness of ovarian follicles to stimulation, and the incidence of immature oocytes may reflect the competence of the mature oocytes cohort for proper embryo development.

Study design, size, duration: This retrospective cohort study included data from 3,920 ICSI cycles performed from June/2010 to August/2016 of couples undergoing first or second ICSI cycle with fresh embryo transfer performed on day five. Immature oocytes rates were defined as the number of Germinal Vesicle and Metasphase I oocytes by the number of retrieved oocytes in each cycle. The FSH/oocyte rate was defined as total dose of FSH administered by the number of oocytes retrieved in each cycle.

Participants/materials, setting, methods: The study was performed in a private university-affiliated IVF center. The influence of administered FSH doses, FSH type, pituitary blockage protocol, and E2 peak on the day of hCG administration on the incidence of immature oocytes were evaluated by generalized linear models. The effects of immature oocytes rates on normal and abnormal fertilization, embryo quality on cleavage stage (days two and three), blastocyst formation, implantation, pregnancy, and miscarriage rates were analyzed by regression models.

Main results and the role of chance: The FSH/oocyte rate was positively correlated with MI/oocyte (β=-0.043, $p = 0.014$) and GV/oocyte (β=-0.107, $p < 0.001$) rates. A higher MI/oocyte rate was observed in patients who received GnRH agonist and recombinant FSH in relation to GnRH antagonist and recombinant FSH (13.34 ± 0.09 vs. $10.73 \pm 0.28\%$ $p = 0.007$). Patients who received recombinant FSH had about 30% increase in GV/oocyte rate in comparison to urinary FSH, both with GnRH agonist (11.29 ± 0.90 vs. 4.18 ± 4.52 $p = 0.048$), and antagonist (11.47 ± 0.28 vs. 8.84 ± 1.41 $p = 0.021$) protocols. The fertilization rate was negatively correlated to MI/oocyte and GV/oocyte rates (β=-0.096, $p < 0.001$; β=-0.059, $p < 0.001$), while abnormal fertilization rate (1PN or 3PN) was positively correlated with GV/oocyte rate (β = 0.155, $p = 0.049$). The incidence of immature oocytes affected negatively the high-quality embryos rate at day two (MI/oocyte β=-0.102, $p < 0.001$; GV/oocyte β=-0.066, $p < 0.001$), and day three (MI/oocyte β=-0.090, $p < 0.001$; GV/oocyte β=-0.087, $p < 0.001$), as well as the blastocyst rate (MI/oocyte β=-0.066, $p < 0.001$.; GV/oocyte β=-0.053, $p < 0.001$). The negative effect of the incidence of MI and GV was also noted in the implantation (MI/oocyte β=-0.074, $p < 0.001$; GV/oocyte β=-0.042, $p = 0.033$) and pregnancy (MI/oocyte B=-0.011 $p = 0.002$; GV/oocyte B=-0.066, $p = 0.013$) rates.

Limitations, reasons for caution: The retrospective nature of this analysis limits the relevance of the study.

Wider implications of the findings: During COS, pharmacological gonadotrophins doses creates a supra-physiological environment, which allows the maturation of oocytes, which under natural conditions, would regress. Our evidence suggests that oocytes derived from a cohort with high incidence of maturation fail may have an inefficient biological machinery, which would have detrimental effects on clinical outcomes.

Trial registration number: None.

O-226 The influence of denudation and injection on ICSI outcome - does timing matter?

M. Carvalho, S. Mota, F. Leal, I. Pereira, C. Rodrigues, A. Aguiar, S. Sousa, J. Nunes, C. Calhaz-Jorge

Reproductive Medicine Unit, Department of Obstetrics Gynaecology and Reproductive Medicine - Hospital de Santa Maria, Lisbon, Portugal

Study question: Does the time interval between oocyte retrieval and denudation or injection have an effect on fertilization and clinical pregnancy rates in ICSI cycles?

Summary answer: Our findings suggest that ICSI outcome is improved when oocytes are cultured for at least 3 hours before denudation and injected 5-6 hours after retrieval.

What is known already: Oocyte maturation is a complex and dynamic process involving structural and biochemical modifications in the cell necessary to support fertilization and early embryo development. While meiotic competence is easily identifiable by the presence of an extruded first polar body, cytoplasmic maturation cannot be assessed microscopically. Culturing oocytes with their surrounding cumulus cells prior to fertilization can enhance the completion of in vitro cytoplasmic maturation; however, prolonged culture may also induce cell degeneration. The optimal culture intervals prior to oocyte denudation and/or injection have not yet been established and may prove relevant for the improvement of ICSI outcome.

Study design, size, duration: Single-centre retrospective analysis of 1583 ICSI cycles performed between 2002 and 2017 in women <40 years old. All women performed controlled ovarian hyperstimulation using a long GnRH-agonist protocol and oocyte retrieval was undertaken 34-36 hours after final ovulation triggering. Time intervals between oocyte retrieval, denudation and injection of the oocytes were exclusively dependent on laboratory workload. The effects of these timings on fertilization and clinical pregnancy rates were compared.

Participants/materials, setting, methods: The effect of oocyte culture duration prior to injection of the oocytes was considered in two separate analysis: (i) time interval between oocyte retrieval and denudation (3.2 h±1.0) and (ii) time interval between oocyte retrieval and injection (5.4 h±0.8). Only cycles with at least one injected oocyte were included. The effect of the before mentioned time intervals on fertilization and clinical pregnancy rates were compared using multivariable regression adjusted for potential confounding variables.

Main results and the role of chance: 10359 metaphase II oocytes were injected and checked for the presence of pronuclei. The fertilization rate was found to be independent of the time interval to denudation and/or injection. Oocyte degeneration rate after ICSI was also comparable considering different time intervals to denudation and injection but the abnormal fertilization rate was significantly increased for longer incubation periods before injection, even after accounting for the time elapsed until denudation (<5 h, 6.1%; 5-6 h, 7.1%; ^{3}6, 9.0%, $p = 0.01$). Extending oocyte culture before denudation significantly improved clinical pregnancy rates, particularly if the time interval comprised of at least 3 hours (<2 h, 34.5%; 2-3 h, 33.7%; 3-4 h, 41.6%; ^{3}4 h; 46.8%, $p < 0.001$). Clinical pregnancy was also dependent on time to injection and optimal results were obtained when ICSI was performed 5-6 hours after retrieval (<5 h, 35.3%; 5-6 h, 42.3%; ^{3}6 h, 39.3%, $p = 0.043$).

Limitations, reasons for caution: This is a retrospective study, with its inherent limitations, and restricted to long agonist cycles. Furthermore, the effect of very short or very long periods of culture before denudation and/or injection was not evaluated and should not be extrapolated from these results.

Wider implications of the findings: Our findings support the importance of extending oocyte culture with their surrounding cumulus cells, but more importantly provide new evidence of a correlation between denudation and injection intervals. Establishing an optimal time window to perform denudation and ICSI and adjusting laboratory practice may prove beneficial and improve clinical pregnancy rates.

Trial registration number: Not applicable.

O-227 The impact of intracytoplasmic sperm injection (ICSI) on embryo development as assessed by Time-Lapse (TL) microscopy on 4126 embryos

C. Sacha[1], G. Christou[2], I. Dimitriadis[1], M. Brock[2], S. McLellan[2], P. Bhowmick[2], C. Bormann[1], I. Souter[1]

[1]*Massachusetts General Hospital, Dept of Obstetrics- Gynecology- and Reproductive Endocrinology and Infertility, Boston, U.S.A.*

[2]*Massachusetts General Hospital Fertility Center, Dept of Obstetrics- Gynecology- and Reproductive Endocrinology and Infertility, Boston, U.S.A.*

Study question: Does the utilization of ICSI versus conventional insemination (CONV) impact either early- or late- morphokinetic parameters in embryos cultured to blastocyst in a TL-monitored incubator?

Summary answer: Time periods from either pronuclei fading (tPN*f*) or 5-cell stage to early blastulation were significantly prolonged when *usable* ICSI embryos were compared to CONV ones.

What is known already: While some studies suggest that correcting for time of fertilization by normalizing all times to tPN*f* may eliminate differences in early cleavage times between embryos undergoing ICSI versus CONV, other data suggests a potential effect of fertilization method on early cleavage times. At the

same time, the potential impact of fertilization method on late-morphokinetic parameters remains unclear.

Study design, size, duration: Retrospective review of data from 4126 embryos (derived from 364 ICSI and 237 CONV cycles) cultured to the blastocyst stage in TL-monitored incubators. 536 women undergoing ART between 9/2013 and 9/2016 at a large academic fertility center were included in the analysis.

Participants/materials, setting, methods: Groups were compared in regard to time periods: i) tPN*f* to 1st-cytokinesis (P_1), ii) 2- to 3-cells (P_2), iii) 3- to 4-cells (P_3), iv) 4- to 5-cells (P_4), v) 5- to 8-cells, and vi) tPN*f* and 5-cells to early blastulation (P_{SB} and P_{5SB}, respectively). *Usable* (selected either for transfer or cryopreservation) and *discarded* embryos were sub-analyzed separately.

Generalized fixed and random effects models, Mann-Whitney *U*-, and χ^2-tests were used as appropriate. $P < 0.05$ was statistically significant.

Main results and the role of chance: Median (interquartile range, IQR) age, BMI, day-3 FSH and AMH were 34.8(32.3, 37.8) vs. 36.2(33.2-39.4) years, $p < 0.01$; 23.1(21.0-26.7) vs. 23.4 (21.6-26.6) kg/m^2, $p = 0.46$; 6.7(5.7-8.0) vs. 7.0(5.9-8.4) IU/L, $p = 0.16$; and 3.0(1.5-5.1) vs. 2.1(1.1-4.0) ng/ml, $p < 0.01$; for ICSI vs. CONV, respectively. Male factor infertility (MFI) was more prevalent among ICSI cycles (40.7% vs. 5.0%, $p < 0.01$ for ICSI vs. CONV, respectively).

When all embryos were included in the analysis and models were adjusted for age, BMI, day-3 FSH, AMH, and MFI, P_{5SB} and P_{SB} were found to be significantly prolonged in ICSI cycles by 2.4(95%CI: 0.6-4.2) hours, $p = 0.01$; and 1.8 (95%CI: 0.2-3.3) hours, $p = 0.02$; respectively. When *usable* were analyzed separately from *discarded* embryos, the impact of ICSI persisted in *usable* embryos only [*usable*: P_{5SB} and P_{SB}: 3.1(95%CI: 1.4-4.7) hours, $p < 0.01$; and 2.3(0.8-3.7), $p < 0.01$; respectively*; discarded*: P_{5SB} and P_{SB} 1.6(-0.9-4.1), $p = 0.20$; and 1.2(-0.8-3.3) hours, $p = 0.23$; respectively].

No impact of ICSI was noted on all other morphokinetic parameters, when either *all* embryos were included in the analysis, or *usable* were analyzed separately from *discarded* embryos.

Limitations, reasons for caution: This study is limited by its retrospective design. Furthermore, all aspects of sperm quality may not have been considered by adjusting for male factor infertility diagnosis.

Wider implications of the findings: ICSI did not impact significantly early cleavage times. However, time to early blastulation was prolonged in ICSI embryos with the impact becoming more prominent from the 5-cell stage and onward, a finding suggestive of a possible an interaction between fertilization method and late paternal genome activation.

Trial registration number: Not applicable.

O-228 Differences in time-lapse practice: is a consensus on standards needed?

C. Hickman

Imperial College London, IRDB- Faculty of Medicine, Stoke Mandeville, United Kingdom

Study question: Do clinics differ in how they implement time-lapse technology into their processes?

Summary answer: How Time-Lapse is used varies between IVF clinics, particularly with regards to patient and cross-department involvement, communication, embryo selection and how process-efficiencies are optimised.

What is known already: Time-Lapse incubation involves culturing the embryo in an incubator that takes regular pictures of the embryos. This has allowed for embryos to be cultured uninterrupted. With increased observation, benefits from the technology started to change how embryology was practised, improving customer service whilst increasing process efficiency. However, not all clinics have experienced these benefits. To our knowledge this is the first study to assess how time-lapse technology is used in different clinics.

Study design, size, duration: In December 2017, 38 experienced time-lapse embryologists from the UK responded to an anonymous questionnaire with 20 questions assessing how far they adapted the clinic wide processes to the time-lapse technology since implementation.

Participants/materials, setting, methods: All participants were Embryoscope users, 48% with 3+ years experience. The questionnaire was presented using Mentimeter in a live presentation and anonymity of respondents was maintained.

Main results and the role of chance: 71% did not train non-laboratory departments in how the Time-Lapse technology affected their processes. 87% had time-lapse related communication processes between the embryologist and the patient, a lower proportion involving other departments (23%-51%). 73% provided the patient access to videos of embryos transferred at the time of transfer with a USB. 52% thought patients would welcome live access to videos whilst in the incubator, whilst 45% affirmed that irrespective of patient's wishes, their clinics would be against giving patients live access. 65% did not provide patients with written reports. 42% only provided access to time-lapse incubation to patients willing to pay. 76% did not adapt embryology process timings to the flexibility provided by time-lapse. 1 clinic adapted the hcg time. Embryo selection differed: 58% did not review the video. Reliance on algorithm increased with the number of years experience. Clinics prioritised morphology on day 5, followed by unusual embryo cleavage, followed by KIDScore. 46% of the clinics reviewed embryo selection consistency. 19% reviewed efficacy. 52% annotate daily, followed by morning of ET (32%), and 4 clinics did not annotate at all. Most clinics reported not having the time required to ensure the annotations are complete, accurate and standardised (56%).

Limitations, reasons for caution: Participants all came from the same country, and the answers may not be reflective of practice in other countries. Participants were all Embryoscope users, and practice may further differ with other Time-Lapse systems.

Wider implications of the findings: This study documents the diversity in the practice of the time-lapse technology between different IVF clinics, suggesting that there is a need for a formal consensus on standards of time-lapse practice to ensure patients and clinics benefit fully from time-lapse technology, irrespective of which clinic they are treated in.

Trial registration number: NA.

O-229 Deconstructing the myth of poor prognosis for fast-cleaving embryos on Day 3. Is it time to change the consensus?

M.C. Pons Gatell, B. Carrasco, M. Parriego, B. Coroleu, P.N. Barri, M. Boada, A. Veiga

Women's Health Dexeus, Reproductive Medicine Service, Barcelona, Spain

Study question: Do fast-cleaving embryos (>8 cells at 68 ± 1hpi) have a lower potential to become euploid blastocysts and implant when compared to 8-cell embryos?

Summary answer: The chance of fast-cleaving embryos on Day 3 (D3) to give rise to euploid blastocysts and implant is comparable to the one of 8-cell embryos.

What is known already: The cell number is one of the most predictive morphological parameters for blastocyst formation, implantation and live-birth rates. The ESHRE-Alpha consensus (2011) established that embryos that cleave slower or faster than the expected rate (8 cells at 68 ± 1hpi) have a reduced implantation potential. Likewise, according to the ASEBIR criteria (2015) fast-cleaving embryos on D3 are included in B or C categories with a lower implantation potential compared to 8-cell embryos classified as A. Regarding the ploidy status, higher percentage of chromosomal abnormalities were found in fast-cleaving embryos compared to 8-cell embryos.

Study design, size, duration: A total of 4028 embryos from 513 PGT-A cycles performed between July 2014 and June 2017 were included in this observational retrospective study. Embryos were classified in groups based on the number of cells on D3 (from 2-cell to >12-cell and compacted).

Participants/materials, setting, methods: Embryos were cultured in single-step medium (Global®, LifeGlobal®; GTL™, Vitrolife) and incubated in *Time-lapse* incubators (Embryoscope®; Geri®). Embryos were biopsied at the blastocyst stage followed by vitrification (Cryotop®, Kitazato). The trophectoderm samples were analysed by a-CGH. A generalized linear mixed model adjusted for confounding factors was performed to assess the chance to become an euploid blastocyst in each and every group compared to the chance of 8-cell embryos.

Main results and the role of chance: In this study, 64.4% of 8-cell embryos on D3 (875/1358) and 59.3% of fast-cleaving embryos on D3 (863/1454) reached the blastocyst stage and then were biopsied. After the genetic test, 22.7% of 8-cell embryos (308/1358) and 20.6% of fast-cleaving embryos (299/1454) were diagnosed as euploid. The statistical analysis showed that the probability of fast-cleaving D3 embryos to give rise to an euploid blastocyst is not significantly different from the chance of 8-cell embryos. The results are valid for every analyzed fast-cleaving D3 group (from 9-cell group to compacted group) as demonstrated by the odd ratios (OR): 9-cell group OR (95%CI): 0.76 (0.57-1.01); 10-cell group OR (95%CI): 0.72 (0.51-1.01); 11-cell group OR (95%CI): 0.95 (0.60-1.51); 12-cell group OR (95%CI): 1.11 (0.75-1.63); >12-cell group OR (95%CI): 1.35 (0.85-2.15) and compacted group OR (95%CI): 1.19 (0.81-1.76). Moreover, euploid blastocysts derived from fast-cleaving D3 embryos and from 8-cell D3 embryos exhibit similar implantation potential (67% vs 55%, p = 0.25).

Limitations, reasons for caution: This is a retrospective study. The findings which originate from a specific culture environment might not be applicable to all in vitro culture conditions.

Wider implications of the findings: Recommendations published by scientific societies (ASEBIR, ESHRE-Alpha) regarding the poor prognosis of fast-cleaving embryos on D3 must be reconsidered.

Trial registration number: Not Applicable.

O-230 Pregnancy and neonatal outcomes of embryos achieving blastulation on day 7: are they of clinical value?

T. Du[1,2], Y. Wang[1], Y. Fan[1], S. Zhang[3], B. Mol[4], Q. Lyu[1], Y. Kuang[1]

[1]Shanghai 9th People's Hospital- Shanghai Jiao Tong University School of Medicine, Department of Assisted Reproduction, Shanghai, China
[2]Shanghai First Maternity and Infant Hospital- Tongji University School of Medicine, Department of Obstetrics and Gynaecology, Shanghai, China
[3]University of Shanghai for Science and Technology, Shanghai-Hamburg College, Shanghai, China
[4]Monash University, Department of Obstetrics and Gynaecology, Clayton, Australia

Study question: Are embryos achieving blastulation on day 7 of clinical value?

Summary answer: Day 7 blastocysts resulted in a 25.2% live birth rate and had similar risk of adverse neonatal outcomes with day 5 and day 6 blastocysts.

What is known already: Advantages of blastocyst transfer over cleavage embryo transfer have led to the shift towards the former in in vitro fertilization (IVF) practice. However, published data about the pregnancy outcomes of embryos with a delayed blastulation on day 7 are scarce and controversial. Moreover, there are few data available on the neonatal outcomes of day 7 embryos. As a result, the clinical value of day 7 embryos cannot be appropriately evaluated.

Study design, size, duration: This was a retrospective cohort study including two parts, first of which involved 2,908 women undergoing 2,908 frozen-thawed embryo transfer (FET) cycles of IVF/intracytoplasmic sperm injection (922, 1,752 and 234 women in day-5, day-6 and day-7 vitrified embryo transfer groups, respectively) from January 2006 to May 2015. In study part II, 1,518 liveborn infants derived from those women were analyzed.

Participants/materials, setting, methods: Women undergoing day-5, day-6 and day-7 vitrified embryo transfers were matched into three comparing cohorts (day 5 vs. day 6, day 5 vs. day 7, and day 6 vs. day 7) by baseline characteristics using propensity score matching. Neonatal outcomes were compared among liveborn infants derived from day-5, day-6 and day-7 vitrified embryo transfers. Logistic regressions were performed to investigate risk factors for implantation failure (among single blastocyst transfers) and congenital malformations (among liveborn infants).

Main results and the role of chance: The included women were matched into 921 pairs, 227 triplets and 227 tetrads of cycles in day 5 vs. day 6 (1:1), day 5 vs. day 7 (2:1), and day 6 vs. day 7 (3:1) cohorts, respectively. In study part I, day-7 vitrified embryo transfers had clinically important but significantly lower rates of intrauterine implantation, clinical pregnancy and live birth than both day-5 (23.9% vs. 49.9%, p<.001, 31.7% vs. 58.1%, p<.001, and 25.1% vs. 46.5%, p<.001, respectively) and day-6 (24.7% vs. 42.3%, p<.001, 33.0% vs. 53.2%, p<.001, and 25.6% vs. 41.4%, p<.001, respectively) vitrified embryo transfers. But no statistically significant difference was observed among the rates of biochemical pregnancy, ectopic pregnancy and miscarriage between the matched cohorts. Female age, year of treatment, developmental stage, morphological grade, and vitrification day of blastocysts transferred were significant factors affecting implantation rate. In study part II, no statistically significant difference was observed in the rates of low birth weight, congenital malformations and early neonatal death among the 616, 932 and 68 newborns in day-5, day-6 and day-7 vitrified embryo transfer groups, respectively. Multiples were 5.70 times more likely to experience congenital malformations compared with singletons (OR: 5.70, 95% CI: 1.42-22.92; P=.014).

Limitations, reasons for caution: This was a single center retrospective study, and most of the neonatal data were extracted from parent questionnaires. Besides, the amount of day-7 vitrified embryo transfer cycles was still limited.

Wider implications of the findings: Vitrification day of embryos transferred is an independent risk factor for implantation failure. The compromised implantation potential in growth-retarded blastocysts might be due to spindle abnormities. The negative effect of potential defects underlying delayed blastulation may be mostly realized during implantation, and affects less afterwards.

Trial registration number: Not applicable.

O-231 The impact of extremely long term human embryo cryopreservation: embryonic, obstetric and neonatal outcomes

Y. Yuan, J. Ma, Y. Xu, C. Zhou, G. Zhuang

The first affiliated hospital of SUN Yat-sen University, The reproductive research center, Guangzhou, China

Study question: Is extremely long term slow freezing of human embryos do harm to their embryonic, obstetric and neonatal outcomes?

Summary answer: The embryonic, obstetric and neonatal outcomes following long term cryopreserved embryo transfer were encouraging, which met the common anticipation of embryo freezing.

What is known already: Due to the mature techniques of embryo cryopreservation and thawing, the cumulative pregnancy outcomes have greatly improved.During the ultra-low temperature storage state, the embryos are also affected by the cosmic background radiation and vibration. The theoretical cryopreservation span is infinite since the mimic experiment with an equal dose of 2000 years cosmic radiation on mice embryos gave us a positive result. While considering future utilization, there is still lacking of solid clinical evidence to draw conclusions about human embryos.The longest existing storage span of successful live birth after frozen embryos transfer is 12 years.

Study design, size, duration: This is a retrospective observational study of 128 embryos of 20 patients who seek to have a second child with the utilization of their long-term cryopreserved embryos (more than 12 years) from March 2012 to April 2017.

Participants/materials, setting, methods: Participants: Patients have received IVF/ICSI treatments between February 1999 and July 2004 and had surplus embryos cryopreserved for at least 12 years in our center.

Setting:University teaching hospital.

Methods:We have closely mesured the length of cryopreservation, survival rate of cryopreserved embryos, blastocyst formation rate, implantation rate, clinical pregnancy rate, abnormal pregnancy rate, live birth rate, perinatal complications and neonatal development.

Main results and the role of chance: A total of 128 embryos of 20 patients were observed. The embryo storage duration was 12.00-17.08 yrs, with a mean of 13.90 ± 1.73 yrs. Among them, 115 embryos were thawed to transfer, with a survival rate of 73.9%. Sixty embryos were further cultured which resulted in 20 blastocysts with a blastocyst formation rate of 33.3%. There were 34 embryos transferred in a total of 23 cycles, which resulted in 1 biochemical pregnancy, 1 first trimester miscarriage, 2 ectopic pregnancies, 3 singletons and 1 case of twins, with a clinical pregnancy rate of 30.4% and live birth rate of 21.7%. Two out of 4 patients who had live birth developed gestational diabete mellitus. One out of 5 live births was pre-term delivery. The physical and psychological development of all live births matched the standard curve in the first 6 months.

Table I

	Cleavage stage	Blastocyst stage	Total
Pregnancy Rate	25%(3/12)	45.5%(5/11)	34.8%(8/23)
Implantation Rate	19.0%(4/21)	30.8%(4/13)	23.5%(8/34)
Clinical Pregnancy Rate	25.0%(3/12)	36.4%(4/11)	30.4%(7/23)
Abnormal Pregnancy Rate	66.7%(2/3)	25%(1/4)	42.9%(3/7)
Live Birth Rate	16.7%(2/12)	27.3%(3/11)	21.7%(5/23)

Limitations, reasons for caution: Due to the limited sample size, we could only present the descriptive data. No further statistical analysis was used to detect the potential correlation factors concerning the clinical outcomes.

Wider implications of the findings: The reassuring results obtained in the study show that embryos after extremely long term cryopreservation could be of great value.

Trial registration number: not applicable.

SELECTED ORAL COMMUNICATIONS

SESSION 63: MALE LIFESTYLE AND REPRODUCTIVE HEALTH

Wednesday 4 July 2018 Room 211 + 212 10:00–11:45

O-232 Has sperm quality been declining for the past 20 years?

C. Huang[1], L. Lei[2], D. Liu[2], X. Yuan[2], L. Fan[1], W. Zhu[2]

[1]*Reproductive & Genetic Hospital of CITIC-Xiangya, spermbank, Changsha- Hunan, China*

[2]*Central South University, Institute of Reproductive and Stem Cell Engineering- Basic Medicine College, Changsha, China*

Study question: To evaluate studies of temporal trends in sperm quality in China.

Summary answer: Sperm concentrations, motility, and morphologies demonstrated substantial changes in China between 1996 and 2017, and Geographical differences exist in various regions of China.

What is known already: In recent years, numerous reports have suggested that semen quality in normal men has been declining. Nevertheless, all of these reviews showed significant changes in sperm quality only in Western countries. There have been few studies from non-Western countries, and those that do demonstrate no trends.

Study design, size, duration: We extracted summary statistics on semen volume, sperm concentration, total sperm count, normal morphology, progressive motile sperm (A + B) and motile sperm (A + B + C), inclusion and exclusion criteria, number of samples per man, and information regarding data completeness.All data could be derived from 186 studies. Ten of these were English language studies, and the other 176 studies were not in English.

Participants/materials, setting, methods: The study was excluded if study participants were selected based on infertile men, genital abnormalities, or other diseases. We also excluded studies limited to men with exposures that may affect fertility, such as occupational exposure, post-intervention, smoking, drinking, and other unhealthy lifestyles. We applied the Cochran–Armitage trend test for trend to evaluate change over time, and linear regression was performed to evaluate change over time of semen parameters.

Main results and the role of chance: The sperm concentration declined by 1.0% per year, and overall by 21.0% between 1996 and 2017 ($P < 0.001$). A similar trend was seen for progressive motile and motile sperm (slope per year = -0.56% and -0.57%; respectively, $P < 0.05$), Sperm with normal morphology declined by 2.4% per year ($P < 0.001$). Although total sperm count declined by 3.37 million per year, there was no statistical significance. Semen volume did not change significantly over the study period (slope per year = 0.005 ml; $P = 0.69$). The Sperm concentrations and progressive motility were greater in the area of Eastern and Central China than in Northeast China.

Limitations, reasons for caution: First, our findings may not be based on a community population, since the study group did not including infertile men and had a limited age range.Second, our study population lives only in some capital cities, and does not represent all cities and geographical areas of China.

Wider implications of the findings: Whether sperm quality is actually declining in some regions and across time periods remains unknown. The debate regarding the question continues, but these findings represent a serious reproductive health warning. The concerns raised regarding the reproductive health of men remain urgent.

Trial registration number: None.

O-233 Male reproductive health is a key determinant of unhealthy aging: results from a longitudinal cohort study

E. Ventimiglia[1], P. Capogrosso[1], W. Cazzaniga[1], L. Boeri[1], F. Pederzoli[1], M. Alfano[1], N. Frego[1], C. Abbate[1], F. Chierigo[1], F. Dehò[1], F. Gaboardi[1], V. Mirone[2], E. Montanari[3], F. Montorsi[1], A. Salonia[1]

[1]*Università Vita-Salute San Raffaele, Urology, Milano, Italy*

[2]*University of Naples Federico II, Urolgy, Naples, Italy*

[3]*University of Milan- Milan- Italy, Urolgy, Milan, Italy*

Study question: To inquire reproductive factors associated with health status decrease in infertile men.

Summary answer: 29% of infertile men had a decrease of the overall health status. Azoospermic men were those at highest risk of health status decrease.

What is known already: A severe male infertility factor has been associated with both lower health status and increased mortality in men from infertile couples. Little is known about the evolution of the health status in infertile men over time.

Study design, size, duration: Cohort study enrolling 645 infertile men evaluated at baseline between 2003 and 2010. Patients were followed-up yearly recording any worsening in their health status until 2017.

Participants/materials, setting, methods: Infertility was defined according to the WHO definition. Health-significant comorbidities were scored with the Charlson Comorbidity Index (CCI). Cox regression models were used to estimate hazard ratios (HR) and 95% confidence intervals (CI) of CCI score increase including as covariates age, BMI, CCI, azoospermia, FSH, and duration of infertility.

Main results and the role of chance: Mean patient age was 37 years (interquartile range, IQR 34-40), median BMI 25 (IQR 23-27), 30 (5%) men had a CCI≥1, and median duration of infertility was 24 months (IQR 13-30). Median follow-up was 9 years (IQR 7-11). 186 men (29%) saw an increase of their CCI score of at least 1 point. The most frequent reason for CCI upgrade was cancer, i.e. 43 solid tumors and 5 lymphomas. Compared to patients without a CCI increase, patients with a CCI increase had a higher proportion of CCI≥1 (9% vs. 3%, $p = 0.001$) and a higher proportion of azoospermia (32% vs 20%, $p = 0.001$) at baseline. Azoospermic men had an increased risk of developing comorbidities at multivariable analysis (HR 1.88, 95% CI 1.31–2.69; $p = 0.001$); along with a basal CCI≥1 (HR 2.61, 95% CI 1.57–4.36; $p < 0.001$), and with a longer duration of infertility (HR 1.02, 95% CI 1.01-1.03; $p = 0.008$) azoospermic men were at higher risk of developing comorbidities during follow-up at multivariate analysis, after accounting for the aforementioned confounders.

Limitations, reasons for caution: The CCI does not include some conditions (e.g. hypertension) that are important contemporary comorbid conditions.

Wider implications of the findings: Infertility is a proxy of decreased health status, therefore infertile men must be strictly follow-up to prevent and early detect the onset of potentially disabling comorbidities.

Trial registration number: not applicable.

O-234 Spermatozoa from patients with seminal alterations and advanced age show lower reproductive competence in egg donation cycles

V. Casciani, E. Iovine, V. Zazzaro, A. Pristerà, A. Colasante, F. Scarselli, M.G. Minasi, A. Ruberti, E. Cursio, S. Muzzì, M.T. Varricchio, A. Caragia, C. Mencacci, A. Greco, E. Greco

European Hospital, Centre for Reproductive Medicine, Rome, Italy

Study question: Do spermatozoa from men with normal or abnormal semen and different age perform differently in terms of fertilization and embryo development in egg donation cycles?

Summary answer: In presence of abnormal semen, older men spermatozoa have lower fertilization and embryo development potential. In presence of normal semen, male age has no effect.

What is known already: The delay in parenthood age observed in the developed world has brought increasing attention to age-related gametes quality, embryo development and reproductive outcomes. Whereas the effect of maternal age has been extensively studied, less is known about the consequences of advanced paternal age. Moreover, no paternal age cut-off value as been widely accepted. The inverse association between male age and semen quality has been reported in literature. However little was said about the combined effect of semen quality and paternal age. Oocyte donation cycles are an ideal model to study the paternal effect on reproductive outcomes.

Study design, size, duration: We retrospectively analyzed 276 egg donation cycles (OD) performed with 1713 vitrified/warmed oocytes and fresh ejaculated semen between October 2014 and December 2017. Our population was divided into 4 groups according to sperm quality (WHO, 2010) and male partner's age. Data are shown as avarage±SD and were analyzed with Chi square test or Student-t test.

Participants/materials, setting, methods: Groups-1 and -2 included men with normal semen and respectively <45 yeras old (N = 53 OD; 383 oocytes; male age 40.5 ± 3.03; donor age 25.7 ± 3.41) or ≥45 yo (N = 50 OD; 363 oocytes; male age 48.9 ± 3.31; donor age 25.8 ± 3.68). Groups-3 and -4 included men with abnormal semen and <45y.o. (N = 84 OD; 580 oocytes; male age 41.0 ± 2.85; donor age 26.4 ± 3.60) or ≥45y.o (N = 89 OD; 616 oocytes; male age 50.4 ± 5.25; donor age 25.0 ± 3.40). Semen samples distribution was similar in groups-3 and -4.

Main results and the role of chance: The number of surviving and injected MII, fertilized oocytes and total developed embryos either transferred or frozen (EC + ET) were, respectively, in group-1, 343, 247 and 202; in group-2, 319, 233 and 198; in group-3, 505, 359 and 307 and in group-4, 546, 359 and 286. Between groups-1 and -2, no difference was observed in the fertilization rate (FR 72.0% and 73.0% respectively) and in the rate of available embryos obtained (EC + ET) calculated either per injected oocytes (58.9% and 62.1% respectively in groups-1 and -2) or per fertilized oocytes (81.8% and 85.0%). Between groups-3 and -4, there was a significant difference in fertilization rate (FR 71.1% and 65.8%, respectively, $p < 0.05$) and in the rate of embryos obtained (EC + ET) calculated per number of injected oocytes (60.8% and 52.4%, Chi square $p < 0.005$) or per number of fertilized oocytes (85.5% and 79.7%, Chi square $p < 0.05$). After fresh embryo transfer, clinical pregnancy rates (CPR) in groups-3 and -4, were 58.8% (47/80) and 38.8% (31/80) ($p < 0.05$) and implantation rates (IR) were 38.4% (58/151) and 23.7%(34/144) ($p < 0.005$). In groups-1 and -2, CPR and IR were not significantly different: CPR were 49.0% (25/51) and 45.8% (22/48); IR were 41.3% (38/92) and 29.7% (25/84), respectively.

Limitations, reasons for caution: Since partners' ages are correlated, in order to compare clinical outcomes between groups and ascribe the outcomes decrease to the father, it should be assumed that maternal ageing has no effect. Additionally, the spermiogram used to categorizes semen is not a clear indicator of male infertility.

Wider implications of the findings: Spermatozoa from ejaculated sperm with abnormal parameters (concentration, motility and morphology) show lower fertilization potential and embryo development when retrieved from older patients as compared to younger patients or patients with normal semen. More oocytes could be necessary in OD cycles with advanced paternal age and poor sperm quality.

Trial registration number: Not applicable.

O-235 Paternal lifestyle factors and its relationship to semen quality and in vitro reproductive outcomes

A.S. Setti[1], D.P.A.F. Braga[2], R.C.S. Figueira[3], R.R. Provenza[4], A. Iaconelli Jr.[5], E. Borges Jr.[5]

[1]Instituto Sapientiae - Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific Department, Sao Paulo, Brazil
[2]Fertility Medical Group, Scientific Department, Sao Paulo, Brazil
[3]Fertility Medical Group, IVF Laboratory, Sao Paulo, Brazil
[4]Fertility Medical Group, Andrology Laboratory, Sao Paulo, Brazil
[5]Fertility Medical Group, Clinical Department, Sao Paulo, Brazil

Study question: Do paternal lifestyle factors influence semen parameters and the outcomes of intracytoplasmic sperm injection (ICSI) cycles?

Summary answer: Cigarette smoking and alcohol consumption appear to reduce semen quality, fertilization and blastocyst formation rates.

What is known already: Seminal parameters have been declining over time worldwide. This decline is likely multifactorial, and a variety of lifestyle factors has been proposed to influence spermatogenesis and reproductive function, either positively or negatively. It is now known that fertilisation and preimplantation embryo development are influenced by sperm-derived factors that may impact ICSI outcomes. Lifestyle factors can be adapted to enhance well-being and are ultimately under one's own control, therefore, adjusting for their influence may yield valuable information for counselling couples submitted to ICSI.

Study design, size, duration: This prospective cohort study included 965 male patients undergoing conventional semen analysis for infertility investigation from October/2015 to December/2016. The influences of alcohol consumption, cigarette smoking, environmental and occupation exposure, medications and physical activity on semen quality were evaluated by regression analyses. For the investigation of the influence of lifestyle factors on ICSI outcomes, only couples with isolated male infertility in which female partner was ≤ 36 y-old were included in the analysis.

Participants/materials, setting, methods: The study was performed in a private university-affiliated in vitro fertilization center. Prior to semen sample collection, participants were asked to complete a detailed non-validated questionnaire containing daily cigarette smoking amount; weekly frequency of alcohol consumption; weekly exercise frequency over the past 3 months; medications used in the past 3 months; exposure to any hazardous agents in workplace.

Main results and the role of chance: Cigarette smoking negatively influenced semen volume (r: -0.417, slope: 1.5700, $p = 0.047$), sperm count/mL (r: -7.363, slope: 52.2981, $p = 0.014$), total sperm count (r: -4.43, slope: 178.165, $p = 0.023$), TMSC (r: - 1.38, slope: 100.276, $p = 0.045$), and sperm DNA fragmentation (r: 0.014, slope: 9.76741, $p = 0.033$). Total sperm motility, progressive sperm motility and sperm morphology were not significantly influenced by smoking habit. Alcohol consumption negatively influenced sperm count/mL (r: -12.527, slope: 42.2553, $p = 0.040$) and SDF (r: 5.833, slope: 9.68068, $p = 0.002$). The other investigated semen parameters were not significantly influenced by alcohol consumption. There were no significant influences of other investigated paternal lifestyle factors on semen quality. Cigarette smoking and alcohol consumption negatively influenced fertilization rate (r: -1.349, slope: 21.9506, p-value: 0.039 and r: -3.617, slope: 20.1380, p-value: 0.041, respectively), and blastocyst formation on day 5 (r: -14.244, slope: 28.8513, p-value: 0.025 and r: -34.801, slope: 30.0446, p-value: 0.042, respectively). There were no significant influences of other investigated paternal lifestyle factors on ICSI outcomes.

Limitations, reasons for caution: Information on paternal lifestyle factors was collected through self-completed non-validated questionnaires and we only assessed lifestyle factors through a few questions, which may have introduced

under-reporting and underestimation of the true association. The female lifestyle were not taken into account, which may have biased the associations with ICSI outcomes.

Wider implications of the findings: Cigarette smoking and alcohol consumption appear to reduce semen quality, fertilization and blastocyst formation rates. Therefore, it would be wise to advise male partners to abstain from smoking and drinking alcohol to avoid decreased in vitro reproduction outcomes.

Trial registration number: None.

O-236 The association between glycemic control and semen parameters

A. Harlev[1], Y. Mizrakli[2], I. Har-Vardi[1], A. Zeadna[1], N. Steiner[1], T. Priel[1], E. Levitas[1]

[1]Soroka University Medical Center- Faculty of Health Sciences- Ben-Gurion Univers, Fertility and IVF Unit- Department of Obstetrics & Gynecology, Beere Sheva, Israel
[2]Soroka University Medical Center- Faculty of Health Sciences- Ben-Gurion Univers, Clinical Research center, Beere Sheva, Israel

Study question: The current study aimed to assess the impact of diabetes mellitus (DM) and impaired fasting glucose (IFG) on seminal fluid and sperm parameters.

Summary answer: Interrupted glycemic control, mainly DM, deteriorates semen volume and sperm morphology, resulting in possible reduced fecundity.

What is known already: The prevalence of diabetes mellitus (DM) and impaired fasting glucose (IFG) is increasing worldwide. DM is known to deteriorate male sexual function, and to affect the endocrine function, a crucial role player in normal spermatogenesis. The impact of abnormal glycemic control on semen parameters and consequently on male fecundity is lacking.

Study design, size, duration: A retrospective case-control study including data from semen analyses of patients undergoing fertility evaluation was conducted. Samples were collected between the years 2009-2017 in a single tertiary hospital. DM and IFG patients were detected according to diagnoses, Lab criteria and prescribed medications documented in their medical records.

Participants/materials, setting, methods: Patients who were younger than 18 or older than 65 years, had previous chemotherapy treatment or radiotherapy, and patients with a diagnosed genetic abnormality (kleinfelter/kallman etc.) were excluded. Semen analyses were conducted and stratified according to the WHO criteria. Multiple regression models were constructed to define independent predictors of abnormal semen parameters. A p value of <0.05 was considered statistically significant.

Main results and the role of chance: A total of 7,118 semen examinations of 3,724 patients were included. Of them, 423 had a valid HbA1c result obtained within ± 90 days of the semen analysis. Comparing DM (n = 336) to IFG (n = 276) and healthy patients (n = 6679), the DM patients were older (41.0 ± 10.0, 39.9 ± 9.1, 32.2 ± 7.2, respectively, $p < 0.001$) with significantly higher smoking rates (47.6%, 36.6, 45.1, respectively, $p = 0.013$) and had higher baseline FSH levels (6.6 ± 4.2, 5.5 ± 3.4 and 5.4 ± 3.9, $p < 0.001$). The BMI of DM and IFG pateints was significantly increased compared to the healthy patients group (28.8 ± 5.4 and 29.4 ± 6.0 vs. 25.9 ± 6.7 respectively, $p < 0.001$). Evaluating the semen analysis, the DM group had higher rates of low semen volume compared to the IFG and non-DM groups (24.1%, 18.1% and 15.3% respectively, $p < 0.001$), asthenozoospermia (40.2%, 39.1% and 34.2% respectively, $p = 0.035$) and teratozoospermia (65.7%, 51.5% and 25.9%, respectively, $p < 0.001$). Using multiple logistic regression models, controlling for confounders including age, BMI and smoking status, DM but not IFG were found as independent risk factors for low seminal fluid volume (OR 1.57, CI 1.18-2.1, $p = 0.002$ vs. OR 0.96, CI 0.67-1.37, $p = 0.809$) and teratozoospermia (OR 1.68, CI 1.23-2.27, $p = 0.001$ vs. OR 0.96, CI 0.7-1.32, $p = 0.791$). Nonetheless, asthenospermia was comparable between the groups.

Limitations, reasons for caution: The study is a retrospective population based study with its inherited limitation.

Wider implications of the findings: Glycemic control is a well-known factor for health in general but as shown in the current study, may alter fecundity of the male partner. Glycemic control should be advocated as part of the fertility treatment consultation.

Trial registration number: not applicable.

O-237 The effects of Mycoplasma genitalium infection on semen: A retrospective study in infertile men of our hospital in China

Z. Wenbing[1,2], L. Weina[3], S. Lin[1], G. Liu[1,4]

[1]Central South University, Institute of Reproduction and Stem Cell Engineering, Changsha, China
[2]Reproductive and Genetic Hospital of CITIC-Xiangya, Sperm bank, Changsha, China
[3]Reproductive and Genetic Hospital of CITIC-Xiangya, Andrology Laboratory, Changsha, China
[4]Reproductive and Genetic Hospital of CITIC-Xiangya, Clinical Laboratory, Changsha, China

Study question: *Mycoplasma genitalium* is an emerging sexually transmitted infections (STIs) that is associated with genital tract infection. Does *Mycoplasma genitalium* infection influence semen quality?

Summary answer: *M.genitalium* incidence (2.49%) in infertile men was higher than in fertile men (0%).It significantly reduced sperm concentration, count, normal morphology, and increased sperm DNA fragmentation.

What is known already: It is estimated that approximately 15% of male infertility is related to infections in the genital tract. *M.genitalium* is associated with male nongonococcal urethritis(NGU), non-chlamydial non-gonococcal urethritis (NCNGU), but evidence supporting its role in male infertility remains inconclusive. And to date there are few large infertile men-based studies of China burden of disease.

Study design, size, duration: The study was performed as a retrospective survey of 30794 semen specimens from 30094 infertile men between October 2016 and December 2017.

Participants/materials, setting, methods: *M.genitalium* was detected using a novel simultaneous amplification testing that is RNA-detection based. Macrolide and tetracycline resistance screening was introduced using PCR and Sanger sequencing from September 2017. Semen analysis, papanicolaou staining, and sperm DNA fragmentation detection were performed on semen samples.

Main results and the role of chance: The incidence (749 of 30094,2.49%;95CI, 2.31%-2.66%) in infertile men was significantly higher than in fertile men (0 of 200, 0%).0.60%(159 of 26627;95CI, 0.50%-0.69%) of infertile couples had concordant infections. There were 123 cases of treatment failure (13.4%,123/918;95%CI, 11.2–15.6). Macrolide and tetracycline resistance were detected in 54 samples (98.18%;95%CI,94.54%-101.83%),27 samples (49.09%;95%CI,35.45%-62.73%) respectively.The most prevalent infection was in oligozoospermia (5.76%). After treatment, semen volume, sperm concentration, sperm count and total motile sperm count were significantly higher than those of before treatment($p = 0.046$, $p < 0.001$,$p = 0.011$,$p = 0.024$,respectively) in 56 patients. Normal morphology in *M. genitalium* positive group(n = 50) was significantly lower than that of negative group(n = 70) (2.98 ± 0.87% vs.3.71 ± 0.91%, $p < 0.001$). Sperm DNA fragmentation (DFI) in *M. genitalium* positive group(n = 50) was significantly higher than that of negative group(n = 70) (13.72 ± 7.61% vs.8.56 ± 4.81%, $p < 0.001$). Our study suggested a low prevalence of *M. Genitalium* in the infertile men in China. >98% of macrolide resistance is an likely explanation for high rates of azithromycin treatment failure (34.48%).*M. genitalium* infection significantly led to a decrease in semen concentration, sperm count, normal morphology, and increased sperm DNA fragmentation(SDF).

Limitations, reasons for caution: A limitation of the study is that we did not study the pregnancy rates before and after antibiotic treatment. Studying the pregnancy rates might better support our findings. And the positive group sizes followed in this study were relatively small.

Wider implications of the findings: Since incidence is very low, caution is required to establish the relationship to *M. genitalium* and male fertility. These findings indicate that *M. genitalium* infection might finally affect semen quality. And there is a need to provide resistance testings, reappraisal the recommended antimicrobial options in China.

Trial registration number: Not applicable.

O-238 Effect of nut consumption on semen quality and functionality in healthy males: a randomized controlled trial

A. Salas-Huetos[1,2], R. Moraleda[1], S. Giardina[1,2], E. Anton[3], J. Blanco[3], J. Salas-Salvadó[1,2], M. Bulló[1,2]

[1]Universitat Rovira i Virgili, Human Nutrition Unit, Reus 43201, Spain
[2]Consorcio CIBER- M.P.- Physiopathology of Obesity and Nutrition CIBERobn, Instituto de Salud Carlos III ISCIII, Madrid 28029, Spain
[3]Genetics of Male Fertility Group, Cell Biology Unit- Department of Cellular Biology-Physiology and Immunology- Faculty of Biosciences- Universitat Autònoma de Barcelona UAB, Bellaterra Cerdanyola del Vallès 08193, Spain

Study question: Can a chronic consumption of a mixture of nuts improve the semen quality parameters and the sperm functionality in healthy individuals?

Summary answer: Including nuts in a regular diet significantly improved the sperm count, vitality, motility, and morphology, partly explained by a reduction of the DNA fragmentation.

What is known already: Human semen quality has declined in industrialized nations where pollution, smoking, and trends toward a western-style diet are hypothesized as potential causes. Recently, some studies described that healthy diets rich in omega-3, antioxidants (e.g. vitamin C and E, selenium and zinc), carnitines and folate could improve semen quality. Because nuts are nutrient dense foods containing some of the above-mentioned nutrients, we hypothesize that, added to a western-style diet, would beneficially affect semen quality and functionality.

Study design, size, duration: The study was designed as a 14-week randomized, controlled, parallel two-group trial. 119 healthy male aged 18-35 were allocated to either following their usual western-style diet supplemented with 60 g/day of a mix of almonds, hazelnuts and walnuts or to follow with their usual western-style diet free of nuts.

Participants/materials, setting, methods: Sperm and blood samples were collected at baseline and after 14 weeks of intervention. Dietary information was recorded in four visits distributed along the trial. Conventional semen parameters (WHO, 2010) were determined as primary outcome. To elucidate at the molecular level the effects of nuts consumption, sperm DNA fragmentation (TUNEL assay), sperm ROS (chemiluminescence using Luminol), sperm chromosome stability (FISH for chromosomes X, Y and 18) and total sperm DNA methylation (ELISA assay) were measured.

Main results and the role of chance: A total of 98 participants completed the study. General characteristics of the study population (age, weight, height, BMI, waist circumference, and systolic and diastolic blood pressure) did not differ between interventions. No significant differences were observed in conventional blood biochemical parameters (fasting plasma glucose, total cholesterol, HDL, LDL and VLDL cholesterol, triglycerides, fasting plasma insulin, C-reactive protein and folate). In nuts group, we found a significant increased intake of total lipids, MUFA, PUFA, magnesium, vitamin E, omega-3, ALA, and omega-6. We found an improvement of sperm count (P-value = 0.0043), vitality (P-value = 0.0027), total motility (P-value = 0.0093), progressive motility (P-value = 0.0207), and morphology (P-value = 0.0073) in the nut group compared to the control. Participants in the nuts group shown a significant reduction of the sperm DNA fragmentation (SDF) (P-value = 0.0018) a parameter closely related with male infertility. Negative correlations between sperm vitality and SDF (rho=-0.2252; P-value = 0.0266), and between total spermatozoa and SDF (rho=-0.3170; P-value = 0.0015) were detected. No changes between interventions were found in ROS (P-value = 0.1996), sperm chromosome (X, Y and 18) anomalies (P-value disomies = 0.3336, P-value nullisomies = 0.9386, and P-value diploidies = 0.0674), and DNA methylation (P-value = 0.8652).

Limitations, reasons for caution: By design, a limitation of this trial is that it focuses on health, apparently fertile and with western-style diet subjects, and the results cannot be extrapolated to the general population.

Wider implications of the findings: Our findings support a beneficial role of chronic nut consumption in sperm quality and explore the molecular mechanism that could explain our results. Additional efforts to identify male-specific dietary recommendations that optimize sperm quality and fertility should be encouraged.

Trial registration number: The trial was registered in ISRCTN registry with identifier ISRCTN12857940 (DOI: 10.1186/ISRCTN12857940).

O-239 Medroxyprogesterone acetate versus ganirelix in oocyte donation cycles stimulated using GnRH antagonist protocol triggered with GnRH-agonist: a randomized controlled trial (RCT)

R. Begueria, D. García, R. Vassena, A. Rodríguez

Clínica EUGIN, Assisted Reproduction, Barcelona, Spain

Study question: To evaluate the non-inferiority of oral medroxiprogesterone acetate (MPA) compared to ganirelix on the number of mature oocytes (MII) retrieved at ovum pick-up (OPU) in oocyte donation cycles.

Summary answer: MPA is comparable to ganirelix in terms of MII retrieved at OPU. However, MPA use during ovarian stimulation might decrease pregnancy rates in oocytes' recipients.

What is known already: Oral treatment with MPA inhibits the pituitary LH surge during ovarian stimulation in infertile patient. Because of its negative effect on the endometrium, MPA suppression is combined with freeze-all. Published reports indicate that both the number of MII retrieved and pregnancy rates from these oocytes are comparable to short protocol of GnRh agonists during IVF cycles with freeze-all. MPA might allow for more comfortable and cost-effective ovarian stimulation in oocyte donation cycles.

Study design, size, duration: Randomized clinical trial (RCT), open-label, conducted from June 2016 to June 2017 to assess the non inferiority of MPA (10 mg/day) versus a GnRH antagonist protocol with ganirelix (0.25 mg/day) from day 7 in ovarian stimulation cycles triggered with triptoreline. Trigger criterion was >3 follicles of diameter>18 mm.

Participants/materials, setting, methods: 280 oocyte donors were selected, 232 randomized and 173 reached OPU: 86 under MPA and 87 under ganirelix. The main outcome was number of MII at OPU. Secondary outcomes were: embryological laboratory outcomes and reproductive outcomes in oocyte recipients. The study was powered to indentify a difference ≥3 MII, with an alpha risk of 0.05 and beta risk of 0.2. Differences were tested using a two-sided Student's t-test or a Pearson's Chi^2 test as applicable.

Main results and the role of chance: All participants were in their first cycle of oocyte donation. On average, donors were 24 ± 4.5 years old and with a BMI of 23 ± 2.9 kg/m^2. Days of stimulation were similar in both groups (11.2), as well as the total gonadotropin doses up to trigger (2162 IU in MPA and 2163 IU in ganirelix). The number of MII retrieved was no different: 15.1 ± 8.3 with MPA and 14.6 ± 7.0 with ganirelix (p = 0.69).

Both recipients' and embryo transfer (ET) characteristics were similar among groups. The average age of recipients was 42 ± 4.8 years and the BMI was 24 ± 4.4 kg/m2. The mean number of MII assigned to each recipients was 6.7 ± 1.1 in MPA and 6.6 ± 1.1 in ganirelix (p = 0.58). MII were fertilized with partner sperm in 84.9% cycles overall and fertilization rate was 75.7% with MPA vs. 73.9% with ganirelix (p = 0.50). Overall, there was 55.2% of double ET and 44.8% of single ET; 39.1% of ETs were performed in D5. Surprisingly, and in spite of similar recipients and cycle characteristics, reproductive outcomes were unexpectedly lower with MPA. Biochemical pregnancy rate was 44.3% vs. 56.2% (p = 0.042); clinical pregnancy rate 29.9% vs. 42.5% (p = 0.026); ongoing pregnancy rate 27.4% vs. 36.9%, (p = 0.085) and live birth rate 15.4% vs. 26.0%, (p = 0.036).

Limitations, reasons for caution: Although oocyte recipient and ET characteristics are similar among groups, this RCT has been designed under a hypothesis of no-inferiority in the number of MII obtained in two treatment groups, therefore the reproductive outcomes in recipients should be evaluated with caution.

Wider implications of the findings: Ovarian stimulation with MPA yield comparable results compared to ganirelix in oocyte donation cycles. The unexpected finding in reproductive outcomes should be further investigated.

Trial registration number: EudraCT Number 2015-004328-73

O-240 Triggering method dramatically alters the cumulus cell transcriptome in high and normal ovarian reserve patients

B. Wyse[1], N. Fuchs Weizman[1], I. Gat[1,2], H. Balakier[1], S. Kenigsberg[1], M. Sangaralingam[1], S. Russell[1], J. Caballero[1], C. Librach[1,3,4,5]

[1]*CReATe Fertility Centre, Research, Toronto, Canada*
[2]*Tel Aviv University, Sackler Faculty of Medicine, Tel Aviv, Israel*
[3]*Women's College Hospital, Department of Gynecology, Toronto, Canada*
[4]*University of Toronto, Department of Obstetrics and Gynecology, Toronto, Canada*
[5]*University of Toronto, Department of Physiology, Toronto, Canada*

Study question: Does triggering oocyte maturation with single vs. dual trigger (GnRHa & hCG) significantly alter the transcriptome of cumulus cells?

Summary answer: Triggering protocol significantly alters the cumulus cell transcriptome; hallmark pathways affected include cell-cycle regulation, ECM remodeling, and ion-channel activity, all important for folliculogenesis and ovulation.

What is known already: Cumulus cells (CCs) support the growing oocyte and their transcriptome could potentially be a valuable non-invasive biomarker for oocyte quality and competence. The CC transcriptome is influenced by the women's age, BMI, infertility diagnosis (eg. Endometriosis, PCOS, low ovarian reserve) and stimulation protocol. Previously, using microarray, when triggering with either GnRHa or hCG, it has been shown that GnRHa enhanced expression of genes involved in steroidogenesis. Differences in the CC transcriptome may potentially affect clinical outcomes, including the number of eggs retrieved, their quality, blastulation rates, aneuploidy, and pregnancy rates.

Study design, size, duration: This study is a part of a larger ongoing RCT comparing outcomes between single trigger (ST) vs. dual trigger (DT), in different patient populations. A total of 21 consented patients (12 with high ovarian reserve and 9 with normal ovarian reserve) undergoing IVF-ICSI at the CReATe Fertility Centre (Toronto, Canada) were enrolled in the study. Patients were matched according to demographic characteristics (age, BMI, etc.), ovarian reserve parameters (AMH and AFC) and stimulation protocol.

Participants/materials, setting, methods: CCs from expanded MII oocytes were trimmed, lysed, and RNA was extracted. Sequencing libraries were prepared (Clonetech SMARTer-v4 and Nextera-XT) and sequenced using a HiSeq 2500. Sequences were aligned to hg19, differential expression was conducted, and filtered by false discovery rate (FDR < 0.05) and fold change (logFC<-2 or logFC>2). Pathway analysis using GSEA was performed to elucidate biologically significant genes involved in hallmark processes in the ovary.

Main results and the role of chance: Samples clustered separately by triggering method in patients with both high and normal ovarian reserve. Eight hundred and forty-one genes were differentially expressed between treatment groups in the high responder cohort, and 2000 genes were differentially expressed in the normal responder cohort. In the high responders, dual trigger led to downregulation of ion channel regulators and G-protein receptor binding pathways when compared with single trigger and upregulation of mesenchymal development. In the normal responder cohort, dual trigger caused downregulation of immune related pathways (MHC complex, antigen processing, etc.) and extracellular matrix remodeling, when compared with single trigger and upregulation of cell division related pathways (mitotic spindle, chromosome segregation, etc.). Furthermore, genes previously associated with live birth were enriched in the normal responders treated with DT. Blastulation rate was significantly higher in normal responders triggered by DT when compared to ST (3.0 ± 0.37;1.67 ± 0.24 $p < 0.01$). Triggering method did not affect clinical outcomes among the high responders.

Limitations, reasons for caution: Our findings are limited by the sample size and biological variability. To adjust for this, "significant DE" between the two triggering cohorts was defined with stringent criteria, increasing confidence in the validity of our findings. No potential confounding variables were deemed significant (Wilcoxon test).

Wider implications of the findings: Triggering protocol alters the transcriptome profile of CCs in both high and normal responders and blastulation rate in normal responders. Hallmark pathways involved in cellular proliferation, oocyte maturation, and ovulation are affected. This study enhances our understanding of the effect triggering has on processes involved in oocyte growth and maturation.

Trial registration number: Not applicable.

O-241 Daytime variation in serum progesterone during the mid-luteal phase in women undergoing IVF treatment

T. Haahr[1], U.S. Kesmodel[2], C.Y. Andersen[3], L.H. Thomsen[4], P. Humaidan[4]

[1]*The Fertility Clinic- Skive- Skive Regional Hospital- Denmark, Department of Clinical Medicine- Aarhus University- Denmark., Skive, Denmark*
[2]*The Fertility Clinic- Herlev Hospital- Herlev- Denmark., Department of Clinical Medicine- University of Copenhagen- Denmark., Herlev, Denmark*
[3]*Laboratory of Reproductive Biology- The Juliane Marie Centre for Women- Children and Reproduction- University Hospital of Copenhagen- Denmark., University of Copenhagen- Denmark, Copenhagen, Denmark*
[4]*The Fertility Clinic Skive- Skive Regional Hospital- Denmark, Department of Clinical Medicine- Aarhus University- Denmark., Skive, Denmark*

Study question: Does mid-luteal serum progesterone (P_4) exhibit clinically significant fluctuations during a 12-hour daytime period in women undergoing *in vitro* fertilization (IVF)?

Summary answer: Large P_4-fluctuations were seen in patients with median P_4>250 nmol/l whereas patients with P_4<60 nmol/l had clinically constant P_4-levels during daytime.

What is known already: Large fluctuations in serum-P_4 levels are present in the mid-luteal phase of the natural cycle, hampering the use of serum-P_4 measurements in the evaluation of corpus luteum function. No study so far examined the possible daytime serum-P_4 fluctuations during the mid-luteal phase in a group of women undergoing IVF treatment.

Study design, size, duration: Observational daytime study of ten women undergoing IVF treatment at the fertility clinic in Skive, Denmark. Patients were prospectively enrolled between December 2014 and December 2015.

Participants/materials, setting, methods: Seven days after oocyte pick-up, patients were admitted to the fertility clinic early in the morning. They had blood samples drawn every 60 minutes for the subsequent 12 hours, and during two of these hours every 15 minutes. Patients were selected to represent different stimulation protocols, different modes of triggering of final oocyte maturation as well as different regimens of luteal phase support. Serum samples were analyzed for progesterone, estradiol and LH.

Main results and the role of chance: There was a significant positive correlation between median P_4-levels and the magnitude of P_4-variations – women with median P_4 < 60 nmol/l had clinically stable P- levels throughout the day, while patients with median P_4 > 250 nmol/l exhibited periodic P_4-peaks of several hundred nmol/l. These endogenous P4-fluctuations were observed irrespective of the type of stimulation protocol or mode of triggering of final oocyte maturation and despite the fact that LH was under the detection limit at the time of measurement. Simultaneously large fluctuations were seen in s-estradiol. There was no obvious common daytime pattern in the secretion of P_4 in the ten women examined.

Limitations, reasons for caution: Although the sample size was small, which may limit the validity of general interpretations, this is the first study to explore mid-luteal P_4-fluctuations in different types of IVF cycles.

Wider implications of the findings: When monitoring mid-luteal P_4-levels during IVF-treatment, clinicians should be aware that large P_4-fluctuations may exist when serum-P_4 exceeds 250 nmol/l. In contrast, a measured serum P_4<60 nmol/l can be regarded as a true low value – thus, the accuracy of an individual mid-luteal serum-P_4 measurement depends on the median P_4-concentration.

Trial registration number: NCT02673034 (Clinicaltrials.gov).

O-242 Effects of high progesterone in in-vitro fertilization cycle on DNA methylation of endometrium receptivity markers during implantation window

Y. Xiong[1], L. Hu[2], T. Zhang[3], H. Xu[1], M. Wang[2], Y. Sun[2], C. Wang[1]

[1]*The Chinese University of Hong Kong, Department of Obsetetrics and Gynaecology, Shatin- New Territories, Hong Kong*

[2]the First Affiliated Hospital of Zhengzhou University, Reproductive Medical Center, Zhengzhou, China
[3]Shenzhen Zhongshan Urology Hospital, Shenzhen Key Laboratory of Reproductive Immunology for Peri-implantation- Fertility Centre, Shenzhen, China

Study question: Does high progesterone level in in-vitro fertilization (IVF) cycle affect DNA methylation of endometrium receptivity markers during implantation window?

Summary answer: The endometrium receptivity markers, MUC1, CDH1 and CTNNB1, in patients with high progesterone were highly methylated, while PAEP was lessly methylated.

What is known already: High progesterone increased endometrium DNA methylation but how methylation affect the endometrium receptivity during implantation window is still unclear.

Study design, size, duration: A cohort study including 20 women with high progesterone level (HP) and 20 women with normal progesterone level (NP) on the day of human chorionic gonadotrophin (hCG) administration after controlled ovarian hyperstimulation in an IVF cycle.

Participants/materials, setting, methods: Endometrial tissues were collected on 7th day after hCG administration from women with NP or HP on hCG day. Immunohistochemical staining of DNA methyltransferases (DNMTs) and receptivity markers (MUC1, CDH1, CTNNB1 and PAEP) was performed. Methylation level of promotor region of receptivity markers was detected by Sequenom MassARRAY and/or bisulfite-sequencing PCR. RT-qPCR was used to quantify mRNA expression levels of the receptivity markers. Then methylation level and expression levels of the receptivity markers were correlated.

Main results and the role of chance: Except for progesterone level on hCG day, no significant demographic difference exists between HP and NP group. Expression of DNMT3B, but not DNMT1 and DNMT3A, in endometrium from HP group was significantly higher than that in NP group. DNA methylation levels of promotor region of MUC1, CDH1, CTNNB1 in HP group was significantly higher, while the PAEP in HP group was significantly lower than that in NP group. On the contrary, expression levels of MUC1, CDH1 and CTNNB1 in HP group were significantly lower, while PAEP in HP group was significantly higher than that in NP group, as detected in RT-qPCR and IHC staining. The DNA methylation level was negatively correlated with the mRNA expression level of the receptivity markers.

Limitations, reasons for caution: The sample size was not sufficiently large to permit in depth analysis of confounding variables.

Wider implications of the findings: Our data demonstrated high progesterone affects DNA methylation and gene expression of endometrium receptivity markers during implantation window, which may contribute the failure of IVF treatment.

Trial registration number: No.

O-243 Implantation enhancement by elective Cryopreservation of all viable Embryos (ICE): randomized controlled trial (RCT) comparing the two safest approaches in IVF/ICSI for high-responders

S. Santos-Ribeiro[1,2], S. Mackens[1], B. Popovic[1], N.P. Polyzos[1,3,4], A. Racca[1,5], P. Drakopoulos[1,6,7], M. De Vos[1], H. Tournaye[1], C. Blockeel[1,8]

[7]University of Liège, Departement of Reproductive Medicine, Liège, Belgium
[8]University of Zagreb-School of Medicine, Department of Obstetrics and Gynaecology, Zagreb, Croatia

Study question: How does the freeze-all strategy compare to GnRH-agonist triggering followed by intensified luteal support and fresh embryo transfer (ET) in terms of pregnancy/safety outcomes?

Summary answer: Pregnancy rates after either fresh ET or freeze-all did not vary significantly. However, ovarian hyperstimulation syndrome (OHSS) occurred more frequently after a fresh ET attempt.

What is known already: GnRH-agonist triggering has drastically reduced the incidence of OHSS. However, the best method to perform an ET after agonist triggering is still widely unknown. Two strategies (the freeze-all approach and a fresh ET attempt using a low-dose bolus of hCG followed by intensified luteal phase support) have shown to be safer alternatives to conventional hCG triggering with comparable pregnancy outcomes. However, these two strategies have never been compared head-to-head.

Study design, size, duration: The ICE trial was an RCT designed to recruit 212 women with an excessive response after ovarian stimulation (≥18 follicles measuring ≥11 mm) for IVF/ICSI in a GnRH antagonist suppressed cycle between 2014-2017. Our primary outcome was clinical pregnancy at 7 weeks after the first ET. Secondary outcomes included live-birth and the development of moderate-to-severe early-onset OHSS.

Participants/materials, setting, methods: Following GnRH-agonist triggering, women were randomized to perform either a fresh ET attempt (after a 1500 IU hCG bolus on the day of oocyte retrieval followed by oral estradiol 2 mg bid and vaginal progesterone 200 mg tid) or to cryopreserve all good-quality embryos followed by a frozen ET in a subsequent artificial cycle.

Main results and the role of chance: The required total of 106 patients in each study arm were recruited in the study, with 3 patients (1 in the fresh ET group and 2 in the freeze-all group) later withdrawing their consent to participate in the study. One patient in the freeze-all group became pregnant spontaneously prior to the first frozen ET. The study arms did not vary significantly in terms of the number of oocytes retrieved and embryos cryopreserved/transferred. The intention-to-treat clinical pregnancy rates after the first ET did not vary significantly among the fresh ET and freeze-all study arms (49% versus 54%, $p = 0.446$). However, moderate-to-severe early-onset OHSS occurred more frequently in the group who had a fresh embryo transfer (9% versus 0%, $p = 0.002$).

Limitations, reasons for caution: These preliminary results are limited by the fact that the accrual of live-births is still ongoing. Furthermore, given that the RCT was powered for the superiority of one of the arms, smaller differences among the groups in terms of clinical pregnancy rates may have failed to reach statistical significance.

Wider implications of the findings: This study offers the first comparative analysis of the two most commonly proposed alternatives for high-responding women performing IVF/ICSI in modern-day medicine. While pregnancy rates seemed comparable, a fresh ET may increase the risk of OHSS. Thus, serious consideration should be made before recommending a fresh ET as first-line treatment.

Trial registration number: ClinicalTrials.gov identifier NCT02148393.

O-244 Oral dydrogesterone is an efficacious and safe alternative to intravaginal progesterone gel for luteal phase support in IVF: a randomized, open-label, multicenter, phase III study

G. Griesinger[1], C. Blockeel[2], A. Patki[3], D.Z. Yang[4], Z.J. Chen[5], E. Kahler[6], C. Pexman-Fieth[7], H. Tournaye[2]

[1]University Hospital of Schleswig-Holstein, Department of Gynecological Endocrinology and Reproductive Medicine, Lübeck, Germany
[2]University Hospital of the Brussels Free University, Center for Reproductive Medicine, Brussels, Belgium
[3]Fertility Associates, Mumbai, India
[4]Sun Yat-Sen University, Department of Obstetrics and Gynecology, Guangzhou, China
[5]Shandong University, Department of Obstetrics and Gynecology, Shandong, China
[6]Abbott Laboratories GmbH, Clinical Development, Hannover, Germany
[7]Abbott GmbH & Co. KG, Women's Health Medical Affairs and Clinical Development, Wiesbaden, Germany

Study question: Is oral dydrogesterone 30 mg daily non-inferior to 8% intravaginal micronized progesterone gel 90 mg daily for luteal phase support in in vitro fertilization (IVF)?

Summary answer: Oral dydrogesterone demonstrated non-inferiority to intravaginal micronized progesterone gel for the presence of fetal heart beats at 12 weeks of gestation (non-inferiority margin 10%).

What is known already: Progesterone therapy for luteal phase support is an accepted treatment practice for women undergoing IVF. The intravaginal route of micronized progesterone administration is routinely used in most clinics; however, it is associated with vaginal irritation, discharge and poor patient compliance. It has been demonstrated that oral dydrogesterone is non-inferior to micronized vaginal progesterone (MVP) capsules for luteal phase support in IVF with a similar safety profile (LOTUS I trial; Tournaye et al., Hum Reprod. 2017); In the present study, the efficacy, safety and tolerability of oral dydrogesterone versus intravaginal micronized progesterone gel (Crinone® 8%) were assessed.

Study design, size, duration: Lotus II was a randomized, open-label, multicenter, phase III clinical study, performed across 37 sites in 10 countries from August 2015 until May 2017. Subjects were premenopausal women (>18 to <42 years) with a documented history of infertility who were planning to undergo IVF. A centralized electronic system was used for randomization to oral dydrogesterone 10 mg tablets three times daily or 8% intravaginal micronized progesterone gel 90 mg (Crinone®) once daily.

Participants/materials, setting, methods: In total, 1034 subjects were randomized to receive either oral dydrogesterone (n = 520) or intravaginal micronized progesterone gel (n = 514). Luteal support was started on the day of oocyte retrieval and continued until 12 weeks of gestation if a positive pregnancy test was obtained 2 weeks after embryo transfer and no miscarriage occurred. The primary outcome measure was the presence of fetal heartbeats at 12 weeks of gestation as determined by transvaginal ultrasound.

Main results and the role of chance: In the oral dydrogesterone and intravaginal micronized progesterone gel groups, 494 and 489 subjects were included in the full analysis set (FAS), and 490 and 481 subjects were included in the per protocol set (PPS), respectively. Pregnancy rates at 12 weeks of gestation for the oral dydrogesterone and intravaginal micronized progesterone gel groups were 38.7% and 35.0% in the FAS (difference 3.7%; 95% CI: -2.3–9.7%), and 36.7% and 34.7% in the PPS (difference 2.0%; 95% CI: -4.0–8.0%), respectively. Thus, in both the FAS and PPS, non-inferiority of oral dydrogesterone versus intravaginal micronized progesterone gel was demonstrated as the lower-bound CI was greater than the non-inferiority margin of -10%. Live birth rates in the FAS were 34.4% and 32.5% (difference 1.9%; 95% CI -4.0–7.8%). The number of women with multiple newborns was comparable in the two treatment groups (20.6% versus 17.6% in the FAS for the oral dydrogesterone and intravaginal micronized progesterone groups, respectively). Oral dydrogesterone was well tolerated, and the incidence of treatment emergent adverse events for mothers and newborns was comparable to that of intravaginal micronized progesterone gel in this study.

Limitations, reasons for caution: The analysis of the results was powered to consider the ongoing pregnancy rate, but a primary objective of greater clinical interest may have been the live birth rate. Conclusions relating to the treatment effects in secondary variables, such as live birth rate, should therefore be made with caution.

Wider implications of the findings: The present study confirms the findings of the Lotus I trial (Tournaye et al., Hum Reprod. 2017), which already established oral dydrogesterone as a viable alternative to vaginally administered micronized progesterone due to its efficacy and comparable tolerability in the studies.

Trial registration number: NCT02491437 (clinicaltrials.gov)

O-245 FSHR type is a risk factor for developing ovarian hyper stimulation syndrome during in vitro fertilisation as observed in vivo and in vitro

H. Nenonen[1], I. Lindgren[1], E. Henic[1], L. Bungum[2], Y. Lundberg Giwercman[1]

[1]*Lund University, Translational Medicin, Malmö, Sweden*
[2]*Copenhagen University Hospital, Department of fertility, Copenhagen, Denmark*

Study question: Is the follicle stimulating hormone genotype of importance when evaluating the risk of ovarian hyper stimulation syndrome (OHSS) in women undergoing in vitro fertilisation (IVF)?

Summary answer: Women with asparagine in the amino acid 680 of the FSHR had an OR of 11 (95% CI 1.4-82; p = 0.022) for OHSS compared to women with serine.

What is known already: A serious and potentially life-treathening complication to IVF-treatment is OHSS, generally affecting 0.5-5% women undergoing controlled ovarian hyperstimulation with exogenous FSH, and there are currently no effective methods to predict the response. It is known that carriers of NN in aminoacid 680 in the FSHR require lower doses of FSH during controlled ovarian stimulation compared to women with SS in order to ovulate. Some cases with mutations in the FSHR and spontaneous OHSS have been reported, but linking this condition with polymorphisms in the FSHR have shown contradicting results.

Study design, size, duration: Retrospective study. Women undergoing IVF at Reproductive Center, Malmö hospital, Malmö, Sweden, were enrolled and genetic variants examined and compared between those who developed OHSS and those who did not. FSHR variants were studied in monkey kidney cells treated with rFSH.

Participants/materials, setting, methods: In total n = 586 women were included in the study and genotyped regarding the polymorphism N680S in the FSHR gene. A risk allele analysis regarding the association between genotype and development of OHSS was done. To study receptor activity *in vitro*, COS-1 cells were transfected with FSHR variants and response was measured as cAMP amount produced when stimulated 1 h with 1, 10 or 90 IU follitropin alpha (Gonal-f, MerckSerono). The experiments were done in duplicates and repeated 3 times.

Main results and the role of chance: The proportion of women who developed OHSS was 6% (n = 36) in the total cohort. The N680S A > G polymorphism in the FSHR was associated with OHSS, ptrend = 0.004 and pallelic = 0.038. Carriers of an N allele had significantly higher OR for OHSS compared to carriers of S (OR 1.7, 95% CI 1.0 – 2.8, p = 0.04). A higher receptor activity in cells expressing N compared to the S variant was also evident at all concentrations of rFSH tested (p < 0.05 for all).

Limitations, reasons for caution: The number of total OHSS cases is small in this study but the genotype distribution for all participants is similar to earlier reports, therefore not indicating selection bias.

Wider implications of the findings: This study strengthens previous findings regarding higher hormonal sensitivity in carriers of N in the FSHR. Genotyping the FSHR before IVF or egg donation could be a help in identifying high risk individuals and precaution could be taken regarding hormonal dose to prevent OHSS in women with this particular genotype.

Trial registration number: not applicable.

Wednesday 4 July 2018 Room 113 + 114 + 115 10:00–11:45

O-246 Vaginal microbiota profile at the time of embryo transfer does not affect pregnancy in IVF cycles with donated oocytes

P. Vergaro[1], G. Tiscornia[1], M. Barragán[1], D. García[1], J. Santaló[2], A. Rodríguez[1], R. Vassena[1]

[1]*Clínica EUGIN, Assisted Reproduction, Barcelona, Spain*
[2]*Universitat Autònoma de Barcelona, Unitat de Biologia Cel·lular- Facultat de Biociències, Barcelona, Spain*

Study question: What is the relationship between the vaginal microbiota profile at the time of embryo transfer and pregnancy rate in women undergoing IVF with donated oocytes?

Summary answer: The vaginal microbiota profile at embryo transfer in women receiving donated oocytes does not seem to be related with the pregnancy rate in this population.

What is known already: Vaginal microbiota, i.e. the community of bacterial species colonizing the vaginal mucosae, plays an important role in the physiology of the female genital tract. The vaginal microbiota of healthy women is dominated by lactic-acid producing bacteria, mainly *Lactobacillus* spp. Dominance of anaerobic species such as *Gardnerella vaginalis* or *Atopobium vaginae* lead to a dysbiosis known as bacterial vaginosis (BV). In some reports, such condition has been correlated with negative results in IVF, while other authors did not find any relation. It is still unclear whether vaginal microbiota status influences IVF outcome or not.

Study design, size, duration: 121 Caucasian women receiving donated oocytes were prospectively included in March-September 2017. Vaginal swabs were taken immediately before transfer of single blastocysts. Genomic DNA was extracted with QIAamp DNA mini kit (Qiagen), and bacterial load as well as the expression of 8 bacterial species was determined by qPCR. The main outcome was βhCG levels in blood 14 days after single blastocyst transfer. Univariate analysis was performed to evaluate the association between microbiota profiles and pregnancy.

Participants/materials, setting, methods: Absolute number of bacterial genomes per sample was determined by qPCR for 4 species of lactobacilli (*L. crispatus, L. gasseri, L. jensenii, L. iners)* commonly found in vaginal microbiota and 4 species related with BV (*Gardnerella vaginalis, Atopobium vaginae, Mycoplasma hominis and Prevotella spp*). Vaginal microbiota profiles for each patient were characterized as *Lactobacillus* dominated (>50% *Lactobacillus* spp), BV associated (>50% BV associated bacteria), or mixed microbiota (dominance not clear) and correlated with biochemical pregnancy.

Main results and the role of chance: Although bacterial load was variable, most samples were dominated by a single species. Overall pregnancy rate was 55.4%. A majority of samples (81.8%) were dominated by Lactobacillus spp. In this group, the pregnancy rate was 52.5%, while in non-Lactobacillus dominated profiles the pregnancy rate was 68.2% ($p = 0.238$). We further analyzed profiles including *Lactobacillus* dominated, BV associated and mixed microbiota. The prevalence of BV associated microbiota was 14.9%, with pregnancy rate of 66.7%. Mixed microbiota samples (composed by a combination of Lactobacilli and BV associated species) had a very low prevalence (3.3%). Pregnancy rates among the three groups did not show significant differences ($p = 0.391$). In addition, we determined microbiota profiles according to the relative expression of bacterial species referred to human and bacterial load. This approach gave similar results, with no statistically significant differences between groups ($p = 0.345$). Our results suggest that a vaginal microbiota dominated by BV associated species is not associated to a pregnancy decrease when high quality embryos derived from donor oocytes are transferred to a receptive endometrium, in absence of ovarian stimulation. Vaginal microbiota profile does not seem to be determinant for oocyte recipient cycles success.

Limitations, reasons for caution: Sampling variations cannot be ruled out; bacterial and human genomic DNA proportion varied slightly between samples. Our three-way group analysis needs to be confirmed using a higher number of samples for BV and mixed microbiota categories.

Wider implications of the findings: Some authors report deleterious effects of BV on reproductive outcomes. Our data suggest that BV-like vaginal microbiota at time of embryo transfer does not directly affect endometrial receptivity and pregnancy rate.

Trial registration number: Not applicable

O-247 Low ovarian response to stimulation in IVF can be related with activation of the NLRP3 inflammasome

L. Rancan[1], R. Núñez Calonge[2], S. Cortés Gallego[2], E. Vara[1], P. Caballero Peregrín[2], J.A.F. Tresguerres[3]

[1]Facultad de Medicina- Universidad Complutense, Bioquímica y Biología Molecular, Madrid, Spain
[2]Clinica Tambre, Scientific Direction, Madrid, Spain
[3]Facultad de Medicina- Universidad Complutense, Fisiología, Madrid, Spain

Study question: Does the NLRP3 inflammasome play a role in low ovarian response to stimulation in IVF?

Summary answer: The activation of NLRP3 is higher in patients with low ovarian response compared to donors. Increased oxidative stress may induce increased expression of inflammatory NLRP3

What is known already: Oxidative stress can stimulate tissue inflammation and induce pyroptosis, a process strongly regulated by inflammasomes. The best-characterized inflammasome is NLRP3, whose activation allows the recruitment of an adaptive ASC protein, which interacts with procaspase-1 and activates caspase-1, the responsible for maturing pro-IL-1b and pro-IL-18 to obtain biologically active forms. Parallel to this process, and as a consequence of caspase activation, apoptosis can be induced too.

It has been also described that large number of miRNAs can bind to coding mRNAs for proteins in the constituents of inflammasome. miR-146, has been described as one of them.

Study design, size, duration: mRNA expression of NLRP3, ASC, and Caspase-1 together with the expression of miR-146 were measured in oocyte-granulose (CGs) complexes and in follicular liquid (FL) retrieved from 8 healthy fertile oocyte donors (<35 y.o. with at least a previous cycle with pregnancy) and compared with 8 low responders patients (<35 y.o. who had ≤ 5 oocytes retrieved after gonadotropic stimulation) whom took part in a prospective observational study realized from July 2016 to December 2017.

Participants/materials, setting, methods: Participants were stimulated with the same protocol (FSHr and triggering with GnRH analogues). GCs and FLs were collected and immediately fresh-frozen. The mRNA expression of NLRP3, ASC and Caspase-1 was measured by qRT-PCR. Exosomes were extracted by ultracentrifugation from FL and miR-146 was measured by qRT-PCR. Relative changes in gene expression were calculated using the 2-ΔΔCT method. No parametric tests were used to identify any significant difference between groups. Statistical significance was set at $p < 0.05$.

Main results and the role of chance: Inflammasome constitutes a high molecular weight signaling platform that leads to the activation of inflammatory caspases. In our study, the mRNA expression of NLRP3, the best-characterized inflammasome, was significantly increased in patients with low ovarian response compared to donors ($p = 0.045$). Also, the adaptive ASC protein, whom activation depends on NLRP3, was significantly increased in the patients group compared to the donors one ($p = 0.0005$). At the same, caspase-1 was found increased in the patients group compared to the donors one ($p < 0.0001$). The activation of caspase-1 can induce the maturing of IL-1b, which has been observed to be increased in patients with low ovarian response in previous studies from our group.

Although a large number of miRNAs can bind to coding mRNAs for proteins in the constituents of inflammasome, miR-146 seems especially important because in addition to control inflammasome, can also regulate inflammation formation by interaction with RNA encoding for adaptive molecules. In our study, the expression of miR-146 observed in the exosomes collected from FL was significantly reduced in patients with low ovarian response compared to donors ($p = 0.009$).

Limitations, reasons for caution: The main limitation of this study was the relatively small sample size. Further studies are needed to elucidate the molecular and cellular mechanisms underlying the relation between the inflammasomes and the oxidative stress observed in relation with infertility as well as their biological role in follicular function and activity.

Wider implications of the findings: To observe significant differences in the activation of inflammasome in patients with low ovarian response suggests that, in these patients, there is an inflammatory state that could diminish their antioxidant defenses. These findings could open up to new therapeutic strategies for the treatment of low ovarian reserve.

Trial registration number: This study received no external funding and there were no competing interests.

O-248 Do female age and body weight help to identify women who benefit from individualised gonadotropin dosing in IVF? A secondary analysis of the OPTIMIST study

H. Torrance[1], J.A. Leijdekkers[1], M.J.C. Eijkemans[2], S.C. Oudshoorn[1], T.C. Van Tilborg[1], C.A.M. Koks[3], C.B. Lambalk[4], J.P. De Bruin[5], K. Fleischer[6], M.H. Mochtar[7], W.K.H. [8]Isala Clinics, Obstetrics and Gynaecology, Zwolle, The Netherlands
[9]Erasmus Medical Centre, Obstetrics and Gynaecology, Rotterdam, The Netherlands
[10]Monash University, Obstetrics and Gynaecology, Clayton, Australia

Study question: Can patient factors, including female age or body weight, serve as markers to guide individualised gonadotropin dosing in IVF treatment?

Summary answer: In predicted hyper responders, there might be a role for female age and body weight in identifying women that benefit from a particular dosing regimen.

What is known already: The OPTIMIST study was a multi-centre prospective cohort study with embedded randomised clinical trials in 1515 women starting IVF treatment in the Netherlands between 2011 and 2014. This study revealed that for women starting IVF treatment, no substantial differences exist between individualised dosing based on the antral follicle count (AFC) (100-450 IU/day) and standard dosing (150 IU/day) in terms of cumulative live birth rates (LBR). On basis of physiological concepts, female age and body weight have been suggested as patient characteristics that might have a differential impact on the effectiveness of individualised gonadotropin dosing.

Study design, size, duration: This was a secondary data-analysis of the OPTIMIST randomised clinical trials, in which women were categorised in subgroups of predicted response according to their AFC, and then randomly allocated to either a standard dose or an AFC based individualised gonadotropin dose. The primary outcome of the OPTIMIST study was cumulative live birth, of which the ongoing status was achieved within 18 months of follow-up.

Participants/materials, setting, methods: Logistic regression modelling with interaction terms was used to investigate whether female age or body weight interact with the treatment effect of individualised dosing. The primary outcome was LBR after the first complete treatment cycle, and secondary outcomes were cumulative LBR, safety (defined as any form of OHSS and/or preventive interventions) and observed response categories. All analysis were performed separately for predicted poor (AFC < 8), low-normal (AFC 8-10) and hyper responders (AFC > 15).

Main results and the role of chance: In the predicted hyper response group (n = 521), a significant interaction was found between female age and the effect of individualised dosing on first cycle LBR (p-value for interaction = 0.002). In women under 32 years of age, individualised dosing seemed to negatively affect first cycle LBR compared to standard dosing, whereas in women above 32 years of age this effect was not present.

Also, in the predicted hyper response group, a significant interaction was observed between body weight and the effect of individualised dosing on safety (p-value for interaction = 0.003). For women with a low body weight (from 50 to 55 kg) lowering the dose did not affect OHSS risks, whereas in women with higher body weights individualised dosing seemed to reduce OHSS risks.

In the predicted poor (n = 234) and predicted low-normal response group (n = 277), no significant interactions were found between female age or body weight and the effect of individualised dosing on the predefined outcomes.

Limitations, reasons for caution: Due to the relatively small sample size of the predicted poor and low-normal response group, the power to detect small associations in these groups was limited. Lack of blinding in the original trial might have introduced performance bias, such as selective cycle cancellation, which could have influenced our findings.

Wider implications of the findings: These preliminary findings suggest that for women with a predicted hyper response, female age and body weight could be possible markers for dose selection in IVF treatment. However, as these secondary analyses were exploratory and therefore hypothesis generating, confirmation of the validity in a new study is necessary.

Trial registration number: The OPTIMIST study was registered at the ICMJE-recognized Dutch Trial Registry (www.trialregister.nl). Registration number: NTR2657.

O-249 The vaginal microbiome as predictor for in vitro fertilization with or without intracytoplasmic sperm injection outcome; a prospective study

R. Koedooder[1], M. Singer[2], D. Budding[2], S. Schoenmakers[1], P. Savelkoul[3], S. Morré[3], J. Laven[1]

[1]Erasmus University Medical Centre, Gynaecology & Obstetrics, Rotterdam, The Netherlands
[2]VU University Medical Centre, Medical Microbiology and Infection Control, Amsterdam, The Netherlands
[3]Maastricht University Medical Centre, Medical Microbiology, Maastricht, The Netherlands

Study question: Could we use the composition of the vaginal microbiome as predictor for IVF/IVF-ICSI outcome?

Summary answer: Microbiome profiling with IS-pro enables correct prediction of embryo implantation failure prior to an IVF/IVF-ICSI treatment with a high predictive accuracy.

What is known already: In the last decade, research has shown that besides the known predictive factors, as duration of subfertility, women's age, body mass index, also micro-organisms have a possible impact on assisted reproduction outcome. Micro-organisms together with their genetic information and the milieu in which they interact is called the microbiome. One common genus that habitats the vagina is the Lactobacillus. Studies have shown that the presence of Lactobacillus during the ART has a positive impact on the outcome. However, the potential role of using the microbiome as a predictor for outcome has not been investigated yet.

Study design, size, duration: In a prospective study, we included 301 women from 8 different IVF centres in the Netherlands. These women were included between June 2015 and March 2016. In total 192 of the 301 women underwent an embryo transfer (ET) and had a sample that could be analysed.

Participants/materials, setting, methods: Participants were women who were eligible for their first IVF/IVF-ICSI attempt. These women provided a vaginal swab prior to the IVF/IVF-ICSI treatment. Microbiome composition was analysed with IS-pro. IS-pro is an eubacterial technique based on the detection and categorisation of 16S-23S rRNA gene interspace regions with lengths that are specific for each microbial species. The predictive accuracy of the composition of the vaginal microbiome for IVF/IVF-ICSI outcome was validated for the fresh ET.

Main results and the role of chance: The vaginal microbiome of each participant was assigned to a community state type based on the dominant microbial species. A low percentage of Lactobacillus had a strong association with embryo implantation failure. With a combined prediction model based on a small number of microbial parameters, a subgroup of women (n = 34) who did not become pregnant could be identified with a low chance of pregnancy following ET (sensitivity 26%, specificity 97%). This failure to implant was correctly predicted in 32 out of 34 women based on the vaginal microbiome, resulting in a predictive accuracy of 94%.

Limitations, reasons for caution: We analysed the vaginal microbiome to determine the predictive accuracy of the microbiome for IVF/IVF-ICSI outcome after the fresh ET. Follow up is needed to investigate whether the predictive accuracy lasts for the consectutive frozen ETs that may be part of the IVF/IVF-ICSI treatment.

Wider implications of the findings: Knowledge of their microbiome profile may enable couples to make a more balanced decision on whether to continue with treatment or not. Hence, the unnecessary physical and emotional burden of an IVF/IVF-ICSI treatment can be avoided.

Trial registration number: Not applicable.

O-250 Endometrial injury in women with previous in vitro fertilization and intra-cytoplasmic sperm injection failure: A systematic review and meta-analysis

Z. Qiaoli, N. Liu, Y. Liu

Beijing Obstetrics and Gynecology Hospital-Capital Medical University, Department of Reproductive Medicine, Beijing, China

Study question: Dose endometrial injury (EI) in the cycle preceding ovarian stimulation improve the pregnancy outcome in women with previous in vitro fertilization/intra cytoplasmic sperm injection failure?

Summary answer: In the meta-analysis of published data, EI does not improve the pregnancy outcome in women with previous unsuccessful IVF/ICSI.

What is known already: The pregnancy outcome of endometrial injury in patients with IVF/ICSI failure is still controversial.

Study design, size, duration: A systematic review and meta-analysis were performed. Main search terms were those related to endometrial injury for the pregnancy outcome in women with previous IVF/ICSI failure. The final computerized database search was performed on 11 october 2017. No language restriction was placed on the published articles. Two authors independently performed the literature screening, scrutinized articles of potential interest, selected relevant studies and extracted data.

Participants/materials, setting, methods: A systematic review was performed in PUBMED, EMBASE, CENTRAL, WEB of SCIENCE, and CLINICALTRIALS. Overall, 11 randomized clinical trials with a total of 1013 subjects in the intervention group and 1019 subjects in the control fulfilled the inclusion criteria. The dichotomous data for live birth rate, clinical pregnancy rate and miscarriage rate were expressed as risk ratios with 95% confidence intervals and were combined in a meta-analysis using the random-effects model or fix-effects model.

Main results and the role of chance: Funnel plot reveals no evidence of publication bias. Meta-analysis demonstrated that: live birth: RR = 1.19, 95% CI 0.91 to1.55; P = 0.21; 10 RCTs, 1917 women; I^2 = 53%; moderate-quality evidence. Clinical pregnancy rate: RR = 1.25, 95% CI 0.98 to1.60; P = 0.07; 10 RCTs, 1972 women; I^2 = 59%; moderate-quality evidence. Sensitivity analysis excluding the studies at high risk of other bias and subgroup analysis showed similar estimates. Miscarriage: RR = 1.04, 95% CI 0.73 to 1.49; P = 0.83; 634 women; I^2 = 0%; moderate-quality evidence.

Limitations, reasons for caution: Although the trials we included are RCTs, there still 5 studies at high risk of other bias, 5 studies at unclear risk of allocation concealment, and 2 study at unclear risk of reporting bias. Sensitivity analysis excluding the 5 studies at high risk of bias revealed similar estimates.

Wider implications of the findings: The advantage of our systematic review is that we only included RCTs, while the most trials included in the meta-analysis before are non-randomized trials. More future RCTs trials on the association between EI and pregnancy outcome of women with previous IVF/ICSI failure are needed.

Trial registration number: not applicable.

O-251 The use of non-donor egg IVF with embryo selection by morphology is efficient for patients aged 40-43

F. Prados Mondéjar, G. Perez-Bermejo, V. Santos, I. Bruna

Hospital HM Montepríncipe, HM Fertility Center, Madrid, Spain

Study question: Can we counsel 40-43 years old female (AMA) patients to consider non-donor IVF without selection by PGT-A as their first option for infertility treatment?

Summary answer: AMA patients have a lower than optimum but not negligible 21% probability of delivery per IVF cycle with their own-oocytes and morphological embryo selection.

What is known already: IVF clinics frequently recommend AMA patients to avoid using their own eggs for the purpose of maximizing success rates. Reimbursed IVF programs often reject treatment to older patients in order to optimize the efficient use of their resources. The high incidence of diagnosed aneuploid embryos in older patients lead to the spread of strategies of routinely selecting embryos by preimplantation genetic testing for aneuploidies (PGT-A) in those patients. In conclusion, AMA patients are often derived to private clinics, submitted to costly PGT-A treatments or advised to accept egg donation as preferred option in the first place.

Study design, size, duration: We analyzed the cumulative (fresh and frozen) delivery rate per oocyte retrieval of non-donor egg, no PGT-A IVF cycles. The study group was composed of 424 oocyte retrievals carried out between 2007 and 2016 to women aged 40-43 and which produced 1729 cleaved embryos. Patients aged 30 to 39 years treated during the same period were studied as control groups: 30-34, Group A; 35-37, Group B; 38-39, Group C.

Participants/materials, setting, methods: Retrospective analysis of the delivery rate of non-donor egg IVF cycles in our clinic. Cycles with total fertilization failure were excluded. Embryos were selected either for fresh transfer or cryopreservation at day 2-3 based on classical morphological evaluation. For the calculation of embryo efficiency, the remaining frozen embryos were discounted. Data from egg donation in the Spanish Registry 2015 were used for comparison of the delivery rate.

Main results and the role of chance: Cumulative delivery rate per oocyte retrieval was 21,2% for patients aged 40-43 (90/424). In Group A the rate was 53,3% (519/973); in Group B: 44,5% (394/885); in Group C: 36,3% (181/498). This means that the study group reached 40%, 48% and 58% of the delivery rates of control groups A, B and C respectively.

The percentages of transferred embryos that resulted in a live baby born were: 26,6% (648/2439) in Group A; 22,1% (470/2125) in Group B; 16,1% (200/1245) in Group C and 10,1% (102/1013) in the study group.

The percentages of cleaved embryos obtained per cycle that resulted in a live baby born (embryo efficiency of the cycles) were: 13,6% (648/4774) in Group A; 11,9% (470/3966) in Group B; 9,0% (200/2217) in Group C and 6,3% (102/1616) in the study group.

All differences were statistically significant.

The 7 Spanish centers with better results in egg donation according to the Spanish Registry achieved a 45,7% (501/1096) delivery rate per fresh embryo transfer in recipients aged > = 40. In our study group, delivery rate per fresh embryo transfer was 18,1% (70/386) this means 40% of the maximum obtained with egg donation in same age recipients.

Limitations, reasons for caution: Retrospective observational study. Lacking a direct comparison of results between egg donation and own oocytes, the adequacy of the observed delivery rate in the study group was established by comparison with other age groups and also by benchmarking against the higher performance Spanish centers with egg donation IVF.

Wider implications of the findings: A 21,2% delivery rate makes advisable for patients aged 40-43 to use their own oocytes without PGT-A selection as first option for IVF treatment as this means 40% of the delivery rate in our good prognosis patients (aged 30-35) or after fresh-embryo transfer with egg-donation in top-quality centers.

Trial registration number: Not applicable.

O-252 Autologous stem cell ovarian transplant (ASCOT), allowed 5 pregnancies in poor responders (PR) women

N. Pellicer De Castellvi[1], S. Herráiz[2], M. Romeu[1], S. Mártinez[1], A. Buigues[2], I. Gómez-Seguí[3], J. Martínez[4], A. Pellicer[5]

[1]*Women´s Health Area, La Fe University Hospital, Valencia, Spain*
[2]*Fundación IVI, Reproductive Medicine Research Group, Valencia, Spain*
[3]*La Fe University Hospital, Hematology Department, Valencia, Spain*
[4]*La Fe University Hospital, Radiology Department, Valencia, Spain*
[5]*IVI Rome, Reproductive Medicine Research Group, Valencia, Spain*

Study question: Can bone marrow (BM)- autologous stem cell ovarian transplantation (ASCOT) improve the impaired ovarian reserve in poor responder (PR) patients?

Summary answer: ASCOT improved ovarian reserve biomarkers in 81.3% of aged PR patients. The number of MII-oocytes increased allowing five pregnancies although the low euploidy rate (16.1%).

What is known already: A number of gonadotropin stimulation protocols have been tested for the clinical management of PR women; nevertheless none

have been proved to be successful, due to the absence of stimulable antral follicles.

Competent oocytes can be retrieved, even in women with premature ovarian insufficiency (POI), after providing them with an appropriate growth-supporting ovarian niche following several approaches. BM transplants in patients with POI, due to chemotherapy or radiotherapy, recovers ovarian function as demonstrated by several spontaneous pregnancies. BM-derived stem cells (BMDSC) can reactivate to growth ovarian follicles through paracrine events occurring in the ovarian niche, as described for other organs.

Study design, size, duration: This is a prospective pilot study developed at La Fe University Hospital from 2014 – 2017 in which a total of 17 PR women, according to the ESHRE criteria, were involved. The patients were ≤ 40 [SH1] years old with 3–5 years of infertility and had[AP2] 24 previous IVF cycles as PR.

BMDSC were injected in one ovary by intra-arterial catheterization, therefore the contralateral ovary served as the control.

Participants/materials, setting, methods: G-CSF was subcutaneously administered to mobilize BMDSC into peripheral blood. Stem cells were isolated on the fifth day by aphaeresis. Cellular populations and growth factors related to follicular growth were also determined in aphaeresis.

Intra-arterial catheterization was performed into one utero-ovarian artery, delivering 50×10^6 non-selected CD133+ cells. After ASCOT, serum AMH and antral follicular count (AFC) were recorded for up to 5 months. COS started on the 2nd menstrual cycle day after AFC increase.

Main results and the role of chance: Ovarian reserve biomarkers enhanced in 81.3% patients. Several patients displayed the AFC increase in both the treated and control ovary. Presence of circulating FGF-2 and THSP-1 positively correlated with both AMH and AFC parameters.

ASCOT promoted an increase in total AFC, compared to baseline, from day 2 to 43 after ASCOT, specially on Day 15 ($p = 0.031$). Some patients also had an important AMH rise during the first 4 weeks.

In the previous 24 COS initiated by 15 PR, a total of 35 MII-oocytes and 24 embryos were obtained; 13 of them were considered as good quality embryos by morphological criteria and transferred but pregnancy was not achieved.

After ASCOT, 28 COS cycles were initiated but only 4 in optimal conditions. Ovum pick-up was performed in 85.7% initiated COS, embryos obtained in 67.8%, and cancellation rate reduced compared to previous attempts (14.2 vs. 29%. Fifty-one MII were retrieved and 35 embryos obtained after ICSI (fertilization rate 75.4%) but only 16.1% were euploid. Five pregnancies were achieved, 2 by ET (1miscarriage) and 3 were spontaneous (1ongoing).

When IVF outcomes were compared with previous cycles, the number of antral follicles ($p = 0.001$), punctured follicles ($p < 0.01$) and MII ($p < 0.01$) increased after ASCOT.

Limitations, reasons for caution: A pilot study, in which COS and ovum pick up was not performed in the most favorable conditions. There were confounding variables such as the fact that these women do have antral follicles, and a small increase might not be detected. The ideal population might be women with POI.

Wider implications of the findings: ASCOT in PR women may have few applications, but this study has shown a potential use in POI women. The finding of a correlation between certain growth factors and outcomes suggests potential development of less invasive procedures in the future.

SESSION 66: RIF AND RM: NEW DIAGNOSTIC APPROACHES

Wednesday 4 July 2018 Room 117 10:00–11:45

O-253 Relationship between uterine natural killer (uNK) cells percentage and chronic endometritis in women with recurrent miscarriage

Y. Zhao, X. Chen, Y. Liu, W.C. Cheung, C.C. Wang, T.C. Li

The Chinese University of Hong Kong, Department of Obstetrics and Gynaecology-Faculty of Medicine, Shatin, Hong Kong

Study question: Is there any significant correlation between uterine natural killer (uNK) cells count and chronic endometritis in women with recurrent miscarriage?

Summary answer: A significantly ($p < 0.01$) increased prevalence of chronic endometritis was observed in high uNK cells group, compared to normal and low uNK cells groups.

What is known already: Our previous work showed an altered number of uNK cells in peri-implantation endometrium of women with recurrent miscarriage. In addition, chronic endometritis was reported to be associated with reproductive failure. However, there has not been any study examining the relationship between uNK cells count and chronic endometritis in recurrent miscarriage.

Study design, size, duration: It was a retrospective study carried out in a university center. A total of 102 women with unexplained recurrent miscarriage were included in this study.

Participants/materials, setting, methods: Endometrial biopsies were obtained precisely 7 days after luteinization hormone surge in natural cycles. Endometrial sections were immunostained for CD56 for uNK cells and CD138 for plasma cells, respectively. UNK cell counting was performed by a standardized protocol (Lash *et al.*, 2016) and results were expressed as percentage of positive uNK cell/ total stromal cells. Chronic endometritis was diagnosed as the presence > 5.15 plasma cells/0.1mm^2 based on our recent work (Liu *et al.*, 2018).

Main results and the role of chance: Based on our published reference range for uNK cells percentage, 21 women were classified into high uNK group, while 62 women in normal uNK group and 19 women in low uNK group. The prevalence of chronic endometritis was 8/21(38.1%), 5/62(8.1%), 1/19(5.3%) in high, normal and low uNK cells percentage group, respectively. A significantly ($p < 0.01$) increased prevalence of chronic endometritis was observed in high uNK cells group, when compared with normal and low uNK cells groups.

Limitations, reasons for caution: The role of other immune cells in the peri-implantation endometrium has yet to be confirmed.

Wider implications of the findings: Observations on the relationship between uNK cells and chronic endometritis may improve the understanding of mechanisms in endometrial immune cells leading to endometrial dysfunction in recurrent miscarriage.

Trial registration number: N/A.

O-254 Anti-Müllerian Hormone does not predict chance of live birth in 565 women with recurrent pregnancy loss

S. Bliddal[1], U. Feldt-Rasmussen[1], A.M. Kolte[2], C.H. Nielsen[3], O.B. Christiansen[2], L. Hilsted[4], E.C. Larsen[2], H.S. Nielsen[2]

[1]*Copenhagen University Hospital Rigshospitalet, Department of Medical Endocrinology, Copenhagen, Denmark*
[2]*Copenhagen University Hospital Rigshospitalet, Recurrent Pregnancy Loss Unit, Copenhagen, Denmark*
[3]*Copenhagen University Hospital Rigshospitalet, Institute for Inflammation Research, Copenhagen, Denmark*
[4]*Copenhagen University Hospital Rigshospitalet, Department of Clinical Biochemistry, Copenhagen, Denmark*

Study question: Do low levels of anti-Müllerian hormone (AMH) predict live birth rate in women with unexplained recurrent pregnancy loss (RPL)?

Summary answer: In women with unexplained RPL, low AMH levels did not reduce the chance of live birth in the first pregnancy achieved after referral.

What is known already: Recurrent pregnancy loss affects 2% of all women and in most of these women no explanation can be identified. In women with RPL compared to infertile women, previous studies have shown a similar incidence of diminished ovarian reserve as assessed by FSH and estradiol levels. AMH is cycle day independent and is currently debated as not only a marker of egg reserve quantity, but also quality. With increasing age, AMH levels decreases, while the pregnancy loss rate increases. Little is known about AMH-levels in women with recurrent pregnancy loss.

Study design, size, duration: Cohort study of 565 women with RPL followed at the tertiary referral center, RPL Unit, Copenhagen University Hospital (Rigshospitalet), from 2011-2014.

Participants/materials, setting, methods: All women attending the RPL unit from 2011-2014. RPL≥3 consecutive losses. AMH drawn more than one year from referral to the RPL unit were excluded. AMH-levels were measured with ELISA Generation I (Beckman Coulter, Marseilles, France). According to our clinical cut-off, low AMH was defined as ≤5 pmol/L. Regression analyses were adjusted for age, previous number of losses, and smoking status.

Main results and the role of chance: A total of 565 women with RPL had attended the unit, of which 478 (84.6%) had a measurement of AMH-levels. Median AMH-levels were 17.5 (interquartile range (IQR), 9.0-30) and AMH levels were below 5 pmol/L in 55 (11.5%) women. In total 355 (74.3%) women had a first pregnancy after referral. These women did not differ from the women who did not conceive in terms of median AMH-level (19 pmol/L vs. 16 pmol/L, Mann-Whitney U $p = 0.44$) or proportion of women with low AMH (10.7% vs 13.8%, $p = 0.41$). In women with unexplained RPL, 301 had singleton intrauterine pregnancies with a last menstrual period of more than nine months before data extraction. In the 28 women with a low AMH level, live birth rate was 50% compared to 60.8% in women with an AMH level above 5 pmol/L ($p = 0.31$). Having a low AMH level was not a predictor for live birth in adjusted analyses (adjusted odds ratio (aOR) 0.7 95% confidence interval (CI);0.2-1.8, $p = 0.39$). Median AMH level was 20 pmol/L in women who gave live birth compared to 19 pmol/L in those who did not (Mann-Whitney U, $p = 0.89$). AMH levels did not predict live birth (aOR 1.0 95%CI:0.88-1.12, $p = 0.95$).

Limitations, reasons for caution: Although this study to our knowledge is the largest to date in women with RPL, there may be a lack of power in calculations of association between live birth rate and AMH levels.

Wider implications of the findings: AMH levels can serve as a clinical guidance to the chance of achieving pregnancy. However, women with unexplained recurrent pregnancy loss can be reassured that the chance of live birth in case of an achieved pregnancy is similar to that of women with normal AMH levels.

Trial registration number: Not applicable.

O-255 The oestro-androgen dehydroepiandrosterone sulphate (DHEAS) may be a critical intracrine regulator of implantation and early pregnancy in Eumenorrhic non-PCOS women undergoing

N. Chimote[1], B. Chimote[2]

[1]*Vaunshdhara Clinic & Assisted Conception Centre, Embryology & Reproductive Endocrinology, Nagpur, India*
[2]*Vaunshdhara Clinic and Assisted Conception Centre, Clinical Embryology-Reproductive Endocrinology, Nagpur, India*

Study question: To evaluate the significance of endogenous levels of circulating DHEAS during implantation in predicting implantation failure/early miscarriage in eumenorrhic non-PCOS women undergoing IVF.

Summary answer: Maintenance of a steady/balanced rise in serum DHEAS levels is an early indicator of successful implantation and predicts implantation-failure/early miscarriage in eumenorrhic women undergoing IVF.

What is known already: Decidualization of endometrial-stroma is necessary for successful implantation; which if improper, may lead to implantation-failure/early pregnancy loss. Elevated levels of DHEA are a causative factor for higher incidences of implantation-failure among PCOS women by inhibiting endometrial-stromal cell differentiation via prevention of glucose-flux through the pentose-phosphate-pathway. Contrarily, low DHEA women with diminished ovarian-reserve, when supplemented with DHEA show significant reduction in early miscarriage rates. Sulphonated-DHEA (DHEAS) is more stable than DHEA, a major oestro-androgen and most abundant circulating steroid precursor for estrogen production in humans. However, no study has yet evaluated significance of innate DHEAS during implantation in eumenorrhic non-PCOS women.

Study design, size, duration: Prospective pilot study of n = 85 non-PCOS eumenorrhic, normo-responder women undergoing conventional antagonist stimulation protocol IVF from March 2016 to March 2017. Poor-responder/premature ovarian failure and hyper-androgenic PCOS women (defined as per Rotterdam consensus) were excluded from the study. All cycles involved day5 fresh, elective single blastocyst transfer (eSBT). Luteal phase support was provided to all women. Serum DHEAS levels in baseline as well as day7 and day14 post-eSBT were measured by radio-immuno-assay using diagnostic kits.

Participants/materials, setting, methods: Serum estradiol, β-hCG and progesterone levels were also measured on day7/day14 post-eSBT. β-hCG measurement on d7 of eSBT was considered early indicator of pregnancy. Implantation rate and live birth rate were main outcome measures. Cycles were classified on the basis of live birth (LB, n = 33), biochemical pregnancy (BCP, n = 3), early miscarriage (EM, n = 2) and no implantation (NI, n = 47). Statistical analysis involved Student's-t test, One-Way ANOVA, ROC analysis, as applicable, using Graph-pad Prism VI software.

Main results and the role of chance: Overall rates of LB, BCP, EM and NI were found to be 38.82%, 3.53%, 2.35% and 55.29% respectively. DHEAS levels depicted a steady rise from baseline to d7 to d14 post-eSBT in women with LB (165 ± 11.01 vs. 390.3 ± 40.26 vs. 737.9 ± 59.47 respectively). Although a rising trend was also observed in women with EM, the rise from baseline to d7 post-eSBT was rather steep (68.5 ± 3.5 vs. 247.5 ± 7.5 vs. 255 ± 10). However, the rising pattern was disrupted in BCP cycles where the levels dropped from baseline to d7 and then increased on d14 post-eSBT (211.7 ± 31.67 vs. 120 ± 5.8 vs. 258.3 ± 10.14); and in NI cycles where a sharp rise on d7 was followed by a decrease in levels on d14 post-eSBT (201.1 ± 13.95 vs. 1321 ± 134 vs. 791.7 ± 103.4). A significant difference in the ratio of d7: baseline DHEAS levels was observed in LB vs. BCP vs. EM vs. NI cycles (2.59 vs. 0.61 vs. 3.61 vs. 9.65; $p = 0.0005$). Similarly, the ratio of d14:d7 DHEAS levels differed significantly in LB vs. BCP vs. EM vs. NI cycles (2.23 vs. 2.16 vs. 1.03 vs. 0.8; $p < 0.0001$). Thus, a twofold rise in DHEAS levels from baseline to d7 and d7 to d14 is critical for successful implantation leading to a live-birth.

Limitations, reasons for caution: This prospective pilot study significantly implicates endogenously circulating levels of DHEAS in the implantation process and as a differentiating factor for various categories of implantation. Although our study has a power of 80%, more systematic studies/RCTs are required to establish DHEAS as an efficient and robust predictor of implantation.

Wider implications of the findings: Although the role of various androgens during pregnancy have been studied, their significance in the implantation process have received less scrutiny. Previous contradictory results with DHEAS have been largely due to improper selection of patient populations. This study underlines the significance of optimum levels of endogenous DHEAS for successful implantation.

Trial registration number: Not Applicable.

O-256 Endometrial proteomic signature in recurrent implantation failure

M. Dogan[1], I. Demiral[2], E. Akgun[3], E. Ulgen[4], B. Gurel[3], B. Sahin[3], A. Nehir Aytan[2], B. Yuksel Ozgor[2], A.T. Baykal[3], U. Sezerman[4], E. Bastu[1], F. Buyru[1]

[1]*Acibadem University School of Medicine, Obstetrics and Gynecology, Istanbul, Turkey*
[2]*Istanbul University School of Medicine, Obstetrics and Gynecology, Istanbul, Turkey*
[3]*Acibadem University School of Medicine, Medical Biochemistry, Istanbul, Turkey*
[4]*Acibadem University School of Medicine, Biostatistics and Medical Informatics, Istanbul, Turkey*

Study question: How endometrial proteomic profile in patients with recurrent implantation failure (RIF) differ from fertile controls?

Summary answer: 6 pathways based on proteomics profile are found to be different in RIF patients compared to fertile patients.

What is known already: Endometrial changes are important for the development of adequate endometrial receptivity and subsequent embryo

implantation. Recently, mitochondria have been found to play a vital role in fertilization and implantation. It provides ATP to the oocyte for embryo development, it affects endometrial receptivity by altering the energy metabolism in the endometrium. Some studies about Coenzyme Q10 supplement in infertility and total parenteral nutrition in patients with RIF patients showing good results may be based on mitochondria's effect.

Study design, size, duration: For this prospective cohort study, RIF was defined as failure of pregnancy in ≥ 3 consecutive IVF cycles with ≥1 transfer(s) of good quality embryo in each cycle. Women with ≥1 live birth(s) and no other comorbidities were included in the fertile control group. 24 patients were included in each groups, all 48 patients were recruited during August 2014-2015.

Participants/materials, setting, methods: From 48 patients recruited in Istanbul University School of Medicine, endometrial samples were taken during mid-secretory phase, stored in -80°C following snap freezing with liquid nitrogen. Once all tissues were obtained, a LC-MSE-based analyzes of peptides by mass spectrometry were performed. Protein expression differences were calculated with Gene Ontology enrichment analysis and DAVID functional annotation bioinformatics microarray analysis.

Main results and the role of chance: From 274 proteins found in different expression in patients with RIF compared to fertile patients, 6 representative pathways were outlined: pathways in carbon metabolism (p value = 1.63E-06), pathways in citrate cycle (TCA cycle) (p value = 5,07E-05), spliceosome metabolism (p value = 2,28E-04), protein processing in endoplasmic reticulum (p values = 3,08E-05), biosynthesis of antibiotics pathway (p values = 6,649E-06) and ribosome pathway (p value = 2,47E-06).

Limitations, reasons for caution: Endometrial samples were not taken on the same exact menstrual day for all patients. We chose to be between day 19-21.

Wider implications of the findings: Our results revealed a disturbance in energy metabolism in endometria of patients with RIF. In conjunction with previous reports, the failure of pregnancy despite good embryos and endometrium may lie in a lack of appropriate energy that would have supported an implanting blastocyst and subsequent progression to a viable pregnancy.

Trial registration number: This research received funding from the Scientific Research Projects Coordination Unit of Istanbul University (grant no. 47795).

O-257 CRISPR/Cas9 genome editing to reveal the effect of implantation related genes on specific cell types which contribute to implantation process in human and mouse models

G.N. Sahin[1], S. Karahuseyinoglu[2], A.C. Taskın[3]

[1]koc university graduate of medicine, medicine, istanbul, Turkey
[2]Koç University School Of Medicine, Histology & Embryology, Istanbul, Turkey
[3]Koç University Research Center for Translational Medicine, Animal Research Facilities, Istanbul, Turkey

Study question: Can we manage to reveal the effects of silencing a single implantation related gene on different cell populations functionally related to implantation process?

Summary answer: Silencing of one gene in isolated cell populations can be achieved and the effect can be evaluated successfully in mouse and human 3D implantation models.

What is known already: Despite all developments in ART, implantation failure is considerably high due to unexplained molecular, genetic and morphological interactions affecting the crosstalk between endometrium and embryo. Complicated nature of this phenomenon still remains obscure as a result of experimental methods that never can be performed effectively to reveal the biological functions specific for each cell type which participates in implantation process. To interfere with cellular functions, CRISPR/Cas9 genome editing technology has been shown to be applicable in a wide spectrum of cells, including cells of the developing embryo. Same technology can be used to detect and manipulate molecular interactions of implantation.

Study design, size, duration: Being expressed by both blastocyst and endometrial cells, LIF was chosen to be silenced separately via transfection in mouse blastocyst, human cell-line derived trophoblastic spheroids and stromal and epithelial cells of human and mouse endometrium. Three-dimensional culture was maintained on extracellular matrix(ECM) based gel systems for 48 hours and implantation parameters related to adherence, invasion and function were evaluated quantitatively by student's t test in wild and mutant groups(n = 24/each group, a total of 192 samples).

Participants/materials, setting, methods: Human and mouse epithelial and stromal cells were isolated separately. The experimental groups (n = 24 samples/group; 2 blastocysts-spheroids/sample) for human and mouse cells separately were: i.mutant(gene-edited) epithelia+wild type(wt) stroma +wt blastocyst/spheroid, ii.wt epithelia+mutant stroma+ wt blastocyst/spheroid,iii. wt epithelia+wt stroma+mutant blastocyst/spheroid,iv. wt epithelia+wt stroma+wt blastocyst/spheroid. Three-dimensional culture was engaging epithelial cells onto and stromal cells into the ECM based gel-system. After 48 hours, implantation parameters (e-cadherin,MMP9, progesterone receptor,invasion depth) were evaluated by qRTPCR(triple-repeats), WB and IF-multiphoton microscopy.

Main results and the role of chance:

i. Both mouse and human control groups composed of wild type cells showed decrease in e-cadherin, increase in MMP9 and PR after 48 hours of culture, where results with mouse blastocysts were more significant ($p < 0.05$). Blastocysts showed a better penetration. Survival and implantation parameters were in acceptable ranges in both control groups, implicating that 3D culture was efficient enough for this experimental model.

ii. LIF was successfully knocked out in all mutant cells as shown by its absence by qRTPCR ($p < 0.01$). In blastocysts trophoblastic cells were silenced more effectively than ICM, as expected due to transfection.

iii. When mutant groups were compared, implantation parameters were significantly affected most in groups with blastocysts/spheroids ($p < 0.05$) in both human and mouse; so LIF can be accepted as primarily working through the embryonic site rather than the endometrial site.

iv. Separate silencing of LIF in epithelial and stromal cells of mouse resulted in differences regarding implantation parameters, as a deeper decrease of expression in MMP9 and PR was observed with silenced epithelial cells. Although significance was less ($p > 0.05$), still it shows the behavioral differences between two cell types. In human however, silencing of stromal cells had a more dramatic effect ($p > 0.05$) on implantation parameters.

Limitations, reasons for caution:

(i) Use of in vitro 3D culture, since a culture totally mimicking in vivo conditions wasn't maintained.
(ii) Use of human spheroids instead of human blastocysts, since spheroids are of trophoblastic cells only, ICM effect was not tested in human groups, while it was taken into account for mouse model.

Wider implications of the findings:

(i) CRISPR/Cas9 genome editing technology can be utilized for all known implantation related genes to reveal the cell specific effects of these genes during implantation process.
(ii) ECM gel based three-dimensional endometrial co-cultures created for human and mouse implantation models are successful enough to run implantation experiments.

Trial registration number: not.

O-258 T helper 1 cell level is associated with reproductive outcome of women with repeated implantation failures who received Tacrolimus treatment

K. Nakagawa[1], J. Kwak-KIm[2], A. Moriyama[1], K. Nakao[1], R. Sugiyama[1], T. Horikawa[1], S. Takamizawa[1], K. Kuroda[1], R. Sugiyama[1], K. Yamaguchi[3]

[1]Sugiyama Clinic Shinjuku, Center for Reproductive Medicine, Tokyo, Japan
[2]Chicago Medical School at Rosalind Franklin University of Medicine and Science, Reproductive Medicine- Department of Obstetrics and Gynecology, Chicago, U.S.A.
[3]National Center for Child Health and Development, Department of Maternal-Fetal Biology, Tokyo, Japan

Study question: Is the peripheral blood T helper (Th) 1 cytokine producing cell level associated with the ongoing pregnancy rate in the repeated implantation failure (RIF) patients treated with tacrolimus?

Summary answer: Women with RIF and increased Th1 cell levels had lower ongoing pregnancy rate even though they were treated with low dose tacrolimus.

What is known already: The peripheral blood Th1 and Th2 cells determine immune inflammatory responses at the maternal fetal interface. Previously, we reported that women with RIF had elevated Th1/Th2 cell ratio. When they were treated with tacrolimus, immunosuppressive agent, pregnancy rate was significantly improved (*Am J Reprod Immunol 2015*).

Study design, size, duration: This is a prospective cohort study of 140 RIF women with elevated Th1/Th2 ($CD4^+IFN\text{-}\gamma^+$/ $CD4^+IL\text{-}4^+$) cell ratios (≥10.3) from November 2011 to July 2017. All received tacrolimus 1-3 mg per day based in Th1/Th2 cell ratios. Study populations were grouped according to the Th1 cell levels; Th1 cell levels <22.8 (Low group), Th1 cell levels 22.8≤Th1<28.8 (Mid group), and Th1 cell levels 28.8≤Th1 (High group).

Participants/materials, setting, methods: All patients received tacrolimus, starting 2 days before the ET to the day of pregnancy test. The daily dose of tacrolimus was depended on the Th1/Th2 ratio as follows; patients with a mild (≥10.3 and <13.0), moderate (>13.0 and <15.8), and high levels of Th1/Th2 ratio (>15.8) were treated with 1, 2, and 3 mg of tacrolimus, respectively. The clinical and ongoing pregnancy rates and miscarriage rates were compared among three groups.

Main results and the role of chance: Out of 140 patients, 65 women got pregnant (pregnancy rate, 46.4%). In the pregnant group, 59 women eventually had a clinical pregnancy, which was documented by the detection of gestational sac using ultrasound (clinical pregnancy rate, 42.1%). Forty-two patients delivered healthy babies and 8 are ongoing pregnancy (Ongoing pregnancy/delivery rate, 35.1%).

The Th1/Th2 cell ratio for the high Th1 group was 18.1 ± 9.0, and this was significantly higher than that in the Low Th1 group (14.5 ± 4.4; $p < 0.05$). The pregnancy rates for the Low, Mid and High Th1 groups were 55.3, 46.8, and 37.0 %, respectively, and there were no significant differences among the three groups. The clinical pregnancy rates for the Low, Mid and High Th1 groups were 48.9%, 44.7%, and 32.6% respectively. The clinical pregnancy rate of the High Th1 group was lower than those of the Low and Mid Th1 groups, however the difference was not significant. The ongoing pregnancy rate (≥12 weeks gestation) of the Low Th1 group was 46.8%, which was significantly higher than that of the High Th1 group (23.9%, $p < 0.05$) but not different from that of the Mid Th1 group (36.2%).

Limitations, reasons for caution: The endometrial changes or peripheral immune responses after tacrolimus treatment were not evaluated thoroughly. Further study is needed for tacrolimus effect on both systematic immune responses and local changes on the uterine endometrium.

Wider implications of the findings: Adjustment of tacrolimus dosing based on Th1 cell level may improve clinical efficacy of the treatment. The study is ongoing, which increases the tacrolimus dose (additional 1 mg) for the patients who have high Th1 cell level.

Trial registration number: N/A.

O-259 Couples' perspectives on their need for treatment, support and follow-up after recurrent pregnancy loss

L. Schmidt[1], E. Koert[2], G.M.H. Malling[1], R. Sylvest[3], M.C. Krog[2], A.M. Kolte[2], H.S. Nielsen[2]

[1]*University of Copenhagen, Department of Public Health- Section of Social Medicine, Copenhagen K, Denmark*

[2]*Copenhagen University Hospital- Rigshospitalet, Recurrent Pregnancy Loss Unit-Fertility Clinic, Copenhagen, Denmark*

[3]*Copenhagen University Hospital- Hvidovre, Dept. of Obstetrics and Gynaecology, Hvidovre, Denmark*

Study question: What do couples attending a recurrent pregnancy loss (RPL) clinic believe they need in terms of treatment, support and follow-up after RPL?

Summary answer: Men and women wish for treatment, support and follow-up that includes attention to the psychological impact of RPL and includes both members of the couple.

What is known already: Previous research has highlighted women's dissatisfaction with medical care provided post-pregnancy loss (PL) and their desire for medical professionals to have increased awareness about PL and recognition of the psychological impact of PL. Less is known about the needs of the male partner, the needs of those experiencing RPL (three or more PL) and if needs change depending on whether it is the first or one of several losses.

Study design, size, duration: This was a qualitative study. Over a two-month period in 2017-2018, 13 couples who were referred to the RPL program in Rigshospitalet, Copenhagen, Denmark were interviewed. Interviews were held at the Rigshospitalet and ranged between 81 and 109 minutes (average 91 minutes).

Participants/materials, setting, methods: Inclusion criteria included: heterosexual couples with at least three consecutive PL under 12 weeks gestation with no children/one child who were willing to be interviewed in English. Couples were interviewed together in a semi-structured format. Data was analyzed using thematic analysis.

Thirty invitations were sent to couples who met the inclusion criteria and indicated an interest in participating and 15 couples contacted the interviewer to schedule an interview. Due to cancellations, 13 interviews were held.

Main results and the role of chance: On average participants had experienced three PL (range 3-6) and had been on the waiting list for the RPL program for six months (range 3-9).

Both men and women described the cumulative effect of RPL with a decrease in hope and increase in pressure and exhaustion in the third and subsequent losses. With each PL their dream of having a child felt further from their reach and they felt a growing sense of dread they would not become parents or not have the family they pictured. Referral to the RPL clinic often resulted in an increase in hope. Inclusion of the male partner in consultations and treatment was seen as important. Couples emphasized medical professionals should recognize that "every loss counts" when recommending and providing treatment and comments such as "It's nature's way" are unhelpful, given it invalidates their sense of loss.

Data showed that couples desired reliable and accurate information about RPL (e.g., common physical/ emotional responses, treatment options). They desired recognition from the medical community that RPL is not only a physical experience, but has a significant psychological impact as well, and stressed that effective treatment should include attention to both physical and psychological aspects of the RPL.

Limitations, reasons for caution: Data was collected until saturation to enhance the trustworthiness of the findings. Participants were self-selected thus findings cannot be generalized to all couples who have experienced RPL. Single women and same-sex partners were not included in the study.

Wider implications of the findings: The findings suggest that medical professionals need to take a holistic approach in their treatment of RPL and include attention to the psychological impact and cumulative effect of the PL on both men and women. The results underscore the need for informational resources psychological support for couples experiencing RPL.

Trial registration number: Not applicable

SESSION 67: CURRENT PERSPECTIVES ON PREIMPLANTATION GENETIC TESTING AND EMBRYO SELECTION

Wednesday 4 July 2018 Room 116 10:00–11:45

O-260 Improved embryo selection: a novel approach for simultaneous genomic and transcriptomic analysis from a single trophectoderm (TE) biopsy

N. Fuchs Weizman[1], B. Wyse[2], R. Antes[2], Z. Ibarrientos[2], M. Sangaralingam[2], V. Kuznyetsov[2], S. Madjunkova[2], C. Librach[2,3,4,5]

[3]*Women's College Hospital, Department of Gynecology, Toronto, Canada*
[4]*University of Toronto, Department of Physiology, Toronto, Canada*
[5]*University of Toronto, Department of Obstetrics and Gynecology, Toronto, Canada*

Study question: Can RNA and DNA be sequenced simultaneously from the same trophectoderm biopsy, and be an addition to the clinical preimplantation genetic screening (PGS)?

Summary answer: The addition of full RNA sequencing to standard PGS did not alter the quality of the genomic data produced and yielded high-quality RNA sequencing data.

What is known already: With elective single embryo transfer (eSET) becoming the leading strategy to avoid multiple gestations, improved embryo selection is key. PGS reduces time to pregnancy and helps avoid miscarriages, but it cannot predict the implantation potential of a euploid embryo. Previous studies attempting to identify genes which are crucial for implantation and fetal development did not control for ploidy, due to the lack of methods to evaluate both together. To accurately interrogate the transcriptome, the ability to simultaneously sequence DNA and RNA from the same trophectoderm (TE) biopsy, without impacting the clinical PGS efficiency, would be a significant advance.

Study design, size, duration: After institutional REB approval, 24 embryos were collected from consented patients undergoing IVF-ICSI treatment at the CReATe Fertility Centre. The first 3 embryos were used for the initial development and optimization of sample processing and sequencing. Thereafter, 21 embryos (3 trisomy-16, 5 monosomy-16, 3 Turner (X0), and 10 euploid, harboring a genetic mutation per PGD) were used to demonstrate the clinical safety and reproducibility.

Participants/materials, setting, methods: Two TE biopsies were taken from each embryo. The first was processed as a clinical sample destined for PGS only. The second TE biopsy was lysed and split into two fractions: 1) for genomic analysis with next generation sequencing (NGS) and 2) for transcriptomic analysis. gDNA was amplified (SurePlex), libraries constructed (VeriSeq), sequenced on a MiSeq, and analyzed using BlueFuse Multi. RNA was sequenced on a NextSeq and analyzed using a custom-built pipeline.

Main results and the role of chance: The DNA fraction from both TE biopsies from each embryo was sequenced using a validated clinical NGS workflow and determined 'clinically acceptable" when the quality control (QC) metrics met/exceeded the Illumina guidelines (reads post-filtering>250,000 and Noise (DLR) < 0.4). There was no statistical difference in NGS QC between control and split samples. All split samples met or exceeded this criteria with average post-filtered reads of 559,769 ± 31,121 and DLR of 0.20 ± 0.005. The concordance between PGS results obtained from split and control samples was 100%, underlining the reliability and safety of our method. High-quality cDNA and libraries were obtained from all split samples. This yielded sufficient sequencing data that, after filtering, met/exceeded QC metrics (average reads 21,563,094 ± 1,636,245; average depth 26.7 ± 3.5; average quality 33.5 ± 0.03) to perform principal component analysis (PCA) and differential expression (DE). All TE biopsies expressed several specific TE markers including CDX2, GATA2, and TGFBR3, further validating the accuracy of our method. Using PCA, the samples clearly clustered in euploid and aneuploid aggregates, highlighting the importance of controlling for ploidy. Euploid embryos showed downregulation of genes involved in anaerobic metabolism, oxidative phosphorylation, and fatty-acid oxidation.

Limitations, reasons for caution: This pilot study assessed the feasibility and safety of adding transcriptomic analysis to the clinical workflow of PGS. As such, clinical outcomes were not collected, impeding our ability to validate the implications of our findings. Future clinical trials will be required to correlate transcriptomic data with outcomes.

Wider implications of the findings: This is the first study to provide full genomic and transcriptomic profiles of a single TE biopsy from human embryos. The addition of RNAseq did not affect the quality of gDNA or actual results of PGS. This method has the potential of improving embryo selection in IVF.

Trial registration number: not applicable.

O-261 Pre-implantation genetic screening (PGS) of in vivo conceived and developed blastocysts recovered by lavage: Preliminary experience

S. Munne[1,2], S. Najmabadi[3,4], S. Nakajima[5], M.V. Sauer[6], T. Escudero[1], J.E. Buster[7]

[7]*Warren Alpert Medical School- Brown University, Department of Obstetrics and Gynecology, Providence, U.S.A.*

Study question: Can in vivo conceived embryos be reliably recovered by uterine lavage for diagnostic characterization?

Summary answer: Uterine lavage performed after insemination successfully recovered blastocysts. Using Next Generation Sequencing (NGS) we performed the first chromosomal characterization, where 27.5% were euploid.

What is known already: Early work performed by Buster and colleagues in 1983 recovered embryos from the uterus by lavage in natural cycles. At that time, genetic testing of embryos was not possible, although approximately 50% of normal appearing blastocysts conceived. Chromosome abnormalities are commonly found in embryos after in vitro fertilization (IVF). In contrast, data on in vivo conceived embryos does not exist. In vivo developed embryos in animal models, possess different characteristics (i.e. rate of chromosomal abnormalities, higher rates of blastocyst formation, different characteristics in development after birth, reduced genetic aberrations) compared toin vitro developed embryos of similar species.

Study design, size, duration: We performed a single site, prospective, feasibility study in 54 women to evaluate the safety and efficacy of a new uterine lavage system (Previvo Genetics, Inc., San Carlos, CA). Patients gave their written informed consent for the research protocol approved by Western Institutional Review Board. All lavages were performed in Punta Mita, Mexico during August 2017 to January 2018 by a single investigator. Subjects were followed for 30-days post-lavage to monitor for complications.

Participants/materials, setting, methods: 54 women were pretreated with oral contraceptives and stimulated with gonadotropins for 69 cycles. Ovulation was triggered with either 5,000 IU of human chorionic gonadotropin (hCG) or Lupron 4 mg and 2,500 IU of hCG, followed by insemination of donor sperm 36 hours after trigger. Uterine lavage occurred 4-6 days after the insemination. Recovered embryos underwent trophectoderm biopsy, vitrified and stored in liquid nitrogen. Biopsies were analyzed using the NGS technique.

Main results and the role of chance: This was the first study to reliably demonstrate the feasibility of recovering in vivo derived human blastocysts following ovarian stimulation. Recovered blastocysts were then successfully characterized using comprehensive chromosomal analysis.

A total of 69 uterine lavages were performed in 54 women undergoing superovulation followed by intrauterine insemination (IUI). After IUI, uterine lavage recovered embryos in 25 (36.2%) cycles. A total of 48 embryos were recovered: 18 (37%) multi-cell embryos, 7 (15%) morulas and 23 blastocysts (48%). Six (12%) morulas progressed to blastocysts, for a total of 29 blastocysts (60%). All embryos regardless of stage were biopsied, vitrified and cryopreserved. Of the 29 tested blastocysts, 27.5% were euploid (8/29), 27.5% were

complex abnormal (8/29), 21% were aneuploidy (6/29), 17% were mosaic (5/29) and 2 had no result (7%).

The data is observational and the number of participants small making it difficult to assess the impact of 'chance" on the database. However, our stated objective was to evaluate the feasibility of using uterine lavage for recovering blastocysts for analysis and it appears that this goal was met.

Limitations, reasons for caution: The sample size is small, and the lavage tool and system are not fully optimized. The ovarian stimulation protocol prescribed may influence the chromosomal profiles observed in the recovered blastocysts. Future experiments are needed to ascertain a potential role in the observed aneuploidy induced by medications.

Wider implications of the findings: This study implies uterine lavage is a feasible method to recover embryos in selected patients who desire to bank embryos or planning for genetic testing (PGS or PGD). Uterine lavage offers a nonsurgical minimally invasive approach to recovering embryos that is different from IVF.

Trial registration number: The trial has been registered at www.clinicaltrials.gov and is pending receipt of a trial registration number.

O-262 Comprehensive mitochondrial DNA (mtDNA) analysis and IVF outcome

B. Lledo[1], J.A. Ortiz[1], R. Morales[1], J. Guerrero[2], A. Bernabeu[3], L. Joaquin[3], R. Bernabeu[3]

[1]*Instituto Bernabeu, Molecular Biology, Alicante, Spain*
[2]*Instituto Bernabeu, Reproductive Biology, Alicante, Spain*
[3]*Instituto Bernabeu, Reproductive Medicine, Alicante, Spain*

Study question: Do the mtDNA copy number, heteroplasmy and haplotypes affect the ongoing pregnancy?

Summary answer: Our study suggests that elevated mtDNA copy number above a threshold is associated with lower ongoing pregnancy rate, a mutational load could be an explanation.

What is known already: Mitochondria plays a vital role in cell function and mtDNA is associated with a number of traits such infertility. Recently, there has been an increasing focus on research in its potential as biomarker of embryo implantation. It has been speculated that both mtDNA-heteroplasmy and copy number contribute to the mitochondrial function but the effects of both factors in embryo implantation were discussed separately. NGS allows us to study in depth mtDNA-hetroplasmy and copy-number simultaneously. Moreover, mitochondrial genomes can be clustered into groups known as haplotypes/haplogroups. mtDNA-haplotypes are responsible for complex diseases and at the cellular level could influence expression patterns.

Study design, size, duration: A prospective non-selection study was performed. We included 159 blastocysts biopsies from 142 couples who attended to our clinic for PGT-A from January 2016 to December 2017. All embryos were biopsied on day 5 or day 6. The aneuploidy testing was performed by NGS using Veriseq® kit and the BlueFuse Multi software (Illumina). All blastocysts were diagnosed as euploid non-mosaic and were transferred. The mtDNA analysis were performed once the diagnosis was known.

Participants/materials, setting, methods: Sequencing reads mapping to the mtDNA genome were extracted from indexed bam files to identify copy number, heteroplasmy and haplotypes. The relative measure of mtDNA copy number was calculated by dividing the mtDNA reads by the nuclearDNA value to normalize for technical variants and the number of cells collected at the biopsy. All the results were subjected to mathematical correction factor according to the embryo genome. Haplogroups were assigned by HaploGrep and heteroplasmy by MitoSeek.

Main results and the role of chance: The average of mtDNA was 0.0016 + 0.0012 with an average depth of 205×. To detect heteroplasmic sites we consider a sequencing coverage >40 and a minor allele count (MAF)> = 2. According to this criterion 40 embryos were heteroplasmy carriers (26.32%). The mtDNA haplogroup of embryos was determined in 94 biopsies, we identified 8 different haplogroups and 87% belonged to the H2a2a. With respect to IVF-outcome for mtDNA copy number analysis, due to the fact that mitochondrial dysfunction is only revealed when overall mictochondrial function drops below a threshold, we set 0.003 for the following analysis. The vast majority of the embryos (142/159) are below the threshold and 17 embryos were classified as high mtDNA. We showed a reduction in ongoing pregnancy rate associated with elevated mtDNA (42.6% vs 17.6%;$p < 0.05$). This result was independent of maternal age, day of the biopsy and embryo morphology as these factors were included as confounding factors. No significance differences were reported for haplotype (43.9% vs 41.7%;$p = 0.884$) and heteroplasmy (40.5 vs 37.8;$p = 0.77$). However, a clear association between heteroplasmy and mtDNA copy number was reported (0.0013 vs 0.0025;$p < 0.001$). With the combination of all the factors a predictive performance of the embryo implantation score was calculated with 83% of specificity.

Limitations, reasons for caution: Limitation may be due to the size of the sample and the high-troughput sequencing technology that might not have detected heteroplasmy levels lower than 2% and requires high sequence depth. A clinical randomized trial will be necessary. More research in the mitochondrial function are needed.

Wider implications of the findings: Our results have demonstrated that elevated mtDNA embryos have a lower chance to produce an ongoing pregnancy. Moreover, our data suggest a link between mutation of the mtDNA and the increased mtDNA. Therefore, mitochondrial activity could be a balance between functional capacity and absolute mtDNA copy number within the cell.

Trial registration number: Conflicts of interest and source of funding none declared.

O-263 Improved concordance rates for aneuploidy detection in spent culture media compared to trophectoderm biopsies: a step forward towards non-invasive preimplantation genetic testing (niPGT-A)

C. Rubio LLuesa[1], L. Rienzi[2], L. Navarro-Sánchez[1], D. Cimadomo[2], C.M. García-Pascual[1], L. Albricci[2], L. Martínez-Merino[1], A. Capalbo[3], F. Ubaldi[2], C. Simón[4]

[1]*IGENOMIX, PGS Research, Paterna Valencia, Spain*
[2]*GENERA Centres for Reproductive Medicine, Reproductive Medicine, Rome, Italy*
[3]*IGENOMIX, Laboratory Director, Rome, Italy*
[4]*University of Valencia- INCLIVA- Igenomix, Obstetrics and Gynecology, Paterna Valencia, Spain*

Study question: Is the embryonic cell-free DNA in the spent culture media representative of the chromosomal constitution of the blastocysts?

Summary answer: Increased knowledge on the dynamics of embryonic cell-free DNA has improved aneuploidy detection in blastocysts by the analysis of spent culture media.

What is known already: Current techniques used for preimplantation genetic testing of aneuploidies (PGT-A) enable the analysis of the full chromosome content of a single cell with high sensitivity and specificity. Recent studies have reported the existence of embryonic cell-free DNA, opening a new era of possibilities for niPGT-A. However, the percentages of informative samples vary widely. These discrepancies, could reflect the existence of mosaicism and presence of DNA from granulosa cells or polar bodies in the spent culture media. Thus, efforts should focus on identifying embryonic cell-free DNA and rule out maternal DNA contamination to translate this non-invasive technology into clinical use.

Study design, size, duration: This is a pilot prospective study that includes analysis of 64 samples of spent culture media from embryos included in a PGT-A program. These samples correspond to 22 patients with ages ranging from 35-45 years (39.1 ± 2.5), with advanced maternal age, recurrent miscarriage, or repetitive implantation failure as PGT-A indications. Collection and analysis of samples were carried out from November 2017 to January 2018. Analysis of both types of samples from each embryo was performed blindly.

Participants/materials, setting, methods: In the PGT-A cycle, chromosome diagnosis from each blastocyst stage embryo was obtained from the trophectoderm biopsy and the spent culture media. Both, spent culture media and trophectoderm biopsies have been analysed by Next Generation Sequencing (NGS). NGS was performed using the Ion ReproSeq PGS Kit (ThermoFisher Scientific) using Ion Chef™ plus the Ion S5™ XL Sequencer™. For the analysis of the spent culture media, the standard protocol has been modified to improve amplification efficiency.

Main results and the role of chance: Informative results were obtained from all 64 trophectoderm biopsies and from 60 spent culture media (93.7% successful amplification in spent culture media). Concordance rate between trophectoderm biopsies and spent culture media in terms of blastocyst diagnosis as aneuploid or euploid was 75.0% (45/60). Concordance rate for autosomes was 80.0% (48/60). Considering the 15 discrepancies, 3 of them corresponded to euploid diagnosis in both types of samples, but with discordant gender (5% gender mismatch); 11 discrepancies were classified as false positives, with the spent culture media diagnosed as aneuploid and the trophectoderm biopsy as euploid (18.3% false positive rate); and only 2 discrepancies were false negatives, with spent culture media diagnosed as euploid and trophectoderm biopsy as aneuploid (3.3% false negative rate). In 4 of the false positive samples, the spent culture media was diagnosed as chaotic (40% of the false positives), with multiple chromosomes altered in a pattern reflecting low input of DNA or poor DNA quality. In the 2 false negative samples, the result in the trophectoderm biopsy was a single uniform monosomy in one case and, a single low-degree mosaic monosomy in the other one, raising the question of which sample better represents full blastocyst chromosome content.

Limitations, reasons for caution: This is a study with limited number of samples. There is a need to fully discard maternal DNA traces in spent culture media, to understand the impact of mosaicism in the accuracy of the diagnosis in PGT-A and niPGT-A and, to unravel why some embryos release more DNA than others.

Wider implications of the findings: In this study, the improvements in methodology and concordance rates prompt us to foresee the possibility of including niPGT-A in the clinical practice. The niPGT-A approach would help patient's access to aneuploidy testing by avoiding the need of invasive biopsy techniques and by reducing the cost of the procedure.

Trial registration number: Not applicable.

O-264 Concordance rates among multiple trophectoderm samples and ICM remain high proving the efficacy of NGS for preimplantation genetic screening

R. Anderson[1], J.B. Whitney[2], C.M. Rios[3], A.E. Jones[4], A. Harutunian[3], M.C. Schiewe[2]

[1]The Southern California Center for Reproductive Medicine, ART Clinic, Newport Beach, U.S.A.
[2]Ovation Fertility, ART Lab, Newport Beach CA, U.S.A.
[3]Ovation Fertility, Genetics, Las Vegas NV, U.S.A.
[4]Ovation Fertility, Genetics, Nashville TN, U.S.A.

Study question: Are human blastocysts homogeneous for chromosomal copy number between multiple samples of the trophectoderm and does trophectoderm ploidy accurately predict ICM ploidy?

Summary answer: Upon re-biopsy, trophectoderm homogeneity for full gain or loss was 97%, while ICM concordance was 100%. Human blastocyst ploidy proved consistent between cell samples.

What is known already: Blastocyst biopsy and preimplantation genetic screening (PGS) allows for ploidy status determination before implantation without adversely impacting embryo competence or baby health and well-being. The efficacy and invasive nature of the trophectoderm biopsy, as well as resultant NGS reports of mosaicism, have been scrutinized. The importance of mosaic profiles on PGS outcomes is not well defined and the effect to the offspring not fully understood. Importantly, the uniformity of aneuploidy within the trophectoderm and ICM remains unclear. It has been shown that increased mosaicism decreases implantation, while low-level mosaics can result in viable pregnancies, questioning the ICM concordance with trophectoderm.

Study design, size, duration: Nine research consented embryos were thawed and a minimum of 3 additional trophectoderm samples were taken. Samples were tubed according to standard NGS amplification protocols and sent blinded to two separate reference labs, including the original testing lab. Furthermore, both labs were unaware of the experimental plan or cell types being tested (i.e, double-blinded design). The geneticists performed NGS and profile examination to produce standard euploid/aneuploid results in accordance with their own established lab guidelines.

Participants/materials, setting, methods: Research consented embryos possessing single/dual chromosomal aneuploidies were selected and blindly sampled. MicroSecure vitrified blastocysts were warmed (100% intact) and cultured in LifeGlobal medium (37°C, tri-gas humidified conditions) for a minimum of 4 hours. Each blastocyst was biopsied 3-5 times according to standard protocols. A final biopsy per embryo attempted to isolate only ICM cells as a separate sample. A total of 28 re-biopsies were performed for a total of 37 samples.

Main results and the role of chance: A full gain or loss was determined if the NGS profile reached >95% gain/loss for each chromosome. This cut-off is contrary to standard calls of ~30%. Of the original samples,7 of the 9 had a single full gain or loss, 1 embryo had a full loss and a mosaic loss of >50%, and another sample had only a mosaic gain of 65%. A total of 36 samples, or 97% were concordant for the same chromosomes called. A total of 7 ICM samples achieved 100% concordance with the original trophectoderm sample result. The one sample not producing concordance was the original 65% mosaic embryo with all re-biopsies resulting in euploidy. Unfortunately, this embryo did not have an ICM tubed to determine relevant mosaicism. Additional low-level mosaics occurred on 3 samples (8%). It is incredibly encouraging that so many of the profiles exhibited mirror images proving the efficacy of NGS repeatability. Our laboratory has previously reported the importance of biopsy technique, so every attempt was made to sample healthy cellular masses free of degeneration. Of note, all mosaic profiles had a documented fair to poor cellular mass result from the biopsy, reinforcing the need for proper technique.

Limitations, reasons for caution: Trophectoderm biopsy with NGS is heavily reliant on proper technique and geneticist interpretations. Genetic calling policies and definitions of euploidy/aneuploidy and mosaic embryos can differ from lab to lab, adding to the growing uncertainty of PGS. Understanding result interpretation is imperative to improving patient education on the risks of mosaicism.

Wider implications of the findings: This study supports that full gain/losses are extremely reproducible among all cells/types of the human blastocyst. Mosaic profiles are potentially detrimental or possibly just artifact. Further research is needed help alleviate the ambiguity of mosaic profile risks, but this study has proven NGS efficacy when full aneuploidy is present.

Trial registration number: None.

O-265 What is the genetic significance of blastomeres excluded from the formation of a morphologically normal blastocyst?

C. Pirkevi Cetinkaya, M.A. Tufekci, Y. Kumtepe Colakoglu, M. Cetinkaya, S. Kahraman

Istanbul Memorial Hospital, Assisted Reproductive Technologies and Reproductive Genetics Center, Istanbul, Turkey

Study question: Is there a correlation between the ploidy of the blastocyst and that of the blastomeres excluded from the formation of the blastocyst?

Summary answer: Morphologically normal blastocysts with excluded blastomeres were diagnosed with aneuploidy affecting maximum three chromosomes whereas excluded blastomeres were chromosomally chaotic.

What is known already: Blastomeres that have arisen throughout cleavage-stage are sometimes excluded from the formation of the blastocyst and are sequestered either between the zona pellucida and the perivitelline space or remain internally during blastocyst formation and are sequestered to the blastocoel cavity. In both ways, once isolated, those cells do not take part in preimplantation development. It has been demonstrated that excluded cells have poor gap junction communication with the embryo *(Hardy et al., 1996)*. It was hypothesized that cell surface markers promoting ingestion by neighboring cells were absent from those isolated cells since phagocytosis is possible in the blastocyst-stage *(Hardy, 1997)*.

Study design, size, duration: This observational study was based on 25 good or top-quality blastocysts (at least 4BB) with blastomeres excluded from the formation of the blastocyst and sequestered between the zona pellucida and the perivitelline space. They were belonging to 20 patients applying for pre-implantation genetic screening (PGS) due to advanced maternal age (>37). Patients with structural abnormalities or a history of abnormal fetal karyotype were not included in the analysis.

Participants/materials, setting, methods: The 25 trophectoderm biopsies were prospectively analyzed and the corresponding excluded blastomeres (2-5/ blastocyst) samples were in parallel diagnosed either by next generation sequencing (NGS) (PGM platform, ThermoFisher) or by array Comparative Genomic Hybridization (aCGH, Illumina). Assisted hatching was done on day-3 and blastocysts having excluded blastomeres in the axis of the zona opening were included in the analysis to decrease manipulation and most importantly, not to harm the blastocyst.

Main results and the role of chance: The PGS analysis of the trophectoderm biopsies revealed 11 monosomies, 11 trisomies, 3 mosaicisms and 4 euploidies, showing that only 16% of the blastocysts with excluded blastomeres were euploid. In 11 blastocysts one chromosome was involved in the aneuploidy whereas for 8 blastocysts two chromosomes were implicated. Only two blastocysts were aneuploid for three chromosomes. None but one of the excluded blastomeres had the same diagnosis with the corresponding embryo (trisomy 4). However, in half of the embryos (12/25) one chromosomal aneuploidy was shared by both samples; the excluded blastomeres having a more complex diagnosis with a mean of four chromosomes involved in the aneuploidy [for example, a diagnosis of monosomy 7, 14 for the blastocyst and a diagnosis of trisomy 1q, monosomy (3, 4, 7, 14, 16, 19) for the corresponding excluded blastomeres]. Only one sample of excluded blastomeres was euploid although the corresponding blastocyst was aneuploid (monosomy 1). It may be hypothesized that either the embryo attempts to exclude blastomeres with chaotic aneuploidies from the blastocyst or that the excluded blastomeres have become chromosomally chaotic because of apoptotic cell death mechanisms that have been already initiated in the aneuploid embryo.

Limitations, reasons for caution: Results were obtained in a small group of blastocysts and in a defined IVF setting. Increasing the number of the study cohort will undeniably give more reliable results.

Wider implications of the findings: In the light of the strong association showed by Munné and colleagues (2017) between center-specific ART treatment practices and the incidence of chromosome abnormality in human embryos, it would be interesting to check the validity of the results in an independent IVF clinic.

Trial registration number: Not applicable.

O-266 Human in vitro post-implantation culture models reveal the depletion of aneuploid cells in chromosomally mosaic embryos 12 days post fertilisation

M. Popovic[1], A. Dheedene[2], L. Dhaenens[1], J. Taelman[1], P. De Sutter[1], S.M. Chuva De Sousa Lopes[1,3], B. Menten[2], B. Heindryckx[1]

[1]Ghent University Hospital, Ghent-Fertility and Stem cell Team G-FaST- Department for Reproductive Medicine, Ghent, Belgium
[2]Ghent University Hospital, Center for Medical Genetics, Ghent, Belgium
[3]Leiden University Medical Center, Department of Anatomy and Embryology, Leiden, The Netherlands

Study question: To what extent does genomic instability at the blastocyst stage affect early post-implantation development *in vitro*, 12 days post fertilisation (dpf)?

Summary answer: While aneuploid blastocysts showed reduced developmental potential during extended culture, mosaic embryos generated euploid outgrowths 12 dpf, indicating no preferential lineage allocation of abnormal cells.

What is known already: Embryo aneuploidy is associated with implantation failure and early pregnancy loss. Yet, a proportion of blastocysts are chromosomally mosaic, containing genomically distinct cell populations. Although mosaic embryos may lead to live births, the clinical implications of chromosomal mosaicism on early pregnancy, including foetal and placental development, remain unknown. The complex nature of genomic instability coupled with the inaccessibility of research material has inherently limited our understanding. Newly established embryo culture systems allow blastocyst attachment, outgrowth formation and extended culture for up to 14 days *in vitro*, providing a unique opportunity for investigating chromosomal instability during early human post-implantation development.

Study design, size, duration: A total of 30 chromosomally abnormal human blastocysts were included in the study. Embryos were donated following preimplantation genetic screening (PGS) and selected based on their original diagnosis. Twenty embryos presented with either one (n = 13) or multiple aberrations (n = 7), while 10 blastocysts showed evidence of mosaicism. The latter were diagnosed with either one mosaic abnormality (n = 5) or both a uniform and a mosaic aberration (n = 5). Vitrified blastocysts were warmed and cultured to 12 dpf.

Participants/materials, setting, methods: We applied established culture protocols to generate embryo outgrowths. Outgrowth viability on day 12 was carefully assessed and correlated to the genomic status of the plated blastocysts. We further selected 13, day 12 embryos for genomic analysis. Of these, 7 outgrowths were separated into two portions, corresponding to inner cell mass (ICM) and trophectoderm (TE) derived lineages. Taken together, whole genome amplification (WGA), followed by next generation sequencing (NGS) was performed on 20 samples.

Main results and the role of chance: Of the total embryos plated, 46.7% remained attached during the extended culture (n = 14). Viable day 12 outgrowths were predominantly generated from blastocysts diagnosed with trisomies, structural duplications or mosaic aberrations (13 out of 14, 92.9%). Conversely, monosomies, deletions and complex aneuploidies significantly impaired *in vitro* embryo development to 12 dpf (1 out of 14, 12.5%; p = 0.01). Interestingly, all embryos originally diagnosed with a single mosaic aberration remained viable at 12 dpf, regardless of the degree of mosaicism originally reported. Remarkably, of these, all sequenced outgrowths presented with normal profiles (n = 4), including 2 embryos that were separated into ICM and TE derived portions. All segments were euploid, suggesting a depletion of aneuploid cells in both embryonic lineages. Moreover, we could not confirm mosaicism in any day 12 outgrowths generated from blastocysts diagnosed with both a uniform and mosaic aberration. Here only uniform abnormalities were detected at 12 dpf. However, within this group, embryos with a higher percentage of mosaicism were more likely to detach during culture. Finally, we determined 100% concordance for uniform aberrations diagnosed at the blastocyst stage and at day 12. This applied to whole outgrowths and those for which lineage-specific profiles were obtained.

Limitations, reasons for caution: To thoroughly evaluate genomic instability and correlate the degree and type of mosaicism to developmental potential, expanding our study to include more outgrowths is currently ongoing. Established models omit the requirement of endometrial tissues, hence do not account for trophoblast-uterine interactions. The known methodological artefacts of WGA warrant careful interpretation.

Wider implications of the findings: Our findings echo current prenatal screening data and further demonstrate the normal developmental potential of mosaic embryos. Further insights into the impact of chromosomal mosaicism will contribute to a better understanding of its clinical significance. This will inherently benefit clinical management, particularly when no euploid embryos are available for transfer.

Trial registration number: not applicable.

INVITED SESSION

SESSION 68: INFERTILITY AROUND THE GLOBE

Wednesday 4 July 2018 Room 211 + 212 12:00–13:00

O-267 Infertility and assisted reproduction in the muslim world: Social, cultural, and religious considerations

M. Inhorn

Yale University, Anthropology & International Affairs, New Haven- Connecticut, U.S.A.

Abstract text

Assisted reproductive technologies (ARTs) to overcome infertility are now widely available across the Muslim world. Islamic *fatwas* (religious decrees) emanating from a variety of Islamic countries have permitted ARTs as a viable solution to overcome marital infertility. However, in the Sunni Muslim world, which spans from Morocco to Malaysia, third-party reproductive assistance (egg, sperm, and embryo donation, plus surrogacy) is religiously disallowed for a number of reasons having to do with kinship, marriage, and inheritance. Having said that, religious rulings emanating from Shia Muslim-dominant Iran have created unique avenues for infertile Muslim couples to overcome their infertility through third-party reproductive assistance. The opening of Iran, followed by Lebanon, to gamete donation has led to reproductive travel across international borders, especially among Sunni Muslim couples in search of donor eggs. Having said that, sperm donation remains unpopular among both Sunni and Shia Muslim men, meaning that they must turn to intracytoplasmic sperm injection (ICSI) to overcome their male infertility. ICSI has become a "masculine hope technology" in the Muslim world, despite its many practical and ethical challenges. In addition, ARTs such as preimplantation genetic diagnosis (PGD) for sex selection and multi-fetal pregnancy reduction (MFPR) for high-order multiple pregnancies (HOMPs) are leading to complex bioethical conundrums. This presentation reviews the key social, cultural, and religious issues facing ART-seeking infertile Muslim couples. Despite complex challenges, ARTs are being used widely and ethically negotiated in novel and unexpected ways in the Muslim world—a region that has embraced ARTs along with other forms of high-tech medicine.

O-268 The burden of infertility and childlessness in Sub-Saharan Africa: how can it be reduced?

T. Gerrits

University of Amsterdam-Faculty of Social and Behavioral Sciences, Amsterdam Institute for Social Science Research, Amsterdam, The Netherlands

Abstract text

Infertility is highly prevalent in Sub-Saharan Africa, in some areas affecting more than 15 % of couples of the reproductive-age population, which is mainly due to a high rate of sexually transmitted infections (STIs) and HIV/AIDS, postpartum and iatrogenic infections, and post-abortive complications. Often, infertility has a devastating impact on the people concerned, as in this context parenthood is 'culturally mandatory'. Infertility does not only have an emotional impact at the personal level (leading to grief and depression), but it also affects marital relationships and may result in disrespectful treatment by husbands and/or in-laws, domestic violence, abandonment, divorce and/or polygamy. Childless women and men may also suffer from social exclusion and stigmatization and their social security might be affected as they do not have children to take care of them at old age or when sick. Further, infertility may lead to economic hardship, as childless couples often spent their incomes on series of (ineffective) traditional and/or biomedical treatments. Finally, infertility may lead to additional health risks because people with fertility problems may be at greater risk of exposure to HIV and other STIs when they attempt to conceive extramaritally. Despite the high prevalence of infertility in Sub-Saharan countries and the huge impact on the daily lives of people concerned, it receives little attention from the public health system, neither to prevent, nor to treat it. Availability, access and quality of interventions to address infertility remain largely insufficient. Even basic interventions such as counselling, medical examinations and information provision are often scarce. Assisted reproductive technologies are - with a few exceptions - only offered in private clinics. De-stigmatization of the condition is also not addressed.

This presentation first provides insight in the burden and social suffering of infertility in the Sub-Saharan African context and subsequently present and discuss concrete recommendations to reduce this suffering. Clearly, this topic needs more attention – and funding - of various stakeholders and organizations, at national and international levels, including also NGOs and donor parties working in the field of Sexual and Reproductive Health and Rights (SRHR).

INVITED SESSION

SESSION 69: CUMULATIVE LIVE BIRTH RATES AFTER UTILIZATION OF ALL FRESH AND FROZEN EMBRYOS IN IVF/ICSI - THE OPTIMAL ENDPOINT

Wednesday 4 July 2018 Room 111 + 112 12:00–13:00

O-269 How many oocytes do we need to maximize cumulative live birth rates after utilization of all fresh and frozen embryos?

S.K. Sunkara

Queens Hospital- Barking- Havering and Redbridge University Hospitals NHSTrust, Gynaecology and Subfertility Unit, Essex, United Kingdom

Abstract text

Traditionally, IVF success has been reported as live birth rate (LBR) per cycle, per oocyte retrieval or per embryo transfer. However, advances in controlled ovarian stimulation (COS) strategies and significant improvements in cryopreservation techniques have introduced cumulative live birth rate (CLBR) as a more robust outcome measure in defining success in ART. There have been steady increases in frozen-thawed embryo transfers (FET) and resulting live births globally. Cumulative live birth rate is defined as live births resulting from one initiated or aspirated ART cycle, including fresh and/or resulting frozen embryo transfers, until a live birth occurs or until all embryos are used, whichever occurs first.

Cumulative live birth rate is a measure of the efficiency of COS regimens and effectiveness of cryopreservation programmes in ART. The aim of COS in ART is to optimise the number of oocytes to maximise success, efficiency, safety and cost-effectiveness. Ovarian response and number of oocytes retrieved is a surrogate outcome for ART success because of important associations with both pre-clinical and clinical outcomes. There is a strong relationship between oocytes retrieved and live birth following IVF, with several studies demonstrating a non-linear association with the number of oocytes and LBR in fresh IVF cycles. These studies have demonstrated an initial linear increase in LBR with increasing number of oocytes up to a consistent threshold of ~15 and a decline in LBR following fresh transfers with excessive oocyte numbers, >20. Current evidence of higher LBR following frozen versus fresh embryo transfers in women with PCOS indirectly concurs with this finding as these women are likely to have excessive response. The assumption for this decline is the very high oestradiol levels affecting the endometrial milieu and implantation in fresh cycles. This finding cannot be extrapolated to frozen transfers where hormone levels are close to physiological range.

Cumulative live birth rate reporting has extended the threshold of oocyte numbers towards increasing ART efficiency. Initial single centre-based studies reported a positive linear association between number of oocytes and CLBR. Subsequent multi-centre and registry based studies have demonstrated patterns of association with CLBR increasing up to 20-24 oocytes and further. This topic continues to be researched currently. In addition to CLBR, other innovative measures of success have also been introduced such as the one-and-done approach. This approach aims to tailor COS to result in successive live births with embryos from one cycle. Although achieving a live birth is dominant with ART programmes, safety is paramount and eliminating OHSS is a continued focus. Large cohort studies have indicated significant increases in clinical OHSS cases with >15, >18, >20 oocytes respectively. However, such studies with historical data are likely to involve a considerable proportion of GnRH agonist cycles associated with higher incidence of OHSS. This notion of an OHSS free clinic could reach near reality with current approaches to COS using the GnRH antagonist regimen, the GnRH agonist trigger and freeze all strategy. These strategies could potentially extend the safety limits for oocyte numbers. Another aspect of safety is the perinatal risks with ART pregnancies and addressing the contribution of ovarian stimulation, ovarian response and number of

oocytes is of interest. There is a higher incidence of preterm birth (PTB) and low birth weight (LBW) with excessive response (>20 oocytes) following fresh transfers. Whilst this could be due to an innate risk for women with PCOS within this category, high peak oestradiol levels have been shown to be associated with risk of LBW.

Understanding important clinical associations is useful for planning COS regimens. Whilst higher oocyte numbers are positively correlated with higher CLBR, maximising CLBR and planning COS should give consideration to safety.

O-270 Cumulative live birth rates after utilization of all fresh and frozen embryos in GnRH antagonist versus agonist protocol

INVITED SESSION

SESSION 70: PRECONCEPTION GENETICS IN CLINICAL FERTILITY PRACTICE: HOW MUCH INFORMATION DO WE NEED?

Wednesday 4 July 2018 Room 113 + 114 + 115 12:00–13:00

O-271 Increasing use of mutation screening in fertility clinics

O-272 Genetic carrier screening in gamete donor programs

A. Veiga, M. Boada, A. Abuli

Reproductive Medicine Service, Dexeus Women's Health, Barcelona, Spain

Abstract text

The data from the ESHRE-EIM Consortium for year 2011 show that more than 15,000 oocyte donation (OD) cycles have been performed in Spain, representing 52% of the OD European cycles. Donor screening has always been an issue that has received utmost attention in Spanish ART centers. European regulations clearly states that genetic screening for autosomal recessive genes known to be prevalent in the donor's ethnic background and assessment of the risk of transmission of inherited conditions known present in the family must be carried out according to international scientific evidence.

Traditionally, in OD programmes, genetic screening has been performed through karyotype analysis and the screening of diseases most prevalent in the donor's country of origin. In the last few years, genetics has experienced important technological progress allowing the screening for multiple genetic diseases at a reasonable cost. Expanded carrier screening (ECS) panels have now been implemented to allow a much deeper analysis of the risk of disease transmission during donor evaluation and better matching between donors and recipients shifting from the screening of limited number of conditions with a high prevalence in specific groups to the pan-ethnic or universal screening of multiple recessive conditions.

Since 2010, different panels have been commercially available, with different numbers and types of diseases. With the aim to provide with up-to date risk assessment of oocyte donors and optimised matching between donors and recipients, we have developed our own ECS panel (qCarrier) in collaboration with Q Genomics, a technological company that deals with genomics in human health. For gene selection, consideration has been given to geographic prevalence, neonatal screening programs and a selection of mutations associated with severe genetic diseases. The panel has been based on Next Generation Sequencing (NGS) technology, including complete sequencing of the coding region of genes associated with the most prevalent diseases and targeted mutational analysis of rare diseases. Complementary techniques for Fragile X syndrome and some deletions have been performed.

The results describe the implementation of a carrier screening test for autosomal recessive and X-linked diseases in our OD Programme. Donors and male partners of the recipients were screened for risk assessment and matching. The ECS test covered 200 genes (68 genes by complete sequencing of the coding region and 132 sequenced by a targeted mutation analysis) associated with 314 diseases (277 recessive autosomal diseases and 22 x-linked). Among participants, 56.4% (761/1350) were identified as carriers of at least one gene mutation. Eleven (1.9%) of oocyte donor candidates were identified as carriers of X-linked diseases, and as such, were excluded from the OD programme. The mean carrier burden was 0.84 mutations per sample. With respect to the matching between oocyte donors and recipients, 26 (3.4%) preassigned matches were at high risk of transmitting a severe autosomal-recessive genetic condition to their offspring (cystic fibrosis, classical congenital adrenal hyperplasia, autosomalrecessive non-syndromic sensorineural deafness, alpha thalassemia, familial Mediterranean fever, Niemann-Pick disease, thyroid dyshormogenesis type 6 and cartilage-hair hypoplasia). The final matching between donors and recipients was performed taking into account the ECS results. A carrier state for an autosomal recessive condition was not an exclusion criterion for oocyte donors, although it implied the assignation of the donor to a recipient whose male partner was not a carrier for the same recessive condition. When performing ECS in an OD, an appropriate genetic counselling is essential for donors and recipients in order to understand the results, to decrease anxiety and to give recommendations about own reproductive risk or that of relatives, when necessary.

INVITED SESSION

SESSION 71: LABORATORY INVITED SESSION: EMBRYO CULTURE: CHANGING THE ATMOSPHERE

Wednesday 4 July 2018 Room 117 12:00–13:00

O-273 Epigenetic changes by stimulation and culture

A. Sunde

Professor emeritus, Department of Clinical and Molecular Medicine- Faculty of Medicine- Norwegian University of Science and Technology. Trondheim- Norway., Trondheim, Norway

Abstract text

Epigenetic changes means that there is a change in the phenotype of a cell or an organism without a simultaneous change in the genotype. It is the expression of genes that are changed. One mechanism of regulation gene expression is trough adding a methyl-group to a Cytosine in the binding site of a transcription regulator or by methylation or acetylation of histones. These chemical modifications of DNA or chromatin can change the likelihood that a gene or sets of genes are expressed.

Assisted reproduction is associated with shifts in the phenotype of the embryos, of the placenta and the children born. Interventions like ovulation induction, *in vitro* fertilization, embryo culture and cryopreservation of embryos are associated with changes in gene expression profiles methylation patterns in the placenta and the birth weight of the offspring. In general, the mechanisms behind the changes in phenotype are unknown, but it is reasonable to assume that this is mediated epigenetically by modulating gene expression.

From epidemiological data, it is well documented that the nutritional status of the mother in early pregnancy may have lasting effects on the health of the offspring. In human IVF, different culture media was shown to induce different gene expression profiles in embryos and a significant difference in birth weight of the children born Similarly, the oxygen concentration in the incubator will influence the gene expression in human embryos and this effect was dependent on the type of culture media used.

Commercially available culture media for ART differ considerably in their chemical composition and it should not come as a big surprise if embryos show different epigenetic responses to these differences in the culture environment.

The consequences of these small shifts in phenotype after IVF and embryo culture is to a large extent unknown, and it is unclear whether this will have an effect on the long-term health of the ART-offspring. Follow-up studies on ART-children in relationship to the intervention done both *in vivo* and *in vitro* are

important in order to understand if there is certain interventions that is associated with an increase in long term health problems.

O-274 Impact of temperature on embryo culture

R. Janssens

UZ Brussel, IVF Laboratory, Jette- Brussels, Belgium

Abstract text

In ART, the pre-implantation development of human embryos – and their subsequent ability to implant - depends heavily on the *in vitro* culture conditions. There is now an increasing understanding that the embryo is highly adaptive to its environment, the embryo is able to develop to morphologically normal blastocysts even in sub-optimal conditions. These culture conditions are set to mimic the *in vivo* conditions as good as possible and mainly include the culture media, the type of culture system and the incubator. The primary function of the incubator is to maintain an appropriate microenvironment (composition of gas phase) and temperature. Temperature can impact gamete and embryo function and meiotic spindle stability [1]. Although the developmental plasticity of embryos permits them to develop over a range of temperatures, from 36.0 to 37.0°C[2], it is know that the micro-environment maintenance ability of incubators significantly influences the formation of good embryos [3]. Most commercial IVF incubators have important temperature variations [4],[5] and statistically significant associations between incubation shelf and clinical pregnancy have been reported[6]. Due to these technical limitations, accurate determination of optimal incubation temperature has not yet been possible. Recent improvements in incubator technology however now allow accurate temperature regulation and determination of optimal incubation temperature. Until now, constant incubator settings matching the core body temperature (37°C) are used, but the optimal culture temperature is yet undefined. Available data on incubation temperature will be reviewed.

Although modern incubators can now regulate incubation temperature precise and stable, the temperature control out of the incubator can be problematic. Limited decrease in temperature can alter the cytoskeleton and spindle of oocytes and there is limited recovery after cooling and rewarming. Temperature issues can occur during follicle puncture, during manipulations on heated stages on stereo microscopes and injection microscopes, in incubators and during embryo transfer. Temperature should be measured in culture dishes under oil and in tubes with calibrated probes. The choice of measuring probe is important. Thin, fast responding non shielded type T thermocouples can be used to detect small temperature gradient and are excellent to detect hot spots on heating stages while more precise, small probes, fixed in culture dishes are more suitable for precise temperature measurements in incubators. While the most stable and accurate sensors are resistance temperature detectors (Pt100, Pt 1000), they are not easily available in small sizes which allow them to be fixed inside a culture dish. For this purpose thermistor probes are probably a better choice. Thermistors with 0.1°C accuracy are now widely available and at a very reasonable price. They have a fast response time and because of their high sensitivity are ideal for detecting temperature changes in culture dishes. Of course, accurate temperature measurement is only possible through the use of suitably calibrated sensors and instruments and the accuracy of these measurements will be meaningless unless the equipment and sensors are correctly used. Good knowledge of measurement science is a basic requirement, often lacking in many laboratories.

[4]*Imperial College of London, Faculty of Medicine, London, United Kingdom*
[5]*Oxford University, Reproductive Biology, Oxford, United Kingdom*
[6]*Sao Paolo State University-UNESP, Applied Mathematics Laboratory, Sao Paolo, Brazil*

Study question: Following from a bovine study presented at ESHRE 2017, we compared AI *versus* five distinct experienced embryologists in the capabilities to grade human blastocysts.

Summary answer: As observed in the bovine model, AI outperformed embryologists who graded human blastocysts using time-lapse images.

What is known already: Morphological grading of blastocysts is clinically used for embryo selection. Our group demonstrated that blastocyst grading by embryologists lead to wide inter- and intra-operator variation. We demonstrated (bovine model) that an image analysis by AI system can reduce variation in blastocyst grading and acquire additional parameters not detectable by operator assessment. Human blastocysts present additional challenges for AI image recognition compared to bovine, given the increased classification categories, diverse trophectoderm thickness, diverse ICM shapes, and lower contrast. Until now, AI has not demonstrated to improve operator blastocyst grading in human embryos, which was the focus of the current study.

Study design, size, duration: 394 human embryo time-lapse images taken at 111.5 hpi were graded for ICM, trophectoderm and expansion using Gardner grading system by 5 different embryologists from 4 different countries. Of these, 171 were excluded as blastocysts that were too early (expansion 1 or earlier), hatched, out of focus or ICM not visible. The mode of the remaining 223 images were used as output for the AI system (70% training, 15% validation and 15% blind test).

Participants/materials, setting, methods: 29 independent mathematical variables were extracted from each time-lapse image taken at precisely 111.5 hpi from the central Z-stack and inputted into the AI system. The agreement was assessed using confusion matrices, ROC curves and Kappa Index. Embryologists originally trained in the same lab were compared to embryologists trained in different labs to assess inter- and intra-clinic agreement variation.

Main results and the role of chance: Agreement among the 5 embryologists was low (Kappa agreement decreasing from Expansion 0.4 to trophectoderm and ICM 0.3). There was no difference between the kappa agreement of embryologists trained in the same clinic to embryologists from different countries. The low inter-operator agreement is likely to be due to the fixed time central stack image selection. Previously, we demonstrated that when images were selected according to focus on ICM, the operator agreement was considerably higher. Improved agreement was observed using AI to predict the mode of the embryologists with substantial agreement with Expansion (Kappa agreement 0.7) and ICM (0.7) and moderate agreement with trophectoderm (0.4). The AI's overall accuracy was almost perfect for prediction of blastocyst expansion (training 93.9% and validation 81.5%) and substantial for prediction of ICM (training 93% and validation 78.8%) and trophectoderm (training 78.8% and validation 78.3%). The AI system was considerably more predictive of Expansion (AUC 0.888-0.956) compared to ICM (AUC 0.605-0.854) and trophectoderm (AUC 0.726-0.769).

Limitations, reasons for caution: Our data suggests that AI is able to cope better than operators with the challenge of grading three dimensional embryos from a single fixed two-dimensional image. This technology has now been demonstrated in two independent centres. Further independent studies are required to demonstrate reproducibility before establishing its clinical application.

Wider implications of the findings: Applying AI to human blastocyst grading is inexpensive, non-invasive, and more reliable than grading by an operator. Instead of a human looking at thousands of images, AI faster assesses them and

continuously learns and quantifies additional information. As demonstrated, this technology can inherently enhance our capabilities of assessing embryo viability.
Trial registration number: not applicable.

O-276 Optimising Machine Learning Algorithms for the Non-Invasive analysis of the embryo secretome to enhance informed decisions imediately prior to embryo transfer

S. Butler[1], F. Sharara[2], R. Zmuidinaite[3], R. Iles[3]

[1]MAP Sciences, R&D, Bedford, United Kingdom
[2]Virginia Centre for Reproductive Medicine, U.S.A.,
[3]MAP Sciences, Research, Bedford, United Kingdom

Study question: Is it possible to mathematically analyse the secretome of blastocysts by non-invasive mass spectrometry of spent culture media to predict viability for embryo selection.
Summary answer: A simple, direct and rapid analysis of mass spectra from spent blastocyst culture media quickly identifies optimal embryos with the best chance of viable pregnancy.
What is known already: All available technologies to evaluate successful implantation, such as PGS, require embryo biopsy. MALDI-ToF MS is successfully exploited in microbiology, but has largely been dismissed in assisted reproduction. Proteins in media from embryos have been detected using MALDI and were consistent with gene expression studies and correlate well with positive pregnancy; however, the findings were not correlated with all pregnancy outcomes. This study represents the first to use mathematical modeling to correlate the spectral analysis of peptides in the embryo secretome with all pregnancy outcomes.
Study design, size, duration: A prospective analysis of 500 culture fluid samples collected at the time of embryo transfer over a three year period which were compared with eventual outcomes of ongoing viable pregnancy, SAB, Biochemical pregnancy, negative pregnancy test or evaluation following PGS.
Participants/materials, setting, methods: Over 500 samples of spent blastocyst culture media were collected from embryos of at the time of transfer from a single clinic in the US. Just 1 µL of media was analyzed using MALDI ToF mass spectrometry in a laboratory in the UK. Quantitative characteristics within the 2000 to 15000 m/z mass range were examined using multiple supervised machine learning algorithms to predict pregnancy outcome.
Main results and the role of chance: Mathematical analysis of secretome spectra following MALDI ToF MS analysis shows distinct differences between high grade embryos which go onto achieve successful pregnancy and those which do not, either as an SAB, Biochemical Pregnancy, negative pregnancy test or aneuploidy PGS result. Some analysis of algorithms used for embryos with negative PGS outcomes samples were able to distinguish different aneuploidies.
Limitations, reasons for caution: More samples tested in a real-time environment using MALDI ToF in a clinic at the time of embryo transfer would help validate this study which is limited by the freezing and shipping of samples to the UK laboratory.
Wider implications of the findings: Many cycles result in negative outcomes due to aneuploidies or implantation failure when embryos appear otherwise viable. Checking for aneuploidies is time consuming, invasive and requires vitrification. Implementation of a quick and simple non-invasive mass spectral analysis could simplify and dramatically improve embryo selection and increase live births.
Trial registration number: Not Applicable.

O-277 Automation in the IVF laboratory: preliminary results with a new device able to do both vitrification/rewarming of mice and bovine oocytes and embryos

P. Patrizio[1], Y. Natan[2], P. Levi Setti[3], M. Leong[4], A. Arav[5]

[4]The Womens Clinic, Reproductive Medicine Clinic, Hong Kong, Hong Kong
[5]FertileSafe Ltd, Experimental Research Laboratory- 11 HaHarash st, Nes Ziona, Israel

Study question: Can both vitrification and rewarming be standardized using a unique automated device capable to do both procedures?
Summary answer: The automatic vitrification/rewarming device (Sarah) produces high survival rates of oocytes/embryos. This novel device will become indispensable for standardization and automation in the IVF laboratories.
What is known already: Clinical demand for oocyte vitrification has been steadily increasing for women electively postponing motherhood or at iatrogenic risk of losing their reproductive ability. However, the lack of standardization of vitrification/rewarming protocols produces variable ranges of survival, pregnancy and live birth rates among ART centers. Currently, most vitrification/rewarming protocols require manual moving of oocytes or embryos one at time between various solutions (often 4 or 5) before completing the task.
Study design, size, duration: Experimental research, using mice (40 oocytes and 242 cleaved embryos) and bovine (234 oocytes and 55 cleaved embryos) samples in a new automatic vitrification/warming device (Sarah, FertileSafe, Ltd).
Participants/materials, setting, methods: Mice oocytes (n = 40) and embryos (8 cells, n = 35 and blastocysts, n = 165) and bovine embryos (2Pn, n = 35) and MII oocytes (n = 84) were vitrified using the automated device (Sarah). A total of 42 (2 cells) mice embryos, 20 (2Pn) bovine embryos, and 150 MII bovine oocytes were used as fresh controls and grown to blastocysts. Upon rewarming with the same device, all were assessed for viability, cleavage, blastocyst and hatching rates.
Main results and the role of chance: Up to 5 oocytes/embryos were loaded into 0.25 ml straws end-closed by special capsules and connected to the robotic arm. For the mice experiments, the samples were exposed to three ES (30, 60, 100%) followed by VS (100%). For the bovine experiments, samples were exposed to six ES (10, 20, 40, 60, 80, 100%) followed by VS (75, 100%). For rewarming straws were plunged into temperature-controlled 5 ml tubes containing WS 100, 50, 25 and 12.5%, at RT for 2.5 minutes each, before arrival to the holding station. 95% (38/40) of the mice MII oocytes regained isotonic volumes and all (95/95, 100%) were viable. Rewarmed 8 cell mice embryos had 95% (33/35) blastulation rate and 80% (28/35) hatched. Rewarmed mice blastocysts had 97% survival rate (160/165) and 81% (135/165) hatched. Fresh control mice embryos had 100% blastulation rate (42/42) and 73% hatching (21/42) (p = ns). Bovine embryos survival was 100% with 54 % (19/35) cleavage and 9% (3/35) reaching blastocyst stage. Fresh control bovine embryos had 65% (13/20) cleavage and 20% (4/20) blastulation rate. Vitrified/warmed bovine oocytes had 100% survival, 73% (61/84) cleavage and 7% (6/84) blastocysts rates; fresh control had 83% (125/150) cleavage and 11% (17/150) blastocyst rate (p = ns).
Limitations, reasons for caution: These successful preliminary results in animal models need to be replicated in the recently started clinical human IVF settings.
Wider implications of the findings: Automation of both vitrification and rewarming of oocytes and embryos will drastically reduce the differences in survival and success rates between ART centers worldwide. Simplification and standardization of protocols will be of great value both for patients requiring fertility preservation or elective cryopreservation and the whole ART industry.

Study question: For human in vitro fertilization embryos, are there differences between male and female on the gene expression level during early development?

Summary answer: There are imbalanced expression of sexual chromosomes between gender from the embryonic genome activation (EGA), with a dosage compensation firstly occurring in female trophectoderm cells.

What is known already: Several animal studies have demonstrated that the gender has an effect in the kinetics and metabolism of early embryo development. At the stage before implantation, sex-specific differences in gene expression become apparent. In rodents, this period of double X chromosome activation occurs between 4-cell and 16-cell stages, but the equivalent timing is uncertain in human embryos. Failure to accomplish dosage compensation normally results in early miscarriage and embryonic lethality. In human, the dosage compensation is started by silencing the expression of both X chromosomes in blastocyst embryos, while the exact procedure remains unclear.

Study design, size, duration: We performed global expression analysis between males and females using single-cell RNA-sequencing data of 1585 individual cells from 98 human preimplantation embryos, covering development stages from 8-cell to late blastocyst.

Participants/materials, setting, methods: We classified all the cells from E3 to E7, corresponding to their developmental stages from 8-cell to late blastocyst. An average of 20 embryos were analyzed per embryonic day. We determined the sex of each embryo after assessing the expression level of Y-linked genes for each cell. Then we performed the comparison of expression between gender for each stage.

Main results and the role of chance: We provide a comprehensive comparison of transcriptional atlas between sex of human preimplantation embryos and reveals the dynamics of sex chromosomes during embryogenesis for the first time. Consistent chromosome-wide transcriptomic level of autosomes was observed in all stages, while sex chromosomes showed significant differences after EGA. We observed a significant enrichment of differentially expressed genes on X chromosome at the 8-cell stage, on both X and Y chromosomes at the morula stage, and on Y chromosome at the blastocyst stage($P < 0.001$). Two of the DE genes on Y chromosome, RPS4Y1 and DDX3Y, achieved abundant expression in all male cells immediately beyond the completion of EGA and could be used as a gender marker in male embryos. For X chromosomes in female, over 100 significantly higher expressed genes were defined in 8-cell stage and both alleles of most heterozygous sites could be detected in our allelic analysis. Contrary to constant pattern of Y chromosome, the expression of X chromosome distinctly dropped at late blastocyst stage, especially in trophectoderm cells, revealing the exact time point and details of dosage compensation.

Limitations, reasons for caution: Lack of genomic data to verify the gender of each embryo is the limitation of this study. In addition, in the allelic analysis, we still need the variants of embryonic genome to get more informative sites.

Wider implications of the findings: Studying the sex differences during human embryogenesis, as well as understanding the procedure of X inactivation and its correlation with early miscarriage, will build upon the capabilities of assisted reproductive technology to improve the treatment of infertility and reproductive health.

Trial registration number: not applicable.

O-279 Parallel single-cell genome and transcriptome sequencing to study chromosomal instability during human embryonic preimplantation development

E. Fernandez Gallardo[1], A. Sifrim[1], S. Debrock[2], J.R. Vermeesch[1], T. Voet[1]

[1]KU Leuven, Center of Human Genetics, Leuven, Belgium
[2]UZ Leuven, Leuven University Fertility Centre, Leuven, Belgium

Study question: Is there any transcriptional signature of aneuploidy at single cell level during human preimplantation embryonic development?

Summary answer: The largest transcriptomic differences between cells are due to embryonic genome activation. Differences due to aneuploidy become detectable comparing cells of the same developmental stage.

What is known already: More than 70% of IVF human cleavage stage embryos are mosaic. Nevertheless, some can potentially develop in healthy babies after transfer. The causative mechanisms of chromosome instability as well as the mechanisms of selection and/or correction of aneuploid cells remain largely unexplored and speculative in the embryo.

Study design, size, duration: All single cells from 31 preimplantation embryos were subjected to parallel single-cell whole genome and transcriptome sequencing. Namely, 8 embryos at Day1 (17 cells), 19 embryos at Day2 (62 cells), 2 embryos at Day3 (17 cells) and 2 embryos at Day4 (23 cells). From each single cell, genome-wide DNA copy number (CNV) and whole transcriptome gene expression levels were determined. The data from this ongoing cross-sectional study was generated between October 2016 and November 2018.

Participants/materials, setting, methods: Thirty-one zygotes donated for research from 14 couples were cultured in a time-lapse incubator after surviving cryopreservation. At a specific cell stage, embryos were mechanically dissociated into 119 single blastomeres, which were subjected to on-bead separation and amplification of DNA and RNA. Single-cell amplification products were subsequently sequenced with Illumina platforms. Single-cell DNA genome-wide CNVs were determined by focal read depth analysis. Single-cell gene expression data was subjected to clustering and principal component analysis (PCA).

Main results and the role of chance: Single-cell DNA CNV analysis revealed frequent missegregations of whole chromosomes as well as segmental rearrangements in all embryonic cell stages. Specifically, 22 out of 31 (70%) embryos contained at least one genetically abnormal cell. At single cell level, 74 out of 92 cells (80%) that passed sequencing quality control contained at least one segmental or whole chromosome aneuploidy. The remaining 18 cells (20%) were normal euploid. Furthermore, using embryonic cell cleavage phenotype and the genomic profile of its single cells, we could deduce the origin of the abnormalities and construct cell lineages.

Single-cell gene expression analysis, classified the cells according to the embryonic cell stage and the embryonic genome activation (EGA). Moreover, we could benchmark our dataset by recapitulating previously described EGA gene expression patterns. Interestingly, two Day3 blastomeres with heavily rearranged genomes clustered separately from the rest of the Day3 cells regardless of the embryo of origin. These results suggest that transcriptomic differences due to abnormal genomes might be subtler between cells from different embryo stages while more detectable when comparing embryos within the same developmental stage.

Limitations, reasons for caution: This is a preliminary analysis of an ongoing study. The current analysis includes a low number of embryos and unevenly distributed across the preimplantation embryonic stages. Further RNA-seq computational analysis in a higher number of samples are required to unravel the effect of CIN in the transcriptome.

Wider implications of the findings: We deliver proof-of-principle that this novel, state-of-the-art method for simultaneous genome and transcriptome sequencing (G&T-seq) of the same single cell can be successfully applied in human blastomeres. To our knowledge, these are the first results of G&T-seq in human embryos. We foresee a great scientific potential to study embryo development.

Trial registration number: not applicable.

O-280 Oocyte retrieval complications: an update after 23,833 procedures in an academic tertiary care ART referral center

P.E. Levi Setti[1], F. Cirillo[1], V. Scolaro[1], F. Heilbron[2], D. Girardello[3], E. Zannoni[1], P. Patrizio[4]

[1]Humanitas Research Hospital, Humanitas Fertility Center- Department of Gynecology- Division of Gynecology and Reproductive Medicine, Rozzano Milan, Italy
[2]Humanitas University, Humanitas University, Rozzano Milan, Italy
[3]Humanitas Research Hospital, Department of Anesthesiology and Intensive Care, Rozzano Milan, Italy
[4]Yale University- School of Medicine- New Haven, Department of Obstetrics-Gynecology and Reproductive Sciences, New Haven- Connecticut-, U.S.A.

Study question: The aim of the present study was to assess complications encountered on the largest single centre series of transvaginal oocyte retrievals (OR).

Summary answer: A significant correlation between complications and women age, BMI, the number oocytes, mean time to complete oocyte retrieval, clinician experience and presence of risk factors.

What is known already: Ultrasound guided transvaginal OR represents the most commonly used technique in ART cycles. Several observational studies evaluating the rates of complications associated with this procedure have shown it to be safe, with very low rates of serious complications.

Study design, size, duration: This is a retrospective analysis including all the oocytes retrievals performed at a large teaching hospital from June1996 to November 2016. The study has been approved by our Institutional Review Board, all patients signed an informed consent to the use of their data, as long as their anonymity and confidentiality were assured. February 28th 2016. All the patients' data were extracted from the Fertility Center external-audit-anonymized electronic research query system.

Participants/materials, setting, methods: 23,833 procedures were included. We did not exclude any patient who performed retrievals during the period in exam. Complications requiring hospital admission for at least 24 hours were considered severe complications. Transvaginal ultrasound–guided OR was performed 34/36 hours after the trigger injection, under deep sedation in an operating theatre, using a 35 mm, 17-gauge aspiration needle. Antibiotic prophylaxis was not routinely used except in situation with surgical risk factors.

Main results and the role of chance: A total of 96 out of 12,615 patients (0.76%) suffered complications, with hospital admission necessary for 71 patients (0.56%). Mean hospital stay was 2.77 ± 2.5 days. When calculated per retrieval, the overall complication rate was 0.4% while 0.29% was the admission rate. A surgical procedure was necessary for 24 patients (0.1% per retrieval and 0.19% per patient). Multivariate analysis showed a significant correlation between complications and women age, BMI, the number oocyte retrieved and mean time to complete oocyte retrieval. The incidence of complications was significantly higher for physicians who had performed fewer than 250 retrievals as compared to those who had completed more than 250 (OR 0.63; 0.40 – 0.99 – p = 0.0472).

In general, the most important risk factors for the occurrence of a complication can be identified in: a) high number of oocytes retrieved; b) a longer duration of operative time; c) inexperience of the surgeon; d) a low BMI and e) a history of prior abdominal or pelvic surgery or pelvic inflammatory disease. Interestingly, sixteen of the fifty-four retrievals (29.63%) with hemoperitoneum had surgical risk factors.

Limitations, reasons for caution: Although the great majority of complications were treated in our institution (94/96 complications), others could have been treated in other hospital and not unreported. This could reflect a possible bias with an underestimation of the incidence of complication related to oocyte retrieval, severe ones are usually reported.

Wider implications of the findings: OR can be considered a safe procedure, although patients and physicians should understand that this technique is not without risks. We found that complications were consistently less when the operator had performed an average of 250 ORs. We can therefore suggest referring to more experienced surgeons OR at higher risk.

Trial registration number: NCT03282279

O-281 Transfer of two non-top quality embryos increases the risk of ectopic pregnancy after fresh and frozen-thawed embryo transfer

S. Anzhel[1,2], S. Mäkinen[3], H. Tinkanen[4], T. Mikkilä[4], A. Haltia[5], A. Perheentupa[3], C. Tomás[6], H. Martikainen[7], A. Tiitinen[1], J. Tapanainen[1], Z. Veleva[1]

[5]Felicitas Mehiläinen Turku, Turku infertility clinic, Turku, Finland
[6]Ovumia and Fertinova Tampere Infertility Clinics, Infertility Clinic, Tampere, Finland
[7]University of Oulu and Oulu University Hospital, Obstetrics and Gynecology, Oulu, Finland

Study question: Is embryo quality associated with ectopic pregnancy (EP)?

Summary answer: The odds for EP are elevated after the transfer of two embryos, even if both are of non-top quality.

What is known already: The incidence of EP after IVF/ICSI varies from 1.6% to 8.6%, and can be up to four times higher than the rate in spontaneous pregnancies. Tubal factor infertility and the transfer of multiple embryos are known to increase the probability of EP. Nowadays, top quality embryos are mostly transferred in single embryo transfers (SET). Double embryo transfers (DET) are therefore performed with non-top quality embryos. The effect of embryo quality on EP has not been investigated until now. Furthermore, there is no consensus on whether the transfer of fresh vs. cryopreserved embryos has a different effect on EP rates.

Study design, size, duration: Retrospective cohort study of 16,891 clinical pregnancies (diagnosed by ultrasound at 6-8 gestational weeks) after non-donor IVF/ICSI with fresh (n = 10,255) or frozen-thawed transfer (FET) (n = 6636), performed in 2000-2017 in Finland (LUMI database). In all cases, there were up to two embryos transferred with known morphological quality. Presence or absence of tubal factor infertility was also recorded. Heterotopic pregnancies were classified as ectopic.

Participants/materials, setting, methods: A single top quality embryo was transferred in 6634 (39.3%) and a single non-top one in 4206 (24.9%) cycles. In DET cycles, there were no (3721 cycles, 22.0%), one (1485 cycles, 8.8%) or two (845 cycles, 5.0%) top quality embryos transferred. We analyzed the effects of female age, the number of embryos transferred, embryo quality, type of cycle (fresh vs. FET) and tubal factor infertility on EP by logistic regression.

Main results and the role of chance: EP was observed in 384 (2.3%) cycles. There was no significant difference in EP rate after fresh embryo transfer or FET (225/10,255, 2.2% vs. 159/6636, 2.4%, P = 0.7). Compared to treatments in which only top quality embryos were transferred (141/7479, 1.9%), EP rate in cycles with only non-top quality embryos transferred was higher (219/7927, 2.8%, P < 0.0001). Tubal factor infertility was diagnosed more often in EP than in intrauterine pregnancies (19.5% vs. 10.2%, P < 0.0001).

Logistic regression revealed that the odds of EP after fresh transfer were similar to those after FET (odds ratio (OR) for FET 1.06, 95% confidence interval (CI) 0.86-1.23, P = 0.6). DET increased significantly the chance of EP, compared to SET (OR 1.45, 95% CI 1.18-1.78, P < 0.0001). Presence of tubal factor infertility was associated with EP (OR 2.06, 95% CI 1.59-2.67, P < 0.0001). In a separate logistic regression analysis, transfer of two non-top quality embryos (OR 1.49, 95% CI 1.13-1.95, P = 0.004) but not of one (OR 0.79, 95% CI 0.60-1.05, P = 0.1) or two top quality embryos (OR 1.31, 95% CI 0.83-2.07, P = 0.3) increased the odds of EP, compared to transfer of a single non-top quality embryo. Female age was not associated with EP (P = 0.3).

Limitations, reasons for caution: The effect of the hormonal environment in FET (spontaneous vs. hormonally-substituted cycles) was not analized due to the limited availability of complete data.

Wider implications of the findings: Transfer of non-top quality embryos decreases the chances of live birth after IVF/ICSI. The present study found that DET with two non-top quality embryos is also associated with increased odds of EP. This is particularly important in tubal factor infertility patients who are already at risk of EP.

Trial registration number: Not applicable

O-282 Hospitalizations due to OHSS after IVF is not diminished during the last 15 years despite presumed improvements in ovarian stimulation - National data from Denmark

L.B. Colmorn[1], Ø. Lidegaard[2], N. Sopa[3], A. Pinborg[1], S. Malchau[3], A. Nyboe Andersen[1]

[1]Rigshospitalet, Fertilityclinic, Copenhagen, Denmark
[2]Rigshospitalet, Gynecology, Copenhagen, Denmark
[3]Hvidovre Hospital, Fertilityclinic, Hvidovre, Denmark

Study question: Do we observe a recent reduction in prevalence of severe OHSS after change towards antagonist protocols, use of response predictive factors and agonist triggering?

Summary answer: National Danish Hospital discharge register data identified 2.564 OHSS cases after 160.803 ART-cycles and no significant prevalence reduction of severe OHSS from 2001 to 2015.

What is known already: OHSS is a known risk of ovarian stimulation, but it is known that the numbers directly reported by ART professionals to the registers are grossly underreported, whereas more accurate numbers may be obtained from hospital discharge registers. Antagonist protocols that lowers the risk of OHSS are more commonly used in recent years, agonist triggering may reduce the OHSS rate, and ovarian response predictive factors like AHM and AFC have been developed. All these changes in IVF should reduce the OHSS risk.

Study design, size, duration: This is a retrospective register based study including 160.803 IVF/ICSI stimulated cycles from all public and private fertility clinics in Denmark from 2001 to 2015.

Participants/materials, setting, methods: From 2001 to 2015, a total of 2.564 women had at least one hospital admission with an OHSS diagnosis. Data on OHSS was obtained from the Danish National Discharge Register and the annual number was compared to the annual number of stimulated IVF/ICSI cycles, obtained from the ART register of the Danish Fertility Society (www.fertilitetsselskab.dk). Changes in the prevalence were estimated by Chi-square test and Cochran-Armitage test for trend.

Main results and the role of chance: The annual number of OHSS ranged from 151 cases in 2001 to 203 cases in 2009 and 2010 and 169 cases in 2015. During the same period the number of stimulated IVF/ICSI cycles increased from 8.805 in 2001 to 12.328 in 2015. The prevalence of OHSS among all stimulated cycles in 2001 was 151/8805 = 1.7% (CI: 1.4 to 1.9) and in 2015 169/12.328 = 1.4% (CI: 1.2% to 1.9%), with a marginal reduction of 0.3%. The prevalence varied with the highest figure in 2005 with 178 /9541 = 1.9% (CI: 1.6 to 2.0), and the lowest in 2007 with 153/11035 = 1.4% (CI: 1.2 to 1.9) and in 2015 with 169/12.328 = 1.4% (CI: 1.2 to 1.9). We found no significant changes between the annual prevalence of OHSS in Denmark (p = 0.126) as well as no trend for changes in the prevalence over the 15 years (p = 0.158).

Limitations, reasons for caution: The present analysis was unable to identify cases of OHSS that may have occurred after ovulation induction for anovulation or intrauterine inseminations. Extensive data sets on those IVF cycles that did and did not result in OHSS would be needed to analyze why OHSS was not reduced.

Wider implications of the findings: We have increased knowledge of risk factors for OHSS and may adapt treatment regiments towards more antagonist protocol, agonist triggering, individualized FSH dosing or a freeze all strategy. However, on a National basis we have not yet seen that the results of such efforts diminish the risk of OHSS.

Trial registration number: 'not applicable'

O-283 Pregnancy after frozen-thawed embryo transfer during hormonal replacement cycle is associated with hypertensive disorders of pregnancy and placenta accreta

K. Saito[1,2,3], A. Kuwahara[4], T. Ishikawa[3], T. Nakasuji[3], M. Miyado[1], K. Miyado[5], M. Fukami[1], N. Miyasaka[3], M. Irahara[4], H. Saito[2]

[1]*National Research Institute for Child Health and Development, Department of Molecular Endocrinology, Tokyo, Japan*
[2]*National Center for Child Health and Development, Department of Perinatal Medicine and Maternal Care, Tokyo, Japan*
[3]*Tokyo Medical and Dental University- Graduate School, Department of Comprehensive Reproductive Medicine, Tokyo, Japan*
[4]*The University of Tokushima Graduate School, Department of Obstetrics and Gynecology, Tokushima, Japan*
[5]*National Research Institute for Child Health and Development, Department of Reproductive Biology, Tokyo, Japan*

Study question: Is there any difference in obstetrical risk between patients who conceived after frozen embryo transfer (FET) during a hormone replacement cycle (HRC-FET) and during a natural ovulatory cycle (NC-FET)?

Summary answer: The patients who conceived by HRC-FET had an increased risk of hypertensive disorders and placenta accreta compared with those who conceived by NC-FET.

What is known already: Previous study has shown that the rate of Caesarean section in pregnancies conceived through HRC-FET is higher than those conceived through NC-FET. Little has been clarified regarding an association between obstetrical complications and endometrium preparation methods.

Study design, size, duration: A retrospective cohort study of patients who conceived after HRC-FET and those who conceived after NC-FET was performed, based on the Japanese assisted reproductive technology registry in 2014.

Participants/materials, setting, methods: Pregnancy outcomes were compared between the cases of NC-FETs (n = 29,760) and HRC-FETs (n = 75,474). Multiple logistic regression analyses were performed to investigate the potential confounding factors for mode of delivery and obstetrical complications.

Main results and the role of chance: The pregnancy rate was significantly lower in HRC-FET cycles than in NC-FET cycles (32.1% vs. 36.1%, $p < 0.001$). Among pregnancies, Caesarean section rate was higher (44.5% vs. 33.7%, $p < 0.001$) for pregnancies conceived through HRC-FET than those conceived through NC-FET. A multiple logistic regression analysis showed that pregnancies after HRC-FET had increased odds of Caesarean section (adjusted odds ratio [aOR] 1.736, 95% confidence interval [CI] 1.632–1.847), hypertensive disorders of pregnancy (aOR 1.443, 95% CI 1.231–1.692), and placenta accreta (aOR 6.817, 95% CI 3.662–12.692) compared to pregnancies after NC-FET.

Limitations, reasons for caution: This study is retrospective, and some cases were excluded due to missing data. The possible role of residual confounding factors and bias must be considered.

Wider implications of the findings: Pregnancies following HRC-FET have higher risks of hypertensive disorders of pregnancy and placenta accreta. The association between endometrium preparation method and these placenta related obstetrical complications merits further attention.

Trial registration number: not applicable.

O-284 Pregnancy complications following assisted reproductive techniques - disentangling the role of multiple gestation

S. Oberg[1], T. VanderWeele[2], C. Almqvist[3], S. Hernandez-Diaz[2]

[1]*Karolinska Institutet, Department of Medical Epidemiology & Biostatistics, Stockholm, Sweden*
[2]*Harvard T.H. Chan School of Public Health, Department of Epidemiology, Boston, U.S.A.*
[3]*Karolinska Institutet, Department of Epidemiology & Biostatistics, Stockholm, Sweden*

Study question: Is there a risk of pregnancy complications following ART among infertile couples, and to what extent is this independent versus mediated by multiple gestations?

Summary answer: Multiple gestations are responsible for a large proportion of common pregnancy complications following use of ART, but nearly none of the risk of placenta previa.

What is known already: Several of the pregnancy complications observed after use of ART are also common complications of multiple gestation, and since multiple gestations are more frequent following ART many studies choose to assess ART risks in singletons and multiples separately. This approach can induce bias if attention is not paid to potential common causes of the multiple gestations mediator and the pregnancy complications outcome, and it does not provide insight into how much of the effect is through the different pathways. Assessing the influence of intervention to reduce multiple gestations should be informative for both clinical practice and public health.

Study design, size, duration: Linkage of national registers allows population-based cohort studies based on prospectively collected data. The Medical Birth register consistently covers 96-99% of all births in Sweden. From the nearly 1.8 million births recorded in the register between 1996 and 2013 we selected the 9.9% (N = 174 067) pregnancies that occurred to couples with known trouble conceiving (clinical infertility).

Participants/materials, setting, methods: Information regarding infertility and fertility assistance was available from antenatal self-reports, medical records, and procedural information from fertility clinics. We used logistic

regression to estimate odds ratios (OR) and their 95% confidence intervals (CI), and decomposing the total effect into direct and mediated effects to estimate the proportion mediated by multiple gestations. Sweden's 2003 implementation of single-embryo transfer (SET) policy further allowed direct observation of an intervention to curb the occurrence of multiples following ART.

Main results and the role of chance: Although the prevalence of multiples from ART was substantially reduced by SET recommendations (13% in 1996-2003 to 6% in 2004-2013) it remained 4 times higher than in non-assisted pregnancies. Prior to the intervention, pregnancies achieved with ART had higher odds of all studied complications except gestational diabetes when compared with non-assisted pregnancies to infertile couples. Associations with placenta previa (OR 2.91, 95% CI 2.31–3.68) and placental abruption (OR 2.57, 95% CI 1.99–3.33) were found almost entirely independent of multiple gestations. In contrast, the majority of the associations with preterm birth (OR 2.79, 95% CI 2.28–3.42), cesarean delivery (OR, 1.79, 95% CI 1.54–2.08) and pre-eclampsia (OR 1.28, 95% CI 1.12–1.46) were mediated by multiple gestations (87%, 84% and 100% of the effect mediated, respectively). Both direct and mediated pathways contributed to the remaining positive associations with chorioamnionitis, labor induction, and postpartum hemorrhage. While ART remained associated with all noted complications also after the intervention (2004-2013), the excess risk dropped markedly for the complications found largely mediated by multiple gestations (preterm birth, cesarean and pre-eclampsia). In contrast, the excess risk of placenta previa was largely unchanged.

Limitations, reasons for caution: Some complications may be more likely detected or recorded in women having undergone ART and/or carrying multiples. Reassuringly, one of the more susceptible such diagnoses, gestational diabetes, was not more common in treated pregnancies, nor in pregnancies with multiples (among infertile) in our study population.

Wider implications of the findings: Interventions to curb the occurrence of multiples may greatly reduce the risk of several pregnancy complications following use of ART. Finding some risk independent of multiple gestations, especially for severe placental complications, demonstrates that pregnancies achieved after ART may be considered high-risk pregnancies irrespective of number of fetuses.

Trial registration number: Not applicable.

SESSION 74: FACTORS AFFECTING FERTILITY POTENTIAL PCOS WOMEN

Wednesday 4 July 2018 Room 111 + 112 14:00–15:15

O-285 Endometrial expression of stanniocalcin-1 (STC-1) during the menstrual cycle in healthy women and in women with polycystic ovary syndrome (PCOS)

M. Khatun[1], M. Kangasniemi[2], A. Ahtikoski[3], R.K. Arffman[2], S. Lehtonen[2], M. Paulson[4], A.L. Hirschberg[4], A. Salumets[5], L.C. Andersson[6], T.T. Piltonen[2]

[5]Institute of Clinical Medicine and Department of Biomedicine- Institute of Biomedicine and Translational Medicine- University of Tartu- Competence Centre on Health Technologies, Department of Obstetrics and Gynecology, Tartu, Estonia
[6]University of Helsinki, Department of Pathology, Helsinki, Finland

Study question: How is stanniocalcin-1 (STC-1) expressed in normal human endometrium and is it altered in women with polycystic ovary syndrome (PCOS)?

Summary answer: STC-1 was dysregulated in PCOS endometrium exerting lower expression in secretory phase and blunted response to 8-bromo-cyclic adenosine monophosphate (8-Br-cAMP) and hypoxia compared with controls.

What is known already: STC-1 has been shown to be one of the receptivity markers but also involved in cancer development. Endometrial STC-1 was recently reported to be dysregulated in endometriosis, a condition with endometrial progesterone resistance and inflammation that characterize PCOS endometrium. Given that women with PCOS present with subfertility, pregnancy complications and increased risk for endometrial cancer, we investigated STC-1 expression in PCOS endometrium.

Study design, size, duration: Prospective case-control study.

Participants/materials, setting, methods: The material consisted of prospectively collected endometrial tissue biopsies from healthy controls (n = 65) and in women with PCOS (n = 38). This sample set included endometrial biopsies from two clinical trials; 8 endometrial samples from control women using hormonal contraceptives for nine consecutive weeks and 14 endometrial samples from over-weight women with PCOS before and after 3-month life style intervention. The samples were investigated by immunohistochemistry, *in situ* hybridization, quantitative RT-PCR and *in vitro* cell culture.

Main results and the role of chance: In normal human endometrium, STC-1 was upregulated in glandular epithelium (GE) in early and mid-secretory phase (ESE and MSE) compared with proliferative phase (PE). Through all cycle phases, endometrial stromal cells showed the highest STC-1 expression in late secretory phase (LSE) ($P = 0.01$) whereas the expression was quiescent during the use of hormonal contraceptives. Interestingly, in non-PCOS women obesity seemed to increase the STC-1 expression in secretory phase ($P = 0.047$). Women with PCOS had comparable STC-1 expression in proliferative phase (PE) as controls but the rise in expression towards the secretory phase (SE) was insignificant. During induced decidualization *in vitro*, estrogen or progesterone (alone or in combination) were not able to trigger STC-1 expression in cultured stromal cells. However, decidualization with 8-Br-cAMP induced high STC-1 response in control stromal cells, whereas in women with PCOS the expression was significantly lower at mRNA ($P < 0.0001$) and protein ($P < 0.01$) levels, despite of the normal levels in classic decidualization markers. Furthermore, hypoxia triggered high STC-1 protein expression in control stromal cells that was blunted in stromal cells from women with PCOS ($P < 0.001$).

Limitations, reasons for caution: The study consists of rare endometrial tissue samples from several cycle phases and from clinical trials. However, the *in vitro* testing did not consider the role of hyperandrogenism or hyperinsulinemia, common in PCOS. Further studies are also warranted to elucidate the mechanisms behind the altered endometrial STC-1 expression in PCOS.

Wider implications of the findings: According to our findings, despite of successful decidualization in women with PCOS, aberrant STC-1 expression was observed possibly reflecting impaired and desynchronized endometrial function during implantation process. Moreover, blunted STC-1 in PCOS endometrium may promote endometrial cancer through defective rescue mechanism related to hypoxia.

Trial registration number: The study of clinical trial testing hormonal contraceptives: SYLVI ClinicalTrials.gov Identifier: NCT02352090, Karolinska Institutet ethical approval number is: IRB 2008/865-32

O-286 Clomiphene citrate or gonadotrophins in women with WHO type II anovulation and CC failure; a role for EMT?

E. Bordewijk[1], N. Weiss[1], C. Lambalk[2], M. Goddijn[1], P. Hompes[2], F. Van der Veen[1], B.W. Mol[3], M. Van Wely[1]

[1]Academic Medical Center, Center for Reproductive Medicine, Amsterdam, The Netherlands
[2]VU University Medical Center, Center for Reproductive Medicine, Amsterdam, The Netherlands
[3]Monash University, Department of Obstetrics and Gynaecology, Melbourne, Australia

Study question: Is endometrial thickness (EMT) a biomarker to select women for clomiphene citrate (CC) or gonadotrophins in women with WHO type II anovulation and CC failure?

Summary answer: EMT measured in the sixth ovulatory CC cycle can be used as biomarker to decide on continuing CC or to switch to gonadotrophins.

What is known already: CC has been a long standing first line treatment in women with normogonadotropic anovulation. We recently showed that in women with normogonadotropic anovulation and CC failure, a switch to gonadotrophins increases the chance of live birth over continued treatment with CC with 10%. This may be due to a thinner EMT after CC compared to gonadotrophins. It is unclear if EMT during ovulation induction with CC is a marker to identify women that benefit from one or the other treatment.

Study design, size, duration: Between Dec 8, 2008, and Dec 16, 2015, 666 women with CC failure (not pregnant after 6 ovulatory cycles) were randomly assigned to receive an additional six cycles with CC (335) or six cycles with gonadotrophins (n = 331). The primary outcome was conception leading to live birth within 8 months after randomisation. In 380 women EMT (n = 190 CC, n = 190 gonadotrophins) was measured before randomisation during their sixth cycle.

Participants/materials, setting, methods: We randomised women aged 18 years and older with normogonadotrophic anovulation not pregnant after six ovulatory cycles of CC from 48 Dutch hospitals. EMT was determined in the sixth cycle of CC before randomisation. An EMT of 8 mm was used as cut-off value. We evaluated if EMT at baseline had interaction with the treatment effect. To account for multiple cycles over time we used cox proportional hazard analysis to calculate hazard rates (HR).

Main results and the role of chance: The EMT of the last CC cycle before randomisation was available in 380 women, of whom 190 were allocated to CC and 190 to gonadotrophins. Among 169 women (44%) with EMT < 8 mm, the live birth rates were 33% with CC versus 54% with gonadotrophins, respectively (RR 0.64, 95% CI 0.47 – 0.87), while in 211 women (56%) with EMT > 8 mm, the live birth rates were 53% with CC versus 48% with gonadotrophins, respectively (RR 1.11, 95% CI 0.83 – 1.50).

Our analysis showed interaction between EMT and treatment success (p = 0.02). The hazard rate (HR) for a live birth in women with CC was 1.37 (95% CI 1.01–1.84) for EMT > 8 versus EMT < 8. Mean time to live birth were 5.4 and 5.8 cycles for EMT > 8 and EMT < 8 respectively (log rank test p = 0.03). The HR for live birth in women treated with gonadotrophins was 0.85 (95% CI 0.66–1.10) for EMT > 8 versus EMT < 8. Mean time to live birth were 5.2 and 4.9 cycles for EMT > 8 and EMT < 8 respectively (log rank test p = 0.2).

Limitations, reasons for caution: This was a post-hoc analysis, and EMT measurements at baseline were not available for all included women. There were many different doctors that performed the ultrasound measurements.

Wider implications of the findings: In women with CC-failure and EMT < 8 mm in the sixth cycle, a switch to gonadotrophins improves fertility outcomes over continuing CC, while in women with CC-failure and EMT > 8 mm continuing CC and switching to gonadotrophins are equally effective. This knowledge can inform clinical decision making.

Trial registration number: Netherlands Trial Register, number NTR1449

O-287 The expression and regulation of inflammatory factor interleukin-18 in the proliferative phase endometrium of PCOS

X. Long

Peking University Third Hospital, Gynecololgy and Obestetrics, beijing, China

Study question: How does the inflammatory factor IL-18 be up regulated in the endometrium of patients with PCOS and the regulatory pathway that mediates this relationship?

Summary answer: SIRT1 interacted with C/EBP-β to activate the SIRT1/C/EBP-β/IL-18 signaling pathway, resulting in the up-regulation of IL-18 expression in the endometrium of patients with PCOS.

What is known already: Polycystic ovary syndrome (PCOS) is a multisystem, reproductive-metabolic disorder characterized by polycystic-appearing ovaries, hyperandrogenism, and irregular menstruation. Recent studies have indicated that patients with PCOS exhibit chronic inflammation, which might be correlated with the pathogenesis of the disease. According to our previous studies, the inflammatory factor IL-18 is increased both in the serum and the endometrium of patients with PCOS. CCAAT enhancer-binding protein (C/EBP) beta is an important transcription factor, and it may up-regulate the expression of IL-18 in the endometrium. However, the regulatory effects of C/EBP-β on IL-18 and the signaling pathway mediating these effects have not been examined.

Study design, size, duration: Endometrial tissue samples of eighteen women with PCOS and eighteen healthy women were obtained during hysteroscopic surgery. In the present study, we explored the expression of C/EBP-β and SIRT1 in the proliferative phase of the endometrium in women with and without PCOS. We investigated whether C/EBP-β regulates IL-18 expression and explored the underlying signaling mechanism that IL-18 was up-regulate in the endometrium of PCOS patients.

Participants/materials, setting, methods: Endometrial tissue samples were obtained during hysteroscopic surgery.IL-18 protein expression was analyzed using immunohistochemistry and western blotting, and IL-18 mRNA expression was analyzed using quantitative real-time polymerase chain reaction. C/EBP-β and Sirt1 protein combination was verified with co-immunohistochemistry. The correlation of C/EBP-β and IL-18 was demonstrated with Dual-luciferase assay. SIRT1 and C/EBP-β mRNA expression was analyzed using quantitative real-time polymerase chain reaction.

Main results and the role of chance: IL-18 was significantly increased in the endometrium of women with PCOS compared with normal groups. In overweight women, IL-18 was obviously over-expressed in the PCOS group compared with the healthy group. However, in normal weight women, there was no statistically significant difference between the two groups, and there was no significant difference in IL-18 expression in PCOS patients with or without insulin resistance. We demonstrated the interaction of CEBP-β and IL-18 by Dual-luciferase assay, and we used CO-IP assay demonstrated the combination of SIRT1 and CEBP-β. Sirt1 and C/EBP-β proteins were over-expression in the endometrium of PCOS patients.

Limitations, reasons for caution: As we known, PCOS patients have irregular menstruation, so it's difficult to obtain the secretary phase endometrium. We only detected and analysed proliferative phase endometrium and larger sample size was needed to carry on.

Wider implications of the findings: We detected the up-regulation of C/EBP-β and SIRT1 in the proliferative endometrium of patients with PCOS. Additionally, SIRT1 interacted with C/EBP-β to activate the SIRT1/C/EBP-β/IL-18 signaling pathway, resulting in the up-regulation of IL-18 expression, and which may related with endometium receptivity abnormality of PCOS patients.

Trial registration number: None.

O-288 Aromatase inhibitors (letrozole) for subfertile women with polycystic ovary syndrome - A Cochrane Systematic Review

S. Franik[1], S. Eltrop[1], J. Kremer[2], L. Kiesel[1], C. Farquhar[3]

[1]University hospital Muenster, Obstetrics and Gynaecology, Münster, Germany
[2]Radboudumc, Obstetrics and Gynaecology, Nijmegen, The Netherlands
[3]University of Auckland, Obstetrics and Gynaecology, Auckland, New Zealand

Study question: Are aromatase inhibitors (letrozole) superior to other agents for ovulation induction for subfertile women with anovulatory PCOS?

Summary answer: Letrozole improves live birth and pregnancy rates in subfertile women with anovulatory PCOS, compared to clomiphene citrate.

What is known already: Polycystic ovary syndrome (PCOS) is the most common cause of infrequent periods (oligomenorrhoea) and absence of periods(amenorrhoea). It affects about 4% to 8% of women worldwide and often leads to anovulatory subfertility. Aromatase inhibitors (AIs) are a novel class of drugs that were introduced for ovulation induction in 2001. Over the last ten years clinical trials have reached differing conclusions as to whether the AI letrozole is at least as effective as the first-line treatment clomiphene citrate (CC).

Study design, size, duration: We searched the following sources from inception to November 2017 to identify relevant randomised controlled trials (RCTs): the Cochrane Gynaecology and Fertility Specialised Register, the Cochrane Central Register of Controlled Trials, MEDLINE, EMBASE, PsycINFO, Pubmed, LILACS, Web of Knowledge, the WHO clinical trials register and Clinicaltrials.gov.

We included all RCTs of aromatase inhibitors used alone or with other medical therapies for ovulation induction in women of reproductive age with anovulatory PCOS.

Participants/materials, setting, methods: Two review authors independently selected trials, extracted the data and assessed trial quality. Studies were pooled where appropriate using a fixed effect model to calculate pooled odds ratios (ORs) and 95% confidence intervals (CIs) for most outcomes and risk differences (RDs) for ovarian hyperstimulation syndrome (OHSS). The primary outcomes were live birth and OHSS. Secondary outcomes were pregnancy, miscarriage and multiple pregnancy. The quality of the evidence for each comparison was assessed using GRADE methods.

Main results and the role of chance: We included 42 RCTs (7935 women). The aromatase inhibitor letrozole was used in all studies.

Live birth rate was reported in 13 RCTs, including 2954 women. The birth rate was higher for letrozole compared to clomiphene (with or without adjuncts) followed by timed intercourse (OR 1.68, 95% CI 1.34 to 1.99, I^2 = 0%, NNT = 10).

There was no evidence of a difference in OHSS rates when letrozole (with or without adjuncts) was compared with clomiphene citrate (with or without adjuncts) followed by timed intercourse (RR 0.00, 95% CI -0.01 to 0.00, twelve RCTs, n = 2536).

Pregnanc rate was reported in 25 RCTs, including 4629 women. The pregnancy rate was higher for letrozole compared to clomiphene (with our without adjuncts) (OR 1.56, 95% CI 1.37 to 1.78, I^2 = 1%).

Miscarriage rate was reported in 18 studies, including 3754 women. There was no evidence for a difference between letrozole or clomiphene with or without adjuncts (OR 0.94, 95% CI 0.70 to 1.26, I^2 = 0%).

Multiple pregnancy rate was reported in 16 studies, including 3519 women. There was insufficient evidence to show a difference between letrozole or clomiphene with our without adjuncts (OR 0.73, 95% CI 0,43 to 1.24, I^2 = 0%).

Limitations, reasons for caution: The quality of the evidence was moderate for live birth and pregnancy outcomes. The reasons for downgrading the evidence were possible publication bias and the tendency for studies that reported live birth to report higher clinical pregnancy rates in the letrozole group than studies that failed to report live birth.

Wider implications of the findings: Our findings suggest that letrozole is superior to clomiphene citrate for the treatment of subfertility in women with PCOS who have had no previous treatment for ovulation induction or are resistant to clomiphene citrate.

Trial registration number: not applicable.

O-289 Higher probability of pregnancy after frozen-embryo transfer using a freeze-all policy compared to fresh-embryo transfer in high, but not in normal responder patients: a meta-analysis

J. Bosdou[1], C. Venetis[2], B. Tarlatzis[3], G. Grimbizis[1], E. Kolibianakis[1]

[1]*Medical School-Aristotle University of Thessaloniki-Greece, Unit for Human Reproduction-1st Dept of Obstetrics & Gynecology, Thessaloniki, Greece*
[2]*University of New South Wales, School of Women's and Children's Health UNSW Medicine, Sydney, Australia*
[3]*Aristotle University of Thessaloniki, Medical School, Thessaloniki, Greece*

Study question: Is frozen embryo transfer (ET) using a freeze-all policy associated with a higher probability of pregnancy when compared to fresh ET?

Summary answer: A higher probability of pregnancy after frozen ET using a freeze-all policy compared to fresh ET is present in high, but not in normal-responder patients.

What is known already: It has been hypothesized that freezing all embryos in a fresh in-vitro fertilization (IVF) cycle and deferring embryo transfers in subsequent cycles may provide a more physiological endometrial environment for embryo implantation when compared to fresh ET. Several relevant randomized controlled trials (RCTs) have recently been published, evaluating the effectiveness of frozen ET using a freeze-all policy compared to fresh ET either in high or in normal responder patients without, however, leading to solid conclusions.

Study design, size, duration: A systematic review and meta-analysis was performed aiming to identify RCTs comparing frozen ET, using a freeze-all policy, to fresh ET. For this purpose, a relevant literature search was carried out until January 2018. Primary outcome measure was achievement of pregnancy, expressed as ongoing pregnancy/live birth rate after the first ET, while severe ovarian hyperstimulation syndrome (OHSS) was evaluated as a secondary outcome.

Participants/materials, setting, methods: Six eligible RCTs were identified including 4831 patients that evaluated frozen ET using a freeze-all policy versus fresh ET either in high responder patients (n = 3), or in normal responder patients (n = 3). Meta-analysis of weighted data using random and fixed effects model was performed. Results are reported as relative risk (RR) with 95% confidence interval (CI).

Main results and the role of chance: The eligible RCTs were published between 1999 and 2018 and the number of patients included in the study ranged from 122 to 2157 patients (median 460). Three studies were conducted in Asia (4447 patients), two studies in USA (259 patients) and a single study in Europe (125 patients). In high responder patients, a significantly higher ongoing pregnancy/live birth rate was observed after a frozen as compared to a fresh ET (RR: 1.16, 95% CI: 1.05 to 1.29; fixed effects model; heterogeneity: I^2 = 0%; n = 1755 patients, respectively). This difference was not present in normal responder patients (RR: 1.06, 95% CI: 0.90 to 1.23; random effects model; heterogeneity: I^2 = 51%; n = 3076 patients, respectively), or overall (RR: 1.09, 95% CI: 0.98 to 1.22; random effects model; heterogeneity: I^2 = 49%; n = 4831 patients, respectively). The risk of moderate/severe OHSS was significantly lower after a frozen as compared to a fresh ET in high responder patients (RR: 0.19, 95% CI: 0.10 to 0.35; fixed effects model; heterogeneity: I^2 = 0%; n = 1633 patients, respectively), in normal responder patients (RR: 0.39, 95% CI: 0.19 to 0.80; fixed effects model; heterogeneity: I^2 = 0%; n = 2939 patients, respectively) as well as overall (RR: 0.25, 95% CI: 0.15 to 0.40; fixed effects model; heterogeneity: I^2 = 9%; n = 4572 patients, respectively).

Limitations, reasons for caution: A considerable heterogeneity was present in the cryopreservation protocols used in the eligible studies. Moreover, gonadotrophin-releasing hormone(GnRH) agonist was not used for triggering final oocyte maturation in the freeze-all arm in the eligible RCTs, which might have further increased the difference in safety between the freeze-all and fresh ET policies.

Wider implications of the findings: The results obtained might be explained by an increased deterioration of endometrial receptivity due to the more intense ovarian response in high as compared to normal responders. Concomitantly, the availability of more embryos in high as compared to normal responders might counteract whatever adverse effect cryopreservation may exert on embryos.

Trial registration number: not applicable

O-290 Endometrial receptivity assessment using a transcriptomic approach for personalized embryo transfer

D. Haouzi[1], F. Entezami[2], A. Ferrières-Hoa[3], L. Delaroche[4], E. Vintejoux[3], A. Torre[5], S. Hamamah[3]

[5]*Division of Child Health- Obstetrics & Gynaecology, Department of Obstetrics and Gynecology, Nottingham, United Kingdom*

Study question: The aim of this study was to optimize pregnancy outcome using personalized embryo replacement according to the evaluation of endometrial receptivity.

Summary answer: Individual evaluation of endometrial receptivity allows a personalized patient care management and improves pregnancy outcome for RIF patients.

What is known already: Many approaches for human endometrial receptivity including microarray has been previously reported. However, efficiency of the tests according to the clinical results is still debated. The aim of this study is to evaluate the endometrial receptivity (ER) using the **Win**dow implantation **Test** (Win Test) in RIFs patients who have had at least 3 implantation failures. The principal of concept which consisting for screening for 13 specific genes of implantation window.

Study design, size, duration: Endometrial biopsies are performed during the implantation windows 7-9 days after the LH surge or 6-9 days after progesterone administration under natural cycles and hormone replacement therapy (HRT), respectively. Then, according to the Win-test result, the transfer strategy was: transfer at the blastocyst stage at the specific day where endometrium has been diagnosed as 'receptive'; transfers at day 2/3 post-fertilization when endometrium is said 'partially receptive'. For non-receptive samples, a second evaluation is proposed later.

Participants/materials, setting, methods: 665 RIF patients with a number of previous failed attempts and number of non-implanted embryos after fresh or frozen embryo transfer cycles was 4.3 ± 2.5 and 7.3 ± 4.2, respectively, were included. RNAs from biopsies were extracted and determination of the mRNA expression levels of 13 genes predictive of endometrial receptivity referred in the Win-Test by qRT-PCR. Clinical pregnancy was defined by visualization of a gestational sac with a positive foetal heart beat.

Main results and the role of chance: Analyses of endometrial receptivity status (n = 1237 biopsies) in a large cohort of 665 RIF patients (age mean ± SD: 37.5 ± 4.6 years) revealed that a strong inter-patient variability i) of the moment of the opening of the implantation window with a delay for the majority of RIF patients between 1 to 4 days, as well as ii) of the duration of this implantation. Then, as soon as the cycle day where endometrium was said receptive, a personalized embryo transfer can to be perform during a subsequent attempt in the respect of the synchronization of the fœto-maternal dialogue. 75 % of personalized embryo transfer have been performed under HRT and 25 % under natural cycles. The implantation rate before and after personalized embryo transfers was 5.5 *vs* 22.7 %, respectively ($p < 0.0001$). Using this strategy, the positive b-hCG and clinical pregnancy rate per cycle in this group of patients with previous RIFs were 39.4 and 25.5 %, respectively (65 and 27 % with blastocysts and day-3 embryo transfers).

Limitations, reasons for caution: The benefits of this innovative strategy will be analyzed in PGS patients.

Wider implications of the findings: This finding demonstrated that for the majority of RIF patients, a delay in their opening implantation window was responsible for the implantation failure. Personalized embryo transfer according to the specific cycle day where endometrium is said receptive improves both implantation rate and pregnancy outcome in RIF patients.

Trial registration number: Not applicable

O-291 Live birth rate after frozen-thawed embryo transfer according to endometrial preparation: mild gonadotropin ovarian stimulation leads to increased success compared to artificial cycle

S. Epelboin[1], X. Ferraretto[2], E. Devouche[3], S. Gricourt[4], C. Gauche-Cazalis[5], J. Lepage[6], C. Patrat[7], D. Luton[8], M. Peigne[9]

[9]Assistance Publique Hôpitaux de Paris Hôpital Bichat-Claude Bernard, Gynecology Obstetrics and Reproductive Medecine, Paris, France

Study question: Which endometrial preparation allows a better outcome after frozen-thawed embryo transfer (FET) between mild stimulated (OS) and artificial cycles (AC)?

Summary answer: Despite a similar pregnancy rate, live birth rate (LBR) was significantly higher with mild OS than with AC preparation, even after adjusting for potential confounders.

What is known already: The best protocol to prepare the endometrium for FET is still debated. A recent meta-analysis concluded that outcomes with natural cycles (NC) were similar to those with AC, but that mild OS may be promising. Some authors described a higher pregnancy rate in AC versus NC, but no significant difference in LBR was found due to higher pregnancy loss rate in AC. A deficient luteal phase in AC group could explain an asynchronised window of implantation leading to pregnancy losses. With OS preparation, a secreting corpus luteum leads to more constant progesterone level. Moreover, hCG triggering can sustain luteotropic effect.

Study design, size, duration: We conducted a retrospective study including all 1021 FET(issued from 1313 started cycles) performed in one French academic fertility centre from January 2013 to December 2016. We compared clinical pregnancy rate (PR), ongoing PR at 12 weeks of gestation (WG), and LBR, according to mild OS or AC endometrial preparation.

Participants/materials, setting, methods: In OS group, gonadotropins (37.5 to 75 IU/day) were initiated between Day 2 and 10 followed by r-hCG triggering. Vaginal micronized progesterone (200 mg/day) was given for 6 WG if pregnancy. In AC group, estradiol orally (4 or 6 mg/day) or transdermally (200 µg/3days) started on Day 1. Vaginal micronized progesterone (600 mg/day) was added to E2 for 12 WG if pregnancy. FET was performed according to embryos stage. Data were analysed using a multiple regression model.

Main results and the role of chance: Among 1021 FET, 357 (35%) patients received OS and 664 (65%) AC preparation. No difference in cycle cancellation rates was observed between both groups. They were comparable for maternal ages (at transfer and at freezing), body mass index, history of recurrent pregnancy losses, viral status and smoking habits. As expected, patients in AC group suffered more from endometriosis (18.5% vs 12.9%; p = .021) and Polycystic Ovarian Syndrome (PCOS) (21.7% v 10.9%; p<.0001) than patients in mild OS group in which masculine infertility was more frequent (49.3% vs 41.1%; p=.012). There was no difference between groups concerning endometrial thickness, number of embryos transferred, development stage at FET, cryopreservation technique, duration of cryopreservation, number of intact blastomeres post thawing for cleaved embryos, embryos' survival. Despite a similar clinical PR (24.4% vs 20.8%; p=.189), the ongoing PR at 12 WG was significantly increased in the OS compared to AC group (17.9% vs 11%; p=.002), leading to an increased LBR (17.1%vs 9.8%; p<.001). After adjusting for parameters usually linked to early pregnancy losses (woman age at freezing, smoking status, PCOS, endometriosis and previous miscarriages), the results remained significant.

Limitations, reasons for caution: Retrospective design of the study may potentially have introduced bias, and the size of the cohort, although more than 1000 cycles, could induce a lack of power to analyze subgroups.

Wider implications of the findings: In the light of LBR results and specific concerns about effects of extended hormonal treatment on periconceptional environment, the first intention endometrial preparation for FET should be OS in most cases. Nevertheless, if AC, a potential defect of luteal phase must be tracked, and treatment adapted to avoid pregnancy losses.

Trial registration number: Not applicable.

O-292 Early stop of progesterone supplementation after confirmation of pregnancy in IVF/ICSI fresh embryo transfer cycles of poor responders does not affect pregnancy outcome

S.P. Pan[1], K.H. Chao[1], M.Y. Wu[1], M.J. Chen[1], C.H. Chang[2], J.H. Yang[1], S.U. Chen[1]

[1]*National Taiwan University Hospital, Department of Obstetrics & Gynecology, Taipei, Taiwan R.O.C.*
[2]*National Taiwan University Hospital, Department of Medical Research, Taipei, Taiwan R.O.C.*

Study question: Does early stop of progesterone supplementation after confirmation of pregnancy affect reproductive outcomes of patients with poor ovarian response (POR) in IVF/ICSI-embryo transfer (ET) cycles?

Summary answer: Women with POR using hCG as luteal phase support (LPS) in fresh ET cycles can safely discontinue progesterone supplementation after positive pregnancy test.

What is known already: Some studies found no significant differences in miscarriage, ongoing pregnancy and live birth rates between general IVF patients who underwent early progesterone cessation and those who received progesterone until gestational age of 7-9 weeks. However, the usual practice of most physicians is to continue progesterone supplementation rather than to take a risk of miscarriage from an earlier stop.

Study design, size, duration: A retrospective cohort study was conducted for patients in IVF/ICSI and fresh ET cycles in single center between January 2010 and June 2016 (N = 4,320 cycles). Patients with POR using hCG as LPS were investigated (N = 480 cycles). Those had negative pregnancy test, ectopic pregnancy or loss of follow-up were excluded (N = 324 cycles). We used the Bologna criteria to define POR.

Participants/materials, setting, methods: The pregnant women of POR were included in this study (N = 156 cycles). They were divided into two groups: one stopped LPS from day of positive pregnancy test (N = 100 cycles), and the other kept progesterone supplementation until 7-9 gestational weeks (N = 56 cycles). We compared implantation, clinical pregnancy, ongoing pregnancy and live-birth rates between the two groups. The data were analyzed with independent t-test, Chi-square test and multivariable logistic regression.

Main results and the role of chance: There were no significant differences in age, body mass index, gravida, parity, causes of infertility, stimulation protocols, hormone data, number of embryos transferred and endometrial thickness between the early stop group and control group. The adjusted odds ratios (AORs) with 95% confidence intervals (CI) were calculated by adjusting for the confounders of stimulation duration and number of oocytes retrieved. After adjustment with multivariable logistic regression analysis, the implantation percentages (81.0% vs. 73.2%, AOR = 1.44, 95% CI: 0.64-3.22), clinical pregnancy rates (55.0% vs. 57.1%, AOR = 1.72, 95% CI: 0.35-1.45), ongoing pregnancy rates (47.0% vs. 46.4%, AOR = 0.86, 95% CI: 0.43-1.71) and live-birth rates (44.0% vs. 46.4%, AOR = 0.75, 95% CI: 0.37-1.50) were not statistically different between early stop group and the control group.

Limitations, reasons for caution: Some limitations included the retrospective nature and somewhat small sample sizes. Whether the early stop of progesterone can be applied for every patient or not for patients of POR using progesterone without hCG for LPS is not studied in this work. This condition may deserve further research.

Wider implications of the findings: We may suggest that an early stop could be based on endogenous activity of corpus luteum by detection of serum progesterone and estradiol levels on the day of pregnancy test.

Trial registration number: Not applicable

O-293 CSRP2BP is a novel marker in trophoblast development and preeclampsia pathogenesis

Y. Ma[1], Q. Jie[2], Z. Wang[1], Y. Wei[1], P. Long[1], C. Tang[1], Q. Li[1], Y. Yu[2]

[1]*The Affiliated Hospital of Hainan Medical College, Reproductive Medical Center, Haikou, China*
[2]*Nanfang Hospital- Southern Medical University, Department of Obestetrics and Gynecology, Guangzhou, China*

Study question: What is the potential function of Cysteine-Rich Protein 2-Binding Protein (CSRP2BP) in the pathogenesis of preeclampsia(PE).

Summary answer: CSRP2BP plays an important role in the pathogenesis of PE by influencing the function of the trophoblast cells.

What is known already: PE is the leading cause of maternal and perinatal mortality and morbidity. The underlying mechanism is still not completely elucidated. Epigenetic abnormalities might be closely related to the pathogenesis of PE. CSRP2BP is a newly defined histone acetyltransferase, however, the research of its function in human cells is very limited. It will be interesting to explore the potential role of CSRP2BP in the process of early trophoblast development and pathogenesis of PE.

Study design, size, duration: The relationship of CSRP2BP expression and PE was explored in clinical samples. Meanwhile, Lentivirus systems and CRISPR/case9 technology were used to generate loss and gain of function models with trophoblast cell line-HTR8 to study the role of CSRP2BP in the pathogenesis of PE.

Participants/materials, setting, methods: We examined the expression of CSRP2BP in placentas from PE patients and normal controls. CSRP2BP loss and gain of function models were generated in HTR8 cells by using lentivirus and with CRISPR/case9 technology. Transwell assays, scratch-wound assays, EDU, cell apoptosis assays and cell cycle assays were used to examine the function of CSRP2BP in HTR8 cells model. RNA-seq was used to examine the gene expression panel which might be regulated by CSRP2BP.

Main results and the role of chance: CSRP2BP was enriched in the nucleus of trophoblast cells from early pregnant stage. It was significantly decreased in placental tissues of PE patients compared with those in control group by qPCR, western blotting and immunohistochemistry. The current data demonstrated that knockdown of CSRP2BP in HTR8 dramatically decreased cell proliferation, cell migration and invasion. It also showed a significantly lower plate clone formation rate in CSRP2BP knockdown -HTR8 cells compare with the WT HTR8 cells.

Limitations, reasons for caution: Although we show that CSRP2BP play an important role in the function of HTR8 by shRNA, the study of working mechanism of CSRP2BP in PE is still very limited. More studies will be performed to explore its underline mechanism.

Wider implications of the findings: This study was the first time to explore the role of CSRP2BP in PE. It will help us to better understand the pathogenesis of PE, which might be helpful to discover novel therapeutic targets in diagnosis and treatment of PE.

Trial registration number: not applicable.

O-294 Reproductive outcome following hyaluronic acid gel application after D&C in women with at least one previous curettage; long-term outcomes of a multicenter, prospective randomized trail

A. Hooker[1], R. Leeuw de[2], P. Van de Ven[3], J. Huirne[2]

[1]*Zaans Medical Center ZMC, Department of Obstetrics and Gynaecology, Zaandam, The Netherlands*
[2]*VU University medial center, Department of Obstetrics and Gynaecology, Amsterdam, The Netherlands*
[3]*VU University medial center, Department of Epidemiology and Biostatistics, Amsterdam, The Netherlands*

Study question: Does intrauterine application of auto-crosslinked hyaluronic acid (ACP) gel following dilatation and curettage (D&C) for miscarriage in women with at least one previous D&C improve reproductive outcome?

Summary answer: Reproductive performance was similar in both groups, with a tendency to a higher pregnancy and live birth rate in women who received ACP gel.

What is known already: Intrauterine adhesions (IUAs) are reported in 19% of women after miscarriage; women with more than one D&C have statistically significant more IUAs compared to women with one D&C. Intrauterine application of ACP gel following D&C for miscarriage in women with at least one previous D&C significantly reduces the incidence and severity of IUAs. Data on reproductive performance following application of ACP gel are lacking.

Study design, size, duration: In the Prevention of Adhesion Post Abortion (PAPA) trial, a multicentre, prospective randomised controlled trail 152 women with an (incomplete) miscarriage or retained products of conception (RPOC) with at least one D&C in history were randomised to D&C plus ACP gel or D&C alone (control group). The study was conducted between December 2011 and July 2015 in 8 centers in the Netherlands. Written and signed informed consent was provided by all participants at inclusion.

Participants/materials, setting, methods: 149 Participants, 77 assigned to the intervention group and 72 to the control group received questionnaires three, six and twelve months after the D&C-procedure. The questionnaire consisted of questions regarding baseline characteristics, current health, interventions received and complications, menstrual pattern, contraceptive use, conception and reproductive outcomes. In women willingly to conceive, miscarriage, ongoing pregnancy and live birth rates were assessed. non-responders were comtacted to minimize follow-up.

Main results and the role of chance: The overall response rate for the questionnaires was 94% at twelve months. There was no significant difference in the menstrual characteristic of the responders in both groups. In the intervention group 84.9% (62/73) versus 88.6% (62/70) women in the control group attempted to conceive. After twelve months 71% conceived in the intervention group compared to 59.7% in the control group, $p = 0.56$. There was no statistical difference in the cumulative miscarriage, ongoing and live birth rate between the two groups. The median time to conception was 5.5 months in the intervention group versus 7.1 months in the control group, hazard ratio (HR): 1.40, 95% Confidence interval (CI): 0.92 – 2.14, $p = 0.12$). Time to conception that resulted in life birth did not reach statistical significance (HR: 1.40, 95% CI: 0.76 – 2.57, $p = 0.28$).

Limitations, reasons for caution: IUAs encountered during follow-up were treated, it was considered unethical not to perform adhesiolysis because of the possible negative impact on fertility and pregnancy outcomes. This RCT was powered to detect differences in occurrence of IUAs between the groups. No power analysis was performed for reproductive outcomes.

Wider implications of the findings: Intrauterine application of ACP gel immediately following D&C for miscarriage reduces the incidence and severity of IUAs. In this study, we did not find any statistical significant, probalby due to the removal of existing IUAs during the routinely planned postoperative hysteroscopy and insufficient powerto detect relevant differences.

Trial registration number: NTR3120 (Dutch Clinical Trail Registry).

[4]Pôle Femmes-Mères-Enfants- Centre Clinico-biologique d'AMP- AP-HM, Hopital de la Conception, Marseille, France

Study question: Does oocyte DNA damage induced by a previous in vivo mouse exposure to chemotherapy agents is transmissible to preimplantation embryos?

Summary answer: DNA damage was observed in preimplantation embryos issued from mice previously exposed to daunorubicin and cytarabine.

What is known already: In acute leukemia, the emergency to start a chemotherapy don't allow a fertility preservation at the time of diagnosis. Some authors have proposed to cryopreserve mature oocytes or embryos after a controlled ovarian stimulation applied shortly after the induction chemotherapy, which is mainly composed by daunorubicin and cytarabine, and reputated to be less gonadotoxic than alkylant agents. We previously observed DNA damage on mouse oocytes issued from antral follicles exposed in vivo to daunorubicin and cytarabine. Little is known about the risk of transmission of oocyte DNA damage to preimplantation embryos after fecundation of oocytes recently exposed to chemotherapy.

Study design, size, duration: By three time, two groups of mice ($n = 11$) were exposed for four days to cytarabine (10 mg/kg IP) or every two days to daunorubicin (1 mg/kg IV). Each group was compared with a negative control group ($n = 11$) and with a positive control group ($n = 11$) injected with cyclophosphamide (75 mg/kg IP). Females were mated one week after exposure and preimplantation embryos were collected by flushing the oviducts.

Participants/materials, setting, methods: 4 weeks female CD1 mice were mated one week after exposure for studying embryos conceived from oocytes exposed to chemotherapy at late pre-antral stage of follicular development. Cytotoxicity has been assessed by ovulation and fertilization rates and by embryo morphology. DNA embryonic damage was assessed by: (i) alkaline comet assay to quantify the tail DNA (ii) fluorescent immunohistochemical staining in blastomeres to quantify accumulating γH2AX foci.

Main results and the role of chance: In mouse, a recent exposure to daunorubicin and cytarabine did not alter the ovarian response to controlled ovarian stimulation with no adverse impact on the fertilization rate and the number of embryo conceived. Ovulation and fertilization rates in mice previously exposed to daunorubicin and cytarabine were similar to those in our negative control group. One week after exposure, we observed with the comet assay a significant increase of embryonic DNA damage after exposure to daunorubicin (16.57 ± 1.3, $p = 0.0003$) and cytarabine (16.46 ± 1.4, $p = 0.0003$) Vs 26.16 ± 2.5 after cyclophosphamide exposure ($p < 0.0001$) and $7{,}01 \pm 1{,}1$ in negative control group exposed to an injection of sterile saline solution. The analysis γ-H2AX on embryos showed a significant increase of foci corresponding to DNA double-strand breaks, after exposure to daunorubicin (7.97 ± 1.1; $p = 0.001$), cytarabine (6.47 ± 0.7, $p = 0.0039$), cyclophosphamide (5.92 ± 0.9; $p = 0.0148$) compared with negative control group ($2{,}8 \pm 0{,}7$).

Limitations, reasons for caution: Mouse oocyte DNA is not exactly similar to human oocyte DNA, and would be more sensitive to genotoxic effects of chemotherapy agents. After chemotherapy, the kinetic of DNA repair before and after fertilization has to be studied by further assays in exposed oocyte and in embryos.

Wider implications of the findings: DNA damage in preimplantation embryos conceived from oocytes exposed to chemotherapy at late pre-antral stage of follicular development lead us to hypothese a transmission of oocyte DNA damage to preimplantation embryo. In acute leukemia, we strongly advise to not cryopreserve mature oocytes or embryo early after induction chemotherapy.

Trial registration number: Experimental protocols and animal handling procedures were reviewed by the French National Ethics Committee on Animal Experimentation (N° 2017033010523688).

O-296 Dynamic regulation of germline-soma communication during oocyte meiotic maturation

L. Abbassi[1], Q. Yang[2], S. El-Hayek[3], H. Clarke[4]

[1]Research Institute of McGill University Health Center, Experimental Medicine, Montreal, Canada
[2]McGill University, Research Institute of McGill University Health Center, Montreal, Canada
[3]Research Institute of McGill University Health Center, Departments of obstetrics and gynecology- Department of Biology, Montreal, Canada
[4]Research Institute of McGill University Health Center, Departments of Obstetrics and gynecology- Experimental Medicine- and Biology, Montreal, Canada

Study question: What happens to the structures coupling the oocyte to the surrounding follicular cells during meiotic maturation? If there are changes, which molecular mechanisms regulate them?

Summary answer: TZPs are lost during the oocyte meiotic maturation under the regulation of EGF-ERK MAPK-ROCK pathway in the cumulus-cells as well as nuclear maturation in oocyte.

What is known already: During the oocyte in mammals, cytoplasmic extensions termed transzonal projections (TZPs) emanate from the granulosa cells, traverse the zona pellucida, and contact the oocyte plasma membrane, enabling transmission via gap junctions of essential signals and metabolites from the granulosa cells to the growing oocyte. During maturation, gap junctional communication is shut off, and TZPs no longer couple the mature metaphase II egg to the adjacent granulosa cells. These results suggest that a mechanism is activated during maturation that leads to the loss of TZPs, thus freeing the oocyte from somatic regulatory signals.

Study design, size, duration: Cumulus-oocyte complexes (COCs) were obtained from antral follicles of mice and incubated under conditions that promote maturation. TZP-numbers were assessed at different time-points. Drugs targeting specific signaling pathways and developmental progression of the cumulus granulosa cells and oocyte were used to identify the to identify molecular mechanisms and relative role of the two cell types in regulating these changes.

Participants/materials, setting, methods: TZPs were stained using fluorochrome-conjugated phalloidin, an actin filament-binding protein, and imaged using high-resolution confocal microscopy. TZPs numbers were quantified using customized mathematical function. Pharmacological manipulation of oocyte meiotic maturation, and ERK MAP kinase and Rho-associated protein kinase activities was used to identify mechanisms that trigger TZPs loss during oocyte maturation. All experiments were performed a minimum of three times.

Main results and the role of chance: When COCs were incubated in the presence of epidermal growth factor (EGF) to reproduce the physiological mechanism of maturation, TZPs underwent retraction, forming large foci of actin in the cumulus granulosa cells, such that fewer than 10% remained by 8 hr after maturation initiation. Strikingly, although β-catenin and E-cadherin were lost from the oocyte plasma membrane during maturation, EGF-stimulated retraction of TZPs was unaffected when oocyte maturation was prevented using inhibitors targeting either cyclin-dependent kinases or phosphodiesterase 3 A, indicating that retraction does not require oocyte maturation. In contrast, it was almost completely prevented by U0126, an inhibitor of the ERK MAP kinase signalling pathway. Moreover, cumulus cell-oocyte gap junctional communication was retained in the presence of U0126, indicating that the TZPs remained functional. EGF-driven loss of TZPs was also blocked by Y-27632, an inhibitor of Rho-associated protein kinase (ROCK), suggesting that EGF induces TZPs loss via Rho kinase activity in the cumulus granulosa cells. Altogether, our findings suggest that activation of the EGF-ERK MAPK-ROCK signaling pathway in cumulus granulosa cells triggers the loss of TZPs during oocyte maturation under physiological conditions.

Limitations, reasons for caution: Mechanisms controlling meiotic maturation and TZP dynamics may differ among species. In vitro studies using drugs may not recapitulate the conditions of oocyte development in vivo.

Wider implications of the findings: Inappropriate activation of ERK signalling in the granulosa cells surrounding growing oocytes may trigger precocious uncoupling between the two cell types prior to the oocyte completing preovulatory development, resulting in oocytes incapable of being fertilized and giving rise to a healthy embryo.

Trial registration number: not applicable

O-297 Plasma microRNAs identified as novel markers of successful implantation

S. Khanjani, R. Islam, S. Lavery, P. Bennett

Imperial College London, Reproductive Medicine, London, United Kingdom

Study question: Can plasma miRNA expression be used as biomarker for 'receptivity' to predict IVF treatment outcome?

Summary answer: 3 distinct miRNAs were found to have a statistically significant expression between the subsequently pregnant and non-pregnant groups.

What is known already: MicroRNAs (miRNAs) are small non-coding RNAs critical for regulating cellular functions. There is growing evidence supporting a role for microRNAs in embryonic and endometrial cell function. miRNAs are present within cells and are exported into plasma where their stability makes them potential biomarkers for health and disease.

Study design, size, duration: This was a prospective cohort study conducted at the IVF unit at Hammersmith Hospital over 6 months. A cohort of 12 patients was used for miRNA analysis selected to exclude confounding factors. Selected patients i) underwent a fresh cycle of IVF, ii) had AMH 5-25, ii) had no endometrial disease and iv) had a single top quality blastocyst transferred. Pregnancy outcomes were recorded.

Participants/materials, setting, methods: Blood samples were collected at two time points, first prior to the start of the IVF treatment cycle and secondly on the day of embryo transfer prior to the procedure. miRNA was extracted using Norgen Biotek kit. miRNA expression profile was obtained using nCounter™ assay. Analysis was performed separately on matching samples before and after the start of treatment and data from women who went to to be pregnant was compered to those who didn't.

Main results and the role of chance: 15 mRNAs were identified to have statistically significant differential expression following IVF treatment compared with matching samples before treatment. 3 distinct miRNAs were found to have a statistically significant expression between the subsequently pregnant and non-pregnant group. Pathway analysis strongly indicated that the identified miRNAs are essential for immune and inflammatory processes. The results have been replicated using PCR.

Limitations, reasons for caution: Due to stringent selection criteria we could only include 12 patients. a replication study is underway and the results have been replicated using PCR.

Wider implications of the findings: To our knowledge, this is the first study that has identified plasma miRNAs as biomarkers of implantation. Once utility is confirmed in replication cohorts these biomarkers have the potential to improve IVF success rates by identifying the cycle with best endometrial receptivity.

Trial registration number: not applicable.

O-298 Progesterone/estradiol (P4/E2) ratio in hormone replacement cycles can predict ongoing pregnancy rates: a prospective study

S. Taguchi, M. Funabiki, N. Amano, T. Takano, Y. Okudaira, N. Suzuki, E. Kawase, L. Young, M. Kobatake, P. Zada, Y. Nakamura

Oak Clinic Infertility Center, Research, Osaka, Japan

Study question: Is progesterone/estradiol (P_4/E_2) ratio useful for predicting ongoing pregnancy rates?

Summary answer: Our data indicate that the P_4/E_2 ratio in hormone replacement cycles can predict ongoing pregnancy rates.

What is known already: P_4/E_2 ratio has been suggested as a marker for prediction of clinical pregnancy rates, but the evidence is conflicting. Furthermore, no prospective study evaluating the clinical value of P_4/E_2 ratio in hormone replacement cycles has been published.

Study design, size, duration: This prospective study evaluated infertile patients (n = 500, median age, 37.8 years old) at our clinic in Japan between July 2016 and December 2017. We evaluated P_4/E_2 ratio in patients undergoing a hormone replacement regimen (Estrogel®: 2.16 mg/day estrogen conversion after 2nd day of menstruation) for thawed blastocyst transfer.

Participants/materials, setting, methods: P_4/E_2 ratio was calculated as P_4 (ng/ml) × 1,000/E_2 (pg/ml). Receiver operating characteristic curve analysis was performed for P_4/E_2 cut-off values detrimental to *in vitro* fertilization (IVF)/intracytoplasmic sperm injection (ICSI)-embryo transfer (ET) outcome. Ongoing pregnancy rate was the primary outcome. Mann-Whitney and chi-square tests were used for statistical analyses. Furthermore, multiple logistic regression was used to study associations between variables and the P_4/E_2 ratio. $P < 0.05$ was considered significant. All patients gave informed consent.

Main results and the role of chance: The optimal cut-off value for P_4/E_2 ratio in hormone replacement cycles was 14.75. Ongoing pregnancy rates were significantly higher at a cut-off value >14.75 than at ≤14.75 (48.6% vs. 22.4%, P < 0.001). Furthermore, the P_4/E_2 ratio in hormone replacement cycles was an independent predictor of ongoing pregnancy rates (P = 0.001), regardless of patient's age (P = 0.53), body mass index (P = 0.17), and endometrial thickness (P = 0.06) in multiple logistic regression analysis. Moreover, sensitivity was 81% and specificity was 70%.

Limitations, reasons for caution: Findings in the present study are limited to a hormone replacement regimen used in our patient population.

Wider implications of the findings: P_4/E_2 ratio in hormone replacement cycles would be useful as a predictor of ongoing pregnancy rates.

Trial registration number: UMIN000016919

O-299 Progesterone levels but not endometrial thickness influence the effectiveness of freeze-only versus fresh embryo transfer: a prespecified subgroup analysis of a randomized clinical trial

T.N.L. Vuong[1], T.D. Pham[2], V.Q. Dang[2], T.M. Ho[2], V.N.A. Ho[2], R.J. Norman[3,4], B.W. Mol[3,5]

[1]University of Medicine and Pharmacy at Ho Chi Minh City, Department of Obstetrics and Gynecology, Ho Chi Minh, Vietnam
[2]My Duc Hospital, IVFMD Center, Ho Chi Minh City, Vietnam
[3]Department of Medicine- University of Adelaide, The Robinson Research Institute, Adelaide, Australia
[4]Fertility SA, Fertility SA, Adelaide, Australia
[5]The South Australian Health and Medical Research Institute, The South Australian Health and Medical Research Institute, Adelaide, Australia

Study question: Can progesterone level or endometrial thickness be used to predict whether a freeze-only or fresh transfer strategy will result in a higher ongoing pregnancy rate?

Summary answer: Women with a serum progesterone >1.14 ng/mL undergoing stimulated IVF will likely benefit from use of a freeze-only approach over a fresh embryo transfer.

What is known already: Both progesterone level and endometrial thickness are potential predictors of outcomes during IVF cycles. Higher progesterone levels at trigger have been associated with lower implantation and ongoing pregnancy rates in fresh embryo transfer cycles, and this might be prevented by using a freeze-only strategy. In addition, thinner endometrium might decrease the chances of successful pregnancy. However, data on the usefulness of both biomarkers are not based on randomized comparisons of the two embryo transfer strategies. We evaluated whether progesterone levels and endometrial thickness can be used as biomarkers to guide a decision about whether to use fresh or frozen transfer.

Study design, size, duration: We present a prespecified secondary analysis of data from a randomised controlled trial (RCT) performed in a large IVF unit in Ho Chi Minh City, Vietnam including 782 women undergoing IVF (Vuong LN, et al. NEJM 2018;378:137-147). The primary endpoint was ongoing pregnancy after the first transfer.

Participants/materials, setting, methods: Infertile women scheduled for IVF with ≤1 previous IVF cycle were randomised to a freeze-only strategy (n = 391) or fresh embryo transfer (n = 391). IVF was performed using a gonadotropin-releasing hormone antagonist protocol. Progesterone level was measured on the day of trigger and endometrial thickness (transvaginal ultrasound) on day 3 after ovum pick-up. We explored the impact of both markers by testing for interaction, and by assessing the treatment effect in four quartiles.

Main results and the role of chance: The initial comparison of all patients showed the interaction between serum progesterone and treatment group for ongoing pregnancy after the first embryo transfer was of borderline statistical significance (p = 0.051). When serum progesterone levels were in the third quartile (Q3, 1.14–1.53 ng/mL), ongoing pregnancy rate was significantly higher in the freeze-only versus fresh embryo transfer group (42.9% vs 24.7%, p = 0.01), while in Q4 the ongoing pregnancy rate was numerically, but not statistically significantly, higher in the freeze-only versus fresh transfer group (35.7% vs 26.9%, p = 0.21). Conversely, when serum progesterone was low (Q1, 0.03–0.82 ng/mL), there was a trend towards a lower ongoing pregnancy rate with freeze-only compared with fresh embryo transfer (33.3% vs 46.6%, p = 0.078). The ongoing pregnancy rate after first embryo transfer did not differ significantly in the freeze-only and fresh embryo transfer groups across all quartiles of endometrial thickness, and there was no significant interaction between endometrial thickness and treatment group for ongoing pregnancy rate. In women with an endometrial thickness below the 10th percentile (<10 mm), ongoing pregnancy rates were 10/30 (33.3%) in the freeze-only group versus 11/40 (27.5%) in the fresh transfer group (relative risk 1.21, 95% confidence interval 0.59–2.47).

Limitations, reasons for caution: Although this analysis was included in the parent RCT protocol, it is a secondary analysis of data. In addition, division of patients into subgroups based on serum progesterone level or endometrial thickness quartiles meant that the sample size in each group was reduced, which affects the power of this analysis.

Wider implications of the findings: Use of a freeze-only strategy could maximise ongoing pregnancy and live birth rates in women with a high serum progesterone level undergoing stimulated IVF. Based on the current findings, treatment decisions regarding a freeze-only strategy do not need to be modified based on endometrial thickness.

Trial registration number: NCT02471573 (clinicaltrials.gov)

[5]Igenomix Foundation/INCLIVA, Igenomix Foundation/INCLIVA, Valencia, Spain
[6]Valencia University, Department of Obstetrics and Gynecology, Valencia, Spain

Study question: Does an RNA sequencing study from endometrium and blood reveal new endometrial receptivity-related microRNAs in healthy women and in patients with recurrent implantation failure (RIF)?

Summary answer: Several annotated and one novel microRNA were found as differentially expressed between early secretory *vs.* mid-secretory phase samples in addition to microRNAs dysregulated in RIF.

What is known already: The involvement of miRNAs in mid-secretory endometrial functions has been shown and aberrant expression of miRNAs in RIF has been identified in a few previous studies, but not from whole blood samples. However, as the analysis settings and platforms have been different and a small number of samples has been analysed, there is no consensus about the miRNAs involved in endometrial receptivity and dysfunction.

Study design, size, duration: Our current study recruited 39 fertile women and 38 infertile RIF patients from Estonia (EST) and Spain (ESP). Paired endometrial and blood samples were collected at early secretory and mid-secretory phases from fertile women and at mid-secretory phase from infertile RIF patients. This is the largest miRNA endometrial receptivity study to date with

novel aspects of combining matched samples of endometrium and blood from two different population cohorts.

Participants/materials, setting, methods: Samples were subjected to Illumina small RNA sequencing. Annotated and novel miRNAs were identified from sequencing reads by miRDeep2 algorithm. miRNAs with significantly altered levels between the study groups in both EST and ESP datasets were considered as differentially expressed. Ingenuity Pathway Analysis was applied for identifying miRNA target genes and canonical pathways from matched mRNA data. Custom TaqMan Small RNA assay was used for the validation of novel miRNA expression levels.

Main results and the role of chance: Among fertile women, 91 differentially expressed miRNAs were identified in mid-secretory *vs.* early secretory endometrium, while no differentially expressed miRNAs were found in the corresponding blood samples. The comparison of mid-secretory phase samples between fertile women and RIF patients revealed 21 differentially expressed miRNAs from endometrium and one from blood samples. miRNA target gene prediction analysis using our mRNA sequencing data from the matched samples detected several canonical pathways to be involved in mid-secretory endometrial functions, including JAK/STAT signalling, leptin signalling and growth hormone signalling. Moreover, JAK/STAT signalling pathway was also revealed in miRNA target analysis of mid-secretory endometrium from RIF patients when compared to fertile women. Further, our study results highlight the involvement of miR-30 and miR-200 families in endometrial receptivity, and miR-424-5p in the development of endometrial dysfunction. We identified several novel miRNAs, of which miRNA chr2_4401, being 37-fold up-regulated in mid-secretory phase, has a potential role in the mid-secretory endometrial functions. From blood samples we identified miR-30a-5p as a possible marker of infertility related to RIF.

Limitations, reasons for caution: Our stringent analysis approach of matching two cohorts and analysing only the common miRNA and mRNA lists could have resulted in missing some true-positive results. Functional experiments to determine the role of differentially expressed miRNAs were not performed.

Wider implications of the findings: In addition to novel findings, our study results agree with previously published data implicating that miR-30 and miR-200 family members are involved in endometrial transition from pre-receptive to receptive state. Our results together with previous studies indicate that miRNAs play an important role in the regulation of endometrial receptivity functions.

Trial registration number: not applicable.

O-301 Sirolimus as a new drug for treatment of RIF patients with elevated Th17/Treg Ratio: a randomized, double-blind, phase II clinical trial

M. Ahmadi[1], S. Danaii[2], K. Berjis[3], M. Nouri[4], M. Yousefi[5]

[5]Department of Immunology- School of Medicine- Tabriz University of Medical Sciences- Tabriz- Iran, Department of Immunology, Tabriz, Iran

Study question: Can we improve clinical pregnancy and ongoing pregnancy in recurrent implantation failure (RIF) patients with increased Th17/Treg ratio by immunosuppressive agent Sirolimus?

Summary answer: Sirolimus treatment in RIF patients can decrease Th17/Treg ratio and improve clinical pregnancy rate and ongoing pregnancy rate.

What is known already: RIF is clinically defined as the failure of good quality embryos to implant into the uterus following at least three cycles of IVF/ET. During pregnancy, a genetically different fetus is allowed to survive within the uterus despite the maternal recognition of fetal alloantigens. Compared with normal pregnancy early loss of embryo is associated with systemic lower levels of Treg cells in IVF. Several lines of evidence have indicated that differentiation of naive T cells into Th17 is deleterious for normal pregnancy and may cause implantation failure. Sirolimus as the most common mTOR inhibitor is able to effectively prevent allograft rejection.

Study design, size, duration: A total 121 patients with a history of at least 3 RIF after IVF/ET cycles that referred to Eastern Azerbaijan ACECR ART center, Alzahra Hospital of Tabriz University of Medical Sciences and Infertility Treatment center ACER Qom from July 2016 to June 2017 were selected and enrolled in this multicenter, randomized, double-blind, phase II study.

Participants/materials, setting, methods: Blood was drawn between cycle day 5 and 10 of a cycle prior to the index IVF/ET cycle for then assessment of a Th17 and regulatory T cells ratios and functions by flow cytometry, real-time PCR and ELISA. Normal ranges for Th17/Treg ratios were established 0.75 by using 50 normal fertile women. In 76 patients with elevated Th17/Treg ratios, 43 of them were treated with Sirolimus (Rapamune®; Pfizer, UK) and 33 patients were not treated.

Main results and the role of chance: Our results demonstrated a significantly higher clinical pregnancy rate (55.81%) in Sirolimus-treated patients compared with control group (20.93%) ($P = 0.0005$). We also found a significantly increased ongoing pregnancy rate (44.18%) in RIF women who received Sirolimus compared with control group (16.26%) ($P = 0.0005$).

Limitations, reasons for caution: We need more research to describe molecular mechanism of sirolimus in Th17/Treg ratio by focusing to mTOR signaling pathway.

Wider implications of the findings: The findings of the current study revealed the fact that Sirolimus is able to improve reproductive outcome in RIF women with imbalanced Th17/Treg ratio, thus representing a new approach for the potential treatment of patients with embryo implantation failure.

Trial registration number: ClinicalTrials.gov Identifier: NCT03161340

O-302 No evidences that implantation of vitrified euploid blastocysts is influenced by ovarian stimulation conducted in luteal vs follicular phase:interim analysis of a prospective multicentre study

A. Vaiarelli[1], D. Cimadomo[1], S. Colamaria[1], S. Ferrero[1], M. Giuliani[1], E. Trabucco[2], R. Carmelo[2], L. Buffo[3], L. Dusi[3], R. Venturella[2,4], L. Rienzi[1,2,3], F.M. Ubaldi[1,2,3]

[1]Valle Giulia Clinic, GENERA Center for reproductive Medicine, Roma, Italy
[2]Clinica Ruesch, Genera, Napoli, Italy
[3]Poliambulatorio SALUS, Genera Marostica, Marostica, Italy
[4]Magna Graecia University, Department of Obstetrics and Gynecology, Catanzaro, Italy

Study question: Is there any difference in ongoing pregnancy rate after single embryo transfer (SET) of vitrified euploid blastocysts obtained after luteal-phase-stimulation (LPS) vs follicular-phase-stimulation (FPS)?

Summary answer: To date, FPS-derived and LPS-derived vitrified euploid blastocysts did not show any evidence of a different reproductive competence.

What is known already: Multiple follicular waves can arise during a single menstrual cycle in humans, thereby highlighting a novel folliculogenesis pattern which overtakes the classic theory. Preliminary studies showed that oocytes obtained from anovulatory waves seem developmentally-similar to those obtained from conventional approaches (namely FPS) in terms of fertilization, blastulation and euploidy rates. These observations led to the introduction of novel protocols for ovarian stimulation: random-start, luteal phase-only stimulation and DuoStim (FPS plus LPS in the same menstrual cycle).

Study design, size, duration: Multicenter prospective study. 278 poor-prognosis women (AMH≤1.5 ng/ml and/or AFC≤6 and/or ≤5oocytes retrieved from a previous cycle and/or ≥35 yr) completed a DuoStim approach combined with preimplantation-genetic-testing (PGT) between October2015–July2017. To date, 174 patients obtained and transferred at least 1 euploid blastocyst either from FPS and/or LPS. Only the first SET performed was included in this study. The primary outcome was the ongoing implantation rate (>20weeks). Biochemical pregnancy loss (BPL), miscarriage and obstetrical/perinatal outcomes were also monitored.

Participants/materials, setting, methods: Both FPS and LPS were performed with gonadotrophins in an antagonist protocol. After the first retrieval from FPS we waited five days before starting LPS. All embryos were cultured to blastocyst, underwent trophectoderm biopsy and vitrification. The samples from FPS and LPS were analyzed in the same run. In presence of euploid blastocysts from both FPS and LPS, the first embryo to be transferred was randomly-chosen. Frozen-SETs were performed in a modified-natural or artificial cycle.

Main results and the role of chance: To achieve 80% power ($\alpha = 0.05$) to rule out a 15% difference in ongoing implantation rate between FPS-derived and LPS-derived euploid blastocysts, we require 174 first SETs per arm (348 overall). In this interim analysis we reached 50% of this sample size. The positive pregnancy rates were 57.0% (n = 49/86) and 55.7% (n = 49/88) from FPS-derived and LPS-derived euploid blastocysts, respectively. The BPL rates were 8.2% (n = 4/49) and 2.0% (n = 1/49), respectively. The miscarriage rates were 11.1% (n = 5/45) and 12.5% (n = 6/48), respectively. The ongoing pregnancy rates were 46.5% (n = 40/86) and 47.7% (42/88), respectively. To date, 30 FPS-derived and 32 LPS-derived babies have been delivered. Gestational age (38.1 ± 1.1 weeks, range 36-40 versus 38.0 ± 2.2 weeks, 36-41) and birthweight (3308 ± 880 g, 2200-4030 versus 3217 ± 584 g, 2010-4152) were similar so far between study arms. One FPS-derived euploid blastocyst underwent spontaneous embryo twinning and resulted in a multiple pregnancy. One and 2 gestational diabetes were reported in the two study groups, respectively. A FPS-derived pregnancy showed polidramnios and neonatal respiratory distress, which involved 7 days in the neonatal intensive care unit after birth. No neonatal issues have been reported for LPS-derived pregnancies up to now.

Limitations, reasons for caution: This is an interim analysis; therefore, we are yet underpowered to draw clear conclusions from these data, especially dealing with obstetrical and perinatal outcomes. Moreover, embryo derived from LPS are obtainted only after DuoStim approach.

Wider implications of the findings: LPS in a DuoStim-approach is promising for poor-prognosis (or oncological) patients that need to collect the highest number of oocytes in a short timeframe.Although, any stimulation protocol which exploits anovulatory waves needs a thorough investigation. Here, we produced clinical data to define the safety of the pregnancies achieved after LPS.

Trial registration number: None.

O-303 Age-related gene expression profiles of immature human oocytes

M.A.J. Smits[1*], K.M. Wong[1*], E. Mantikou[1], C. Korver[1], A. Jongejan[1], T.M. Breit[2], M. Goddijn[1], S. Mastenbroek[1], S. Repping[1]

[1]Academic Medical Center, Center for Reproductive Medicine, Amsterdam, The Netherlands
[2]Swammerdam Institute for Life Sciences- Faculty of Science FNWI, MicroArray Department and Integrative Bioinformatics Unit, Amsterdam, The Netherlands
**Contributed equally*

Study question: What is the difference in gene expression profile in human germinal vesicle (GV) oocytes from women of different ages?

Summary answer: There were no significant differences in gene expression profiles of human GV oocytes from women of different ages (range 25-43).

What is known already: It is well established that reproductive capacity declines as women age. This age-related decline is almost entirely attributed to oocyte quality, since this decline is counterbalanced in older women receiving young donor oocytes. Multiple molecular mechanisms explaining the decrease in oocyte quality with increasing female age have been suggested, but none have been firmly demonstrated. Altered gene expression of human oocytes at different stages of development in relation to female age is one of the suggested mechanisms for age-related fertility decline.

Study design, size, duration: Between 2012 and 2014, 40 human GV oocytes of 40 women were obtained during follicular aspiration as part of routine ICSI treatment. Gene expression profiles were determined in four different age groups: 25-30, 31-35, 36-38 and 39-43 years of age.

Participants/materials, setting, methods: GV oocytes were snap-frozen shortly after follicular aspiration. Gene expression profile analyses were performed using 4×180 K Agilent arrays containing ~42000 probe-sets. Gene expression profiles were visualized by hierarchical clustering and multidimensional scaling. Transcripts were analyzed in a class comparison between the four age groups and for indicators of biological age: antral follicle count (AFC) and the total dosage of follicle stimulating hormone (FSH) used for ovarian hyper stimulation. Individual transcripts were analyzed using linear regression.

Main results and the role of chance: Visualization of gene expression profiles of GV oocytes with hierarchal clustering and MDS demonstrated no clear clustering of samples based on female age, AFC or FSH dosage. The gene expression profile of GV oocytes classified in four age groups revealed no significantly differentially expressed genes between the four different age groups (FDR < 0.05). There were also no significantly differentially expressed genes in the linear regression analysis for individual transcripts analyses per age year (FDR < 0.05).

Limitations, reasons for caution: Immature (GV) oocytes obtained after follicular aspiration in ICSI cycles were used. Findings may be different for in vivo matured oocytes at other developmental stages, under physiological conditions. Due to our relatively large, but still limited study sample, we cannot exclude that there might be smaller age-related gene-expression differences.

Wider implications of the findings: We did not find an effect of age on gene expression profiles of individual human GV oocytes. Other studies have suggested that gene-expression profiles are affected in mature oocytes, which might implicate that female age affects oocyte maturation. Alternatively, other mechanisms in human oocytes might affect age-related fertility decline.

Trial registration number: not applicable.

O-304 Age related differences in the translational landscape of mammalian oocytes

E. Del LLano[1], T. Mašek[2], A. Tetkova[1], D. Jansova[1], M. Koncicka[1], L. Gahurova[3], A. Šušor[1], M. Pospišek[2], M. Kubelka[1]

[1]Institute of Animal Physiology and Genetics, Laboratory of Biochemistry and Molecular Biology of Germ Cells, Libechov, Czech Republic
[2]Faculty of Science- Charles University in Prague, Department of Genetics and Microbiology, Prague, Czech Republic
[3]University of South Bohemia, Department of Molecular Biology, České Budějovice, Czech Republic

Study question: How global translational program differs in mammalian oocytes after aging of females?

Summary answer: We have identified several genes with potentially altered expression in the oocytes of aged females which might contribute to defective meiosis I and consequent aneuploidy.

What is known already: Oocyte aneuploidy is the result of abnormal chromosome segregation during meiosis, giving rise to a ready to be fertilized oocyte which possesses an aberrant number of chromosomes. These anomalies are inherited by the embryo drastically reducing its developmental potential. Importantly, aneuploidy is not infrequent in mammalian oocytes but rather a common feature which increases in correlation with female age.

Furthermore, maturing oocytes are transcriptionally silent and rely on the utilization of mRNAs synthesized and stored during the growth period. To our knowledge a global analysis of translation in oocytes related to the maternal age has not yet been performed.

Study design, size, duration: Mouse model for aging: Study group - 1 year old mouse females / Control 2 months old mouse females.

Samples: 200 oocytes at nuclear envelope break down stage.

Participants/materials, setting, methods: We aim to study age-related aneuploidy in mammalian oocytes by comparing and analyzing the active transcriptome in oocytes from young and aged mouse females. We have developed a polysome fractionation protocol to isolate the RNA population involved with the translational machinery from a minute amount of cells/oocytes. These have been sequenced by Illumina NextGen to be able to identify differences in the translational program of the oocytes from young and aged females.

Main results and the role of chance: We have successfully developed a polysomal fractionation protocol to be used with as low as only 200 oocytes. Thanks to this method, we have been able to obtain database of actively translated mRNAs using Illumina NextGen sequencing. After studying the obtained data, we have found several genes with differences in expression between

oocytes from young and aged females. These might therefore contribute to the increased aneuplody characteristic in oocytes from aged females.

Limitations, reasons for caution: Our study samples are oocytes from aged female mice. This material is scarce due to the time and resources required to age females. Moreover, these produce only around 5 viable oocytes.

We used polysome fractionation which is generally performed with high amounts of material. We reduced the input to 200 oocytes.

Wider implications of the findings: This project can shed some light upon the reasons behind the loss of oocyte quality from women of advanced age. It may help to improve assisted reproduction techniques with a potential development of gene therapy to treat the high aneuploidy rates in oocytes of women of advanced age.

P-001 Sperm donors' opinion towards donation and the release of identifying information in the Belgian context

F. Mahieu[1], W. Decleer[2], K. Osmanagaoglu[1], V. Provoost[3]

[1]AZ Jan Palfijn, IVF Laboratory, Ghent, Belgium
[2]AZ Jan Palfijn, IVF Centre, Ghent, Belgium
[3]Ghent University, Department of Philosophy and Moral Science, Ghent, Belgium

Study question: What is the opinion of sperm donors towards the release of identifying information in the Belgian context of strict anonymous donation?

Summary answer: One in five (20,1%; n = 30) of the respondents indicated they would continue to donate if the legislation would change from anonymous towards identifiable donation.

What is known already: Belgian legislation restricts clinic recruitment advertising. It allows only strictly anonymous gamete donation and known donation (donation to a recipient known by the donor). Recently an amendment of the legislation was proposed which would grant donor offspring, as of 18 years old, the right to claim the identifying information of their donor. International studies have shown that in countries with anonymous donation programmes, 11% to 50% of the donors would be willing to continue donating upon donor anonymity abolishment. In two Belgian studies, 26% and 28,8% of the candidate donors and donors would continue donating if legislation would change.

Study design, size, duration: The survey was composed of questions derived from the international literature. Eight experts validated the survey via a Delphi procedure. In addition, the survey was examined by two donors to ensure clarity of wording.

The survey was online from October 27th until December 8th, 2017. Questions (n = 36) were asked about motivation to donate, attitude towards anonymous donation and social demographics.

Participants/materials, setting, methods: Al men who were accepted as sperm donor (n = 242) by Jan Palfijn Hospital (Ghent, Belgium), from a period of 2009 to 2017 were contacted by e-mail and were invited to complete an anonymous online survey. Two reminder e-mails were sent to the study population to maximize the response rate. All statistical analyses were performed using SPSS. The response rate was 65,5% (150 donors completed the survey; 13 men were not reachable).

Main results and the role of chance: At the time of the survey, the sperm donors had a mean age of 32 years (20-46; SD 5,97). Half of the respondents (51,7%; n = 77) also were blood donors. Two thirds of the men (66,4%; n = 99) did not have children of their own. Most (86,6%; n = 129) of them were motivated by altruism although the majority (59,1%; n = 88) was (also) motivated by the compensation fee and nearly half (45,0%; n = 67) by access to blood and fertility tests. One in five (22,8%) would continue to donate without a compensation fee.

79,2% (n = 118) of the respondents were non-active sperm donors. Of those men, 68,6% (n = 81) said they were non-active because they thought that there was enough donor sperm in the sperm bank. The others (31,4%; n = 37) were non-active for personal reasons, mainly related to lack of time to donate or a non-supportive partner.

One in five (20,1%; n = 30) would continue sperm donation upon a legislation change towards identifiable donations whereas 53,7% (n = 80) would no longer donate. 26,2% (n = 39) were undecided.

No significant relationship was observed between the willingness to continue donating in an identifiable system and education (p = 0,724), age (p = 0,725), having children (p = 0,918), being a blood donor (p = 0,822) or sexual orientation (p = 0,156).

Limitations, reasons for caution: A limitation of this study is that the data originate from a single centre and may not represent the opinion of all Belgian sperm donors.

Wider implications of the findings: Currently, 40% of donor sperm used in Belgian ART is of indigenous origin. Consequently, the tendency that only 20,1% of the Belgian sperm donors would continue to donate in an identifiable system, could be detrimental for the future availability of donor sperm in Belgium.

Trial registration number: The study was approved by the Ethics Committee of the University Hospital of Ghent.

Belgian Registration Number: B0201733518.

P-002 The effect of unilateral tubal block on clinical pregnancy rate in intrauterine insemination cycles: Systematic review & meta-analysis

J. Tan[1], S. Tannus[2], O. Taskin[1], A. Kan[1], A.Y. Albert[1], M.A. Bedaiwy[1]

[1]University of British Columbia, Obstetrics & Gynecology, Vancouver, Canada
[2]McGill University Health Care Centre, Department of Obstetrics and Gynecology-Division of Reproductive Endocrinology and Infertility, Montreal, Canada

Study question: What are pregnancy rates after intrauterine insemination (IUI) among infertile women with unilateral tubal block (UTB) diagnosed by hysterosalpingogram (HSG) compared to women with unexplained infertility and bilateral patent tubes?

Summary answer: Infertile patients with proximal UTB diagnosed by HSG can expect good pregnancy outcomes after IUI while patients with distal UTB have lower odds of pregnancy.

What is known already: Fallopian tube occlusion is a common cause of infertility. For normal fallopian tube function, the tube must be patent, freely mobile, and in close proximity to the ovary. However, several pathologies are implicated in distorting this normal physiology, including pelvic infections, endometriosis, and surgical adhesions. Depending on the etiology, tubal pathology may involve the proximal, distal, or entire tube, and may be transient due to obstruction or permanent due to occlusion. While bilateral tubal block confers poor pregnancy rates (PR) after controlled ovarian hyperstimulation and intrauterine insemination (COH-IUI), the effect of unilateral tubal block (UTB) remains controversial.

Study design, size, duration: We systematically searched the Cochrane Library, EMBASE and MEDLINE databases from inception to September 2017. Key words included IUI, intrauterine insemination, tubal block, tubal occlusion, fallopian tube diseases. Original research articles including randomized and non-randomized controlled trials, cohort studies, patient series and case reports were included. All included studies reported either pregnancy rates (PR) per cycle and/or cumulative pregnancy rates (CPR). Additional studies were extracted from the references in the full text articles.

Participants/materials, setting, methods: Two authors independently selected trials and extracted study characteristics. Methodological quality was

assessed using Preferred Reporting Items for Systematic Reviews and Meta-analysis (PRISMA) guidelines. Clinical pregnancy data were pooled using a random-effects model to calculate estimated average Odds Ratios (OR). In order to provide greater weight to larger studies, OR were weighted by the inverse variance. The I^2 metric was calculated to assess study heterogeneity. Publication bias was assessed by visual inspection of funnel plots.

Main results and the role of chance: 10 observational studies investigating pregnancy outcomes after IUI in women with unilateral tubal block (UTB) compared to those with bilateral patent tubes and unexplained infertility (control) were included. All included studies provided diagnostic criteria for assessing tubal block and screened for appropriate male and female factors through detailed reproductive history and infertility evaluation. Furthermore, subgroup analyses were performed among studies that differentiated proximal and distal tubal blocks. The following comparisons were evaluated based on pregnancy rate (PR) per IUI cycle and cumulative pregnancy rate (CPR): unilateral tubal block vs. control, proximal tubal block vs. control, distal tubal block vs. control, and proximal vs. distal tubal block. Among 2965 patients and 5,749 IUI cycles across 10 studies, no significant difference in PR/cycle (OR = 0.88, CI = 0.69-1.12) and cumulative PR (OR = 0.80, CI = 0.62-1.04) was observed. Patients with proximal UTB demonstrated similar PR/cycle (OR = 1.06, CI = 0.68-1.66) and cumulative PR (OR = 1.10, CI = 0.75-1.62) compared to controls while patients with distal UTB had significantly lower cumulative PR (OR = 0.49, CI = 0.25-0.97, p = 0.04). Patients with proximal block also demonstrated significantly improved cumulative PR compared to patients with distal block (OR = 2.41, CI = 1.37-4.25, p = 0.002).

Limitations, reasons for caution: All included studies were retrospective and hence susceptible to confounding. Differences in screening/exclusion criteria and lack of standardized IUI techniques between studies also bias their comparability. Indeed, differences in sperm quality and processing, cycle timing, and overall differences in ovarian stimulation treatment have all been shown to affect IUI outcomes.

Wider implications of the findings: Our review demonstrates that infertile patients with proximal UTB diagnosed by HSG can expect good pregnancy outcomes after COH-IUI while patients with distal UTB have lower pregnancy odds and may benefit from laparoscopic assessment or IVF. This difference may reflect inherent diagnostic limitations of HSG or differences in underlying pathologies.

Trial registration number: Not applicable.

P-003 Bilateral versus unilateral cryptorchidism in non-obstructive azoospermia: outcomes of testicular sperm extraction and ICSI

A.L. Barbotin[1], A. Dauvergne[2], A. Dumont[3], V. Mitchell[1], J.M. Rigot[2], F. Boitrelle[4], G. Robin[3]

[1]*Hôpital Jeanne de Flandre, institut de biologie de la reproduction, Lille, France*
[2]*Hopital Calmette, Service d'Andrologie, Lille, France*
[3]*Hôpital Jeanne de Flandre, Service de Gynécologie Endocrinienne et Médecine de la Reproduction, Lille, France*
[4]*Hôpital de Poissy, Service de Biologie de la Reproduction et de Cytogénétique, Poissy, France*

Study question: How successful is testicular sperm extraction (TESE) in non-obstructive azoospermia (NOA) in case of unilateral versus bilateral cryptorchidism?

Summary answer: NOA men with a history of unilateral cryptorchidism exhibited similar sperm retrieval rate but better clinical pregnancy rate than those who had bilateral cryptorchidism.

What is known already: Cryptorchidism is a very common genital disorder affecting almost 3% of male children and it represents one of the most frequent causes of NOA in adulthood. Although, it is well known that spermatogenesis is more impaired in bilateral cryptorchidism than in unilateral cryptorchidism, data available in the literature only refer to small cohorts or inhomogeneous population. To date, comparison of testicular sperm extraction and ICSI outcomes in men with a history of bilateral versus unilateral cryptorchidism is still lacking.

Study design, size, duration: This is a retrospective comparative study performed in the Centre of Reproductive Medicine and Andrology, University Hospital of Lille. Among the 1274 azoospermic men who underwent TESE procedure from 1995 to 2014, 314 had a history of cryptorchidism. Out of these patients, 35 had an additional obstructive cause and were therefore excluded. In the end, we identified and included a total of 249 patients with a history of cryptorchidism as only aetiopathogenetic factor for NOA.

Participants/materials, setting, methods: Patients were divided into two groups according to the history of cryptorchidism: bilateral (65.1%, 162/249) or unilateral (34.9%, 87/249). We compared hormonal profiles and sperm retrieval rates (SRR) between the two groups. Additionally, we studied ICSI outcomes with testicular frozen-thawed sperm.

Main results and the role of chance: This is the largest consecutive cryptorchid cohort reported to date. There was no difference in the andrological phenotype with similar FSH levels (21.7 IU/L vs. 18.8 IU/L; p = 0.17), inhibin B levels (35.5 pg/mL vs. 37 pg/mL; p = 0.15) and mean testicular volumes (7.7 mL vs. 7.9 mL, p = 0.71). Similar SRR were observed between the groups (62.3% vs. 59.8%; p = 0.7,8 respectively). Implantation rate was higher in the unilateral group (23.7% vs. 10.3%; p = 0.02). Cumulative pregnancy rates per embryo transfer and cumulative live birth rates were both significantly higher in the unilateral group (28.9% vs. 17.5%; p = 0.04 and 27.6% vs. 17.3%; p = 0.04, respectively).

Limitations, reasons for caution: This is a retrospective study, which inevitably creates a risk a bias towards the recording of the data. In addition, reproductive outcomes might be interpreted with caution regarding the assessment of the ovarian reserve, which has changed over time due to the evolution in serum AMH thresholds and ultrasound equipment.

Wider implications of the findings: We showed for the first time that ICSI outcomes were better in NOA patients with a history of unilateral versus bilateral cryptorchidism, despite similar SRR. This suggests that cryptorchidism could reflect a bilateral testicular impairment, even in unilateral cases, and should be considered when counseling patients before TESE attempts.

Trial registration number: not applicable.

P-004 Parameters associated with sperm quality prior to chemotherapy treatment in patients with lymphoma

N. Feigin[1], G. Karavani[2], T. Tachover[2], D. Ben-Yehuda[3], D. Lavie[3], A. Ben-Meir[2]

[1]*Hadassah hospital, General Interns, Jerusalem, Israel*
[2]*Hadassah hospital, Obstetrics and gynecology, Jerusalem, Israel*
[3]*Hadassah hospital, Hematology, Jerusalem, Israel*

Study question: What parameters are associated with poor sperm quality in lymphoma patients prior to chemotherapy treatment?

Summary answer: The study shows a link between known prognostic factors of lymphoma (B symptoms, low hemoglobin and albumin levels) and sperm quality before chemotherapy.

What is known already: Chemotherapy treatment in patients with lymphoma may result in reduction in sperm quality. Therefore, patients are strongly advised to undergo sperm cryopreservation prior to the initiation of treatment. It is still unknown what factors are associated with increased semen analysis abnormalities prior to chemotherapy.

Study design, size, duration: Retrospective descriptive analytic study. One-hundred ninety one lymphoma patients attempting sperm cryopreservation between 1999 and 2016.

Participants/materials, setting, methods: One hundred and one Hodgkin lymphoma patients and ninety Non Hodgkin lymphoma patients were included in the study. Lymphoma prognostic factors (presence of B symptoms, albumin and hemoglobin levels, stage etc.) were compared between patients with normal and abnormal sperm (according to World Health Organization 2009 guidelines). Another parameter compared between the groups was the Prognostic Score Ratio (PSR), an index representing the number of negative lymphoma prognostic measures that exist in a given patient.

Main results and the role of chance: Among the prognostic factors of lymphomas, the following factors were found to be associated with reduced sperm quality: B symptoms (p = 0.021), albumin (p < 0.001) and hemoglobin (p < 0.001) levels. Logistic regression showed significant association of albumin and hemoglobin indexes with reduced sperm quality (p = 0.013, OR = 2.7 and

p = 0.015, OR = 13.5, respectively). However, in Hodgkin's lymphoma specifically, only hemoglobin was found to be statistically significant. Another measure that showed a significant relationship was the Prognostic Score Ratio (PSR) ($p < 0.001$).

Limitations, reasons for caution: The study included only patients who were eligible for sperm cryopreservation. Therefore, this study did not include very ill patients, who started chemotherapy immediately, or older patients who were not interested in sperm cryopreservation.

Wider implications of the findings: The prognostic factors mentioned above are related to a general inflammatory state and therefore might affect sperm production. A further investigation of inflammatory factors levels in plasma and seminal fluid is reasonable.

Trial registration number: Not applicable.

P-005 Effects of oral cysteamine on fertility in male mice

A. Reda[1], P. Kadam[2], C. Camps[1], K. Veys[1], L. Van Den Heuvel[1], E. Levtchenko[1], E. Goossens[2]

[1]*KU Leuven, Organ system, Leuven, Belgium*
[2]*Vrije Universiteit Brussel, Biology of the testis BITE, Brussels, Belgium*

Study question: Does oral cysteamine affect fertility in male mice?

Summary answer: Oral cysteamine does not affect fertility in male mice.

What is known already: Cystinosis is a rare autosomal recessive metabolic disease caused by mutations in the lysosomal membrane protein, cystinosin, which leads to intra-cellular accumulation of cystine crystals. The main clinical presentation is renal Fanconi syndrome, leading to end stage renal disease (ESRD) by the age of 10, if the patient is left untreated. Female cystinosis patients could get successful pregnancies. However, male patients suffer from unexplained infertility. The only available treatment for cystinosis is the oral cysteamine, which depletes the intra-cellular cystine crystals. However, the effects of oral cysteamine on male fertility was not investigated thoroughly yet.

Study design, size, duration: C57/BL6J male adult (2 months of age) wild type mice (n = 24) were randomized into 3 groups (n = 8 each); control group (fed with normal food), treatment group I (fed with 250 mg cysteamine/kg/day mixed with normal food), and treatment group II (fed with 500 mg cysteamine/kg/day mixed with normal food). After two months, mice were sacrificed. Body weights, testis weights, seminal vesicle weights, plasma samples, epididymal sperm, and testicular tissues were collected at sacrifice time.

Participants/materials, setting, methods: Plasma levels of testosterone, luteinizing hormone (LH) and follicle stimulating hormone (FSH) were evaluated, using the appropriate ELISA kit for each hormone. Testicular tissues were fixed in formalin, embedded in paraffin, and sectioned. The sections were stained by periodic acid-Schiff's (PAS) staining. Number of seminiferous tubules at stage VIII were quantified, relative to the total number of tubules. Results were compared between the control and treatment groups.

Main results and the role of chance: After two months of treatment, we found no statistically significant differences between groups (control, 250 mg, and 500 mg) regarding the total body weight (31.6 ± 1.9, 30.6 ± 2.7, and 29.6 ± 2.6 g respectively), body weight gain (5.9 ± 0.4, 5.0 ± 1.8, and 6.0 ± 1.8 g respectively), body weight gain normalized to body weight before treatment (23.4 ± 2.6, 19.6 ± 6.8, and 25.8 ± 8.0 % respectively), seminal vesicle weight normalized to total body weight (11.9 ± 1.2, 10.7 ± 1.9, and 10.9 ± 1.1 % respectively), testis weight normalized to total body weight (3.2 ± 0.2, 3.4 ± 0.3, and 3.3 ± 0.2 % respectively), and epididymal sperm count (2.5 ± 0.9, 3.6 ± 1.1, and 3.1 ± 1.2 million respectively), using one-way ANOVA test.

Moreover, there was no statistically significant difference between groups in plasma testosterone (4.4 ± 7.2, 3.4 ± 5.8, and 5.0 ± 7.3 ng/ml respectively) using Kruskal Wallis ANOVA on ranks test. In addition, after two months of treatment, plasma LH (4.6 ± 3.5, 4.4 ± 2.2, and 5.6 ± 3.3 ng/ml respectively), plasma FSH (2.5 ± 0.7, 2.8 ± 1.1, and 2.1 ± 0.5 ng/ml respectively) and number of tubules at stage VIII normalized to total number of tubules (13.9 ± 2.6, 12.5 ± 1.7, and 11.0 ± 2.1 % respectively) were similar.

Limitations, reasons for caution: The study is performed in wild type C57/BL6J mice, so the combined effect of cystinosis and cysteamine treatment was not investigated. Moreover, the effect of treatment is investigated after two months treatment, while the patients take cysteamine life-long. Hence, the results should be interpreted cautiously.

Wider implications of the findings: The results obtained in the study suggest that cysteamine treatment, the only available oral treatment for cystinosis, may have no negative impact on fertility.

Trial registration number: Not applicable.

P-006 A comparison of reproductive outcome using testicular sperm Vs. ejaculated sperm in ICSI for patients with abnormal DNA fragmentation

M. Hozain[1], H. Alkhader[1], S. Eltanbouly[1], H. Zaki[2]

[1]*Ganin Fertility Center, IVF Laboratory, cairo, Egypt*
[2]*Ganin Fertility Center, Gynecology and Obstrics, cairo, Egypt*

Study question: Is testicular sperm better than ejaculated sperm in ICSI in terms of reproductive outcome in men with abnormal DNA fragmentation?

Summary answer: There is no significant difference in ICSI clinical outcome between using Testicular sperm or ejaculated sperm with abnormal DNA fragmentation patients.

What is known already: Abnormal levels of DNA fragmentation has negative impact on embryological parameters (fertilization, cleavage, blast).which lowers the level of pregnancy rate, ongoing pregnancy rate and increase miscarriage rate.

The topographic mapping of sperm DNA fragmentation in male genital tract represent that testicular sperm have lower DFI than ejaculated sperm which is better to use in ICSI.Using testicular sperm in ICSI can potentially solve the problem of abnormal DNA fragmentation and would improve the clinical outcome.

Study design, size, duration: Prospective cohort study included 111 couples have abnormal DNA fragmentation levels undergoing ICSI in GFC from June 2016 to July 2017.Patiens were randomized into two groups; first group was ICSI using testicular sperm and the second group was ICSI using ejaculated sperm.

Participants/materials, setting, methods: This study included 111 couples with abnormal DNA fragmentation and randomized into two groups. Sperm DNA fragmentation test was done by TUNEL assay using bench top flow cytometry and DFI cutoff value was (20%). Women were eligible to participate in the study if they were ≤37 years old and had ≥ 5 (MII)oocytes collected. Embryological data were recorded and results were compared using IMB SPSS Software Version 22 For Microsoft windows.

Main results and the role of chance: A total 111 cases with abnormal DFI underwent ICSI and divided into 53 cases injected using testicular sperm and 58 cases injected by ejaculated sperm with no significant difference in male or female age between the two groups. DFI level was (26.7%, 23.8%) in Testi-ICSI and Ejac-ICSI respectively with (P = 0.7). Fertilization rate was (62.98%, 77.16%) in Testi-ICSI and Ejac-ICSI respectively with (P = 0.1). Blastulation rate was (38.02%, 65.17%) with (P = 0.004) this significant value might be due to the larger number of D3 ET in Testi-ICSI group vs Ejac-ICSI group. Pregnancy rate was (50%, 51.02%) in Testi-ICSI and Ejac-ICSI respectively with (P = 0.9). Implantation rate was(41.4%, 26.7%) in Testi-ICSI and Ejac-ICSI respectively with (P = 0.1).Ongoing pregnancy was (48%, 42.8%) in Testi-ICSI and Ejac-ICSI respectively with (P = 0.5) and the miscarriage rate was (7.40%, 16%) in Testi-ICSI and Ejac-ICSI respectively with (P = 0.16).So there is no significant difference favoring Testi-ICSI over Ejac-ICSI in men with abnormal DNA fragmentation.

Limitations, reasons for caution: Ten patients vitrified all their embryos in both groups, and were excluded from the pregnancy rate, implantation rate and ongoing pregnancy rate. Also there are many factors might affect DFI such as infertility duration, use of medication, presence of varicocele, elevated ROS levels and other relevant male factors.

Wider implications of the findings: More studies are needed with larger number of cases for more statistically powered findings, to determine which is better for ICSI cycles with men who have abnormal DNA fragmentation, the usage of testicular sperm or ejaculated sperm.

Trial registration number: N/A.

P-007 Male accessory sexual glands secretion as a potential predictor of fertilization in conventional IVF

C. Bisioli[1], D. Mesquiatti[1], I. Paredes[2], M. Rolón[2], R. Molinas[3], D. Ferrer[4], M. Horton[1], I. De Zúñiga[5], G. Terrado[5], F. Sobral[5], M. Gomez Peña[1], C. Avendaño[6]

[1]Pregna Medicina Reproductiva, Embryology, Buenos Aires, Argentina
[2]Neolife Medicina y Cirugía Reproductiva, Embriology, Asunción, Paraguay
[3]Neolife Medicina y Cirugía Reproductiva, Medical, Asunción, Paraguay
[4]Androlab Cba, Andrology, Cordoba, Argentina
[5]Pregna Medicina Reproductiva, Medical, Buenos Aires, Argentina
[6]Androlab Cba / Gynesis, Andrology, Cordoba, Argentina

Study question: Do male accessory sexual glands secretions have a predictive value on the fertilization outcome in conventional IVF?

Summary answer: Prostatic hyper-secretion may have a negative impact in the fertilization rate.

What is known already: The use of conventional in vitro insemination (CIVI) has been declining worldwide while intracytoplasmic sperm injection (ICSI) has dramatically increased. The main argument supporting ICSI overuse is to prevent fertilization failure. Basic seminal parameters are usually the criteria for choosing between CIVI and ICSI. Although an association between male accessory sexual glands secretion and fertilization has been shown in animal models, its evaluation has been sidelined from the basic exam of male fertility due to the absence of clinical studies.

Study design, size, duration: Eighty five patients younger than 40 yo, with more than 4 mature oocytes, with male partners with normal semen parameters, undergoing conventional IVF between November 2015 and October 2016 were included in this controlled, prospective, blinded, multicenter study. One-way analysis of variance or Kruskall-Wallis analysis was performed to detect any possible differences between parameter means. All the categorical variables were compared with a Chi-square test among groups.

Participants/materials, setting, methods: An aliquot of the IVF semen sample was centrifuged to keep in the supernatant a free-cell plasma fraction. Fructose seminal vesicle and citric acid prostate secretions were estimated by spectrophotometry. Fructose levels between 150-450 mg/dL and citric acid of 350-670 mg/dL were considered as normal while lower or higher values were considered as pathological. No differences in patients age, basic seminal parameters and number of recovered metaphase II oocytes were observed between groups.

Main results and the role of chance: No differences were observed in fertilization rates between patients with normal and hyper seminal vesicle secretion (0.79 ± 0.03 vs 0.80 ± 0.05) or normal vs hypo secretions (0.79 ± 0.03 vs 0.80 ± 0.07) were compared. Differences in fertilization rates were found between normal and hyper prostatic secretions (0.84 ± 0.03 vs 0.70 ± 0.04, $p < 0.01$) but not when normal vs hypo secretions (0.84 ± 0.03 vs 0.74 ± 0.04) were compared.

Limitations, reasons for caution: To determine the true extent of any clinical benefit of these preliminary results a randomized clinical trial will be necessary. Research is needed to understand the putative relationship between prostatic secretions and fertilization potential.

Wider implications of the findings: Our data suggest a negative correlation between a pathological prostatic hyper-secretion and sperm fertilization potential. We have described for the first time the use of a simple, inexpensive and objective method that could be useful to choose the most suitable type of in vitro insemination between CIVI and ICSI.

Trial registration number: N/A.

P-008 Technical standardization as a first step to maximize the prognostic value of ejaculate related parameters in a homologous intrauterine insemination programme

L. Van de Velde, D. De Neubourg, H. Van Mulders, I. Goovaerts, K. Peeters, U. Punjabi

University hospital of Antwerp - CRG, Centre for reproductive medicine, Edegem, Belgium

Study question: Does standardization of the laboratory procedures help to evaluate the prognostic value of ejaculate related determinants in an intrauterine insemination (IUI) programme.

Summary answer: When technical parameters were held stable, time-interval between sample production and insemination significantly influenced positive hCG outcome, clinical pregnancies and live birth rate after IUI.

What is known already: IUI remains a relatively simple, non-invasive, cheap treatment option for a well selected population with a sufficient number of motile spermatozoa. There is a considerable amount of literature on several prognostic factors either related to patient characteristics, semen sample or the IUI procedure itself. But, results are controversial due to the lack of technical standardization and good-quality prospective cohort trials. Although minimum standards required were defined by WHO and ESHRE Special Interest Group Andrology, large inter-laboratory variations occur. For example, inseminating motile count varies between 0.8–5 million to maximize predictive performance (our own validation was ≥ 2 million).

Study design, size, duration: A prospective cohort study of 1795 homologous IUI cycles were included from April 2013 to March 2017. Cycles with cryopreserved semen or with two consecutive semen samples were excluded. Only complete semen samples prepared by density gradient centrifugation were included. The IUI procedure was divided into 3 phases to study the influence of the determinants: pre-analysis (abstinence time); analysis (macroscopic and microscopic examination and sperm preparation) and post-analysis (after sample preparation and before insemination).

Participants/materials, setting, methods: Five hundred and eighty one couples presenting at the Centre for Reproductive Medicine underwent 1447 IUI cycles. Semen samples were analyzed using WHO 2010 recommendations and prepared with a two-step discontinuous density gradient. Reprotoxicity for disposables and media was controlled. Staff members were trained in basic semen analysis and semen preparation and participated regularly in internal and external quality control. A soft IUI catheter was rinsed with medium and the inseminating volume was held constant.

Main results and the role of chance: IUI resulted in a positive hCG in 15.3% cycles with 14.5% clinical pregnancies and 12.6% live births per cycle. Pre-analysis phase: Only complete samples (93.4% of all samples) were considered for this analysis. Although not significantly different, abstinence time of 0-1 days reduced live births from 12.5 to 8.5% as compared to 2-7 days as recommended by WHO. Analysis phase: Analysis was initiated within 60 minutes (99.2% of all samples) after semen production. Semen viscosity (>3 cm) reduced live births from 13.0% to 8.6% but not significantly. Total motile sperm count and sperm morphology in the native semen did not influence clinical IUI outcome. After density gradient, inseminating motile count was ≥2 million (as previously validated). Post-analysis phase: Under standardized conditions, the time interval between sample production and effective IUI was significantly better if held <110 mins ($P = 0.01$; 17.1% versus 12.3% positive hCG; 16.2% versus 11.5% clinical pregnancies; 14.2% versus 9.5% live births, Receiver operating curve: area under the curve: 0.533; sensitivity 69.6 and specificity 42.3).

Limitations, reasons for caution: All participants in this study were already selected according to initial sperm parameters and reasons of subfertility. Clinical parameters such as female and male age, indication and lifestyle parameters were not taken into account.

Wider implications of the findings: This is the first monocentric study to standardize the technical aspects for IUI, paving the way to prospective multicenter approach. With technical determinants under control, attention can now be drawn to clinical variables influencing IUI outcome.

Trial registration number: not applicable.

P-009 Effect of varicocele repair on sperm DNA fragmentation: A systematic review

M. Bertoncelli Tanaka[1], M. Roque[2], A. Agarwal[3], S.C. Esteves[4]

[1]University of Campinas, Department of Surgery- Division Urology, Campinas, Brazil
[2]ORIGEN, Center for Reproductive Medicine, Rio de Janeiro, Brazil
[3]Cleveland Clinic, American Center for Reproductive Medicine-Glickman Urological and Kidney Institute, Cleveland, U.S.A.
[4]ANDROFERT, Andrology and Human Reproduction Clinic, Campinas, Brazil

Study question: Does the level of sperm DNA fragmentation decrease after varicocele repair in patients with male infertility?

Summary answer: Varicocele repair decreases sperm DNA fragmentation levels in infertile men with clinical varicocele.

What is known already: Varicocele, the leading cause of male infertility, can impair sperm quality and fertility via various oxidative stress (OS) mechanisms. Imbalance between excessive reactive oxygen species (ROS) production and antioxidant protection causes alterations in nuclear and mitochondrial sperm DNA, thus rendering the spermatozoa less fertile in a subset of varicocele men. Sperm DNA fragmentation (SDF) is known to be elevated in men with clinical varicocele in both abnormal and normal semen parameters by the current World Health Organization criteria. Surgical varicocele repair has been advocated as a means of reducing the oxidative-induced sperm DNA damage in men with varicocele-associated infertility.

Study design, size, duration: We conducted a systematic search using MEDLINE/PubMed, Scielo, and Google Scholar to identify all relevant studies published until December 2017. The search combined terms related to "sperm DNA fragmentation", "sperm DNA damage", "sperm chromatin integrity OR damage", "varicocele", "varicocelectomy OR varicocele repair", with the filters "human" and "English" language. For the advanced search, article types selected were: clinical study, comparative study, journal article, meta-analysis, observational study, randomized controlled trial (RCT), case series, and systematic review.

Participants/materials, setting, methods: Participants were men with varicocele subjected to varicocele repair in whom sperm DNA fragmentation had been measured before and after surgery regardless of assay type. The preoperative and postoperative levels of SDF in semen were the primary outcomes. The secondary outcomes were levels of other oxidative stress markers and pregnancy rates according to postoperative SDF levels.

Main results and the role of chance: We identified 21 studies (3 RCT, 7 prospective, 7 retrospective, 4 not specified) including 1,270 infertile men with varicocele subjected to surgery. Twelve studies included a control group and/or evaluated other OS markers. The majority of studies included men with clinical varicocele and abnormal semen parameters according to the WHO criteria. Despite the use of different SDF sperm assays, the mixed design, and variable sample size, all studies involving infertile men with palpable varicocele unequivocally reported a significant postoperative decrease in SDF rates in a follow-up period ranging from 3 to 12 months. A single report including men with subclinical varicoceles showed that SDF levels remained unchanged after surgery. Of the 4 studies out of 21 reports providing pregnancy outcomes, the overall postoperative SDF rates fell in men from couples who had a successful pregnancy than those who did not. Among studies assessing OS markers, the vast majority reported higher levels of seminal OS or sperm DNA decondensation in infertile men with clinical varicocele than healthy fertile counterparts without varicocele and men with subclinical varicocele. Although these studies (n = 8) unequivocally reported significant reductions in SDF after varicocelectomy, two studies have failed to demonstrate reduction in OS markers after varicocelectomy.

Limitations, reasons for caution: Not all risk factors such as participant age, use of over the counter medication, and smoking were consistently reported. These factors may influence the rates of SDF and varicocele repair outcomes. Another limitation refers to the quality of included studies, which also varied.

Wider implications of the findings: Current evidence based on careful review of published studies confirms the effectiveness of varicocelectomy as a means of both reducing oxidatively-induced sperm DNA damage and potentially improving fertility. Varicocele repair should be offered as part of treatment option for male partners of infertile couples presenting with palpable varicoceles.

Trial registration number: NA.

P-010 Effects and mechanisms of a heterozygous truncation mutation in BNC1 on male subfertility

J. Li[1], Y. Liu[1], H. Xu[2], P. Lv[1], D. Zhang[1], J. Sheng[2], H. Huang[2]

[1]*Women's Hospital - School of Medicine - Zhejiang University, Department of Reproductive Endocrinology, Hangzhou, China*

[2]*Zhejiang University, Key Laboratory of Reproductive Genetics, Hangzhou, China*

Study question: What is the effects and mechanisms of basonuclin1(BNC1) gene truncation mutation in male infertility.

Summary answer: BNC1 truncating mutation would lead to impaired spermatogenesis via expression dysregulation of several genes essential for spermatogenesis including Tex14, Klhl10, Spatc1, Hook1, Tssk6, and Tnp2.

What is known already: Basonuclin (BNC1) is expressed primarily in proliferative keratinocytes and gametogenic cells. However, its role in spermatogenesis is not clear. Previous study reported that BNC1 was present in spermatogonia, spermatocytes, and spermatids, but absent in Sertoli cells, and *Bnc1*-null male mice were sub-fertile, losing germ cells progressively with age. We recently discovered a novel heterozygous BNC1 truncating mutation, which led to male subfertility both in mice and human.Yet, the underlying molecular mechanism of BNC1 mutation on male subfertility remains unknown.

Study design, size, duration: Transgene mouse model study. Generate BNC1 truncation mutation mice. Investigate spermatogenesis of wild-type (+/+), heterozygous (+/tr), and homozygous (tr/tr) BNC1 truncation mutation mice. Assess expression profiling and direct binding (ChIP-seq) studies of wild-type and heterozygous BNC1 truncation mutation mice testis. Explore the underlying mechanisms of BNC1 on spermatogenesis.

Participants/materials, setting, methods: We generated BNC1 truncation mutation mice using homologous recombination. Based on the subfertility phenotype, expression profiling study was carried out. Key differentiated genes were confirmed by RNA extraction and real-time RT-PCR. Furthermore, ChIP-seq and ChIP-qPCR study with BNC1 in mouse testis was used to identify spermatogenesis specific gene promoters targeted by BNC1.

Main results and the role of chance: BNC1 truncation mutation male mouse model exhibited infertility or subfertility, significantly increased serum FSH and LH levels, lowered testerone level, and decreased testis size. Taken together, the data from the mouse model indicated BNC1 truncation mice had impaired spermatogenesis. Go-analysis, pathway-analysis, Gene-act-network, co-expression network of differentiated expression genes and ChIP-seq bindings were analyzed, and Tex14, Klhl10, Spatc1,Hook1, Tssk6, and Tnp2 were considered to be the possible genes involved in the mechanisms of BNC1 truncation mutation leading to impaired spermatogenesis.

Limitations, reasons for caution: Further studies performed with germ cells of different stages may help to explore the entire molecular mechanisms involved in the function of BNC1 in spermatogenesis.

Wider implications of the findings: Our findings described the first time the effects and mechanisms of BNC1 truncation mutation in spermatogenesis disorder, and provided unique evidences that BNC1 was an important transcription factor involved in spermatogenesis. The testis-specific role of BNC1 identifies this regulator as a potential target for male contraceptive intervention.

Trial registration number: No.

P-011 Efficacy of triple seminal lavage in patients with positive serology for HIV and HCV

E. Cordts[1], I. Yoshida[2], E. Vieira[2], C. Zulim[2], C. Lopes[2], P. Beirigo[2], B. Parra[2], C. Nogueira[2], C. Suganuma[2], J. Romanini[2], C. Barbosa[1]

[1]*Instituto Ideia Fertil, Gynecology, Santo André, Brazil*

[2]*Instituto Ideia Fertil, Embryology, Santo André, Brazil*

Study question: Evaluation of sperm recovery and viral load in samples from patients affected by HIV and HCV after triple washing and qPCR.

Summary answer: The qPCR for detection of viral load after triple seminal washing is essential for serodiscordant couples, although it is undetectable in the blood.

What is known already: Coombs et al., 1998 reported that in 27% of cases, the theory of compartmentalization occurs: there is a disagreement between blood viral load and semen. Reproductive and serodiscordant couples for HIV and HCV can perform in vitro fertilization without risk of transmission of the disease to descendants. However, seminal washing is recommended in situations where the man is a carrier of the virus.

Study design, size, duration: A cross sectional study where 125 seminal samples from HIV and HCV patients were evaluated from January 2012 to December 2017.

Participants/materials, setting, methods: A total of 125 seminal samples from HIV-positive patients were evaluated, 83 of them by HIV and 42 by HCV. The samples were submitted to triple washing using the techniques of Sperm-Wash, Density Discontinuous Gradient and Swim up for subsequent quantification of viral load by qPCR. Only samples from ejaculate were included. The efficacy and the seminal recovery rate were evaluated after the triple washing.

Main results and the role of chance: An overall recovery of 8% sperm after triple washing was found. Comparing the serologies, the seminal recovery of patients with HIV of 7.69% and 8.65% of HCV was observed. The qPCR was performed and the presence of the virus was found in 1.6% (2/125) of the samples after the triple washing. Both samples were from men infected with HIV virus with undetectable viral load in the blood. The clinical decision for these cases was not to proceed with oocyte fertilization.

Limitations, reasons for caution: More studies are needed with greater casuistry to confirm the data found in this study.

Wider implications of the findings: Although patients have undetectable viral load in the blood, this study demonstrated the need to perform the triple semen washing associated with quantification of the viral load by qPCR to prevent transmission of the virus to the descendants.

Trial registration number: None.

P-012 Male fertility under fire- the association between semen parameters and armed conflict related stress: a population-based study

Y. Mizrakli[1], I. Har-Vardi[2], T. Priel[2], A. Harlev[2], A. Zeadna[2], N. Steiner[2], V. Novack[1], E. Levitas[2]

[1]Soroka University Medical Center and the Faculty of Health Sciences- Ben-Gurion University of the Negev, Clinical Research Center, Beer-Sheva, Israel
[2]Soroka University Medical Center and Faculty of Health Sciences- Ben-Gurion University of the Negev, Fertility and IVF Unit- Department of Obstetrics and Gynecology, Beer-Sheva, Israel

Study question: Whether the population exposure to the stress, peaking during two large military operations (MO), was associated with poor semen quality.

Summary answer: This ecological study showed that acute psychological stress can potentially impact sperm quality resulting in decreased sperm motility and reduced normal sperm forms.

What is known already: Psychological stress has been established as having a negative impact on infertility. However, research examining the association between psychological stress and semen quality has been inconsistent. Many studies were small and did not asses stress objectively or dealt with selected study populations.

Study design, size, duration: An ecological study. The data for 11,195 consecutive semen analyses of 6,819 couples between 2009-2017 were analyzed.

Participants/materials, setting, methods: In recent years the civilian population of Southern Israel experienced multiple alert sirens and rocket fire on a daily basis, creating a stressogenic environment. MO adjacent samples were defined as those obtained during the MO and the two subsequent months following cease-fire. Semen analyses were collected as part of basic fertility evaluation and conducted according to WHO criteria. Multivariate analysis was performed using Logistic Regression models.

Main results and the role of chance: Comparison of 659 semen analyses taken during and adjacent to MO to 10,536 semen samples obtained during the rest of the time period showed similarity in the mean age (31.8 ± 7.8 vs. 32.1 ± 8.1 years, respectively, $p = 0.246$), BMI (26.1 ± 4.7 vs. 26.1 ± 8.1, $p = 0.813$) and smoking (44.2% vs. 43.5%, $p = 0.320$). In the MO adjacent group, mean total motility was lower (47.4%±22.9% vs. 49.5%±22.0%, $p = 0.019$), as well as mean progressive motility (39.7%±21.5% vs. 43.3%±21.5%, $p < 0.001$) and mean normal sperm forms (3.4%±1.9% vs. 3.7%±2.3%, $p = 0.010$).

The prevalence of low progressive motility was higher in the MO group (37.5% vs. 30.8%, $p < 0.001$). In multivariate analysis MO adjacency adjusted for age, BMI and smoking was found to be associated with lower progressive motility (adjusted O.R = 1.47 C.I 95% 1.16-1.61).

Limitations, reasons for caution: This is an ecological study assigning stress based on the exposure of the total population. Also, we did not take into consideration the time before the operations when missiles were already fired and the stress may have been increasing.

Wider implications of the findings: We detected a negative association between psychological stress and semen quality. This finding is of public health importance, as stress is common and might be a modifiable factor. In a clinical setting, psychological stress should be considered upon the interpretation of semen analysis data. Future studies should address causality.

Trial registration number: not applicable.

P-013 The impact of male smoking on intracytoplasmic sperm injection outcomes in In vitro fertilization procedures

Z. Petanovski[1], G. Dimitrov[2], M. Hadzi Lega[3], D. Shushleski[4], V. Matevski[5], S. Saltirovski[4], S. Stojkovska[5], E. Petanovska[5], V. Sotiroska[5]

[1]Associate Professor, Medical Faculty, Skopje, Macedonia

[3]First Private General Hospital ReMedika- Skopje- Macedonia, In Vitro Fertilisation Centre, Skopje, Macedonia
[4]In Vitro Fertilisation Centre- First Private General Hospital ReMedika- Skopje- Macedonia, In Vitro Fertilisation Centre-, Skopje, Macedonia
[5]First Private General Hospital ReMedika- Skopje- Macedonia, In Vitro Fertilisation Centre-, Skopje, Macedonia

Study question: How does male cigarette smoking influence in vitro fertilization outcomes?

Summary answer: The results suggest that male smoking negatively influences the IVF outcome resulting in reduced ongoing pregnancy and delivery rate.

What is known already: Cigarette smoke comprises toxic, mutagenic chemicals and carcinogens such as cotinine, cadmium, nicotine metabolites, which were found in the seminal plasma at concentrations proportional to those in the serum, suggesting that they can cross the blood-testis barrier providing genotoxic environment for germ cells. An evidence based review suggests that oxidative stress and the causing genetic and epigenetic changes that result from smoking may correlate directly with reduced sperm parameters and reduced sperm function.

Study design, size, duration: This prospective study encompassed the period from 2012 to 2013 with 702 performed cycles from which 329 (46.9%) men were non-smokers and 373 (53.1%) were smokers The exclusion criteria for women were poor responders (basal FSH greater than 10mIU/ml, less than 5 pre-antral follicles) and patients above 39 years of age. The male exclusion criteria were azozoospermia, severe oligozoospermia, donation, chromosome alteration, genitourinary infections and operations, chemotherapy treatment and diabetes mellitus.

Participants/materials, setting, methods: To minimize the bias, only the first IVF cycle was analyzed. Binary logistic regression analysis was used to study the effect of male smoking on clinical pregnancy and delivery after controlling for potential confounding variables, (maternal age, maternal smoking status and asthenozoospermia). Significant differences were considered all values of $p < 0.05$

Main results and the role of chance: Our study indicates that male smoking does not have a significant influence on the clinical pregnancy rate (OR = 1.21, 95%CI 0.89-1.25). After the adjustment for asthenozoospermia (OR = 1.22,CI 0.91-1.65) and female smoking (OR = 1.21 CI 0.89-1.62), male smoking was again confirmed to be non-significant predictor for reaching clinical pregnancy. These findings support the observations of ICSI as preferred fertilization method. The results also demonstrated that male smoking compromised the quality of the ongoing pregnancy. Significant number of early miscarriages was observed among group of smoker men (18.3% as opposed to 5.6% $p < 0.05$ among smokers and non-smokers respectively) resulting in lower ongoing pregnancy rate in this group of patients (45.9% vs 35.9% $p < 0.05$). We found that male smoking generally is

significant factor for increasing the chances for not achieving delivery for 1.53 times (CI 1,13-2,07). Women older than 35 years in group of paternal smoker had 2.27 times (CI 1,39-4,56) higher risk for not achieving delivery. It is likely that if the oocyte's repair capacities are inadequate (low oocyte quality/increased age), a low rate of embryonic development resulting in a high rate of early pregnancy loss.

Limitations, reasons for caution: Our study should be further investigated. The data on smoking and male fertility reinforce the preferred preventive approach of discouraging smoking and eliminating exposure to tobacco smoke in particular while trying to conceive. Antioxidant supplementation may then be taken together to improve the patient's health outcomes.

Wider implications of the findings: It is also very important to comment that all smokers are not infertile, which suggests that genetic variations or polymorphisms in DNA repair, apoptosis and xenobiotic metabolism genes among smokers may increase susceptibility to infertility.

Trial registration number: N/A.

P-014 Is "real time" conventional TESE (cTESE) an obsolete sperm retrieval technique in patients with non obstructive azoospermia (NOA)?

R. Oses[1], P. Medel[1], A. Valcarcel[2], M. Tiveron[2], M. Guidobono[2], M. Felici[2], E. Young[3]

[1]*IFER, Andrology, Buenos Aires, Argentina*
[2]*IFER, Embryology, Buenos Aires, Argentina*
[3]*IFER, Gynecology, Buenos Aires, Argentina*

Study question: How successful is cTESE as a sperm retrieval technique in patients with NOA when performed in a systematic fashion?

Summary answer: Our results show that "real time" cTESE is a highly efficient sperm retrieval technique in patients with NOA.

What is known already: Recent reports in the literature suggest that there is a tendency to replace cTESE with mTESE in NOA patients in many centers around the world. mTESE was introduced as a surgical approach in patients with very small testicles with the notion of preserving an already diminished testicular parenchyma but it has not proven to be superior in most cases of NOA. In order to perform mTESE an operating microscope is required and a highly trained microsurgeon needs to be always available at the time of egg retrieval, if done simultaneously.

Study design, size, duration: Retrospective clinical study, January 1996 to December 2016: all patients who underwent cTESE were included in the study. All patients were surgically approached in the same fashion by the same team. In some instances the procedure was carried out at the time of egg retrieval and in other cases for diagnostic purposes and sperm cryopreservation. The diagnosis was obtained post operatively in most patients.

Participants/materials, setting, methods: A total of 635 patients underwent cTESE under local anestesia with IV sedation. A scrotal incision was performed on one side with up to four testicular incisions at random until sperm were observed. Only if no sperm were present in any of the chosen areas, was the contralateral testis approached in the same fashion. A small specimen was separated for histopathological diagnosis and the patient discharged four hours later.

Main results and the role of chance: Out of 635 patients who underwent cTESE we were able to identify 388 patients with the histological diagnosis of NOA who had their first testicular biopsy along with sperm retrieval attempt. In 30 cases the procedure was a repeat, in 20 cases the patients had been unable to produce a fresh sample the day of oocyte retrieval, in 10 cases the procedure was undertaken due to absolute asthenospermia/necrospermia or severe oligospermia, in 28 cases the patients had a single testis, in 100 cases the diagnosis was obstructive azoospermia (OA), and in 59 cases we were unable to retrieve their histological reports. All these cases were excluded from our study. In the 388 patients identified with the confirmed diagnosis of NOA we found sperm for ICSI or cryopreservation in 234 (234/388; 60%). In 167 cases a unilateral procedure was sufficient (167/388; 43%), in 33 cases sperm were only found in the contralateral testis (33/388; 8%), and in 35 cases (35/388; 9%) a bilateral procedure was needed in order to obtain enough sperm for ICSI or cryopreservation since only scarce sperm could be harvested from each testicle. In patients with a single testis the sperm retrieval rate was 28.5% (8/28).

Limitations, reasons for caution: This is a retropective study. Only one sperm analysis with centrifugation was performed preoperatively to rule out cryptozoospermia.

Wider implications of the findings: Our extensive experience indicates that "real time" cTESE provides optimal sperm retrieval rates when performed in a systematic fashion. The procedure is simpler and less invasive than mTESE, carries less post operative complications and there is no need for an operating microscope and a trained microsurgeon.

Trial registration number: not applicable.

P-015 Correlation between spermatic dna fragmentation and sperm motility in infertile subjects

G. Peluso[1], A. Palmieri[2], P.P. Cozza[1], G. Morrone[1], P. Verze[2], N. Longo[2], V. Mirone[2]

[1]*Annunziata Hospital of Cosenza, U.O.S.D. of Physiophatology of Human Reproduction, Cosenza, Italy*
[2]*University Federico II°, Urological Clinic, Naples, Italy*

Study question: Why the pathophysiology of the testicular damage associated with varicocele remains unclear, sperm DNA damage has been identified as a potential explanation for this cause of male infertility?

Summary answer: Current study determines the extent of sperm nuclear DNA damage in patients with varicocele, and to examine its relationship with parameters of seminal motility.

What is known already: Varicocele is one of the most common adrological pathologies in the general population and particularly common in infertile men. The varicocele negatively influences spermatic function is well documented although the exact mechanisms are still not understood. In fact, infertility may be associated to a variety of spermatogenetic conditions ranging from normozoospermia to moderate oligoasthenoteratozoospermia (OAT), to azoospermia. Several authors have suggested that patients with varicocele have a significantly higher DNA fragmentation index. Studies show that varicocele samples contain a higher proportion of spermatozoa with abnormal DNA and immature chromatin than those from fertile men as well as infertile without varicocele.

Study design, size, duration: One hundred and fifty subjects analyzed in this study ranged in age between 20-50 with the median age of 35 and attending to Andrology Service for infertility diagnosis and other andrological problems. For each patient included in the study, the spermatozoon population was determined. On the basis of the usual seminologic criteria, patients considered in this phase of the study were characterized by isolated asthenospermia, in according to WHO 2010

Participants/materials, setting, methods: Semen samples from 60 patients with clinical varicocele and 90 infertile men without varicocele were examined. Varicocele sperm samples were classified as normal or pathological according to the 2010 World Health Organization guidelines. Sperm DNA damage was evaluated using the Halosperm kit, an improved Sperm Chromatin Dispersion (SCD) test. All data were calculated as average with standard deviation on experiments which were repeated and analized statistically using the statistical program SPSS.

Main results and the role of chance: DNA fragmentation index (DFI: percentage of sperm with denatured nuclei) values was significantly higher in patients with varicocele, either with normal or abnormal (DFI 25.8 ± 3.2 vs 17.4 ± 2.8- $P < 0,01$) semen profiles. Therefore, most significant data of our study came from the analysis of correlation between the DFI values calculated and progressive a + b motility values expressed in % and calculated in patients with varicocele associated with the condition of isolated asthenozoospermia.

Statistical analysis of the data found a semi-empirical correlation of 0,9982 between the index of percentage fragmentation (DFI) and percentage sperm motility according to the: Eq.1: DFI = 49,48 exp (-0,022 motility)

Limitations, reasons for caution: no limitations took place in the study.

Wider implications of the findings: Results of our study, on the higher frequency of DNA fragmentation presented in the sperm cells of infertile patients with varicocele compared to patients suffering from other typologies of

infertility and the fertile controls, supporting the hypothesis which has been proposed by other authors.

Trial registration number: not applicable.

P-016 Development of sperm searching system using artificial intelligence in assisted reproductive technology

T. Takeshima[1], S. Kuroda[1], M. Yamamoto[2], M. Murase[2], Y. Yumura[1], H. Sasaki[3], T. Hamagami[3]

[1]Yokohama City University Medical enter, Department of Urology- Reproduction Center, Yokohama City- Kanagwa, Japan
[2]Yokohama City University Medical enter, Department of Gynecology- Reproduction Center, Yokohama City- Kanagwa, Japan
[3]Yokohama National University, Faculty of Engineering, Yokohama City, Japan

Study question: This study aims to improve the accuracy of normal sperm selection and to reduce burden on embryologists by introducing AI incorporating their skills and experiences to support detection and selection.

Summary answer: Efficient sperm detection and selection, and improving ART treatment outcome will be expected by development of this AI system.

What is known already: The number of ART cycles in Japan has been increasing year by year. Detection and selection of morphologically normal and motile spermatozoa are carried out by the embryologists out of the cell suspension of prepared semen or testicular tissue. However, the treatment outcome is greatly dependent on the individual technique and experience, and it takes a lot of time and labors. It is difficult for all embryologists to detect and select them with equivalent reproducibility. AI excels in universalizing the elements such as technology and experience.

Study design, size, duration: We conducted a preliminary experiment as a collaborative research between our center and the faculty of engineering of Yokohama National University from 2017. In the training data, 8020 positive examples (spermatozoa) and 25522 negative examples (non-spermatozoa) were labeled and AI was made to identify as spermatozoa.

Participants/materials, setting, methods: Embryologists performed labeling target cells in selecting spermatozoa during ICSI and then recorded on HDD and transported to research facilities. Thereafter, we aim to establish the system in following 4 steps: (1)detection and indexing of spermatozoa, (2)extraction of morphology and motility characteristics of spermatozoa, and accurate reproduction of embryologists' point of view in combination with multidimensional feature quantities, (3)assessment of spermatozoa by ensemble learning, (4)collection and evaluation of data by the urological specialists and embryologists.

Main results and the role of chance: Although the linear discrimination plane was learned from the histogram for both the learning data and the test data by the histograms of oriented gradient (HOG) feature extraction method, and the recall rate 0.99 was obtained, the false positive rate> 0.50 in the test data.

Limitations, reasons for caution: Limitation is that this system is still in the development stage.We are now in the stage of confirmation of sperm detection and grading capability with outlier detection on non-sperm HOG by nonlinear discrimination, and it is not yet applied to clinical application.

Wider implications of the findings: Using AI is a new attempt for searching spermatozoa not reported in the past, and establishing this system make it possible to search sperm with high accuracy.

Trial registration number: not applicable.

P-017 Ultrasonographic (US) visualization of the scrotal vas deferens

K. Nakano, G. Sukegawa, Y. Tsuji

Ebisu Tsuji Clinic, Andrology, Tokyo, Japan

Study question: Can the normal scrotal vas deferens be visualized by ultrasonography (US)?

Summary answer: US can visualize the normal scrotal vas deferens and may provide further insights into pathological conditions of the proximal seminal tract.

What is known already: Obstructive azoospermia results from obstruction of the seminal tract between the rete testis and the ejaculatory duct. Determination of the location of the obstruction is extremely important for selecting an appropriate management. Due to its firmness, the vas deferens can be easily palpated through the scrotum. However, subtle changes in the vas deferens including luminal dilation are difficult to identify by physical examination. Although transrectal US clearly reveals the caudal junction of the vas deferens and seminal vesicles, US visualization of the scrotal vas deferens is considered to be difficult due to the complex structure of the spermatic cord.

Study design, size, duration: This prospective observational study involved 463 infertile men who visited our andrology outpatient clinic from April to December 2017. We excluded from the study patients who had any clinical signs of seminal tract abnormality.

Participants/materials, setting, methods: Because unilateral orchiectomy had been performed in two patients, a total of 924 vas deferens in 463 patients aged 25 to 69 years were examined. After physical examination of the scrotum, we evaluated the testis, rete testis, epididymis and scrotal vas deferens by US using a 14-MHz linear array transducer.

Main results and the role of chance: Of the 924 normal vas deferens, only one with very severe varicocele was not visualized by US. The ultrasonographic features of the normal vas deferens are as follows. Above the proximal tortuous part connected to the tail of the epididymis, the vas runs linearly up to the external inguinal ring. The thick muscular wall of the vas appears hypoechoic, and the lumen is shown as "double-line echoes" at the center of the tube. By color Doppler US, while the vas itself lacks blood flow signals, pulsatile signals of the artery of the vas deferens are evident beside the vas.

Limitations, reasons for caution: US does not allow visualization of the vas deferens from the inguinal canal to just before the ampulla.

Wider implications of the findings: Our experience provides further information for diagnosing anatomical abnormalities of the proximal seminal tract in certain conditions, including vasal obstruction after inguinal hernia repair.

Trial registration number: Not required.

P-018 Ameliorative effects of Naringenin in altered testicular ultrastructural and antioxidant activity following use of antiretroviral therapy in Sprague Dawley rats, a randomised trial

M. Adana[1], E. Akang[2], E. Naidu[2], O. Azu[3]

[1]University of Ilorin, Anatomy, Ilorin, Nigeria
[2]University of KwaZulu-Natal, Clinical Anatomy, Durban, South Africa
[3]University of Namibia, Anatomy, Windhoek, Namibia

Study question: What is the role of naringenin a bioflavonoid on antiretroviral therapy induced testicular ultrastructural changes and altered fertility potentials in Sprague Dawley rats?

Summary answer: Antiretroviral therapy induced testicular ultrastructural changes associated with altered antioxidant activity, impaired semen parameters and decline in fertility index which was partly restored by Naringenin.

What is known already: Even though infection with Human Immunodeficiency Virus (HIV) depresses the health status of men, it does not eliminate the desire for future fertility yet testicular toxicity has been associated with Highly Active Antiretroviral Therapy (HAART). HAART induced histopathological changes in the testes has been linked to increased activity of reactive oxygen species that ultimately overwhelms the tissue's total antioxidant status. The seminiferous tubules has been shown to be particularly sensitive to the effects of HAART thereby rendering patients oligospermic and even azoospermic. Various flavonoids have been shown to mitigate against free radical/oxidative stress induced tissue damage.

Study design, size, duration: A randomized, controlled animal trial involving 30 male and 18 non- mated female Sprague Dawley rats. Animals were housed in standard cages under controlled environmental conditions (25oC and a 12-h light/dark cycle). The study lasted for a period of 10 weeks.

Participants/materials, setting, methods: Thirty male SD rats weighing 200–220 g, were randomly assigned into groups; viz **DW**: Distilled water, **H**: HAART, **N40**: Naringenin, 40 mg/kg, **N80**: Naringenin, 80 mg/kg, **HN40**: HAART+Naringenin, 40 mg/kg and HN80: HAART+Naringenin, 80 mg/kg. After treatment, copulation was allowed to take place. The number of

pregnancies and litters per group were noted. Semen was analysed. Oxidative enzyme activities were assayed using enzyme linked immunoassay and testicular ultrastructural changes were noted via electron microscopy.

Main results and the role of chance: Sperm count was significantly different between the groups. There was a significantly lower count in group H compared to DW [p = 0.01] and N40 [p = 0.032]. There were significantly lower progressive sperms in group H when compared to DW [p < 0.0001], N40 [P = 0.001], N80 [p = 0.00], HN40 [p = 0.00] and HN80 (HAART+Naringenin 80 mg/kg) [p = 0.001]. Group N40 [P = 0.001] and HN40 [P = 0.002] also displayed significantly lower progressive motility when compared to DW.

The testicular glutathione peroxidase levels was higher in the N40 and N80 groups when compared to H group. Lower levels were also observed in groups DW, HN40 and HN80. The N80 group showed significantly higher level of testicular catalase activity than groups DW (p = 0.024) and H (p = 0.003)

Group H displayed thickening and irregularity in the outline of the basement membrane. Normal cellular progression in the germinal epithelium was altered. Spermatids appeared in the basal compartment. There was widening of the internuclear space between Sertoli cells. Degenerative changes appeared in the nuclear membrane, abnormally formed spermatid heads and disorganised axonemes were observed the in the midpiece.

The fertility index was higher in the DW group than in the H and N40 groups. The number of pubs per group were also higher.

Limitations, reasons for caution: A larger sample size would have been more convincing especially in the aspect of fertility index. The study considered the effect of a FDC of HAART, it is therefore difficult to associate the effects observed to a single drug in the combination.

Wider implications of the findings: The study suggests that HAART has deleterious effects on testicular function and male fertility. This agrees with earlier findings. Naringenin, a bioflavonoid may be a useful adjuvant therapy in protecting against testicular toxicity.

Trial registration number: The Animal Research Ethical Committee (AREC), UKZN, South Africa approved this research with a reference number AREC/046/016D.

P-019 CD147 deficiency is associated with impaired acrosome reaction in patients with asthenozoospermia

E. Fok[1], H. Chen[2,3], H.C. Chan[4]

[1]The Chinese University of Hong Kong, School of Biomedical Sciences, Hong Kong, Hong Kong
[2]Guangdong University of Technology, Institute of Biomedical and Pharmaceutical Sciences, Guangzhou, China
[3]First Affiliated Hospital of Shenzhen University, Shenzhen Second People's Hospital, Shenzhen, China
[4]The Chinese University of Hong Kong, Epithelial Cell Biology Research Centre, Hong Kong, Hong Kong

Study question: What is the etiological factor underlying the impaired acrosome reaction in asthenozoospermia infertile patient?

Summary answer: Our study showed that CD147 deficiency is associated with impaired acrosome reaction in patients with asthenozoospermia.

What is known already: Asthenozoospermia, a condition which sperm exhibit motility lower than the normal threshold, accounts for approximately 18% of all male subfertility and infertility cases. A previous study has shown that deficient human β-defensin 1, a small antimicrobial peptide released into the epididymis and female reproductive tract, underlies poor sperm motility observed in asthenozoospermia patients. Intriguingly, sperm from asthenozoospermia patients has been shown to have a significantly lowered rate of ionophore-induced acrosome reaction, suggesting that the infertility outcome of asthenozoospermia patients could be attributed to multifaceted factors. However, the molecular mechanisms underlying defects in acrosome reaction leading to infertility remain incompletely understood.

Study design, size, duration: Sperm from fertile men (n = 36) and asthenozoospermia patients (n = 27) were included in the study. The samples were evaluated for the protein level of CD147 on sperm and used as an in vitro model to study the effect of soluble CD147 on sperm functions and its underlying molecular mechanism.

Participants/materials, setting, methods: The level of CD147 on sperm was assessed by immunofluorescence staining and semi-quantitative Western blot. Sperm samples were treated with recombinant CD147 proteins or conditioned media containing soluble CD147. Sperm functions were evaluated by computer-assisted sperm analysis (CASA), fluorescein-Pisum sativum agglutinin (FITC-PSA) assay, hyaluronan binding assay and oocyte penetration assay. Calcium imaging was used to examine the mechanism underlying the effect of CD147 on sperm functions.

Main results and the role of chance: The localization of CD147 was shifted from the mid-piece to the head region upon capacitation. The expression levels of CD147 were lower in sperm from asthenozoospermia infertile patients that exhibited defects in both sperm motility and acrosome reaction. The reproductive female tract-derived soluble CD147 interacted with sperm-bound CD147. The dimerization of CD147 induced a 2-fold increase in intracellular calcium level and a 3-fold increase in the percentage of acrosome reaction in normal capacitated sperm. Soluble CD147 treatment restored the acrosome reaction from 10% to 37% and enhanced the fertility potential of sperm from asthenozoospermia patients.

Limitations, reasons for caution: The gain- and loss-of-function in human sperm were only achieved by neutralizing antibody against CD147 and recombinant CD147. A more reliable genetic overexpression or knockout approach was not possible in human sperm.

Wider implications of the findings: CD147 deficiency may underlie the acrosome reaction defects in male infertile patients. CD147 is a potential diagnostic marker for male infertility and soluble CD147 is a feasible approach to enhance the fertility outcome of assisted reproductive technologies.

Trial registration number: Not applicable.

P-020 Sperm vitality and DNA fragmentation index (DFI) are good predictors of progressive sperm motility in oligozooasthenospermic men treated with metabolic and essential nutrients

S. Micic[1], N. Lalic[1], D. Djordjevic[2], N. Bojanic[2], A. Virmani[3], A. Agarwal[4]

[1]Uromedica Polyclinic, Andrology department, Belgrade, Serbia
[2]Clinical Center of Serbia, Urologic Clinic, Belgrade, Serbia
[3]Sigma tau Helath Science, Innovation- Research and Development, Utrecht, The Netherlands
[4]American Center for Reproductive Medicine, Andrology Center, Cleveland, U.S.A.

Study question: The goal of this study was to examine correlation between sperm vitality and DFI with progressive sperm motility after 6 months therapy of oligoasthenospermic men.

Summary answer: The increase of the vitality of spermatozoa and decrease DFI have very good predictive and diagnostic characteristics of progressive sperm motility after 6 months therapy.

What is known already: Sperm vitality is a reflection of the proportion of live, membrane-intact spermatozoa determined by either dye exclusion or osmoregulatory capacity under hypo-osmotic conditions. Sperm DNA damage has been associated with adverse reproductive outcomes and has been increasingly utilised in the management of male infertility in the era of IVF and ICSI. L-carnitine is essential for the normal mitochondrial oxidation of fatty acids, protects cell membrane and DNA against damage induced by free oxygen radicals. Both L-C and acetyl-L-carnitine (ALC) also have important roles in the post-gonadal maturation of spermatozoa.

Study design, size, duration: The study was randomized, double blind, placebo controlled (DBPC) and examined the effect of test formulation, Proxeed Plus, containing L-C 2 g and ALC 1 g, as well as antioxidants, vitamins and minerals, in men with idiopathic oligo-asthenozoospermia (age group18-50 years). The protocol was 2 months wash-out and 6 months treatment (T-2, T0, T + 3, T + 6), with test formulation (125 patients) or placebo (50 patients).

Participants/materials, setting, methods: The subjects with oligoasthenozoospermia and history of infertile marriage more than one year, were randomized to receive treatment or placebo in a double blind protocol. Analysis of ejaculate was done according to WHO 5th guideline. Progressive sperm motility (A + B grade of rapid) was done manually. DFI was evaluated by Halosperm kit

(Halotech DNA, S.L) and sperm vitality was done by the one-step eosin-nigrosin technique.

Main results and the role of chance: The results of treated group: DFI (%) was T0 = 38,50 (32,00-48,75), T3 = 35,50 (25,50-44,00) and T6 = 31,00 (25,00-41,00); sperm vitality (%) was T0 = 0.52 (0.43-0.60), T3 = 0.57 (0.46-0.64) and T6 = 0.56 (0.56-0.65; the progressive sperm motility: T0 = 28.00% (12.00 ± 38.00), T3 = 30.00%(12.00 ± 39.00) and T6 = 31.00%(20.00 ± 41.00). All showed significance of $p < 0.001$ by Friedman test. The increase of spermatozoa vitality has the best predictive and diagnostic characteristics. Men who have increased this parameter by 1% have 1,119 times more likely to have a progressive motility of spermatozoa greater than 20% after 6 months of therapy. If the spermatozoa vitality after six months of therapy increases by 5.9% and more (cut off value), the probability that sperm motility will be greater than 10% or 20% is 100% (PPV = 100%). If DFI drops by more than 3% (cut-off), after 6 months of therapy, it can be expected, with moderate accuracy, that men have sperm motility greater than 10% (AUC = 0.793; $p < 0.001$). DFI reduction (odds ratios = 1.106 with 95% confidence intervals) independently increases the likelihood that sperm motility is > 10%. Placebo group: no significant difference in sperm motility, vitality and DFI, between T0 and T6.

Limitations, reasons for caution: No technical limitations.

Wider implications of the findings: This analysis showed that the increase of the vitality of spermatozoa has the best predictive and diagnostic characteristics of progressive sperm motility after 6 months therapy. Further, the percentage of change in DFI after therapy can be used with moderate accuracy in the detection of men with better sperm motility.

Trial registration number: TXT-001-B

P-021 Does replacement of the sperm donor increase the chance of achieving a pregnancy?

R. Hauser, Y. Cohen, H. Yavetz, S. Kleiman, O. Lehavi, S. Barda

Lis Maternity Hospital, The Institute for the Study of Fertility, Tel Aviv, Israel

Study question: to assess whether replacing a sperm donor affects the chances of achieving pregnancy via intrauterine insemination treatments.

Summary answer: A sperm donor replacement may increase the chances to conceive in women who failed to achieve a pregnancy within a few AID treatments.

What is known already: The primary recipients of donor sperm are single women, lesbian couples and heterosexual couples suffering from male infertility. Artificial insemination by sperm donor (AID) is a widely used treatment to achieve pregnancy in those cases. There is a common belief among some of the recipients that replacement of the donor will improve their chances to conceive in cases of repeated failures.

Study design, size, duration: Study population included 312 women who conceived using artificial insemination by sperm donor.

Participants/materials, setting, methods: Group A consisted of 242 women were treated with one donor only and group B of 70 women were treated with one donor for a few cycles and with a different donor for additional cycles. Statistical analysis was conducted using a multivariate model, with consideration of various factors such as age, hormonal treatment, number of inseminations, etc.

Main results and the role of chance: The age of the participants in groups A and B was similar with mean±SD of 37.02 ± 3.58 and 37.26 ± 3.38, respectively. Baseline FSH levels on day 3 of the cycle was similar in groups A and B. There was a significant difference between the number of AID cycles till pregnancy achievement with a single donor (group A) and changed donor (group B, $p < 0.001$) with mean number of 3.78 ± 1.90 and 6.07 ± 2.95, respectively. Further subdivision of groups A and B according to the type of fertility treatment showed significant difference between the number of AID cycles of the first and the second donors of group B ($p < 0.001$).

Limitations, reasons for caution: A retrospective study of women who achieved pregnancies.

Wider implications of the findings: Our results suggest that among women who failed to achieve a pregnancy within a few AID treatments, a sperm donor replacement may increase their chances to conceive regardless of ovulation protocol. Further study is needed to provide explanation for this phenomenon.

Trial registration number: 0726-15-TLV.

P-022 Impact of cigarette smoking on sperm DNA methylation patterns and gene expression

Y. Alkhaled, M. Laqqan, M.A.D. Jahmani, A. Abu Dayyih, M. Abd Al-razaq, M.E. Hammadeh

University of Saarland, Gynecology and Obstetrics, Homburg, Germany

Study question: Are there any implicating consequences of cigarette smoking on sperm DNA methylation level and gene expression?

Summary answer: Cigarette smoking leads to an alteration in the sperm DNA methylation patterns of *PTPRN2* and *TYRO3* genes. Besides, an influence on gene expression level.

What is known already: Various factors affect the sperm DNA methylation patterns including, but not limited, to other environmental, social, racial and biological factors. The effect of cigarette smoking on DNA methylation and consequently gene expression is still considered a contradictory issue.

Study design, size, duration: This study is a prospective cohort study. A total of 108 human semen samples were collected during the period of September 2016 to July 2017. Fifty-nine samples were obtained from fertile heavy smokers, who smoked ≥ 20 cigarettes per day (as a case), and forty-nine from fertile non-smokers males (as control).

Participants/materials, setting, methods: All participants came from the same region without demographic differences such as race. They were all in reproductive age and normal body mass index. Thirty samples (15 Cases and 15 controls) were subjected to Infinium 450 K BeadChip arrays to identify variations in sperm DNA methylation between case and control groups. Furthermore, the local deep bisulfite sequencing was applied to 108 samples to validate CpGs, followed by qPCR to assess the gene expression levels.

Main results and the role of chance: The results of 450 K BeadChip arrays revealed a significant difference in 7 CpGs of the DNA methylation level between case and control groups. Five of them were overlapped with the annotated SNPs. Therefore, they were excluded from this study. The remaining CpGs(cg23841288, and cg19169023) were directly linked to the *PTPRN2*, and *TYRO3* genes and underwent further validation using deep bisulfite sequencing. According to the results of validation, significant differences in the methylation patterns at more than one CpGs and related to *PTPRN2* and *TYRO3* genes amplicon in cases compared to control groups were shown. Whereas, nine of twelve CpG sites in the *PTPRN2* gene-related amplicon ($p \leq 0.006$, $p \leq 0.004$, $p \leq 0.01$, $p \leq 0.01$, $p \leq 0.01$, $p \leq 0.01$, $p \leq 0.03$, $p \leq 0.006$ and $p \leq 0.01$ respectively) and three CpGs of four tested CpGs in the *TYRO3* gene ($p \leq 0.008$, $p \leq 0.005$, p and $p \leq 0.02$ respectively) were found. Furthermore, the present study demonstrates significant differences in the gene expression levels of the *PTPRN2* and *TYRO3* genes in the cases compared to controls ($P \leq 0.01$, and $P \leq 0.04$ respectively), with fold change (0.6 and 1.2 respectively).

Limitations, reasons for caution: The sample size was a constraint towards getting a strong outcome. Therefore, more samples are required to demonstrate the impact of this variation on sperm DNA methylation patterns and the effect of genes expression on human male fertility.

Wider implications of the findings: The study results were a concurrent confirmation towards the drawbacks of cigarette smoking. It should be noted that significant correlations between the variation in the sperm DNA methylation patterns and semen parameters were found. This was furtherly elucidated through the positive results of gene expression of the related genes.

Trial registration number: NO.

P-023 Assessment of sperm apoptosis by flow cytometry technique using 7-Amino-Actinomycin D staining

M. Ben Amor[1], A. Sellami[1], S. Ben Zarrouk[1], S. Daoud[1], F. Hammami[1], H. Mnif[2], N. Chakroun[1], T. Rebai[1]

[1]Medical School of Sfax- Histology-Embryology Laboratory and Research Unit- Sfax-Tunisia

[2]Regional Center of Blood Transfusion Sfax Tunisia, Sfax, Tunisia

Study question: Does the analysis of sperm vitality and apoptosis by the flow cytometry technique offer an interesting sperm biomarker to predict male fertility potential?

Summary answer: Flow cytometry allows identifying the apoptotic spermatozoa not individualized by classic microscopic evaluation.

What is known already: Conventional sperm analysis is a subjective method and shows an average prediction of male infertility. New processes can indicate a more accurate prediction for the state and function of the sperm. Therefore, flow cytometry has become an important technique in sperm evaluation and is increasingly used both for routine assessment and for research in human reproduction.

Study design, size, duration: This basic research study was performed on semen samples collected from 52 patients attending our center for couple infertility investigation.

Participants/materials, setting, methods: Semen analysis was carried out according to WHO 2010 guidelines. Sperm vitality was evaluated respectively by the stain exclusion method (Eosin-Nigrosin) and the flow cytometry technique using 7AAD (7-Amino-Actinomycin D) a DNA specific marker witch label dead spermatozoa. Sperm mitochondrial membrane potential was also analyzed by the flow cytometry technique using JC1 staining.

Main results and the role of chance: Sperm vitality values assessed by Eosin-Nigrosin method were significantly higher than those noted by cytometry analysis (74.5% vs 62.3%, $p < 0.001$). The apoptotic sperm levels were significantly correlated with sperm motility ($r=-0.283$, $p = 0.04$), sperm mitochondrial membrane potential ($r = -0.395$, $p = 0.005$) and leukocyte concentrations ($r=+0.434$, $p = 0.01$).

Limitations, reasons for caution: The present study was performed in relatively small number of samples. Further studies with larger sample size are needed.

Wider implications of the findings: Active oxygen species produced by leukocytes cause significant damage to sperm membranes with severe alterations of mitochondrial functions inducing sperm apoptosis. Sperm mitochondrial membrane potential combined with sperm apoptosis level could be interesting parameters for predicting natural conception and might be used prior to IVF/ART program.

Trial registration number: No trial registration number.

P-024 The impact of seminal hyperviscosity on sperm parameters and male fertility

F. Hammami, S. Daoud, M. Ben Abdallah, N. Chakroun, T. Rebai, A. Sellami

Medical School of Sfax- Histology-Embryology Laboratory and Research Unit, Sfax, Tunisia

Study question: Is there an effect of increased seminal viscosity on sperm parameters and does it contribute in male reproduction disorders?

Summary answer: Semen hyperviscosity significantly affects sperm parameters mainly motility and negatively decreases male fertility rates.

What is known already: Semen hyperviscosity (SHV) is a condition that can impair the physical and chemical characteristics of seminal fluid, which leads to an adverse impact on sperm functions. SHV also leads to certain technical difficulties in the handling of samples, such as when using different methods of semen preparation for *in vitro* fertilization (IVF) programs. Some procedures used to treat SHV may damage sperm structure and should be revised.

Study design, size, duration: This retrospective study was performed on semen samples collected over period of 8 years from 2585 patients attending our center for couple's infertility.

Participants/materials, setting, methods: Semen analysis was caried out according to WHO guidelines. Sperm viscosity was estimated by gently aspirating it into a wide bore pipette, allowing semen to drop by gravity and observing the lenght of any thread, getting 3 groups: G1 (normal viscosity; $n = 2139$): sperm leaves the pipette in seperate drops; G2 (moderate hyperviscosity; $n = 56$): sperm drop from a thread more than 2 cm long; G3 (severe hyperviscosity; $n = 390$): sperm flows very difficult or stays blocked.

Main results and the role of chance: The observed prevalence of SHV was 17.2% (446/ 2585). The mean values of sperm parameters including: volume, numeration, motility, vitality and normal morphology in G1 group were significantly higher than those in G2 and G3 ($p = 0.02$, $p = 0.01$, $p < 0.001$, $p < 0.001$, $p < 0.001$; respectively). Asthenospermia associated to SHV would be related to liquefaction process disturbance secondary to semen kallikreins variability and the abscence of semenogelins matrix hydrolysis. Hypofunction of the prostate or seminal vesicles result in the developmet of SHV.

Limitations, reasons for caution: A potential limitation for this study is its retrospective design. Moreover, semen hyperviscosity does not seem to be induced by a single pathogenic factor, but rather by several (biochemical, enzymatic, and genetic) factors that act in synergy. These factors should be studied further.

Wider implications of the findings: Biochemical changes on SHV could impair male fertility linked to a reduce of seminal antioxydant capacity, sperm membrane lipid peroxidation and sperm nuclear DNA damage. Otherwise, the mechanism in which the depletion of antioxidants in the seminal plasma of patients occurs has not been fully elucidated.

Trial registration number: not applicable.

P-025 Genome wide DNA methylation analysis of ROS-mediated sperm chromatin integrity damage suffering from idiopathic male infertility

B. Song, X. He, H. Wu, Z. Wei, Y. Cao

The First Affiliated Hospital of Anhui Medical University, Reproductive Medicine Center, Hefei- Anhui, China

Study question: The objective of this study was to assess genome-wide sperm DNA methylation alteration between idiopathic male infertility with ROS-mediated DNA damage and normal fertile males.

Summary answer: The results show that there are significant differences in sperm DNA methylation levels between sperm chromatin integrity damage patients and fertile males.

What is known already: It is now clear that ROS-mediated sperm chromatin integrity damage is critical in male infertility. What is not clear is whether ROS could induce epigenetic alterations that further contribute to male infertility.

Study design, size, duration: A genome-wide DNA methylation study was performed using sperm samples of men who were idiopathic infertility with sever sperm chromatin integrity damage. Human semen samples were collected during the period between July 2017 to September 2017.

Participants/materials, setting, methods: Firstly, Infinium 850 K Methylation BeadChip arrays were used to determine whether sperm DNA methylation alterations between 4 infertility males with high sperm DNA damage compared to 4 proven fertile males. Then the top five sites with highest difference in methylation levels were underwent to further analysis using deep bisulfite sequencing in a large samples (100 controls and 100 cases).

Main results and the role of chance: We observed significantly different DNA methylation profiles for the sperm chromatin integrity damage patients and fertile controls. The DNA methylation patterns showed that in the cases, 225 of the 445 CpG sites were hypermethylated and 220 hypomethylatedwere (relative to the fertile controls). Furthermore, we identified genes that may provide insight into the mechanism of ROS-mediated idiopathic male infertility. The top 5 CpGs were found to be directly linked to the genes ZFAT, SOX6, SCARNA17, RP11-5P22.1 and MIR300. Currently, these results are under validation through local deep bisulfite sequencing and are planned to be tested on a larger sample cohort. Gene Ontology analysis indicated the genes are associated with some molecular function and biological process, such as phosphatase binding, DNA binding, nucleic acid binding transcription factor activity, cell differentiation regulation of metabolic process and RNA polymerase II transcription factor activity. KEGG pathway analysis suggested that the DMRs were distributed among pathways of ErbB signaling, Gap junction, GnRH signaling and pathways in cancer, which will lay the theoretical foundation to further excavating the functional genes of ROS-related DNA damage.

Limitations, reasons for caution: The DNA methylation patterns in sperm chromatin integrity damage patients should be confirmed with an mRNA expression analysis and correlated with immunohistochemical data on protein

expression and localization. More studies are needed to elucidate the mechanisms relating to these alterations and to identify their significance and consequences on male infertility.

Wider implications of the findings: The comprehension of mechanisms leading to epigenetic modifications associated with ROS may help better understand the male infertility, as well as aid in the development of potential biomarkers for better male infertility diagnostics and novel therapeutic strategies.

Trial registration number: No.

P-026 Evaluating the predictability of oxidation–reduction potential in male factor infertility in conjunction with semen analysis: A multicenter study

A. Agarwal[1], H. Elbardisi[2], M. Arafa[2], H. Okada[3], K. Suzuki[3], S. Homa[4], A. Kileen[5], B. Balaban[6], A. Ayaz[7], R. Saleh[8], A. Armagan[9], C. Dorsey[10], S. Roychoudhury[11], S. Sikka[7]

[11]*Assam University, Life Science and Bioinformatics, Silchar, India*

Study question: Identify if ORP measure could reliably predict semen samples that meet normal reference range of WHO criteria from those that fail to meet across fertility centers.

Summary answer: Of the 1644 samples analyzed, the ORP measure provided the greatest predictability when distinguishing abnormal from normal semen quality among patients undergoing infertility evaluation.

What is known already: Discrete measures of free radicals, antioxidant activity, and oxidative damage suggest an ambiguous relationship between the redox system and male fertility. Oxidation-reduction potential (ORP) measures the balance between all oxidants and antioxidants providing a comprehensive status of the redox system. In previous studies, ORP has been tested in semen samples using the MiOXSYS System as an alternative method for measuring oxidative stress and distinguishing normal controls from male factor infertility patients; thus ORP levels may be used to clarify the relationship between the redox system and semen parameters associated with male infertility.

Study design, size, duration: This prospective study was carried out jointly by nine participating fertility centers on 1644 subjects. The study was approved by the institutional ethics committee and subjects were consented prior to participation. Subjects were grouped into those that had all normal semen parameters (concentration, total concentration, total motility, progressive motility, and morphology) according to WHO 2010 guidelines and those who failed to meet one or more criteria.

Participants/materials, setting, methods: Exclusion criteria included azoospermia, presence of sexually transmitted disease or chronic diseases, use of prescription, OTC medications or antioxidants. Samples were collected and semen parameters assessed using the WHO 2010 guidelines. ORP was measured (mV) using the MiOXSYS system and normalized to concentration (mV/10^6 sperm/mL). For group comparisons, only those samples with a concentration >0.999 × 10^6 sperm/mL were included.

Main results and the role of chance: In the current study, using an ORP test in conjunction with the semen analysis measures resulted in the detection of abnormal semen quality with a 98.1% sensitivity, 40.6% specificity, 94.7% positive predictive value, and 66.6% negative predictive value. ORP provides a unique and statistically significant contribution in classifying semen quality into abnormal and normal status. A logistic regression performed on all measures (six semen analysis parameters and ORP measure) revealed the predictability of identifying abnormal / normal semen quality within the samples (Table 1). Measures were categorized according to overall contribution and significance. ORP ranked the highest (beta 2.88, p = 0.01) in terms of predicting abnormal / normal semen quality, followed by progressive motility (beta 2.29, p = 0.001), and total motility (beta .494, p = 0.005). Utilizing ORP and semen analysis combined, the overall performance characteristics (Table 2) were 98.1 sensitivity, 40.6 specificity, 93.3% positive predictive value, and 66.7% negative predictive value.

Table 1

	BETA	S.E.	DF	Sig.
(ORP)	2.880	1.152	1	0.012**
(SpermTotal)	−0.150	0.202	1	0.458
(PRMot)	−2.297	0.211	1	0.001***
(TotalMot)	0.494	0.177	1	0.005***
(NormlMorph)	−0.115	0.097	1	0.233
(SpermConc)	−0.356	0.186	1	0.055
(Volume)	0.149	0.162	1	0.358

Limitations, reasons for caution: A number of healthy controls with proven fertility was limited in comparison to the male infertility group. While semen parameters are an important part of the assessment of the infertile male, the gold standard is the reproductive outcome. Pregnancy outcomes were not prospectively measured in the infertile group.

Wider implications of the findings: Abnormal ORP levels will be especially useful in pinpointing the altered functional status of the sperm in patients with idiopathic male infertility and thereby directing those men toward accurate therapeutic management.

Trial registration number: (not applicable) WIRB PRO NUM: 20170761

P-027 Ultrasonographic (US) analysis of seminiferous tubules in patients with complete deletion of the AZFc region

G. Sukegawa[1], T. Sho[2], K. Nakano[1], S. Nariyoshi[2], Y. Tsuji[1,2]

[1]*Ebisu Tsuji Clinic, Andrology, Tokyo, Japan*
[2]*Tenjin Tsuji Clinic, Andrology, Fukuoka, Japan*

Study question: Can US findings regarding seminiferous tubules predict sperm production in patients with complete deletion of the AZFc region?

Summary answer: Thick seminiferous tubules on US images imply sperm production in patients with complete deletion of the AZFc region.

What is known already: Microdeletion of the AZF region located on the long arm of chromosome Y is the most frequent genetic cause of spermatogenic failure. Complete deletion of the AZFc region causes a variable clinical phenotype ranging from azoospermia to severe oligozoospermia.

We have previously demonstrated that seminiferous tubules over 200 μm in diameter can be visualized by US, and thick seminiferous tubules (over 300 μm in diameter) suggest a high rate of successful sperm retrieval in patients with non-obstructive azoospermia.

Seminiferous tubules in patients with complete deletion of the AZFc region have not yet been analyzed by US.

Study design, size, duration: This retrospective study included 802 consecutive patients with non-obstructive azoospermia or severe oligozoospermia who underwent an evaluation for Y chromosome microdeletions at our andrology clinic from June 2014 to October 2017.

Participants/materials, setting, methods: All of the study patients underwent a physical examination, endocrine assessment, karyotyping, Y chromosome microdeletion analysis and US evaluation of the testis, which involved measurement of the testicular volume and the diameter of seminiferous tubules.

US was performed using a 10- or 14-MHz linear array transducer. To optimize US images for visualization of the seminiferous tubules, gain and contrast were appropriately adjusted with graphics software.

Main results and the role of chance: Complete deletion of the AZFc region was identified in 49 patients. After we excluded 2 patients with chromosomal abnormalities and 1 patient with orchitis, 46 patients were included in this study. Of these patients, 31 had sperm in the ejaculate, whereas 15 were azoospermic. Microdissection TESE (micro-TESE) was performed in 6 of the 15 patients with azoospermia, and testicular sperm were retrieved in 2 of these 6 patients.

Thick seminal tubules, defined as more than 300 μm in diameter on US images, were visualized in all patients with sperm in the ejaculate and in both patients with testicular sperm. In contrast, thick seminal tubules were not observed in any of the 4 patients in whom sperm was not retrieved by micro-TESE.

Almost 90% (33/37) of patients with complete deletion of the AZFc region had sperm in the ejaculate or testis. Thick seminiferous tubules on US images in patients with complete deletion of the AZFc region indicate sperm production. Furthermore, a lack of thick seminiferous tubules on US images may suggest a poor outcome of micro-TESE in patients with complete deletion of the AZFc region.

Limitations, reasons for caution: Only 6 of 15 azoospermic patients with complete deletion of the AZFc region underwent micro-TESE, and thick seminiferous tubules were not observed in US in any of the 9 patients who did not choose micro-TESE. More data will be needed before we can draw definitive conclusions concerning this small category.

Wider implications of the findings: US analysis of seminiferous tubules may be helpful for estimating the potential for sperm production in patients with various types of genetic disorders.

Trial registration number: Not applicable.

P-028 Adverse effects of Reactive Oxygen Species in semen to the development of ICSI cleavage embryo

S. Kuroda[1], K. Takeshima[2], K. Usui[1], K. Mori[1], T. Asai[1], K. Yasuda[1], H. Sanjo[1], H. Yamanaka[1], T. Takeshima[1], T. Kawahara[3], Y. Miyoshi[3], Y. Arai[2], W. Izumi[2], M. Murase[2], Y. Yumura[1]

[1]Yokohama City University Medical Center, Department of Urology- Reproduction center, Yokohama, Japan
[2]Yokohama City University Medical Center, Department of Gynecology-Reproduction center, Yokohama, Japan
[3]Yokohama City University Medical Center, Department of Urology and Renal Transplantation, Yokohama, Japan

Study question: Does Reactive Oxygen Species (ROS) in semen have adverse effects to the embryo development in ICSI?

Summary answer: The ROS level in semen was significantly higher in non-successfully developed cleavage embryo group compared to successful developed cleavage embryo group.

What is known already: Reactive Oxygen Species(ROS) in semen is created from immature spermatozoa and seminal leukocytes. High ROS level results in lipid peroxidation, DNA damage and induction of apoptosis, which has been reported to have negative efffect to sperm concentration, motility and male fertile capacity.

Study design, size, duration: This is a retrospective study between March 2013 and December 2016. 887 embryos from 141 cycles were analyzed, which were divided into to successfully developed group and non-successfully developed group and the level of ROS was compered between two groups.

Participants/materials, setting, methods: 77 infertile couples who perfomed ICSI at our center were enrolled. 887 embryos from 141 cycles were analyzed.The ROS level were measured by monolight 3010® using whole semen, which were compared 1) between fertilized group and non fertilized group, 2) between good cleavage embryo group and non-developed embryo group. 3) The cut-off ROS level was calculated for the prediction of good cleavage embryo development.

Main results and the role of chance: 1) The mean ROS level were 50842 (±178426) relative light unit(RLU) and 50118 (±157274) RLU, respectively. No significant difference was observed between the two groups($p = 0.952$). 2) The ROS level was significantly higher in non-developed embryo group compared to good cleavage embryo group(81450 ± 128610 RLU vs 35645 ± 128610 RLU, $p = 0.026$). 3)The cut off value was 6601 RLU calculated from receiver operating characteristic curve (Area under the curve = 0.539), and the embryos were diveded into high ROS group and low ROS group using this cut-off value. Good cleavage embryo rate was significantly lower in high ROS group compared to low ROS group(51.5% vs 63.8%, $p = 0.004$).

Limitations, reasons for caution: This is a retrospective and a single-institute study, prospective and multi center analysis is needed for further investigation. Anti-oxidant capacity in semen against the ROS were not evaluated in this study.

Wider implications of the findings: ROS in semen have adverse effect under the environment of embryo development in ICSI, especially for the good cleavage embryo development than for the fertilization. It may help unveiling the mechanism of cleavage embryo development.

Trial registration number: not applicable.

P-029 Pregnancy rate and infertility in patients with varicocele and/or oligoasthenoteratozoospermia: evaluation of antioxidant supplementation effect on sperm parameters

G.M. Busetto[1], A. Agarwal[2], A. Virmani[3], F. Del Giudice[1], S. Micic[4], V. Gentile[1], E. De Berardinis[1]

[1]Sapienza University Policlinico Umberto I, Urology, Roma, Italy
[2]American Center for Reproductive Medicine, Andrology Center, Cleveland, U.S.A.
[3]Sigma-tau HealthScience, Nutraceuticals, Utrecht, The Netherlands
[4]Uromedica Polyclinic, Andrology, Belgrade, Serbia

Study question: Are functional substances able to treat male infertility and which is the role of varicocele and oligoasthenoteratozoospermia?

Summary answer: The use of functional substances is an efficacious strategy to handle male infertility. All sperm parameters and pregnancy rate significantly increased in treated subjects.

What is known already: Varicocele has adverse effects on spermatogenesis and to date is considered as the first cause of male infertility. Many factors negatively affecting semen quality act through decreasing energy availability by mitochondrial dysfunction and sperm are also vulnerable to reactive oxygen species because their accumulation leads to membrane damage, instability and functional alterations. However, for normal sperm cell function, a delicate redox balance of reduction and oxidation is required. Thus, a therapeutic strategy would need to use supplements to increase sperm energy metabolism, minimize free radical damage and improve the cellular processes connected with the formation and maturation of sperm.

Study design, size, duration: To evaluate, utilizing a randomized double-blind placebo controlled trial, the effect of supplementation with selected naturally compounds on pregnancy rate and sperm quality. The effect was evaluated in subjects with oligo or asthenoteratozoospermia, as well as with or without varicocele.

Participants/materials, setting, methods: With a block randomization 104 patients were enrolled: 52 had grade I-III varicocele and 52 were not affected. Patients were further divided in two groups consisting of the supplementation arm and the placebo arm. The supplementation formulation consisted of L-carnitine, fumarate, acetyl-L-carnitine, fructose, citric acid, selenium, coenzyme Q10, vitamin C, zinc, folic acid and vitamin B12. Spermogram evaluation was done at the beginning of treatment and after 6 months, at the end.

Main results and the role of chance: Adverse events occurred only in the treatment group: 4 patients had nausea and 3 vertigo or headache. Twelve pregnancies occurred during follow-up time: 10 in supplementation group (9 non-varicocele and 1 varicocele) and 2 in placebo group (1 non-varicocele and 1 varicocele). One spontaneous abortion was reported in placebo arm. Mean changes of number of sperm ($10^6 \times$ mL) after treatment were 1.7 in the placebo group and 9.8 in the supplemented group ($p = 0.0186$). Mean changes of sperm concentration ($10^6 \times$ mL) after treatment were 13.0 in the placebo group and 46.9 in the supplemented group ($p = 0.0117$). Mean changes of progressive motility of sperm (%) were 1.7 in the placebo group and 5.9 in the supplement group ($p = 0.0088$). Mean changes of total motility of sperm (%) were 1.6 in the placebo

group and 7.3 in the supplement group (p = 0.0120). Analyzing typical and atypical morphology there was, respectively, a difference of -6.1 and 5.9 in the placebo group while -6.7 and 3.6 in the supplement group.

Limitations, reasons for caution: We did not compare the effect of this treatment with surgical treatment of varicocele and we did not evaluate DNA fragmentation and level of ROS. Furthermore, latest evidences report that evaluating OS can be a diagnostic tool in predicting the best responders to supplementation.

Wider implications of the findings: Oxidative stress is a cause of male infertility with significant negative effect on semen parameters and varicocele is an additional cause of poor sperm quality. The use of functional substances is an efficacious strategy to handle male infertility. All sperm parameters and pregnancy rate increased in treated subjects.

Trial registration number: PXP-001A

P-030 Novel measures of sperm DNA damage increase its usefulness to diagnose male infertility and predict live births following both IVF and ICSI

A.J. Vicens-Morton[1], T. Yap[1], J. Nicopoullos[2], S.E.M. Lewis[3], K. Lee[4], P. Larsen[5], J. Ramsay[6], S. Minhas[7]

[1]*Guy's and St Thomas NHS foundation trust, Urology-Andrology, London, United Kingdom*
[2]*Lister Fertility Clinic, Reproductive Medicine & Surgery, London, United Kingdom*
[3]*Queen's University Belfast, Andrology, Belfast, United Kingdom*
[4]*SpermComet Ltd, Spermcomet, Belfast, United Kingdom*
[5]*Cryos International Sperm Bank, Sperm bank, Copenhagen, Denmark*
[6]*Charing Cross Hospital / Chelsea & Westminster Hospital / Hammersmith Hospital, Urology-Andrology, London, United Kingdom*
[7]*University College London Hospital, Urology/Andrology, London, United Kingdom*

Study question: Predictive power of novel Comet parameters that quantify damage levels in the semen sample and utility in prediction of ART live birth rates.

Summary answer: The proportion of sperm with low or high levels of DNA damage provides discriminatory information for male infertility diagnosis and treatment outcomes.

What is known already: The Comet assay measures the DNA damage in individual sperm enabling the degree of heterogeneity of the whole sperm population to be assessed.

Study design, size, duration: Retrospective study of 381 men of couples attending a Lister Fertility Clinic for IVF or ICSI treatment were recruited during 2015-2017

Participants/materials, setting, methods: 381 couples attending for IVF or ICSI. Sperm DNA damage quantified using the average Comet Score (ACS) and two novel parameters: the low and the high Comet Score. Sperm from 166 men with idiopathic infertility were compared with those from 76 sperm donors, using ROC analysis. 79 IVF and 229 ICSI cycles were included to determine thresholds for each parameter using ROC analysis. Thresholds were used to compare live birth rates (LBRs) following ART.

Main results and the role of chance: 80% of sperm from fertile men had less than 33% DNA damage. ACS, HCS and LCS were all highly predictive of male infertility (ROC > 0.9, p < 0.0001). IVF LBRs declined sharply once sperm DNA damage exceeded all threshold levels with HCS showing the sharpest decline. ICSI LBRs were also impacted by sperm DNA damage with highest LBRs in men whose sperm DNA approached the fertile range. Trends in IVF and ICSI differed in that IVF LBRs decreased as damage increased whereas in ICSI, LBRs decreased but then remained stable.

Limitations, reasons for caution: A prospective study choosing IVF or ICSI based on these thresholds should be performed to confirm this data.

Wider implications of the findings: The proportion of sperm with low or high levels of DNA damage provides discriminatory information for male infertility diagnosis and chance of success by IVF compared to ICSI. Implementing these new test thresholds will enable better selection of ART treatment pathways.

Trial registration number: None.

P-031 High concentrations of interleukin-18 induce Leydig cell apoptosis and steroidogenesis disorder

T. Inoue[1,2], M. Aoyama-Ishikawa[1], M. Uemura[3], H. Yamashita[4], Y. Koga[4], M. Usami[5], J. Kotani[6]

[1]*Hyogo College of Medicine, Department of Emergency- Disaster and Critical Care Medicine, Nishinomiya- Hyogo, Japan*
[2]*Umeda Fertility Clinic, Department of Gynecology, Osaka, Japan*
[3]*Kobe Gakuin University, Faculty of Rehabilitation, Kobe, Japan*
[4]*Kobe University Graduate School of Health Sciences, Department of Biophysics, Kobe, Japan*
[5]*Konan Women's University, Department of Clinical Dietics and Nutrition, Kobe, Japan*
[6]*Kobe University Hospital, Department of Emergency and Critical Care Medicine, Kobe, Japan*

Study question: Do high concentrations of interleukin (IL)-18 influence a drop in steroidogenesis by increasing apoptosis of Leydig cells?

Summary answer: High IL-18 concentrations increased apoptosis-related proteins (cleaved caspase [CC]-8 and -3) and death receptor pathway-related mRNAs levels but reduced streroidogenic acute regulatory (StAR) protein levels.

What is known already: IL-18, which is produced by germ cells, Leydig cells and resident macrophages, is an indispensable cytokine in the maintenance of testis homeostasis. IL-18 is known to be an inflammasome-mediated cytokine, and IL-18 levels are increased by inflammatory stimulation such as lipopolysaccharide (LPS) in mouse testis. We showed that endogenous IL-18 induced testicular germ cell apoptosis during endotoxin-mediated inflammation when the plasma IL-18 levels were very high (Inoue T. *et al. Reproduction.* 2015;150:105-114).

Study design, size, duration: LPS stimulation: Mouse Leydig cell line TM3 cells and mouse macrophage cell line RAW264.7 cells were stimulated with 200 or 1,000 ng/mL LPS and were sampled at 0, 1, 6, 12, 24 and 48 hours. Recombinant IL-18 (rIL-18) stimulation: TM3 cells were stimulated with 0.1, 1, 10 and 100 ng/mL rIL-18 and were sampled at 12 h. Vehicle: TM3 or RAW264.7 cells were incubated in the medium only.

Participants/materials, setting, methods: Cells were cultured on 6-well microplate (4×10^5 cells) with DMEM-F12 medium for 48 h at 37°C, 5% CO_2. CC-3, CC-8, IL-18 and StAR protein levels were measured by western blotting. The expression levels of *Tnf-α, Il-6, Il-18, Fas, Fas ligand (FasL), Tnfr1* and *Fadd* mRNAs were analysed using reverse transcriptional real-time PCR. Statistical analysis was performed using Student's t-test or Welch's t-test and Tukey-Kramer's post-hoc test (statistically significant: $p < 0.05$).

Main results and the role of chance: LPS significantly increased *Tnf-α* and *Il-6* expressions at 1 h ($p < 0.01$) and *Fas* and *Tnfr1* expressions at 6 h ($p < 0.01$). LPS also increased CC-8 and CC-3 expressions at 6 and 12 h, respectively, and these levels were maintained until 48 h. However, *FasL* and *Fadd* mRNA expressions did not differ significantly between the LPS and control groups. LPS stimulation did not increase IL-18 protein and mRNA expressions in TM3 cells. The expression of StAR was reduced at 12 h and maintained until 48 h after LPS stimulation. These results suggest that LPS-induced Leydig cell apoptosis may lead to steroidogenesis reduction. We hypothesised that IL-18 level increased in testes after inflammation was derived from immune cells. *Il-18* expression in RAW264.7 was significantly increased at 6 h ($p < 0.01$) and maintained at a high level until 48 h after LPS stimulation. High-concentrated (10 or 100 ng/mL) rIL-18 increased CC-3, CC-8, *Tnf-α, Fas* and *Fadd* expressions. Contrariwise, high-concentrated rIL-18 reduced the expression of StAR protein. There was no significant difference between control and rIL-18 stimulation on *FasL* and *Tnfr1* mRNA expressions. These results suggest the overproduction of IL-18 induced Leydig cell apoptosis and reduced steroidogenesis during acute inflammation.

Limitations, reasons for caution: The limitation of this study is that Leydig cell-macrophage interactions during inflammatory condition could not be evaluated. Therefore, even though our results may not completely explain the relationship between Leydig cell apoptosis/steroidogenesis and immune cell-derived overproduction of IL-18, they should help to elucidate the underlying cell-cell interactions.

Wider implications of the findings: Our results suggest that the overproduction of IL-18 may induce Leydig cell apoptosis, which may lead to the reduction of steroidogenesis. Monitoring IL-18 levels and controlling the overexpression of IL-18 could be a new therapeutic target to prevent Leydig cell apoptosis and the dysfunction of steroidogenesis during acute inflammation.

Trial registration number: Not applicable.

P-032 Magnetic-activated cell sorting as a complement to swim-up improves efficiency of spermatozoa separation

M. Jeseta, E. Bozenkova, J. Zakova, P. Ventruba, I. Crha, E. Lousova

Faculty of Medicine- Masaryk University Brno and University Hospital Brno, Gynecology and Obstetrics, Brno, Czech Republic

Study question: Is it beneficial to use swim-up before or after magnetic-activated cell sorting (MACS) for effective spermatozoa selection for IVF?

Summary answer: Our results showed that the combination of swim-up and magnetic-activated cell sorting brings better results in sperm selection when the first step is the swim-up.

What is known already: Spermatozoa selection is one of the most important steps in IVF methods. Magnetic-Activated Cell Sorting (MACS) is a selection method which reduces apoptotic spermatozoa in sample and improves IVF outcome. Many reports indicate that MACS is a beneficial technique compared to classical sperm selection techniques. However, the possible positive effects of this method in clinical application are still debatable. Although a positive effect of swim-up and MACS on spermatozoa selection was presented, further studies are needed to investigate the benefits of using the combination of swim-up and MACS on separation of spermatozoa.

Study design, size, duration: A prospective study was carried out to investigate the effects of spermatozoa separation procedure on concentration, motility and DNA integrity after using swim-up and MACS methods and their combinations. A total of 26 normozoospermic patients were included in this study from January to December 2017. A sample from each volunteer was divided into 5 subgroups according to separation procedure as follows: 1) native 2) swim-up 3) MACS 4) MACS/swim-up 5) swim-up/MACS.

Participants/materials, setting, methods: Semen samples from the volunteers were separated by swim-up, MACS or combination of these methods according to the manufacturer's instructions (Miltenyi Biotec). The analysis of sperm concentration and motility was performed both in raw and subgrouped semen samples according to the WHO manual. Sperm DNA fragmentation was assessed using sperm chromatin dispersion test (Halosperm G). Proportion of spermatozoa with fragmented DNA was expressed as DNA Fragmentation Index (DFI). P value <0.05 was considered statistically significant.

Main results and the role of chance: Compared to spermatozoa concentration in the native sperm samples (average 81.4 mil/ml), this parameter significantly decreased in all the other groups. A statistically significant decrease was observed in swim-up (23.2 mil/ml), MACS (29.6 mil/ml) swim-up/MACS (16.8 mil/ml) and also MACS/swim-up (23.4 mil/ml). Total sperm motility was significantly higher in all the groups where swim-up method was applied (92.7 %), swim-up/MACS (84.5 %) or MACS/swim-up (88.1 %) in comparison with native ejaculate (52.7 %) and MACS method alone (37.8 %). In the case of sperm chromatin integrity, no significant differences were observed among native (DFI 30.52 %), MACS (DFI 28.65 %) and MACS/swim-up (DFI 22.7 %). However, swim-up/MACS significantly reduced the proportion of spermatozoa with fragmented DNA (DFI 13.8 %) as well as swim-up alone (DFI 18.2 %). Indeed, the combination of swim-up/MACS significantly decreased the proportion of spermatozoa with fragmented DNA in comparison with native ejaculate and also with MACS method alone. Based on our results we recommend to use swim-up followed by MACS method. This approach brings better results in sperm selection – lower proportion of spermatozoa with fragmented DNA and also better gain in terms of total sperm count usable for next IVF or ICSI methods.

Limitations, reasons for caution: The limitation is the number of semen samples included and analysed in this study which slightly reduced the power of the statistical analysis.

Wider implications of the findings: Combination of the swim-up method followed by MACS is the most effective. MACS have its limitations regarding sperm concentration and volume for loading. Indeed, loading of raw semen to column may reduce the filtering function of MACS, since dead/apoptotic sperm cells bound to the MACS column compete with motile/non-apoptotic spermatozoa.

Trial registration number: not applicable.

Supported by MH CZ – DRO (FNBr, 65269705) and fund from Faculty of Medicine MU to junior researcher Michal Jeseta.

P-033 The impact of semen infections over sperm parameters in primary infertile men - results of a real-life, cross-sectional study

F. Pederzoli[1], E. Ventimiglia[1], P. Capogrosso[1], L. Boeri[2], W. Cazzaniga[1], M. Alfano[1], F. Chierigo[1], E. Pozzi[1], N. Frego[1], F. Dehò[1], E. Montanari[2], F. Gaboardi[1], V. Mirone[3], F. Montorsi[1], A. Salonia[1]

[1]IRCCS Ospedale San Raffaele, Division of Experimental Oncology/Unit of Urology, Milan, Italy
[2]IRCCS Fondazione Ca' Granda - Ospedale Maggiore Policlinico, Dept. of Urology, Milan, Italy
[3]School of Medicine and Surgery- University of Naples Federico II, Dept. of Urology, Naples, Italy

Study question: To assess the prevalence of urogenital infections and their impact on sperm and hormonal parameters in Caucasian-European men presenting for primary couple infertility.

Summary answer: Semen infections are highly prevalent in infertile Caucasian-European men. Non-obstructive azoospermia (NOA) is more frequently found in patients with a positive semen culture.

What is known already: Among the possibly reversible factors associated with male infertility and abnormal semen parameters, acute and chronic infections of the male urogenital tract are of great relevance as they account for 15-20% of all cases. Overall, cellular reactions against the pathogenic agents and activation of immunity cells present in the seminal fluid can lead to defects of spermatozoa function, obstruction of the seminal tract and even deterioration of spermatogenesis. However, the debate about the cause-effect relationship between genitourinary infections and male infertility is far from over and the available guidelines do not give clear indications yet.

Study design, size, duration: Real life, cross-sectional study based on a cohort of 2464 consecutive white-European men assessed at a single academic centre for couple's infertility (non-interracial infertile couples only) between September 2006 and September 2016.

Participants/materials, setting, methods: Demographic, clinical and laboratory data of the entire cohort were analyzed. Health-significant comorbidities were scored with Charlson Comorbidity Index (CCI; categorized 0 vs. ≥1). Semen analysis was based on WHO 2010. Only patients assessed with semen culture tests were included in the analysis. Hypogonadism was defined as a total testosterone level <3.0 ng/ml. Descriptive statistics and logistic regression models tested the association between sperm infection and clinical, seminal, and hormonal characteristics in the entire cohort.

Main results and the role of chance: Overall, 1662 patients (67.5%) underwent sperm cultures. Of them, semen cultures were positive in 271 patients (16.3%). Most commonly identified bacteria were Ureaplasma spp. and Enterobacteriaceae spp. (32.9% and 14.8%, respectively). A concomitant infection with 2+ agents was reported in 15.1% cases. Patients with a positive semen culture had higher mean (SD) BMI [26.1 (4.0) vs. 25.6 (3.3)], lower ejaculate volume [2.99 (1.6) vs. 3.35 (1.8) ml], lower inhibin B levels [98.1 (74.8) vs. 115.9 (83.3) pg/ml], were more frequently active smokers compared to those without semen infections (all $p \leq 0.02$). No significant correlations were found between the different infectious agents and sperm parameters. Azoospermia (NOA + OA) was more frequently reported in patients with positive vs. negative semen cultures (27.7% vs. 17.0%, $X^2 = 16.29$; $p < 0.001$); semen infections were more frequently found in NOA patients ($X^2 = 17.84$; $p < 0.001$) but not in OA men ($p = 0.8$). At multivariate analysis, a positive semen culture achieved independent predictor status for azoospermia (NOA + OA; OR 2.50, $p < 0.001$) and for NOA (OR 2.59, $p < 0.001$), after accounting for

CCI status, genetic abnormalities, history of cryptorchidism and hypogonadal status.

Limitations, reasons for caution: No comparison with a same-race, age-matched cohort of fertile individuals. Lack of data regarding potential molecular alterations in spermatogenesis, which may be important to understand the possible impact of infections on semen parameters.

Wider implications of the findings: Infections of the urogenital tract are thought to be potentially modifiable causes of male infertility, so that a detailed and extensive investigation on them may be advisable to prevent long, potentially unnecessary infertility treatments.

Trial registration number: N/N.

P-034 The effect of autologous platelet-rich plasma on human sperm parameters: in vitro experimental study

R. Bader[1,2], M. Moussa[2], A. Mourad[3], J. Azoury[1], J. Ibrahim[4], G. Raad[T], J. Azoury[1*], N. Alaaeddine[5*]

[1]Mount Lebanon Hospital, Azoury IVF Clinic, Beirut, Lebanon

[4]Lebanese University, Faculty of Public Health II, Beirut, Lebanon
[5]Saint-Joseph University, Regenerative Medicine and Inflammation Laboratory - Faculty of Medicine, Beirut
**Contributed equally to this work*

Study question: Study the effect of autologous PRP (platelet-rich plasma) on sperm parameters in the presence and absence of oxidative stress.

Summary answer: Autologous PRP improves the quality of the sperm, more so in the presence of oxidative stress.

What is known already: Around 65 to 80% of infertile men suffer primary testicular defects in spermatogenesis, detected by abnormal semen analysis. In addition to standard parameters, specialized tests, such as oxidative stress measurement and sperm DNA fragmentation test, can help in the diagnosis and prognosis of infertility. The role of oxidative stress in male infertility is well established and all sperm parameters are highly affected by its damage. Recently, a review of growth factors, cytokines, and antioxidants present in PRP and their effect on sperm parameters have lead to a theoretical conclusion that PRP might be a novel therapeutic option for male infertility.

Study design, size, duration: Semen samples of 30 healthy men in their fourth decade attending a fertility clinic, between November 2016 and December 2017, were enrolled in this cohort study. After obtaining a written informed consent from all patients, a questionnaire about age, previous diseases and habits was filled, and biological samples (blood and sperm) were obtained.

Participants/materials, setting, methods: After establishing H2O2 suitable concentration (10 mM) for oxidative stress induction, semen samples were prepared and cultured in the presence or absence of H2O2. Following preparation of autologous PRP, semen samples were left untreated or treated with increasing concentrations of PRP (2%, 5% and 10%). After 24 hours, sperm motility, morphology, vacuolization, viability, DNA fragmentation, and oxidative stress assessment were evaluated using light microscopy, Spermoscan kit, eosin-nigrosine staining, halosperm kit and nitroblue tetrazolium test, respectively.

Main results and the role of chance: This study demonstrated the harmful effect of oxidative stress on sperm parameters, showing a significant increase in the percentage of vacuolization ($p = 0.047$) and sperm DNA fragmentation ($p = 0.030$), and a significant decrease in the percentage of progressive ($p = 0.026$) and total motility ($p = 0.012$) in the H2O2 treated group compared to non-stressed sperm. As expected ROS positive sperm cells were extremely higher in the H2O2 treated samples. When different concentrations of PRP were added to all specimens, an improvement of the studied parameters were noted mainly with PRP 2%, leading to the conclusion that a concentration of 2% is the best to achieve a positive effect on sperm parameters. As expected the percentage of dead sperm and the cell morphology didn't differ between the group treated with PRP and the untreated group ($p > 0.05$). However, DNA fragmentation, and ROS positive cells were significantly decreased when PRP was added to both stressed ($p < 0.0001$) and non-stressed samples ($p = 0.025$ and $p = 0.008$ respectively), and immotile sperm and vacuolization were also decreased when PRP was added but only for the stressed specimens ($p < 0.0001$). Finally, the same beneficial effect of PRP was noted with increased percentage of progressive and total motility in the stressed group only ($p < 0.0001$).

Limitations, reasons for caution: Due to financial limitations, we could not be able to include infertile patients in the present study. The correlation of our findings with sperm parameters in patients with fertility problems would give better understanding of the involvement of oxidative stress in male infertility.

Wider implications of the findings: Findings from the present study contribute to the understanding of sperm physiology and would have relevance in the diagnosis and/or treatment of infertile patients.

Trial registration number: Not applicable.

P-035 Effect of paternal age on semen parameters and the live birth rate of in-vitro fertilization treatment

S.F. Lai, H.W.R. Li, Y. Shu Biu William, H.Y.E. Ng

The University of Hong Kong, Obstetrics and Gynaecology, Hong Kong, Hong Kong

Study question: To determine the effect of paternal age on semen parameters and the live birth rate of first IVF cycles.

Summary answer: Paternal age is negatively correlated with some semen parameters but it could not predict the likelihood of a live birth in the fresh IVF cycle.

What is known already: Two systematic reviews looking at the effect of paternal age on assisted reproduction outcomes showed conflicting results on both semen parameters and IVF outcomes. The conclusion drawn was that except for volume and possibly motility, other sperm characteristics such as concentration and morphology did not alter with age and advancing paternal age was not associated with adverse IVF outcomes.

Study design, size, duration: This is a retrospective analysis of all first IVF cycles carried out between 2004 and 2014 at the Centre of Assisted Reproduction and Embryology, The University of Hong Kong - Queen Mary Hospital. Only those using ejaculated sperms were included for analysis to avoid any potential bias. Those requiring preimplantation genetic diagnosis and using donor sperms or surgically retrieved sperms were excluded from the study.

Participants/materials, setting, methods: Women received ovarian stimulation using either the long gonadotrophin releasing hormone agonist or antagonist protocol. Embryo transfer was performed two or five days after the oocyte retrieval. Up to three embryos were transferred before 2006 and a maximum of two embryos were transferred after 2006. Luteal phase was supported with vaginal progesterone pessaries or intramuscular injection of hCG. Data of all first IVF cycles was retrieved from the Assisted Reproduction Clinical Database of the Centre.

Main results and the role of chance: A total of 3549 first IVF cycles fulfilling the inclusion criteria were analysed. In the raw semen, paternal age is negatively correlated with semen volume, progressive motility, total motility and total motile count with normal morphology (TNMC) ($p < 0.005$). It is positively correlated with sperm concentration ($p < 0.001$) but does not correlate with sperm count, normal morphology and total motile count (TMC). Paternal age does not correlate significantly with fertilization rate, both in the conventional insemination group, ICSI group and overall ($p = 0.786$, 0.977 and 0.810 respectively). Paternal age positively correlates with maternal age (Spearman's correlation coefficient 0.487, $p < 0.001$). Paternal age is significantly lower in those who attained pregnancy, ongoing pregnancy and live birth compared with those who did not ($p < 0.001$). Logistic regression showed that maternal age, total numbers of oocytes retrieved and number of embryos transferred, but not paternal age, were the significant factors which independently predicted the likelihood of live birth in the first IVF cycles after controlling for the others ($p < 0.001$).

Limitations, reasons for caution: We do not have the information on congenital abnormalities of the live born and the long term data of the babies born from IVF/ICSI. The present study examined patients who have undergone IVF treatment and the results may not be applicable to natural conception.

Wider implications of the findings: Infertile couples can be counselled that although there is a decline in some semen parameters with paternal age, the live birth rate of IVF depends on the maternal age, the number of oocytes retrieved and the number of embryos transferred but not the paternal age.

Trial registration number: Not applicable.

P-036 Animal enriched serum contains vitamin E and omega-3 fatty acids; a new suggestion to improve frozen-thawed human sperm quality

S. Seifi[1,2], A. Shahverdi[1], A.R. Alizadeh[1], H. Choobineh[3], M. Hezavei[1]

[1]*Department of Embryology, Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR, Tehran, Iran*
[2]*Rouyesh Helal Infertility Treatment Center, Helal Iran Pharmaceutical and Clinical Complex, Tehran, Iran*
[3]*Assisted Professor of School of Allied Medical Sciences, Tehran University of Medical Sciences, Tehran, Iran*

Study question: This study was performed to evaluate the effects of ram enriched serum contains vitamin E and omega-3 fatty acids on human sperm cryopreservation.

Summary answer: Low concentration of enriched serum contained vitamin E and fish oil + vitamin E in commercially freezing medium improved frozen-thawed human sperm parameters.

What is known already: Cryopreservation media has crucial role in protection of sperm against cryo-injuries during freezing-thawing. Therefore, developing this media can improve the fertility potential of sperm during this process. It seems that using nutrients in freezing media is leading to improve thawed sperm parameters. Although effectiveness roles of antioxidants and omega 3 fatty acids for improvement of sperm quality after freezing are reported, the potential of dietary enriched serum contains vitamin E is currently unclear. Therefore, the purpose of this study was to evaluate the addition of enrich serum contains these nutrients in commercially freezing media for cryopreservation of human sperm.

Study design, size, duration: To produce enriched serum, 16 rams (n = 4) were fed diets as follows: Control (CTR), vitamin E (VITE; 200 IU/ram/day), fish oil (FO; 40 g/ram/day) and fish oil + vitamin E (FO+VITE). In the second phase, semen samples were collected from 25 normospermic men and then were divided into six equal experimental groups for cryopreservation in freezing media (SpermFreez™, Fertipro) containing enriched 5% ram serum as mentioned above.

Participants/materials, setting, methods: Fetal Bovine Serum (5% FBS) and commercially freezing media without serum (Control) were used as other experimental groups. To evaluate the effects of enriched serum on the quality of frozen-thawed sperm, several parameters such as motion characteristics (CASA), viability (Eosin-nigrosin), DNA fragmentation (SCSA) and total ROS (Chemiluminescence assay) were recorded. Data were analyzed using SPSS and statistical differences among various groups were determined by ANOVA and Tuckey's post hoc test.

Main results and the role of chance: The highest significant ($p < 0.05$) percentage of sperm motility and viability were observed in groups containing VITE (49.78 ± 1.96 and 44 ± 8.03) and FO+VITE (51.28 ± 2.71 and 48 ± 7.74) compared to control group (38.66 ± 1.89 and 37 ± 8.47), respectively. Moreover, FBS produced the lowest significant ($p < 0.05$) percentage of motility and viability (33.66 ± 1.88 and 30 ± 7.33) compared to control group, respectively. Interestingly, adding serum contains FO+VITE to freezing media improved curvilinear velocity (VCL) than other groups (53 vs. 31, 36, 37, 44, 48 µm/s for FO +VITE, FBS, FO, control, CTR, VITE, respectively). ROS concentrations were not significantly ($p > 0.05$) affected by the serum supplementation. Flow cytometry parameters in this study confirmed our results related to motility and viability. Straight linear velocity (VSL) as well as Average path velocity (VAP) were changed by serum inclusion. This improvement is mostly related to characteristic of antioxidant activity of vitamin E and omega-3 fatty acids. This combination has several characteristic that may improve the quality of sperm such as membrane flexibility and improve signal transduction during cryopreservation.

Limitations, reasons for caution: The limitations of the present study included the limited volume of sample test for more investigations and functional tests. We cannot test the fertility potential of frozen-thawed sperm in current study.

Wider implications of the findings: Our study has clinical relevance and may result in considerable improvement from a wide range of cryopreservation procedures and assisted reproductive techniques (ART) which warrants further studies. Furthermore, this attitude may improve the aspects of sperm freezing protocols in several species.

Trial registration number: Not applicable.

P-037 Male's advanced age negatively impacts embryo development on short-term insemination IVF cycles with younger female patients

R. Taniguchi, S. Hatakeyama, H. Anakubo, Y. Nagahama, Y. Taga, S. Shioya, N. Nakasuji, S. Ohgi, A. Yanaihara

Yanaihara Women's Clinic, Obstetrics and Gynecology, Kamakura, Japan

Study question: Do the couple ages affect short-term insemination conventional in vitro fertilization (c-IVF) results?

Summary answer: Male's advanced age on short-term insemination c-IVF has a negative influence on fertilization and embryo development.

What is known already: Female age has been shown in multiple studies to be a predictor of poor reproductive success with assisted reproductive technology (ART). In addition, the influence of male age is suggested in undergoing ART.

Study design, size, duration: This retrospective cohort study included a total of 3249 c-IVF cycles of infertile couples between January, 2012 and October, 2017 at Yanaihara Women's clinic.

Participants/materials, setting, methods: Male and female patients were divied into two age groups (31-37 years, and 38-44 years), and a male age on IVF outcomes for short-term insemination was studied. The protocol for all the cycles was insemination for 3 hours, PB check(two polar body, 2PB) 4-6 houers later, and fertilization check(two pronuclei, 2PN) 20 hours after insemination. We compared the rates of fertilization, embryo development, and clinical pregnancy on day 5 after ET among different age groups.

Main results and the role of chance: In the 31-37 years age female group between the same age male partner group and older age male partner group (38-44 years), the second polar body release rates (80.6% vs 77.5, $p < 0.01$), fertilization rates (74.0% vs 70.5% $p < 0.05$), Day 3 good embryo rates (56.2% vs 52.0%, $p < 0.01$) and blastocyst formation rates (57.8% vs 49.2%, $p < 0.01$) werer compared, and all the above outcomes were significantly lower in the older male partner group. However, there were showed no significant differences on day 5 good blastocyst rates (53.5% vs 51.6%) and clinical pregnancy rates (52.9% vs 52.9%) after embryo transfers. Women 38-44 years groups showed no statistically significant differences in the rates among different male age partner groups ($p > 0.05$).

Limitations, reasons for caution: Male age affects short-term insemination IVF outcomes, but female factors outperforms male factor in cases with older patients.

Wider implications of the findings: Male age affects c-IVF outcomes, and it is necessary to think about treatment options with the male age as well as female age in consideration.

Trial registration number: None.

P-038 The effect of paternal trans fatty acids diet on sperm quality and expression profile of PPAR genes in the testis of rat offspring

N. Khamehiee[1,2,3], G. Javadi[1], B. Ebrahimi[3], A. Alizadeh Moghaddam[3], M. Shahhoseini[2]

[1]*Science and research- Islamic Azad University, Department of genetics-, Tehran, Iran*
[2]*Reproductive Biomedicine Research Centre- Royan Institute for Reproductive Biomedicine- ACECR, Department of Genetics-, Tehran, Iran*
[3]*Reproductive Biomedicine Research Centre- Royan Institute for Reproductive Biomedicine- ACECR, Department of Embryology-, Tehran, Iran*

Study question: Does the paternal trans fatty acids diet influence on sperm quality and expression profile of *PPAR* genes in testis tissue of rat offspring?

Summary answer: Paternal intake of trans fatty acids caused to significant decrease in sperm parameters and expression profile of *PPARβ* and *PPARγ* genes in male offspring rats.

What is known already: High fat diets especially trans fatty acids can affect on the expression of a wide variety of metabolic factors including peroxisome proliferator-activated receptor, *PPAR*. *PPARs* are nuclear receptors that their normal expression levels in testis tissues of adults are associated with their normal spermatogenesis. Recently, it has been shown by investigators that suboptimal diet during male gametogenesis can influence the metabolic status of the offspring.

Study design, size, duration: This study is included 20 adult male Wistar rats (5 in each groups) that their fathers were fed for 60 days in the following four diet groups: control diet (C) - control diet with trans fatty acid (CT) - a diet containing vitamin E (E) and a diet containing vitamin E and trans fatty acid (ET).

Participants/materials, setting, methods: Epididymal tissue was taken from male offspring rats and sperm parameters were analyzed by using CASA computer analysis. On the other hands, total RNA was extracted from testis tissues and after cDNA synthesis the mRNA expression of *PPARα*, *PPARβ* and *PPARγ* genes were measured by using quantitative PCR. Data were statistically analyzed using one-way Anova.

Main results and the role of chance: The results of this study showed statistical significant differences between concentration, progressive and total motility of sperm parameters among groups. Duncan's test showed that sperm concentration in group with vitamin E intake was significantly higher than other groups ($P < 0.05$). Also, the mean of progressive and total motility of sperms in groups C and E were significantly higher than two other groups. The expression of *PPARβ* gene in two groups (E and C) was significantly higher than other groups (the CT and ET). Also the expression of *PPARγ* gene in group E was significantly higher than other groups. Eventually, the expression of *PPARγ* gene in group C was significantly higher than ET group.

Limitations, reasons for caution: The difference in nutrition of fathers before dietary treatment and also the low sample size of offspring in each group can be a limited factor in this study.

Wider implications of the findings: This study showed paternal trans fatty acid consumption can have negative effects on normal spermatogenesis in male offspring, resulting to decrease in the quality and quantity of sperms. Additionally, contrary to our expectations, vitamin E supplement could not neutralize enough the negative effect of trans fatty acids in this regard.

Trial registration number: NA.

P-039 Changes in ultrasonographic (US) images of the seminiferous tubules during gonadotropin replacement therapy in men with hypogonadotropic hypogonadism

S. Nariyoshi[1], T. Sho[1], K. Nakano[2], G. Sukegawa[2], Y. Tsuji[1]

[1]*Tenjin Tsuji Clinic, Urology, Fukuoka, Japan*
[2]*Ebisu Tsuji Clinic, Urology, Shibuya, Japan*

Study question: Are changes in US images of seminiferous tubules during gonadotropin replacement therapy related to the progression of spermatogenesis in men with hypogonadotropic hypogonadism?

Summary answer: The density of thick seminiferous tubules on US images is related to the extent of spermatogenesis induced by gonadotropin therapy in men with hypogonadotropic hypogonadism.

What is known already: Gonadotropin replacement therapy using hCG and rFSH is effective for inducing spermatogenesis in patients with hypogonadotropic hypogonadism. However, the progression of spermatogenesis during hCG +rFSH treatment in these patients has not been well elucidated. We previously demonstrated that thick seminiferous tubules on US images suggest a high rate of successful sperm retrieval in patients with non-obstructive azoospermia (ESHRE2016 P-014). US analysis of seminiferous tubules may provide valuable information for determining the extent of spermatogenesis in patients with hypogonadotropic hypogonadism who are being treated with gonadotropins.

Study design, size, duration: This prospective observational study involved 7 azoospermic patients with male hypogonadotropic hypogonadism who underwent hCG+rFSH therapy at our outpatient clinic from May 2008 to November 2017.

Participants/materials, setting, methods: We studied 7 men with hypogonadotropic hypogonadism, aged 34 to 49 years. Of these patients, 6 had idiopathic hypogonadotropic hypogonadism, including 2 patients with Kallmann syndrome and 1 had iatrogenic hypogonadotropic hypogonadism after brain surgery. Semen analysis and US evaluation of the testis were performed before and during gonadotropin therapy. To optimize US images for visualization of the seminiferous tubules, gain and contrast were appropriately adjusted with graphics software.

Main results and the role of chance: Gonadotropin replacement therapy induced spermatogenesis in 5 of the 7 patients. The first appearance of sperm in the ejaculate was achieved after a median duration of treatment of 3 months. Although testicular volume in these patients increased from 2.5 to 4.0 mL, there was no further increase in testicular volume 3 months after the initiation of treatment. Thick seminiferous tubules, defined as more than 300 μm in diameter on the US image, and the first sperm in the ejaculate were detected at almost the same time. Furthermore, an increase in sperm output was associated with an increase in the density of thick seminiferous tubules.

In contrast, two patients remained azoospermic 10 and 24 months after the initiation of treatment, respectively. Neither an increase in testicular volume nor thick seminiferous tubules on US were observed in these patients.

An increase in testicular volume only suggests the induction of spermatogenesis by gonadotropin therapy in patients with hypogonadotropic hypogonadism, while the extent of spermatogenesis can be assessed by the change in the density of thick seminal tubules on US images.

Our results suggest that the appearance of thick seminiferous tubules on US images may predict a good future response to gonadotropin therapy in hypogonadotropic hypogonadism.

Limitations, reasons for caution: In patients with intrascrotal calcification including severe testicular microlithiasis, testicular parenchyma cannot be assessed by US.

Wider implications of the findings: The status of spermatogenesis in patients whose semen is not available for testing due to an ejaculatory disorder may be estimated by the US analysis of seminiferous tubules.

Trial registration number: Not applicable.

P-040 Dishevelled-associated activator of morphogenesis 1 or DAAM1: expression and localization in human testicular tissue and spermatozoa

G. Coppola[1], C. Fasano[1], M. Venditti[2], S. Del Grande[1], S. Riccio[1], B. Dale[1], L. Di Matteo[2]

[1]*Centro Fecondazione Assistita, Reproductive Biology, Napoli, Italy*
[2]*Università degli studi della Campania "Luigi Vanvitelli", Department of Medicine, Napoli, Italy*

Study question: Is the protein Dishevelled-associated activator of morphogenesis 1 (DAAM1) present in human testicular tissue and spermatozoa and, if so, where is it located.

Summary answer: DAAM1 is present in both human testicular tissue and spermatozoa localized in the germ cells and Sertoli cells and in the tail in mature spermatozoa.

What is known already: DAAM1 is a protein involved in the nucleation of actin filaments and in cytoskeletal organization; however, to date it has not been described in the human male reproductive tract. In a recent study, DAAM1 has been shown to be expressed in the post-natal development of rat testis and spermatozoa. The level of expression of DAAM1 in the rat decreases during development and changes its localization; from the cells near the basement membrane towards the lumen of the tubule. In the spermatozoa it is found in the tail.

Study design, size, duration: Human testicular tissue was obtained from 15 males, with an average age of 37 years, following Testicular Sperm Extraction (T.E.S.E.), while human sperm samples were collected from 20 patients undergoing regular sperm analysis, at 'Centro di Fecondazione Assistita (CFA)" in

Naples. Only samples with concentration higher than 20 mil/ml, and normal motility and morphology according to WHO 2010 were used.

Participants/materials, setting, methods: Part of the tissue was frozen and stored in liquid nitrogen until protein extraction. The proteins were separated by SDS-PAGE and identified by Western Blot. The remaining tissue was fixed in formalin, embedded in paraffin and stained with haematoxylin and eosin to check the quality of the tissue and identify the cell types. Subsequently immunofluorescence was performed both on the tissue and spermatozoa.

Main results and the role of chance: Western blot analysis confirmed the presence of the protein in human testicular tissues. The tissues samples showed different levels of DAAM1 expression (O.D. DAAM1/Actin ratio ranges from 0,9 – to 2,3). We have also shown the presence of this protein in all sperm samples studied (O.D. DAAM1/Actin ratio ranges from 0,07 – to 1). In testicular tissue the protein signal was localized in the cytoplasm of Sertoli cells, gonocytes, spermatogonia and spermatids. In spermatozoa, the protein was mainly detectable inside the flagellum.

Limitations, reasons for caution: Human testicular tissues were obtained from males following surgical intervention (Testicular Sperm Extraction, TESE) at 'Centro di Fecondazione Assistita" of Naples; these men enrolled in the study were affected by azoospermia. A limit of the study was the absence of material and experimentation on healthy individuals.

Wider implications of the findings: This is the first report to show the presence of DAAM1 in human testicular tissues and spermatozoa. Further studies are needed to elucidate the role of DAAM1 in human spermatogenesis and male fertility.

Trial registration number: This is basic science.

P-041 Diagnostic value of sperm DNA fragmentation for predicting IVF fertilization failure in males with mild or medium asthenospermia

S. Zhao, L. Tang, M. Rao

The First Affiliated Hospital of Kunming Medical University, Department of Reproduction and Genetics, Kunming, China

Study question: Is sperm DNA fragmentation (SDF) valuable for predicting IVF fertilization failure in males with mild or medium asthenospermia?

Summary answer: SDF greater than 31.25% could be associated with higher probability of IVF fertilization failure in males with mild or medium asthenospermia.

What is known already: Low levels of natural fertility are detected in couples with a high percentage of SDF. But studies on effects of SDF on IVF/ICSI outcomes report controversial results.

Study design, size, duration: Retrospective clinical study.

Participants/materials, setting, methods: Data from a cohort of 116 couples who underwent their first IVF cycle between January 2016 and December 2017 at an University-affiliated teaching hospital under criteria as follows: males with progressive sperm rate between 10% and 32%, woman age < 38 years, number of oocyte retrieved ≥5. Women diagnosed with PCOS were excluded. The SDF was detected by chromatin dispersion test.

Main results and the role of chance: The area under the receiver operating characteristic curve was 0.772 ($p = 0.003$). A cutoff value for SDF to predict the IVF fertilization failure is 31.25%. When the SDF exceeded 31.25%, the fertilization rate, number of embryo and number of good embryo were statistically decreased, but the cleavage rate, good embryo rate and clinical pregnancy rate were not affected.

Limitations, reasons for caution: A weakness of our study is that SDF was measured on neat semen samples 1 to 2 months before the initiation of IVF instead of on sperm collected the day of oocyte retrieval.

Wider implications of the findings: High rate of SDF may be used as a clinical indication for ICSI in couples with mild or medium asthenospermia.

Trial registration number: not applicable.

This work was supported by the National Natural Science Foundation of China under grants 81760269, Personnel Training Program of Academic and Technical Leaders of Yunnan Province (2017HB046), the Applied basic research projects in Yunnan province (2017FE467(-137)).

P-042 The assessment of clinical intracytoplamic sperm injection (ICSI) outcome using immotile testicular spermatozoa in non-obstructive azoospermia (NOA)

T. Ishikawa, S. Mizuta, K. Yamaguchi, Y. Takaya, H. Matsubayashi, T. Takeuchi, K. Kitaya

Reproduction Clinic Osaka, Reproductive Medicine, Osaka, Japan

Study question: What is the fertilization rate, embryonic development, and clinical outcome for TESE-ICSI using immotile testicular spermatozoa even after pentoxifyllin administration among NOA couples?

Summary answer: Better fertilization and embryonic development were achieved and clinical pregnancy rate per embryo transfer (ET) by motile spermatozoa was significantly higher than by immotile spermatozoa.

What is known already: The testicular spermatozoa are often immotile immediately after testicular sperm extraction (TESE) and especially after thawing of frozen testicular samples and spermatozoa showing reliable signs of vitality are preferred for ICSI because the use of motile sperm significantly increases the efficacy of the ICSI procedure. To select TESE-retrieved viable spermatozoa for ICSI, pentoxifylline administration or hypo-osmotic swelling test (HOST) were often used, however, the testicular sperm from microdissection (micro) TESE and frozen-thawed tissue are often immotile and we have often observed the NOA patients whose testicular spermatozoa are immotile only even after pentoxifylline administration.

Study design, size, duration: We performed a retrospective study based on a reproduction center in Japan and evaluated 966 NOA patinets including after orchidopexy, Klinefelter syndrome, cryptozoospermia, mumps orchitis, azoospermia factor (AZF) microdeletion and unexplained NOA and 369 couples had 646 TESE-ICSI cycles were performed between September 2013 and December 2017. TESE-ICSI was performed with only motile spermatozoa (268 patients 482 cycles, Mo+), motile/immotile spermatozoa (58 patients 98 cycles, Mo+/-), and immotile spermatozoa only (43 patients 46 cycles, Mo-).

Participants/materials, setting, methods: Sperm preparation medium with pentoxifylline added (1 mg/mL) was applied to a droplet of testicular cell suspension in the ratio 1:1 when we could not detect motile spermatozoa. When immotile spermatozoa was injected even after pentoxifyllin administration, oocytes were incubated with calcium ionophore (A23187) for 15 minutes. Two pronuclei (2PN), blastocyst development, good-quality blastocyst, and clinical pregnancy rates (CPR) were compared. Statistical analysis was performed using unpaired t-tests and chi-squared tests.

Main results and the role of chance: Wives age was not different between groups. The sperm retrieval rate with micro TESE was 36.5% (353/ 966), in which motile spermatozoa were retrieved in 79.6% (281/353). Hormonal and any clinical data did not predict before TESE whether motile spermatozoa could be retrieved. 2PN and blastocyst rates of oocytes injected by motile spermatozoa (57.8% and 50.4%, respectively) were significantly higher than by immotile spermatozoa (41.1% and 15.4%, respectively) ($P < 0.001$). Good-blastocyst rates of these oocytes were not observed significant differences (42.7% and 47.4%, respectively). CPR per embryo transfer in embryo by motile spermatozoa was significantly higher than by immotile spermatozoa (35.2% (227/ 644) and 10.6% (7/66), respectively). In all 11 pregnancies of Mo+/- group, all embryo which lead to pregnant were injected by only motile spermatozoa. Another 5 patients with immotile spermatozoa injected into oocyte could achieve pregnancy of Mo+/- group (double embryo transfer using motile and immotile sperm; four from AZFc microdeletion and one from unexplained NOA. Seven patients with immotile spermatozoa injected into oocyte achieved pregnancy of Mo- group; four had delivered healthy babies from 2 unexplained NOAs, Klinefelter syndrome, and post orchidopexy and the other three were ongoing pregnancy from unexplained NOA.

Limitations, reasons for caution: There was a lack of standardization with respect to the frozen-thaw and fresh cycles. The safety and screening for congenital malformations among these children has not been fully investigated. No study compared the outcome of ICSI with initially immotile and induced motile testicular sperm.

Wider implications of the findings: The patients with NOA no longer should be considered sterile without performing micro TESE-ICSI. Sperm motility is the most important to deliver a baby in TESE-ICSI. However, embryologists should not give up when only immotile spermatozoa was injected even after pentoxifyllin administration.

Trial registration number: Not applicable.

P-043 Successful clinical outcome of ICSI cycles with sperm of HIV- positive men after antiretroviral treatment

B. Desmet[1], I. Mateizel[1], I. Pletincx[1], E. Vancutsem[2], A. Van De Vijver[1], G. Verheyen[1]

[1]UZ Brussel, Centre for Reproductive Medicine, Jette- Brussels, Belgium
[2]UZ Brussel, Microbiology Department, Jette- Brussels, Belgium

Study question: Does the clinical outcome of ICSI with extensively processed semen of HIV-positive male patients reach acceptable values?

Summary answer: A high clinical pregnancy rate is obtained after ICSI with extensively processed sperm of HIV- positive man who underwent antiretroviral treatment.

What is known already: HIV men undergo antiretroviral therapy before undergoing ICSI treatment. However, in ejaculated semen, the HIV virus may still be present in the cell-free fraction or bound to lymphocytes. Therefore, the preparation of semen for assisted reproduction still requires special attention in order to reduce the viral load in the final sperm fraction. Special devices for the preparation of sperm samples from HIV-positive men are available in order to improve safety. Different combinations of sperm preparation techniques can be applied.

Study design, size, duration: A single-centre retrospective analysis was performed on ICSI cycles of HIV-serodiscordant couples with HIV^+-male partners, referred to our unit between August 2009 and December 2017. The male patients were under antiretroviral therapy and had a blood viral load <40 copies/ml. The semen samples were tested before and after extensive preparation for the presence of HIV-virus using COBAS-AmpliPrep/COBAS-TaqMan-HIV-1 quantitative test. The final sperm fraction was frozen and released for later ICSI if no HIV viruses detected.

Participants/materials, setting, methods: Twenty-five couples underwent 45 fresh ICSI cycles and 32 frozen embryo cycles. Based on sperm origin and quality, different semen preparation protocols were performed: density-gradient-centrifugation (DGC) combined with swim-up for good-quality semen, DGC only for fair to low-quality semen, and sperm wash for very low-quality semen or for testicular sperm. The pro-insert Kit (Nidacon) was used during DGC procedure. The end-point was clinical pregnancy with fetal heart beat (CP) per patient.

Main results and the role of chance: From the 45 fresh ICSI cycles, 5 cycles had no embryo transfer (ET) due to abnormal fertilization (n = 3) or insufficient embryo quality (n = 2). In 13 cycles, all embryos were frozen for different reasons, while fresh ET was performed in 27 cycles (27/45; 60.0%). In total, 90 embryos were frozen. Regarding the frozen cycles, 43 embryos were thawed in 32 cycles, all resulting in ET. The CP rate per ET was 33.3% (9/27) in cycles with fresh ET and 25% (8/32) in frozen cycles. The total number of CPs obtained by the 25 couples who started an ICSI cycle was 17 (68.0%). In total, we report 9 deliveries in the fresh cycles, and 3 deliveries, 3 ongoing pregnancies and 2 miscarriages in the frozen cycles. In addition, 42 embryos are still frozen, and have the potential to increase the cumulative delivery rate. Twenty-one of these embryos belong to 8 patients who did not get pregnant so far. It can be concluded that the outcome of ICSI cycles in the present patient population is re-assuring.

Limitations, reasons for caution: The present study is limited by its observational retrospective nature and by the small number of patients included. The analysis is restricted to sero-discordant couples with HIV-positive men. A similar analysis will be performed for HIV-positive women only, and for HIV sero-concordant couples.

Wider implications of the findings: Our data show that despite the antiretroviral treatment and extensive processing of the semen in cases of HIV-positive men, the outcome of ICSI treatment in sero-discordant couples is successful. Moreover, the use of semen fractions with undetectable HIV virus in ICSI cycles is reassuring for the patients and clinical staff.

Trial registration number: none.

P-044 Impact of the sperm DNA fragmentation on clinical outcome in treatments with oocyte donation

F. Giacone, S. Chamayou, E.T. Maniscalchi, D. Lombardo, E.W. Venti, C. Alecci, A. Liprino, A. Guglielmino

Unità di Medicina della Riproduzione - Centro HERA, Unità di Medicina della Riproduzione - Centro HERA, Sant'Agata Li Battiati Catania, Italy

Study question: Which is the impact of sperm DNA fragmentation in male patient on clinical outcomes oocyte donation programs?

Summary answer: The sperm DNA fragmentation of male patient has no impact on clinical outcome in oocyte donation programs.

What is known already: It has been observed that the high sperm DNA fragmentation (DNA fragmentation index >30%) in normozoospermic males could be a cause of infertility. Different studies show a correlation between high levels of sperm DNA fragmentation and the decrease of the pregnancy rate in homologous treatments. On the other hand, it is known that oocytes from healthy young women such as donors have the ability to repair sperm DNA.

Study design, size, duration: The present retrospective study was performed on 173 couples undergoing cycles of ICSI with cryopreserved donated oocytes between June 2016 and December 2017.

Participants/materials, setting, methods: The mean age was 42.5 years for female recipients and 44.5 years for male patients. The donated metaphase II oocytes were obtained and cryopreserved from donors with a mean age of age 24.1 years. The sperm DNA fragmentation was evaluated by TUNEL test and fluorescence microscopy few weeks before ICSI. The percentage of sperm DNA fragmentation was calculated on fresh sample and sperm preparation after density gradient treatment.

Main results and the role of chance: The DNA fragmentation of the spermatozoa resulted to be 14.8%±13.1% (mean±SD) for the fresh sample, and 7.7%±10.02% (media±SD) after sperm preparation.

No correlation was observed between the two samples and the age of the patient (in fresh r = 0.13; selected spermatozoa r = 0.03), between the two samples of spermatozoa and the result of bHCG test (in fresh r = 0.00; selected spermatozoa: r = 0.05), and the two samples of spermatozoa and clinical pregnancy rate (in fresh r = 0.06; selected spermatozoa: r = 0.03).

Limitations, reasons for caution: Limitations might be represented by the limited number of cases with fragmentation over 30% and by the fact that DNA fragmentation has been evaluated few weeks before ICSI.

Wider implications of the findings: Cryopreserved oocytes from young donors have the ability to repair the sperm DNA. In these cases the valuation of sperm DNA fragmentation, in the diagnostic phase, couldbe avoided.

Trial registration number: No one.

P-045 Prevalence of HPV infection in potential sperm donors and in men from infertile couples in the czech republic

H. Jaworek[1], I. Oborna[2], B. Zborilova[3], J. Brezinova[4], D. Ruzickova[5], V. Koudelakova[1], J. Vrbkova[1], M. Hajduch[1]

[1]Faculty of Medicine and Dentistry- Palacky University, Institute of Molecular and Translational Medicine, Olomouc, Czech Republic
[2]Faculty of Medicine and Dentistry- Palacky University, Dept. of Obstetrics and Gynaecology, Olomouc, Czech Republic
[3]Fertimed Ltd., Fertimed Ltd., Olomouc, Czech Republic
[4]SpermBank International Ltd., SpermBank International Ltd., Olomouc, Czech Republic
[5]Arleta IVF Ltd., Arleta IVF Ltd., Kostelec nad Orlici, Czech Republic

Study question: What is the prevalence of hrHPV infection in potential sperm donors (SD) and men from infertile couples (IM)? Does the presence of hrHPV influence the semen parameters?

Summary answer: HrHPV prevalence in SD was 28.9% compared to 35.1% in IM. Men with hrHPV+semen sample had lower sperm volume, sperm concentration, and total sperm count.

What is known already: HPV infection could play a role in human fertility like other sexually transmitted diseases (STDs). Unlike other STDs, HPV is not tested obligatorily for gamete donors or infertile couples, although it might affect fertility and pregnancy outcome.

Study design, size, duration: In this laboratory-based study semen samples and penile swabs of potential sperm donors (n = 97) and men from infertile couples (n = 328) were collected between July 2013 and November 2016. All participants filled a questionnaire focused on their health status and sexual behavior.

Participants/materials, setting, methods: Semen samples were analyzed for the presence of 14 hrHPV genotypes by cobas 4800 HPV system (Roche) than genotyped using PapilloCheck HPV-Screening system (Greiner Bio-One) which detects 18 hrHPVs. Penile swabs were analyzed only by PapilloCheck HPV-Screening system. The association between hrHPV positivity, sexual behavior, and semen parameters was assessed using statistical software R.

Main results and the role of chance: The hrHPV prevalence in SD (n = 97) was 28.9% compared to 35.1% in IM (n = 328, $P = 0.312$). Penile swabs were more frequently hrHPV+ than semen samples in both IM (32.3% vs. 11.9%, $P < 0.001$) as well as in SD (26.8% vs. 6.2%, $P = 0.006$).

Men with hrHPV+ semen sample had lower semen volume (median volume 2.5 ml vs. 3 ml, $P = 0.009$), sperm concentration (median concentration 16×10^6/ml vs. 31×10^6/ml, $P = 0.009$) and total sperm count (median count 46×10^6 vs. 82×10^6, $P = 0.009$). No association between penile hrHPV positivity and semen parameters was found.

HPV16 was the most frequent hrHPV genotype in penile swabs in both SD (6.19% [6/97]) and IM (5.49% [18/328]). The most frequently occurring genotype co-infection was HPV42 in SD (5.15% [5/97]) and HPV44/55 in IM (3.35% [11/328]). In semen samples the single-genotype infection was HPV66 in SD (2.06% [2/97]) and HPV53 in IM (2.13% [7/328]).

Men who tested hrHPV+ in penile swabs from both groups had more sexual partners than those who tested hrHPV- (in SD median number of 6 vs. 3 [hrHPV + vs. hrHPV-] with $P = 0.008$; in IM, median number of 6 vs. 4 with $P = 0.003$).

Limitations, reasons for caution: Only penile swabs and semen samples have been analyzed in this study. No data about female partners, number of pregnancies and abortion rates were evaluated.

Wider implications of the findings: HPV positivity of the semen during a time of donation or use may be of interest for facilities dealing with the treatment of infertility because of the risk of transfer and interference with the further development of the pregnancy.

Trial registration number: not applicable.

P-046 Diagnostic evaluation of static oxidation-reduction potential with MiOXSYS System (Male Infertility Oxidative System) in normospermic versus teratozoospermic patients: a retrospective study

F. Scarselli, S. Gatti, E. Cursio, A. Pristerà, V. Zazzaro, M.G. Minasi, A. Ruberti, S. Muzzì, M.T. Varricchio, A. Caragia, P. Greco, E. Iovine, V. Casciani, E. Greco

European Hospital, Reproductive Medicine, Rome, Italy

Study question: Does evaluation of static oxidation-reduction potential (sORP) with MiOXSYS System relate with WHO 2010 (World Health Organization) sperm parameters and DNA fragmentation in infertile patients?

Summary answer: There is association between sORP and sperm parameters: sORP levels are higher in patients with lower concentration, motility and morphology and with higher DNA fragmentation.

What is known already: Spermatozoa have a physiological equilibrium between ROS (Reactive Oxygen Species) and anti-oxidants. This equilibrium assures ordinary functions such as chromatin compaction, lipid membrane modification and sperm-oocyte fusion. When ROS are overproduced this equilibrium is lost, generating oxidative stress (OS), possible cause of lipid peroxidation, apoptosis and DNA damages or fragmentation. Seminal plasma contains anti-oxidant factors (enzymatic and non-enzymatic) to prevent post-ejaculation OS, however many studies demonstrate that in infertile men anti-oxidant levels are low and ROS are high; these concentrations may be influenced by both exogenous and endogenous factors: smoking, alcohol assumption, infection and inflammation of male uro-genital tract.

Study design, size, duration: Semen from 84 infertile men were evaluated, according to WHO 2010, during June and July 2017. On their first visit at Reproductive Medicine Unit, patients underwent semen analysis and sORP evaluation and divided in two groups according to semen morphology. Group A (N = 45) included patients with morphology ^{3} 4 and group B (N = 39) patients with morphology <4. Men with ejaculatory dysfunction, varicocele, sexually transmitted diseases and exposed to radiation or chemotherapeutic agents were excluded.

Participants/materials, setting, methods: Semen samples were produced after 72-120 hours of sexual abstinence and analyzed after complete liquefaction, evaluating semen parameters and DNA fragmentation with TUNEL (Terminal deoxynucleotidyl transferase UTP-driven Nick End Labeling) test. MiOXSYS was used to evaluate sORP (expressed in millivolt/sperm concentration 10^6/mL), a 'snapshot' of the current balance of the redox system. A higher sORP level indicates an imbalance in the activity of all available oxidants relative to all available antioxidants in ejaculates.

Main results and the role of chance: Mean male age was 42.1 ± 6.3 in group A and 38.2 ± 6.5 in group B ($p < 0.05$). Semen volume was 3.2 ± 2.3 mL in group A and 3.0 ± 2.0 in group B (NS). Sperm concentration was 47.2 ± 18.0 mil/mL in group A and 24.7 ± 19.0 mil/mL in group B ($p < 0.05$). Sperm motility (progressive plus not progressive) was 66.7 ± 7.4 and 44.3 ± 20.0 in group A and B respectively ($p < 0.05$). Morphology was 4.2 ± 0.5 in group A and 2.1 ± 0.7 in group B (NS). Round cells concentration was 2.3 ± 2.0 and 2.7 ± 2.0 mil/mL in group A and B respectively (NS). DNA fragmentation measure with TUNEL test resulted to be 7.5 ± 6.4 in group A and 11.0 ± 8.1 in group B ($p < 0.05$). sORP level was 1.6 ± 2.5 and 15.5 ± 34.3 in group A and B respectively ($p < 0.05$). Statistical analysis was made using Student t-test. Correlation between sORP level and sperm concentration, motility and DNA fragmentation resulted statistically significant, while there isn't any statistically significant correlation with morphology, semen volume and round cells concentration. A small concentration of white blood cells in semen, such as polymorphonuclear granulocytes and lymphocytes, should contribute to ROS production, but our study didn't highlight this correlation and maybe further studies should be performed to confirm this parameter.

Limitations, reasons for caution: Our study included only infertile patients, but including a group of men with proven fertility may improve the cutoff values for sORP and increase the sensitivity of the assay. Another possible limit is sORP levels are normalized for sperm concentration, leading to an over estimation in men with severe oligozoospermia.

Wider implications of the findings: Currently available assays for OS measure only discrete quantity of oxidants (ROS by chemiluminescence assay), antioxidants (total antioxidant capacity [TAC] assay) or post-hoc damage (MDA assay) and are tedious, time consuming and expensive. MiOXSYS System is innovative in measuring ORP level in semen for its easiness and readiness.

Trial registration number: Not applicable.

P-047 Sperm preparation for Intra-Cytoplasmic Sperm Injection (ICSI) in cattle

J. Gómez[1], R. Alberio[1], W.Y. Kwong[1], B.J. Woodward[1], C. Kershaw-Young[2], K.D. Sinclair[1]

[1]University of Nottingham, School of Biosciences, Nottingham, United Kingdom
[2]Harper Adams University College, Animal Production- Welfare and Veterinary Sciences, Newport, United Kingdom

Study question: Main aim is to develop improved sperm pre-treatment procedures required to trigger acrosome reaction (AR) and sperm DNA decondensation for bovine ICSI.

Summary answer: Lyshophosphatidylcholine (LPC)/Heparin (Hep) combined with L-glutathione (GSH)/Hep increases the proportion of 2 pronuclei (PN) after bovine ICSI compare to LPC/Hep or GSH/Hep alone.

What is known already: Bovine ICSI can overcome deficiencies of poor sperm viability and motility, typically associated with frozen-thawed sexed semen. Unlike human IVP, technical challenges exist with bovine ICSI, leading to low fertilization rates and poor embryo development. This is may be due to suboptimal sperm preparation (capacitation, AR), delay in sperm chromatin decondensation and/or deficient egg activation.

Study design, size, duration: Percoll-gradient separated semen from a single frozen-thawed sire were split into three treatments (T): T1, exposure to Hep (80 μg/ml, 15 min), involved in capacitation followed by LPC (15 min, 100 μg/ml) which induces AR; T2, co-incubation in GSH (15 mM) and Hep (80 μM) for 20 hours (h) required to facilitate the sperm DNA decondensation; T3, combination of both treatments. Then, pre-treated spermatozoa were microinjected into bovine mature oocytes and activated chemically.

Participants/materials, setting, methods: Sperm viability and AR were determined simultaneously by a lectin fluorescence staining, counting at least 200 spermatozoa per replicate in four repeated experiments. Decondensed sperm heads were evaluated under a bright field microscope in three replicates.

Microinjected oocytes (n = 175) were exposed to a novel activation protocol optimized previously. Calcium ionophore-A23187 (5 µg/ml for 5 min) followed by strontium chloride (20 mM) and cyclohexamide (10 µg/ml) for 6 h. Pronuclear formation (16h-post-activation) and blastocyst quality were assessed by fluorescent probes.

Main results and the role of chance: We found that sperm pre-treated with LPC/Hep under the working conditions described before led to 0.81 ± 0.021 of AR spermatozoa over the total sperm population. When, sperm were exposed to GSH/Hep 0.53 ± 0.054 showed decondensed heads. After the application of both treatments, slightly lower proportion (0.44 ± 0.008) of spermatozoa had decondensed sperm heads. However, the majority were AR (0.97 ± 0.013).

PN assessment 16 hpa following ICSI indicated that LPC/Hep + GSH/Hep increased (P = 0.012) the proportion of 2PN zygotes relative to LPC/Hep or GSH/Hep (0.31 ± 0.058, 0.042 ± 0.026, 0.16 ± 0.055, respectively). Finally, microinjected oocytes using pre-treated sperm with the optimal protocol (LPC/Hep + GSH/Hep) were cultured until the blastocyst stage (192 hpa). We observed similar proportions of cleaved (48 hpa) and blastocysts between the treatment group (0.67 ± 0.059 and 0.09 ± 0.056) and non-treated sperm (0.61 ± 0.062 and 0), and IVF control (0.81 ± 0.038 and 0.27 ± 0.073). Total cell number between treatment and controls was similar but LPC + GSH embryos were less competent than those derived by IVF.

Limitations, reasons for caution: Aggressive sperm treatment (LPC/Hep + GSH/Hep) reduced sperm concentration, restricting sperm counting during the evaluation process.

Wider implications of the findings: With further development bovine ICSI has the potential to improve success with sex-sorted semen in bovine in vitro embryo production. However, the use of sex-sorted semen leads to poor fertilisation rates compared to non-sorted semen from the same sire as a result of the sorting process.

Trial registration number: Not applicable.

P-048 The effects of incubation at two different oxygen concentrations on oxidation-reduction potential of bull semen of various breeders

E. Yalcinkaya[1], S. Can Celik[1], E. Caliskan[2], F. Martinez Pastor[3]

[1]Private Adatıp Hospital, Assisted Reproduction Unit, Sakarya, Turkey
[2]Bahcesehir University, Obstetrics and Gynecology, Istanbul, Turkey
[3]INDEGSAL, University of Leon, Leon, Spain

Study question: Do higher oxygen concentrations in incubation conditions have a more negative impact on the oxidation reduction potential (ORP) of thawed bull semen?

Summary answer: This preliminary analysis revealed a nonsignificant difference in ORP levels of spermatozoa incubated at two different oxygen concentrations.

What is known already: High concentrations of reactive oxygen species have been reported to exert negative effects on sperm quality including increased DNA fragmentation. Lowering oxygen levels in embryo culture was also reported to enhance blastocyst development rates. However, there is no consensus between different IVF laboratories on the incubation conditions of sperm cells before use for IVF or ICSI.

Study design, size, duration: Thawed bull semen samples were divided into five aliquots including one for ORP measurement at zero timepoint, two for the incubation conditions at 39°C, 5% CO_2 and 5% O_2 and two for the conditions at 39°C, 5% CO_2 and 20% O_2. ORP measurements were done at 0, 4-6 and 18-22 hours. ORP values were normalized and represented as mV/10^6 spermatozoa.

Participants/materials, setting, methods: Seven cryopreserved bull semen samples of different breeders were used in the study. Two straws from each sample were thawed and washed by density gradient centrifugation (Sperm Grad TM, Vitrolife, Sweden). Total number of spermatozoa was counted for each and the sample was then diluted with commercial media for bovine IVF (BO IVF, IVF Bioscience, UK).

Main results and the role of chance: Compared to starting levels, an increase was observed in ORP values under both oxygen levels at both time intervals (66.1 vs 70.05 and 80.7 mV/10^6 (6 h, 5% and 20% O_2, respectively); 66.1 vs 87.8 and 90.8 mV/10^6 (22 h, 5% and 20% O_2, respectively) ($p > 0.05$ for both).

When differences between both oxygen concentrations in time were evaluated, a slight increase was found in 20% compared to 5% at both times, but the differences were not statistically significant ($p > 0.05$).

Limitations, reasons for caution: The main limitation of our study was bull variability. Since ORP values were found to be higher in the semen of worst quality, it might be better to use semen of comparable quality to make a generalized interpretation.

Wider implications of the findings: Our findings showed that especially within 4-6 hours of incubation, higher oxygen level seemed to increase ORP levels slightly more than lower oxygen concentration, but the difference did not reach significance. However, this finding may be important to focus on best culture conditions for human spermatozoa before IVF and ICSI.

Trial registration number: None.

P-049 Impact of spermatozoa origin and quality on fertilization, pregnancy, miscarriage and live births: a comparative study of azoospermic, cryptozoospermic, normozoospermic patients and donors as control

A. Palomar[1], I. Molina[1], M.J. Soriano[1], J.V. Martinez[1], S. Balasch[2], J.M. Rubio[1]

[1]Hospital Universitari i Politecnic La Fe, Assisted Reproduction Unit, Valencia, Spain
[2]Universitat Politecnica de Valencia, Departamento de Estadistica e Investigación Operativa Aplicadas y Calidad, Valencia, Spain

Study question: This study aims to compare reproductive outcomes after ICSI in a large patient series considering spermatozoa from non-ejaculated origin and ejaculates of different quality baseline.

Summary answer: Reproductive outcomes, in terms of pregnancy, miscarriage and live births, after using non-ejaculated spermatozoa are similar or even better compared with ejaculated spermatozoa.

What is known already: Azoospermic patients represent 5% to 15% of infertile males, so they are scarce but not rare. Therefore, it is important to research in depth clinical outcomes and new treatments to improve management of azoospermic patients. Nowadays, the use non-ejaculated spermatozoa in ICSI when severe male factor is present is still a concern. It is widely discussed whether different degrees of DNA fragmentation or maturation status of spermatozoa from non-ejaculate sources impair ICSI outcomes, affecting to fertilization and embryo development. Published studies regarding this issue often consider limited sample size or they do not include donor and/or ejaculates of different qualities.

Study design, size, duration: Retrospective cohort study held in HUiP La Fe (Spain) from April 2010 to April 2017. In total, 2638 ICSI cycles followed by double fresh embryotransferences of cleavaged embryos were included. Study groups considered, established according to semen origin and diagnostic. Post-vasectomy controls and patients currently reporting active sexual transmitted diseases were excluded. Normal fertilization rate, embryo quality, biochemical pregnancy, miscarriage rate and live births were reproductive variables considered to be compared among study groups.

Participants/materials, setting, methods: Study groups comprised testicular/epididymal spermatozoa (T:183 cycles), fresh cryptozoospermic (C:510 cycles) and normozoospermic (N:1563 cycles) ejaculates and donor sperm (D:382 cycles) as control group. ANCOVA and Chi-square tests were performed to establish the impact of spermatozoa origin and quality on reproductive variables. Moreover, spermatozoa origin and quality were studied together with female age by logistic regressions and ordinal logistic regressions to demonstrate the impact of both effects on the reproductive outcome. P-values<0.05 were considered significant.

Main results and the role of chance: No differences regarding number of oocytes retrieved or MII oocytes were reported but it was observed, as

expected, differences in sperm count and progressive motility in fresh and prepared sperm among the groups. Fertilization rate (FR) of testicular/epididymal spermatozoa (66.49 ± 1.58) was the lowest ($p < 0.01$) in comparison with cryptozoospermic patients (71.05 ± 0.94), normozoospermic males (77.89 ± 0.53) and donors (77.67 ± 1.23). However, testicular/epididymal spermatozoa presented the highest pregnancy rate (PR) (T: 56.29%; C:37.2%; N:36.10; D:39.84; $p = 0.029$). In addition, testicular/epididymal spermatozoa presented the lowest miscarriage rate (MR) although differences did not reach statistical significance (T: 12.94%; C:18.82%; N:19.96; D:18.37; $p = 0.493$). No differences were found neither in the quality of embryos transferred (QET), live birth rate (LBR) nor percentage of singletons/multiplets deliveries. Outcomes regarding the impact of female age considered together with spermatozoa origin confirmed that (QET), MR and LBR are influenced by maternal age ($p = 0.01$, $p < 0.01$ and $p = 0.04$) but not by the spermatozoa's origin ($p > 0.05$ in all cases). It is also revealed that FR was only influenced by spermatozoa origin ($p < 0.01$), not by female age ($p = 0.147$). Furthermore, PR is not only strongly influenced by female age ($p < 0.01$) but also it is still observed that spermatozoa origin tends to have an impact on achieving pregnancy ($p = 0.08$).

Limitations, reasons for caution: Even though only transferences of embryos at the same development stage were considered to prevent biased conclusions, further studies could consider a cohort of transferences in other embryo development stages as blastocysts. Also the current study does not distinguish about the cause of azoospermia (obstructive or no obstructive).

Wider implications of the findings: Outcomes derived from this large series study are a valuable aid to azoospermic patient counseling. It demonstrates that the use of non-ejaculated spermatozoa has similar or better likelihood of success that the use of donor sperm, offering a treatment option for those azoospermic patients who desire biological offspring.

Trial registration number: This study is not a clinical trial.

P-050 Myoinositol is a good freezing supplement to improve human semen parameters and DNA fragmentation

A. Vatannejad[1,2], N. Varanlou[3], F. Mohamadi[4], M. Haghighi[4], F. Amjadi[4,5], R. Aflatoonian[6], Z. Zandieh[4,5]

[1]*Department of Cellular and Molecular Nutrition, School of Nutritional Sciences and Dietetics, Tehran University of Medical Sciences*
[2]*Department of Biochemistry, School of Medicine, Tehran- University of Medical Science Tehran Iran*
[3]*Department of basic sciences, Tehran Central Branch of Islamic Azad University, Tehran, Iran*
[4]*Anatomy Department, School of Medicine, Iran University of Medical Science*
[5]*Akbarabadi IVF clinic, Akbarabadi Hospital, Iran University of Medical Science*
[6]*Department of Endocrinology and Female Infertility at Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR*

Study question: What is the effect of myoinositol as a supplement on sperm parameters, DNA fragmentation, total antioxidant capacity, the level of malondialdehyde and reactive oxygen species in human sperm freezing process?

Summary answer: Myoinosito improves sperm motility, morphology, Total antioxidant capacity and decreases DNA fragmentation and the level of malondealdehyde (MDA).

What is known already: sperm freezing has detrimental effects on sperm parameters, like motility, morphology, ROS level and sperm DNA. Myoinositol belongs to the vitamin B complex group and has many phisiological function. It plays a role in the regulation of calcium intracellular concentration, reproductive disorders and improve the mitochondrial function.

Study design, size, duration: 40 Fresh semen samples were obtained from normospermic men. All the samples after primary analysis, were immediately freezed in two groups, group 1: myoinositol (2 mg per ml) + freezing medium (Fertipro), group 2: freezing medium. After one month, all samples were thawed and assessed.

Participants/materials, setting, methods: semen parameters in two groups were analyzed by CASA for motility and morphology and live ratio. Also, the level of total ROS, TAC, DNA fragmentation and MDA were evaluated by DCFH(by Fluorimetry), ELISA kit, TUNEL assay by flow cytometry and ELISA respectively.

Main results and the role of chance: Our data clearly showed that total motility, morphology and live ratio were higher in myoinositol group. Also, DNA fragmentation is notably lower in myoinositol than control(20.72 vs 15.28, $p = 0.001$). TAC is higher ($p < 0.0001$) and MDA is lower ($p = 0.007$) significantly in myoinositol than normal.The level of ROS was decreased in myoinositol group but not significant ($p = 0.1$).

Limitations, reasons for caution: It is better to use this supplement on freezing process of oligoastenotratospermic (OAT) patients.

Wider implications of the findings: It seems that the effect of myoinositol on mitochondria and other parts of the sperm, improve semen parameters after thawing. So, myoinositol protect normal sperm from detrimental effect of freezing. This study showed the effective role of myoinositol for the first time in human sperm parameters during freezing process.

Trial registration number: NA.

P-051 Improving effectiveness of a human sperm cryopreservation program for Assisted Reproduction by testing the effect of different cryoprotectants and freezing protocols on the post-thawing outcomes

J. Romero[1], A. Palomar[1], G. Aida[1], J.V. Martinez[1], S. Balasch[2], I. Molina[1]

[1]*Hospital Universitari i Politecnic La Fe, Assisted Reproduction Unit, Valencia, Spain*
[2]*Universitat Politecnica de Valencia, Departamento de Estadística e Investigación Operativa Aplicadas y Calidad, Valencia, Spain*

Study question: Evaluate thawing outcomes of two different commercial cryoprotectants, testing its mode of use in combination with each different freezing protocol, in a sperm cryopreservation program.

Summary answer: Liquid nitrogen vapors freezing achieves more viable spermatozoa than slow freezing. Moreover, the effectiveness of a cryoprotectant can be increased by varying its addition method.

What is known already: Sperm freezing is the only method implemented nowadays in clinical practice to preserve male fertility. In this scenario, it is paramount to achieve the best semen quality after thawing since sample's availability is limited. Cryoprotectants are needed during the freezing process. However, at high concentrations, they are toxic. To minimize its toxicity, addition and removal methods are important. The most common extender of cryoprotectants is egg yolk. However, it derives from animal origin. Hence, it could be a potential source of infectious animal diseases. Therefore, more research is needed to find new animal-free extenders that contribute to standardize sperm freezing.

Study design, size, duration: Prospective cohort study held in Hospital La Fe (Spain) from June to November 2017. In total, 29 normozoospermic males were considered. Sperm count (SC), progressive (PM) and total sperm motility (TM) were evaluated using a CASA system. Aliquots from the same sample were used to test each freezing protocol performed (liquid nitrogen vapors, LN and slow freezing, SF) using both cryoprotectants (Test Yolk Buffer, TYB and a commercial cryoprotectant with animal-free extenders, AFE).

Participants/materials, setting, methods: Firstly, 13 samples were mixed with AFE following provider's recommendations (ratio cryoprotectant:sample 2:1). In last 16 samples, another addition procedure, consisting on diminishing the ratio to 1:1, was tested for AFE. In both cases TYB was mixed volume to volume. Each mix was loaded in two 0.5 ml straws, one used for SF, and the other used for LN. T-tests of dependent and independent samples were performed to compare cryopreservation outcomes. P-values<0.05 were considered significant.

Main results and the role of chance: LN leads to a higher number of viable spermatozoa than SF when TYB is used (15.14 ± 4.37 vs 9.24 ± 3.39, p-value = 0.066) while it is equally effective as SF when AFE is used (1.48 ± 0.82 vs 2.39 ± 3.77, p-value = 0.211). Considering the first sample set, use of AFE is associated with a decreased total motile sperm count (TMSC) when compared with TYB in both freezing protocols (LN: 1.48 ± 0.82 vs 15.14 ± 4.37, p-value = 0.003; SF: 2.39 ± 3.77 vs 9.24 ± 3.39, p-value = 0.016), worsening cryopreservation outcomes. However, a tendency of increased TMSC is observed in LN freezing when the mix ratio of AFE is diminished in the second sample set compared with the ratio used for AFE in the first sample set (3.49 ± 1.92 vs 1.48 ± 0.82, p-value = 0.084). Moreover, another comparison considering the

second sample set in which the mix ratio had been changed was performed. Interestingly, no significant differences were found when comparing the use of AFE and TYB in LN freezing (p-value = 0.294).

Limitations, reasons for caution: The current study prevents biased conclusions since it uses aliquots from the same sample to test freezing protocols and both cryoprotectants. However, in further studies the sample size should be increased and other patients apart from normozoospermic males should be included to validate the results.

Wider implications of the findings: LN freezing leads to sperm cryopreservation program's optimization due to its equal effectiveness and reduced operation costs. Moreover, if AFE is going to be used as animal-free extender cryoprotectant, diminishing the volume of AFE is recommended since outcomes are improved, so similar results as those associated to TYB are reached.

Trial registration number: This study is not a clinical trial.

P-052 Human Sperm Aminopeptidase N is related to embryo development and viability during ART

M. Gianzo[1], I. Urizar-Arenaza[1], I. Muñoa-Hoyos[1], Z. Larreategui[2], J. Irazusta[1], N. Subirán[1]

[1]University of Basque Country, Department of Physiology, Leioa, Spain
[2]IVI Bilbao, IVF Laboratory, Bilbao- Leioa-, Spain

Study question: to investigate the association between the levels of aminopeptidase N (APN) present in human spermatozoa with embryo development and viability.

Summary answer: Semen samples with less number of Aminopeptidase N molecules per spermatozoon are related to higher-quality early-embryos, more evolved blastocysts and blastocyst viability during IVF procedures.

What is known already: 20%-30% of men with normal seminal-parameters have impaired fertility ability and inability to achieve pregnancy, suggesting that male infertility can be caused by different deficiencies not yet described. One of the major predictors of ART success is embryo quality, and abnormal embryos have been linked to poor sperm quality. Sperm molecular features, such as proteins, are involved in fertilization and embryo development. Aminopeptidase N can be a relevant biomarker due to its high concentration in spermatozoa and its role in human sperm motility, mussel acrosome reaction and several seminal pathologies. However, its role in embryo development is not completely understood.

Study design, size, duration: This prospective cohorts study was conducted February 2014 to July 2015. Normal and/or pathologic semen samples of couples undergoing oocytes donation cycles, at Clínica IVI Bilbao, were used to determine the APN levels in human spermatozoa and to analyze the association between the APN and human embryo development and viability.

Participants/materials, setting, methods: A total of 81 human semen samples and 611 embryos were examined. Sperm samples and embryo quality were examined following WHO and "Asociación Española para el Estudio de la Biología de la Reproducción" (ASEBIR) guidelines, respectively. APN levels were measured by semi-quantitative and quantitative flow cytometry assays, in the same processed sperm sample used for the *in vitro* techniques. Statistics: Spearman´s rank correlation, Kruskal-Wallis and Mann-Whitney U-test.

Main results and the role of chance: Sperm samples with higher percentages of APN-positive spermatozoa and lower levels of this enzyme per spermatozoon correlate to sperm samples with better motility. In regard to embryo quality, embryos with higher implantation potential came from semen samples with less APN molecules per spermatozoon in early human embryos, at day 2 and 3 of development. Similarly, in the later phase of *in vitro* development, blastocyst with higher implantation potential, such as fully expanded and hatching blastocyst, also came from semen samples with less APN molecules per spermatozoon. Furthermore, concerning embryo viability at day 5 and 6 of development, we observed similar results, viable human blastocysts came from semen samples with less number of APN molecules per spermatozoa than non viable blastocysts.

Limitations, reasons for caution: Duration of the study.

Wider implications of the findings: APN levels can provide very valuable information for semen sample quality and embryo development in humans. In conclusion, the sperm APN could be a potential sperm biomarker to orient embryologist for embryo selection in IVF procedures in order to obtain a future embryos with higher implantation potential.

Trial registration number: CEISH/61/2011.

P-053 The impact of sperm chromatin condensation and ploidy on IVF/ICSI outcome

L. Lazaros[1,2], E. Hatzi[1], S. Markoula[3], C. Kitsou[1], K. Zikopoulos[1], G. Vartholomatos[4], E. Kanavakis[2], I. Georgiou[1]

[1]University of Ioannina, Medical School- Department of Obstetrics and Gynecology-Genetics and IVF Unit, Ioannina, Greece
[2]Genesis Genoma Lab, Genetic Diagnosis-Clinical Genetics-Research, Athens, Greece
[3]University of Ioannina, Medical School- Department of Neurology, Ioannina, Greece
[4]Ioannina University Hospital, Laboratory of Hematology- Molecular Biology Unit, Ioannina, Greece

Study question: To explore whether sperm chromatin condensation and ploidy affect the *in vitro* fertilization (IVF) and intracytoplasmic sperm injection (ICSI) outcome.

Summary answer: Our data show that sperm nuclear chromatin condensation and ploidy constitute critical parameters for a successful IVF/ICSI outcome.

What is known already: Fifteen per cent of the couples worldwide face infertility problems, while half of them are affected by male factor infertility. The development of medically assisted reproduction technology has allowed infertile couples to achieve a pregnancy. Sperm morphology, concentration and motility are taken into account for the selection of the appropriate assisted reproduction procedure. However, noteworthy percentages of IVF/ICSI cycles remain unsuccessful, suggesting the need of additional parameters for the evaluation of sperm quality, such as sperm nuclear chromatin condensation and ploidy. Sperm flow cytometry (SFC) has been suggested as a reliable method for the evaluation of these parameters.

Study design, size, duration: The study population was consisted of 280 couples that referred to the Ioannina University Medical School IVF Unit for IVF or ICSI due to male factor infertility. Men with karyotype abnormalities, Y microdeletions, hypogonadotropic hypogonadism and seminal tract disorders were excluded from the study. Furthermore, women suffering from endometriosis, polycystic ovary syndrome, ovulatory disorders and reproductive organ malformations were also excluded so as to analyze the real impact of male factor infertility on IVF/ICSI outcome.

Participants/materials, setting, methods: Semen analysis was performed according to World Health Organization guidelines. SFC after Acridine Orange and Propidium Iodide stainings was used to study the chromatin condensation and the ploidy of human spermatozoa, respectively. For the ovarian stimulation, a standard GnRH-antagonist protocol was used. IVF was performed in 130 couples and ICSI in 150 couples. The fertilization rate, the embryo quality and the clinical pregnancy rate per cycle begun were the IVF/ICSI outcome measures.

Main results and the role of chance: SFC analysis revealed that 70 ± 20.3% of the spermatozoa in the IVF group and 61.3 ± 19.9% of the spermatozoa in the ICSI group had fully condensed chromatin (FCC). Furthermore, 16.3 ± 12.2% of the spermatozoa in the IVF group and 18.5 ± 16.7% of the spermatozoa in the ICSI group were aneuploid.

In the IVF group, couples with FCC≥70% presented higher fertilization ($p = 0.006$) and clinical pregnancy ($p = 0.019$) rates compared to couples with FCC < 70%. Furthermore, they were characterized by higher grade A ($p = 0.008$) and lower grade C ($p = 0.004$) embryo rates. As concerns the ICSI group, couples with FCC≥61.3% were characterized by higher fertilization ($p = 0.01$) and clinical pregnancy ($p = 0.008$) rates compared to couples with FCC < 61.3%. Additionally, they presented higher grade A ($p = 0.009$) and lower grade C ($p = 0.03$) embryo rates.

In the IVF group, couples with aneuploidy rate<16.3% presented higher fertilization ($p = 0.008$) and clinical pregnancy ($p = 0.017$) rates compared to couples with aneuploidy rate≥16.3%. Moreover, they were characterized by higher grade A ($p = 0.01$) and lower grade C ($p = 0.005$) embryo rates. Regarding the ICSI group, couples with aneuploidy rate<18.5% showed higher fertilization ($p = 0.01$) and clinical pregnancy ($p = 0.02$) rates compared to couples with aneuploidy rate≥18.5%. Finally, they were characterized by higher grade A ($p = 0.01$) and lower grade C ($p = 0.03$) embryo rates.

Limitations, reasons for caution: Our findings were based on 280 couples undergoing IVF or ICSI due to male factor infertility. Larger population and multicenter studies are needed to verify our preliminary results.

Wider implications of the findings: SFC analysis could provide a better screening of the male partner's clinical condition leading to a more appropriate treatment. The combination of SFC with sperm selection methods could help in the fractionation/isolation of spermatozoa with normal genetic constitution, fully condensed chromatin and elevated pregnancy potential post-ICSI from defective semen samples.

Trial registration number: N/A.

P-054 Metabolomics profiles of the seminal plasma in samples collected following long (4-5 days) and short (2 hours) sexual abstinence periods

H. Alipour[1], F. Dardmeh[1], R.K. Duus[1], R. Wimmer[2], S.S. Du Plessis[3], N. Jørgensen[4], O.B. Christiansen[5], C. Hnida[5], H.I. Nielsen[1], M. Afshani[6], G. Van Der Horst[7]

[3]*Stellenbosch University, Division of Medical Physiology- Faculty of Medicine and Health Sciences, Tygerberg, South Africa*
[4]*Rigshospitalet, University Department of Growth and Reproduction and International Center for Research and Research Training in Endocrine Disruption of Male Reproduction and Child Health EDMaRC-, Copenhagen, Denmark*
[5]*Aalborg University Hospital, Dept. of Obstetrics and Gynecology- Fertility unit, Aalborg, Denmark*
[6]*Eastern Mediterranean University, Faculty of Medicine, Famagusta- North Cyprus, Turkey*
[7]*University of the Western Cape, Department of Medical Biosciences, Capetown, South Africa*

Study question: Is there a within-subject variation in Seminal plasma metabolomics profiles following long (4-5 days) and short (2 hours) sexual abstinence periods?

Summary answer: Short ejaculation abstinence was associated with lower amounts of all detected seminal plasma metabolites, except for pyruvate and taurine.

What is known already: The metabolome is a dynamic environment and can be influenced by genetic or environmental cues. Metabolomic profiling of seminal plasma has been suggested as a possible approach for a fast and non-invasive diagnosis in the evaluation of male infertility, but the metabolomics profiles in normozoospermic men have not been thoroughly investigated. The different sperm motility characteristics in samples collected following long and short abstinence periods have been previously documented but the possible change of seminal metabolomic profiles following different abstinence periods has not been studied.

Study design, size, duration: Repeated measures study based on seminal plasma from 31 normozoospermic men who delivered a semen sample after 4-7 days of abstinence, followed by a second sample 2 hours later. The study was conducted during 2015–2017.

Participants/materials, setting, methods: Participants included normozoospermic male partners of couples attending IVF treatment at the Fertility Unit of Aalborg University Hospital (Aalborg, Denmark). All semen samples were assessed for concentration, total counts and motility characteristics by using the SCA® (Microptic S.L., Barcelona, Spain) computer aided sperm analysis system. Metabolite profiles of the seminal plasma were determined using untargeted Nuclear Magnetic Resonance Spectroscopy by a Bruker AVIII-600 NMR spectrometer (Bruker Biospin, Germany and Switzerland).

Main results and the role of chance: 30 metabolites were identified in the ejaculates. Among these, the concentration of pyruvate was higher in samples collected after a two hours abstinence (vs. 4-7 days), and the concentrations of fructose, acetate, choline, methanol, N-acetylglucosamine, O-acetylcarnitine, uridine and sn-glycero-3-phosphocoline were lower. There was no difference for the remaining 21 metabolites. Sperm concentration was also lower in samples obtained after the short abstinence period. Consequently, the absolute amounts of pyruvate and taurine per spermatozoa were higher in samples obtained after the short abstinence ($P < 0.001$ and $P < 0.05$ respectively).

Limitations, reasons for caution: The possible physiological explanations for the findings cannot be determined by the study, and furthermore we do not know if the metabolomics patterns we detected are different from those of men with oligozoospermia. The effect of sperm metabolism after ejaculation and during liquefaction could not be determined in this study.

Wider implications of the findings: The concomitant increase in percentages of motile spermatozoa and pyruvate and taurine per spermatozoa might indicate that these two metabolites are beneficial for sperm motility, which should be further investigated in future studies.

Trial registration number: -

P-055 Varicocelectomy in patients with elevated serum FSH: correlation between changes in semen parameters and serum FSH

T. Sho[1], S. Nariyoshi[1], K. Nakano[2], G. Sukegawa[2], Y. Tsuji[1]

[1]*Tenjin Tsuji Clinic, Urology, Fukuoka, Japan*
[2]*Ebisu Tsuji Clinic, Urology, Shibuya, Japan*

Study question: Can varicocele repair improve semen quality and decrease serum FSH levels in infertile patients with elevated serum FSH and varicocele?

Summary answer: Even in patients with elevated serum FSH, varicocele repair can significantly improve semen parameters with a substantial decrease in serum FSH.

What is known already: Varicocele is present in approximately 35% of infertile men and in 81% of those with secondary infertility. Most previous studies have demonstrated that varicocele repair is associated with a significant improvement in semen parameters as well as spontaneous pregnancy rates. Furthermore, the benefits of varicocelectomy have been reported even among patients with non-obstructive azoospermia or hypogonadism. However, the role of varicocelectomy in patients with severe spermatogenic failure and hormonal abnormalities, including those with an elevated serum FSH level, is still under debate.

Study design, size, duration: We retrospectively reviewed the records of 2,368 consecutive patients who underwent varicocelectomy for subfertility at our clinics from July 2003 to September 2017.

Participants/materials, setting, methods: Multiple semen analyses were performed before and after varicocelectomy. The total motile sperm count per ejaculate was calculated as semen volume x sperm concentration x percent motility divided by 100. We defined a greater than 50% increase in the total motile sperm count per ejaculate at three months after surgery as a significant improvement.

Microsurgical subinguinal varicocelectomy was performed under local anesthesia.

Main results and the role of chance: The serum FSH level was greater than 10 mIU/mL in 282 patients. After we excluded 43 patients with azoospermia, 5 patients with prior endocrine therapy and 27 patients who were lost to follow-up, 207 patients were included in this study. After surgery, 135 of these patients (65.2%) experienced a significant improvement of semen parameters.

Preoperative serum FSH levels were not significantly different between the improved patients (14.0 ± 4.3 mIU/mL) and not-improved patients (15.6 ± 5.9 mIU/mL). Serum FSH was measured in 34 improved patients and 15 not-improved patients after surgery. The decrease in the serum FSH level in the improved patients (1.8 ± 2.6 mIU/mL) was significantly greater than that in the not-improved patients (-0.6 ± 3.2 mIU/mL).

These data indicate that varicocelectomy in patients with elevated serum FSH levels and varicocele improves semen quality associated with a decrease in the serum FSH level.

Limitations, reasons for caution: Because we measured serum FSH only in selected patients after surgery, further studies with more patients will be needed to avoid being misled by changes in serum FSH levels induced by varicocele repair.

Wider implications of the findings: In patients with non-obstructive azoospermia, changes in the serum FSH level after varicocele repair may predict the outcome of microdissection TESE.

Trial registration number: Not applicable.

P-056 Delayed and impaired development in early mouse embryo was induced by sperm DNA damage

M. Kobayashi[1], A. Yoshida[2]

[1]*Kiba Park Clinic, Research Center, Tokyo, Japan*
[2]*Kiba Park Clinic, Reproductive Medicine, Tokyo, Japan*

Study question: Does sperm DNA damage affect to developmental ability and developmental events such as pronuclear formation, DNA replication, and cleavage?

Summary answer: DNA damage in spermatozoa induced slowing DNA replication at the pronuclear stage and delayed time points of early developmental events.

What is known already: Some studies have indicated that DNA damage in mammalian spermatozoa could induce some developmental defects such as low fertilization rates, poor embryo quality, and developmental arrest. Further, it is suggested that spontaneous miscarriage and childhood disease may be related to sperm DNA damage. However, the mechanisms of these defects on embryos with damaged sperm DNA have not yet been cleared.

Study design, size, duration: Spermatozoa obtained from C57BL/6J mouse were exposed to 1 mM H_2O_2 for 30 min to induce DNA damage (oxidatively damaged spermatozoa: ODS), and embryos were produced by ICSI with ODS and normal spermatozoa (control) (n = 70-80 embryos/group). The timing of developmental events (pronuclear formation, DNA replication, syngamy, and cleavage) and the developmental ability were compared between ODS and control groups.

Participants/materials, setting, methods: Time-lapse monitoring has been used to examine the developmental events of each embryo. After 4.5-6.0 hr from ICSI, DNA replication in pronuclei was estimated by using the DNA replication assay kit with EdU. Further, DNA damages in male pronucleus and nuclei in developing embryos were detected by immunohistochemical staining with gamma-H2AX antibody.

Main results and the role of chance: There was no significantly difference in the rate of male and female pronuclear formation between ODS and control groups. However, DNA replication assay at 5.5 hr after ICSI revealed that the rate of EdU-positive pronuclei in ODS embryos was significantly lower than that of control (58.8% vs 81.3%, $p < 0.05$). The time-lapse analysis revealed that the average time points of syngamy, 1st cleavage, and 3rd cleavage of ODS embryos were delayed remarkably compared with control (16.9 hr vs 14.7 hr, 20.1 hr vs 17.0 hr, 43.5 hr vs 40.1 hr, respectively, $p < 0.01$). By immunohistchemical staining, male pronucleus and nuclei in embryos with ODS were positive for gamma-H2AX, and extranuclear DNA fragments were frequently observed in ODS embryos. In addition, the blastocyst rate of ODS embryos was significantly lower than control (15.4% vs 76.7%, $p < 0.05$).

Limitations, reasons for caution: This study was conducted using a mouse model with artificially induced DNA damage by exposing to H_2O_2. This finding does not directly represent human reproductive medicine.

Wider implications of the findings: This study shows clearly that sperm DNA damage induced the delay of developmental events and impaired the developmental ability. Also, our results suggest that damage on sperm DNA persists during early development. Therefore, this study may provide novel insights for understanding the relationship between sperm DNA damage and embryonic development.

Trial registration number: Not applicable.

P-057 Effect of varicocelectomy on oxidation reduction potential in varicocele associated male infertility

H. Elbardisi[1], A. Majzoub[1], S. AlSaid[1], A. Agarwal[2], R. Henkel[3], H. Shehadeh[1], K. Alrumaihi[1], M. Arafa[1]

[1]*Hamad Medical Corporation, Urology, Doha, Qatar*
[2]*Cleveland clinic, Urology, Ohaio, U.S.A.*
[3]*University of the Western Cape, Medical Bioscience, Bellville, South Africa*

Study question: Does varicocelectomy improve Oxidation Reduction Potential (ORP) as an independent measure of oxidative stress (OS) in infertile men?

Summary answer: Elevated oxidative stress is related with poor semen quality in men with varicocele. Varicocele surgery reduces the ORP levels and improves sperm count.

What is known already: Patients with varicocele tend to have poor sperm quality and are at higher risk of being infertile. Although the pathophysiology of infertility in males with varicocele has been extensively studied, the underlying mechanism remains unclear. Many reports have shown that oxidative stress is one of the underlying mechanisms of poor semen quality in infertile men with varicocele. ORP has been validated as a diagnostic marker of poor semen quality and oxidative stress in men with infertility.

Study design, size, duration: Prospective, case control study of 43 infertile patients with clinical grade 2-3 varicocele attending a male infertility clinic during January to November 2017.

Participants/materials, setting, methods: All patients underwent microsurgical subinguinal varicocelectomy. Full medical history and clinical examination was collected. Semen samples were done using WHO Fifth edition criteria and ORP levels were measured by MiOXSYS analyzer before surgery and 3 months post-varicocelectomy. The results were compared by Wilcoxon rank sum test and Spearman's correlation test and a P value < 0.05 was considered significant.

Main results and the role of chance: Table 1 compares results of semen parameters and ORP values before and 3 months after the surgery (n = 43). All semen parameters (concentration, total motility and normal sperm form) showed an improvement post- surgery but it was not statistically significant. However, the ORP level was significantly reduced after the surgery (10.4 ± 3.3 vs. 4.6 ± 1.1, p value <0.001). Table 2 shows the correlation between semen parameters and ORP before and after surgery. All semen parameters (concentration, total motility and normal form) were negatively correlated with ORP pre-operatively. However, only sperm count maintained this significant negative correlation post operatively.

Table I

	Before Surgery	After Surgery	P value
Sperm Count	25.2 +/− 3.4	29.9 +/− 3.1	0.029
Total Motility	44.8 +/− 3.1	46.1 +/− 2.3	0.645
Progressive Motility	9.3 +/− 1.6	10.3 +/− 1.6	0.64
Normal forms	5.5 +/− 1.6	3.6 +/− 0.4	0.893
sORP	10.4 +/− 3.3	4.6 +/− 1.1	<0.001
Wilcoxon Rank test			

Table II

	Before Surgery	After Surgery
Sperm Count	−0.871**	−0.827**
Total motility	−0.359**	−0.288
Progressive motility	−0.461**	−0.155
Normal forms	−0.526**	−0.332*
Spearman's correlation		

*p < 0.05
**p < 0.01

Limitations, reasons for caution: The small sample size of this study may be a limitation. However, we report on a pilot study describing the effect of varicocelectomy on oxidative stress measures using the ORP system.

Wider implications of the findings: ORP can be used as a prognostic factor for counselling patients before varicocelectomy.
Trial registration number: Non.

P-058 Oxidation reduction potential is correlated to spermatogenic testicular function in infertile men

M. Arafa[1], A. Majzoub[2], A. Agarwal[3], R. Henkel[4], J. Eliwa[5], S. AlSaid[2], A. AlAnsari[1], H. Elbardisi[1]

[4]University of the Western Cape, Department of Medical Bioscience, Bellville, South Africa
[5]University of Kuwait, Faculty of Medicine, Kuwait, Kuwait

Study question: Is oxidative stress a clinical indicator for testicular function in infertile men?
Summary answer: Oxidative stress measured by oxidation reduction potential (ORP) can be considered a clinical indicator of spermatogenic and not endocrine function of the testis.
What is known already: Oxidative stress plays a major role in the pathogenesis of male infertility. ORP is a new marker of oxidative stress that has been shown to correlate inversely with important semen parameters in infertile men. ORP levels can be used to discriminate normal fertile men from infertile males. Besides semen parameters, testicular size and FSH are considered as prognostic markers of spermatogenesis.
Study design, size, duration: Cross sectional, retrospective study on 660 patients attending a male infertility clinic during January to March 2017.
Participants/materials, setting, methods: Medical records of recruited patients were reviewed. The data extracted included medical history, clinical examination, semen analysis (WHO 5th edition), ORP (using MiOXSYS system), hormonal assay including FSH, LH, prolactin, testosterone and estradiol as well as testicular size assessment by scrotal ultrasound. After checking for normal distribution of the data by the Chi-squared test, Spearman rank test was used to detect correlations between different parameters. Statistical significance was defined as $p < 0.05$.
Main results and the role of chance: ORP showed negative correlation with sperm count ($r = -0.793$, $P < 0.0001$), motile sperm count ($r = -0.579$; $P < 0.0001$), progressive motility ($r = -0.431$; $P < 0.0001$) and normal sperm morphology ($r = -0.458$; $P < 0.0001$). ORP also correlated with sperm DNA fragmentation ($r = 0.264$, $P < 0.0001$) (Table 1).

ORP levels showed significant correlation with the testicular size ($r = -0.386$; $P < 0.0001$), serum FSH ($r = 0.273$; $P < 0.0001$) and serum LH concentrations ($r = 0.182$; $P = 0.0002$), but not with testosterone, estradiol and prolactin.
Limitations, reasons for caution: The main limitation is the lack of fertile controls in this study.
Wider implications of the findings: ORP can be used as a marker of spermatogenesis in infertile men. Further studies should be carried out to demonstrate the effect of treating OS on spermatogenesis. Since varicocele patients show seminal oxidative stress, smaller testes and higher FSH values, ORP could possibly be used as adjunct indicator of varicocele.
Trial registration number: None.

P-059 Integrity of human sperm DNA assessed by the neutral comet assay and its relationship to oxidative stress and poor spermatic morphology

A. Oumaima, Z. Ines, A. Tesnim, H.A. Assila, A. Hana, J. Ali, H. Zohra, M. Meriem

Laboratory of Histology Embryology and Cytogenetic UR 12 ES 10- Faculty of Medicine University of Monastir- Street Avicenne- Monastir 5019- Tunisia., Department of Histology Embryology and Cytogenetic, Monastir, Tunisia

Study question: The current study aimed to determine the extent of sperm nuclear DNA damage in patients with isolated teratozoospermia and to examine its relationship with oxidative stress.
Summary answer: Our results may explain the complex biological relationship between teratozoospermia, oxidative stress, and DNA damage.
What is known already: The physiopathology of the morphological abnormalities of the spermatozoa has not been completely understood. In the present study, we found an impaired seminal antioxidant status and an increased seminal level of both Lipid peroxidation and Iron can affect sperm nuclear integrity resulting in DNA Breaks and can be associated with poor sperm morphology.
Study design, size, duration: Semen samples from 60 patients with isolated teratozoospermia and 30 normozoospermic donors were examined. DNA damage was evaluated by Comet assay. Seminal antioxidant activities (Superoxide dismutase; Glutathione peroxidase; Catalase), Iron and malondialdehyde concentrations were measured spectrophotometrically.
Participants/materials, setting, methods: Methods and endpoints used:

patients: 60 patients with isolated teratozoospermia and 30 normozoospermic donors,

Methods: Comet assay, spectrophotometer, chemicals reagents.
Main results and the role of chance: Sperm DNA damage; malondialdehyde and Iron levels were more elevated in study groups than control groups. Nevertheless, the antioxidant enzymes activity was significantly lower in the group of patients with teratozoospermia compared to the controls. Sperm DNA damage was positively correlated to malondialdehyde and seminal Iron level, While reduced seminal antioxidant status was negatively associated with sperm DNA Breaks. Interestingly, we noted that sperm DNA damage; lipid peroxidation, Iron level, and impaired antioxidant status were negatively correlated to normal sperm morphology.
Limitations, reasons for caution: only in vitro study.
Wider implications of the findings: This work was supported by funds allocated to the Research Unit of Histology and Genetic UR12ES10 by the Ministère Tunisien de l'Enseingement Supérieur et de la Recherché Scientifique.
Trial registration number: not applicable.

P-060 Alterations in disease activity and fertility potential in men with rheumatoid arthritis by yoga based lifestyle intervention

S. Gautam[1], U. Kumar[2], S. Chandna[1], D. Kumar[1], R. Dada[1]

[1]All India Institute of Medical Sciences, Anatomy, New Delhi, India
[2]All India Institute of Medical Sciences, Rheumatology, New Delhi, India

Study question: Can a simple lifestyle modification program including yoga bring about positive alterations in fertility potential and reduction in disease activity in men with Rheumatoid arthritis?
Summary answer: Yoga based lifestyle intervention may not only reduce disease severity, minimize usage of drugs with minimum side effects especially on sperm.
What is known already: The complex mechanism of Rheumatoid arthritis with infertility in men involves interactions between endocrine, immune, and reproductive systems. Association of autoimmunity with dysregulated androgen (hypogonadism) levels may cause transient infertility in men. Furthermore, usage of disease-modifying antirheumatic drugs (DMARDs) like cyclophosphamide, methotrexate, sulphasalazine etc. may result into decreased quantity and quality of sperm, reduced fertility potential and ultimately permanent infertility. These drugs can cross blood-testis-barrier and induce changes in sperm impairing spermatogenesis. Complementary and alternative medicine like yoga reduces seminal oxidative stress and its consequences like DNA fragmentation in sperm nuclear/mitochondrial genome.
Study design, size, duration: Seventy five males with RA were enrolled in this 12-week prospective, open-label, single-arm exploratory study, designed to explore the impact of yoga based lifestyle intervention (YBLI) on disease activity and fertility potential in men with Rheumatoid arthritis.
Participants/materials, setting, methods: The participants were evaluated for pre (day 0) and post (12th week) levels of C reactive protein (CRP), IL-6, IL-17A and soluble HLA-G for systemic inflammation. Sperm parameters as per WHO 2010 guidelines and reactive oxygen species (ROS), DNA fragmentation index (DFI), 8-hydroxy-2'-deoxy guanosine (8-OHdG) were estimated. Parameters of disease activity i.e. disease activity score (DAS28-ESR) and pain

acuity i.e. visual analogue scale (VAS) and disability quotient i.e. health assessment questionnaire (HAQ) were assessed.

Main results and the role of chance: The mean levels of ROS ($p < 0.05$***), DFI ($p < 0.05$**) and 8-OH2dG ($p < 0.05$**) levels were significantly reduced after 12 weeks of yoga intervention. We observed reduction in mean levels of CRP ($p < 0.05$***), IL-6 ($p < 0.05$**), IL-17A ($p < 0.05$**) and soluble HLA-G ($p < 0.05$**) at 12 weeks compared to base line level (day 0). There was reduction seen in DAS28-ESR ($p < 0.05$***), VAS ($p < 0.05$***) and HAQ ($p < 0.05$***) after 12 weeks with respect to the base line levels (day 0).

Limitations, reasons for caution: Compliance of patients for Yoga based lifestyle intervention was poor, hence we enrolled large number of patients to achieve the desirable sample size.

Wider implications of the findings: Adoption of yoga based lifestyle intervention as an integral part of our lifestyle may hold the key to reduce the disease activity, minimize dosage of DMARDs and its associated consequences like disabilities associated with physical, mental and reproductive health.

Trial registration number: Not applicable.

P-061 Reproductive potentials of testicular versus ejaculated sperm for intracytoplasmic sperm injection (ICSI) using sibling oocytes for men with high sperm dna fragmentation

R. Nayak[1], K. Vasanth[1], N. Thondehal Math[2], G. Deepanjali[2], U. Gayatri[2], W.Y. Son[3]

[1]Gunasheela Surgical & Maternity Hospital, Andrology, Bangalore, India
[2]Gunasheela Surgical & Maternity Hospital, embryology, Bangalore, India
[3]McGill University Health Centre MUHC- Royal Victoria Hospital- Canada, Embryology, Montreal, Canada

Study question: In couples with high sperm DNA fragmentation (SDF), is reproductive potential improved with intracytoplasmic sperm injection (ICSI) using testicular sperm (Testi-ICSI) compared to ejaculated sperm (Ejac-ICSI)?

Summary answer: ICSI with testicular sperm in couples with high SDF seemed not to have a beneficial effect on reproductive potential compared to using ejaculated sperm.

What is known already: High SDF may have an adverse impact in reproductive outcomes, reducing the fertilization rate, poor embryo development and high miscarriages. Although testicular sperm have higher aneuploidy rates, testicular sperm have lower levels of SDF than ejaculated ones. Therefore, some studies have been reporting better reproductive outcomes with ICSI using testicular sperm for men with high levels of SDF. However, these studies were done on women-based randomization, not on oocyte-based randomization.

Study design, size, duration: In this prospective pilot study, performed from November 2016 to November 2017, 29 women (32.2 ± 4.4 years old) whose male-partners (38.6 ± 4.5 years old) had high sperm DNA fragmentation (>30% DNA fragmentation index (DFI)) and unsuccessful antioxidant treatment. This study was performed to compare reproductive potential between Testi-ICSI (n = 158) and Ejac-ICSI (n = 169) in same patients with persistently high SDF despite prior antioxidant treatment.

Participants/materials, setting, methods: Sperm DNA damage was examined by Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay using flow cytometric analysis. All male-partners in this study had high sperm DNA fragmentation (> 30% DNA fragmentation index (DFI). Male partners were produced ejaculate sperm and underwent testicular sperm aspiration (TESA). Approximately half of mature eggs obtained per ICSI cycle were Testi-ICSI and half with Ejac-ICSI. Fertilization, good-quality blastocyst development and reproductive outcomes were analyzed between two groups.

Main results and the role of chance: Average seminal DFI of patients was 45.2 ± 12.7%. A total of 327 mature oocytes were injected; 158 with Testi-ICSI and 169 with Ejac-ICSI. Fertilization rate per oocyte was 65.7 ± 20.5 % and 78.1 ± 20.7 % in Testi-ICSI and Ejac-ICSI, respectively ($P < 0.01$). Good-quality blastocyst formation rates (> 4BB) per embryo were 60.2 ± 35.9 % and 65.5 ± 32.4 % in Testi-ICSI and Ejac-ICSI, respectively (NS). Seventeen cycles out of 29 ICSI cycles had fresh embryo transfer (ET), twelve cycles cancelled because of high risk of developing OHSS. In Testi-ICSI, 11 blastocysts were transferred in 7 ET cycles resulting in 3 clinical pregnancy rate (CPR) of 42.9% and an implantation rate (IR) of 27.3% (N = 3). It resulted in one live birth, one ongoing and one miscarriage. In Ejac-ICSI, 10 ET cycles were performed transferring 17 blastocysts obtaining the CPR and IR of 50 % (5/10) and 35.3% (6/17). One of the clinical pregnancies of this group resulted in an abortion. The other 4 pregnancies had live births.

Limitations, reasons for caution: Sample size is still too low and it should be enlarged; furthermore a high number of mature oocytes available for the injection per patient is needed. Finally, frozen embryos have still to be transferred before drawing final conclusions.

Wider implications of the findings: Due to variable factors between patients, study on sibling oocytes might be the actual valid method to see usefulness of Testi-ICSI. Our study implies that more studies are necessary before changing clinical practice for the couples with high SDF because of potential known/unknown risks of using testicular sperm.

Trial registration number: Not applicable.

P-062 Effect of paternal high values of sperm DNA fragmentation on the outcomes of PGT-A programs in couples with different age groups of female patients

I. Ushakova, A. Kirillova, J. Kiseleva, T. Kodyleva, T. Volodjaeva, O. Golubeva, N. Mishyeva, A. Ekimov, A. Abubakirov

Federal State Budget Institution "Research Center for Obstetrics- Gynecology and Perinatology" Ministry of Helthcare of the Russian Federation- Moscow- Russia, Department of preservation and restoration of reproductive function- Moscow-Russia., Moscow

Study question: Does the maternal age influence the outcomes of the PGT-A programs with high levels of partner's DNA fragmentation?

Summary answer: A high level of DNA fragmentation does not affect the frequency of clinical pregnancy in women under 30 years of age in the PGT-A programs.

What is known already: High sperm DNA fragmentation in couples undergoing assisted reproductive technologies is associated with lower live birth rate.

Sperm DNA damage has a close inverse relationship with live-birth rates after IVF.

Study design, size, duration: Retrospective, experimental study of 126 couples, undergoing IVF treatment with the evaluation of functional semen parameters (concentration, motility, morphology), and sperm DNA fragmentation from January 2016 to January 2017

Primary endpoints:
The fertilization rates groups.
The rates of blastocyst formation in groups.
The rates of clinical pregnancy in groups.

Participants/materials, setting, methods: Sperm DNA fragmentation was evaluated using the TUNEL assay (the normal level of DNA fragmentation is < 15%).

ICSI+PGT-A program, fertilization and embryo culture according to the manufacturers recommendations of William A. COOK (Australia).

Array CGH (Agilent, USA) was used for 24-chromosome embryonic genome analysis.

The rates of fertilization, rates of blastocyst formation, and rates of implantation were evaluated.

Main results and the role of chance: 126 women who were enrolled in the study were distributed according to their age as followed: under 30 years old (30 patients); 31-34 years old (35 patients); 35-40 years old (45 patients); older than 40 years old (16 patients).

Our results showed that there are lower fertilization rates (71,1% vs. 83,4%, $p < 0.05$) and significantly lower rates of blastocyst formation (23,7% vs. 53,2%, $p < 0.05$) in the group with high values of sperm DNA fragmentation in comparison with the group with normal values of this parameter.

Our data demonstrated that for couples with a female partner under 30 years there is no difference in the rates of clinical pregnancies between the group with high values of paternal sperm DNA fragmentation and the group with normal values of this parameter (63% and 63%, respectively). On the

contrary, for couples with female partners older than 31 the rates of clinical pregnancies were higher for groups with normal values of paternal sperm DNA fragmentation compared to the groups with high values of this parameter: 53% vs. 44% for women 31-34 years old; 32% vs.24% for wome 35-40 years old and 25% vs.0% for women > 40 years.

Limitations, reasons for caution: Our study didn't include a large number of couples, and new bigger studies with extra criteria's of comparison are required.

Wider implications of the findings: Our study shows that high values of sperm DNA fragmentation do not influence the outcomes of the IVF programs only when a female partner is younger than 30 yours old. Thus, we can speculate that oocytes of younger women have an ability to compensate the spermatozoa damaged DNA.

Trial registration number: not applicable.

P-063 Clinical outcomes of microdissection testicular sperm extraction (micro tese) and intracytoplasmic sperm injection (ICSI) in non-obstructive azoospermia (NOA) with the history of cryptorchidism

A. Ishida[1], S. Mizuta[1,2], H. Matsubayashi[1,2], T. Takeuchi[2], K. Kitaya[1], T. Ishikawa[1,2]

[1]Reproduction Clinic Osaka, Reproductive Medicine, Osaka, Japan
[2]Reproduction Clinic Tokyo, Reproductive Medicine, Tokyo, Japan

Study question: To assess the prevalence and significance including SRR by micro TESE and ICSI outcomes with embryonic development in NOA couples with the history of cryptorchidism.

Summary answer: Micro TESE is particularly helpful for sperm retrieval in UT cases and ICSI outcomes in NOA with UT are equivalent to OA and unexplained NOA.

What is known already: Undescended testis (UT) is associated with impairment of germ cell maturation and subsequent infertility in adulthood because the UT is exposed to a higher temperature compared with the scrotal temperature and there is progressive Leydig and Sertoli cell atrophy. There have been very few studies of ICSI with a focus on, or large enough numbers to examine, the specific outcomes associated with male factor infertility including NOA with the history of cryptorchidism.

Study design, size, duration: This study was conducted in 50 NOA patients post cryptorchidism, 526 unexplained NOA patients without past history (unexplained NOA; not including after orchidopexy, Klinefelter syndrome, cryptozoospermia, mumps orchitis, etc), and 141 OA patients and the ICSI outcomes of their wives are retrospect assessed between September 2013 to December 2017.

Participants/materials, setting, methods: We evaluated SRR of micro TESE, two pronuclei (2PN) oocyte rates, blastocyst development rates, good-quality blastocyst (Grade 3BB and above on day 5 by the Gardner scoring) rates, and clinical pregnancy rates per embryo transfer (ET) in 25 cases the history of UT, 94 cases of unexplained NOA, and 107 cases of OA. The wives age at ICSI after cryptorchidism, Unexplained NOA, and OA were 34.1 ± 3.5 years, 34.6 ± 4.6 years, and 34.9 ± 3.9 years, respectively.

Main results and the role of chance: SRR of micro TESE NOA with the history of cryptorchidism (32/50 = 64.0%) was higher than unexplained NOA (107/526 = 20.3%) ($p < 0.001$). No correlation was found between serum FSH, LH, and T level with the success of sperm retrieval. Testicular volume and patient age at orchidopexy also did not affect the SRR for micro TESE. 2PN oocytes, blastocyst development, and good-quality blastocyst rates were 54.8%, 46.6%, and 38.2% in NOA with the history of cryptorchidism, 55.7%, 34.2%, and 40.9% in unexplained NOA with the history of cryptorchidism, and 62.7%, 37.7%, and 42.6% in OA, respectively (no significant differences). Clinical pregnancy rates per ET were 31.6% in unexplained NOA with the history of cryptorchidism, 30.8% in unexplained NOA, and 40.4% in OA, respectively (no significant differences).

Limitations, reasons for caution: In the present series, we could not assess whether the children born had a cryptorchidism or not. It would be worthwhile evaluating, in a larger series, the prevalence of cryptorchidism in boys born from fathers with an undescended testis.

Wider implications of the findings: However testicular function is considered to be severely impaired, orchidopexy for undescended testes in even adulthood could be considered to have any effect on spermatogenesis. Objective counselling of the NOA patinets with the history of cryptorchidism for the chance of having a healthy baby is of utmost importance.

Trial registration number: N/A.

P-064 Raman spectroscopical assessment of human sperm capacitation in vitro

A. De Angelis[1], G. Coppola[2], A.C. De Luca[3], N. Angiolelli[2], M.A. Ferrara[4], L. Siani[2], G. Coppola[4], B. Dale[2]

[1]CNR, Institute of Protein Biochemistry, Naples, Italy
[2]Centro Fecondazione Assistita, Biology or Reproduction, Naples, Italy
[3]Italy National Research Council, Institute of Protein BiochemistryCNR, naples, Italy
[4]Italy National Research Council, Institute of Protein BiochemistryCInstitute for Microelectronics and Microsystems, Naples, Italy

Study question: Is it possible to assess human sperm function using a label-free and non-destructive method.

Summary answer: Raman microspectroscopy (RM) can enables label-free, non-invasive, accurate and reproducible assessment of sperm function, including the discrimination of capacitated from un-capacitated spermatozoa.

What is known already: Current methods for evaluating sperm function are indirect and of limited clinical applicability since they render the analysed spermatozoon unfit for IVF. We applied RM as a spectroscopic method to provide detailed biochemical maps of cells, including spermatozoa, without affecting their viability, revealing DNA fragmentation, nuclear composition (such as discrimination of X and Y-bearing bovine sperm cells) and protein/lipid oxidation. Can RM could be used for the biochemical assessment of sperm physiology?

Study design, size, duration: Raman spectra and images of capacitated versus untreated human spermatozoa were analysed. A concentration of 10 million of sperm/ml was divided into four aliquots: the untreated serving as a control; the others were added with a 100 mg/ml of heparin and incubated at 37°C for different times: 1, 2, 3 and 4 hours. A totality of 5 samples from 5 different patients were analysed through CTC assay and Raman spectroscopy.

Participants/materials, setting, methods: Semen samples were obtained from men (age: 35-48 years) attending the Centre for Assisted Fertilization (Naples). The ejaculates were collected after 3–5 days of sexual abstinence and processed. Following a routine spermiogram and washing on a Percoll density gradient, capacitation was induced in vitro using heparin, and the percentage of capacitated spermatozoa was evaluated using a CTC staining assay. Finally, control and treated samples were analysed by RS at the Institute of Protein Biochemistry (Naples).

Main results and the role of chance: The average spectra acquired from different regions of the human sperm head (acrosome, middle region) for both control cells and those treated at different timeswith heparin were analysed. Capacitated spermatozoa reveal important spectral variation in the Raman bands associated with proteins and lipids content (1200-1600 cm^{-1}), reflecting the protein/lipid migration and scrambling especially in the acrosoma region. On the contrary, the average spectra from the mid-head region (mainly nucleus) did not show any significant changes in lipid peak intensity, as expected. Interestingly, the Raman peaks at 2850 cm^{-1} and 2885 cm^{-1}, assigned to cholesterol decreases in the Raman spectra of capacitated spermatozoa, coinciding with the cholesterol efflux that triggers capacitation. All these variations increase with increasing the incubation time with heparin. Finally, multivariate statistical analysis (PCA, principal component analysis) was used for revealing the main specific Raman biomarkers associated with capacitation, and to use them for the efficient identification and sorting ofcontrol and capacitated sperm cells.

Limitations, reasons for caution: Raman analysis was performed on fixed spermatozoa. The results demonstrated only proof of principle of using RS as a method to study sperm function without clinical validation. The complexity in interpreting our results make the translation of RS technique into clinical practice challenging.

Wider implications of the findings: Assessment and classification of male infertility based on sperm function, useful for choosing the best technique for ART.

Complete sperm quality assessment for selecting a fertile spermatozoon for IVF.

Evaluating or comparing media or conditions used to handle sperm in vitro or in cryopreservation processes.

Trial registration number: This in basic science.

P-065 A multicenter study to evaluate oxidative stress by oxidation–reduction potential, a reliable and reproducible method

A. Agarwal[1], R. Chandrakumar[1], M. Arafa[2], H. Elbardisi[2], H. Okada[3], K. Suzuki[3], S. Homa[4], A. Killeen[5], B. Balaban[6], A. Ayaz[7], R. Saleh[8], A. Armagan[9], S. Roychoudhury[10], S. Sikka[7]

[10]*Assam University, Life Science and Bioinformatics, Silchar, India*

Study question: Investigate the reproducibility and reliability of the ORP measurement as a marker of sperm quality across different fertility centers.

Summary answer: ORP provided equal or less variability than the current semen analysis measures across 9 different fertility centers.

What is known already: Discrete measures of free radicals, antioxidant activity, and oxidative damage suggest an ambiguous relationship between the redox system and male fertility. Static oxidation-reduction potential (sORP) measures the balance between all oxidants and antioxidants providing a comprehensive status of the redox system. In a previous study, ORP and semen analysis data were compared between two andrology laboratories, in which ORP remained consistent in both datasets individually or in combined data.

Study design, size, duration: This prospective study was carried out jointly by nine participating fertility centers on 1644 subjects. The study was approved by the institutional ethics committee and subjects were consented prior to participation. Subjects were grouped into those that had all normal semen parameters (concentration, total cell, total motility, progressive motility, and morphology) according to WHO 2010 guidelines and those who failed to meet one or more criteria. ANOVA/t-test measures were used to determine significant differences.

Participants/materials, setting, methods: Exclusion criteria included azoospermia, presence of sexually transmitted disease or chronic disease, use of prescription, OTC medications or antioxidants. Samples were collected and semen parameters assessed using the WHO 2010 guidelines. ORP was measured (mV) using the MiOXSYS system and normalized to sperm concentration (mV/10^6 sperm/mL). For group comparisons, only those samples with a concentration >0.999 × 10^6 sperm/mL were included.

Main results and the role of chance: The results of ORP reflects the oxidative relationship between the sperm cell and its environment - the expulsion of oxidants, a by-product of cellular metabolism, into the seminal environment and the deactivation of them by extracellular antioxidants. The resulting ORP measurement reflects the average of the final ten (10) seconds (or twenty readings) of the sample. Of the 1644 samples, 138 were found to have normal semen parameters and 1506 were found to have abnormal semen parameters. The mean ORP value (mV/10^6 sperm/mL) in the semen of the abnormal group was 5.07 mV/10^6 sperm/mL whereas that of the normal group was 0.88 mV/10^6 sperm/mL ($p = 0.001$). The SD for ORP was equal to or better than most measures, with exception to morphology. However, it should be noted that morphology is the parameter with the highest variability typically found between laboratories.

Table I Sperm parameters and ORP values (mv/10^6 sperm) in patients with at least one abnormal semen parameter (n = 1506) versus patients with normal semen parameters (n = 138) [values are presented as mean ± SEM].

	Group	Mean	SEM
ORP	Normal	0.88	0.14
	Abnormal	5.07	0.37
Progressive Motility	Normal	48.08	0.93
	Abnormal	15.81	0.39
Normal Morphology	Normal	6.76	0.30
	Abnormal	4.87	0.19

Limitations, reasons for caution: Study enrollment of an even number of healthy controls with proven fertility was limited in comparison to the male infertility group.

Wider implications of the findings: ORP remains stable even with measurable differences in sperm parameters, and it therefore can be used as a supplementary test to semen analysis to confirm oxidative stress and poor semen quality.

Trial registration number: There are no competing interests.

P-066 Protein Kinase A modulation by nitric oxide during human sperm capacitation

F.D. Staicu[1], J.C. Martinez-Soto[2], C. Matas[1]

[1]*Veterinary Faculty- University of Murcia, Animal Physiology, Murcia, Spain*
[2]*IVI-RMA, Andrology laboratory, Murcia, Spain*

Study question: To further examine how nitric oxide (NO) modulates Protein Kinase A (PKA) activity during the *in vitro* capacitation of human spermatozoa.

Summary answer: We provide further evidence that NO plays a role in regulating specific phosphorylation events during human sperm capacitation.

What is known already: Several studies have identified important factors involved in the regulation of sperm capacitation, a physiological process necessary to achieve the fertilization ability. Reactive Oxygen Species such as NO are generated during this process and are beneficial in low concentrations for its progress. It has been reported that NO can modulate PKA-dependent phosphorylation events linked to the capacitation in different species. NO can activate the sAC-cAMP-PKA pathway either directly or by increasing the cGMP levels. A rise in the cGMP concentration may inhibit cAMP degradation, which subsequently leads to PKA activation.

Study design, size, duration: Semen samples were obtained from normozoospermic donors (n = 7) by masturbation after 3–5 days of sexual abstinence. Spermatozoa were incubated for 4 hours in capacitating and non-capacitating conditions. The media were supplemented with 100 µM S-Nitrosoglutathione, a NO donor, and two inhibitors of NO synthesis: 10 mM N^G-Nitro-L-arginine Methyl Ester Hydrochloride and 10 mM Aminoguanidine hemisulfate salt. The experiments were performed in absence and presence of 10 mM L-Arginine monohydrochloride, the substrate for NO production.

Participants/materials, setting, methods: The protein phosphorylation pattern on Serine and Threonine residues (i.e. PKA activity) was evaluated by Western blotting (WB). Proteins were separated by electrophoresis on 4-15% SDS-polyacrylamide gels and electrotransferred to PVDF membranes. The latter were treated with the following antibodies: rabbit monoclonal antibody anti-protein kinase A (1:2000) and goat anti-rabbit IgG-HRP (1:10000). The relative amount of signal in each membrane was quantified using the ImageQuant TL v8.1 software (GE Healthcare, Life Sciences, Buckinghamshire, UK).

Main results and the role of chance: Our results indicated that in the presence of Nitric Oxide Synthase inhibitors, spermatozoa showed a lower Serine and Threonine phosphorylation pattern than those capacitated with the NO donor ($p < 0.05$) when quantifying the signal corresponding to the whole WB lane. Moreover, we observed a specific phosphorylation pattern for two PKA substrate species, ~ 87 and ~ 62 kDa, which showed a higher degree of phosphorylation in the presence of S-Nitrosoglutathione ($p < 0.05$). The inhibitory effect on PKA activity when blocking NO synthesis was again evident in the ~ 87 and ~ 62 kDa species.

Our data showed that the presence of L-Arginine had no significant effect when analyzing the signal corresponding to the whole WB lane. However, similarly to the experiment where L-Arginine was not used, the ~ 62 kDa species showed a lower amount of phosphorylation when using NOS inhibitors ($p < 0.05$).

These effects were not observed under non-capacitating conditions.

Limitations, reasons for caution: The number of samples is small and should be increased. Also, the study should include infertile men in the future.

Wider implications of the findings: We identified specific PKA substrates such as the species of approximately 87 and 62 kDa, which show a distinct Serine and Threonine phosphorylation pattern. These bands might include key proteins in modulating the events downstream of NO-mediated signaling and could be differently regulated in infertile men.

Trial registration number: Not applicable.

P-067 Determination of aneuploidy in spermatozoa by flow cytometry and its relationship on reproductive results

R. Lafuente[1], K. Lattes[2], S. Brazal[3], D. García[3], R. Vassena[3], M. Brassesco[2]

[1]CIRH, Andrology Lab, Barcelona, Spain
[2]CIRH, Medical Dpt., Barcelona, Spain
[3]Clínica EUGIN, Research Dpt., Barcelona, Spain

Study question: Is it possible to link the determination of semen aneuploidy by flow cytometry to the reproductive results of IVF?

Summary answer: The degree of semen aneuploidy is not related to reproductive outcomes and should not be routinely included before IVF.

What is known already: Previous studies have confirmed an inverse correlation between aneuploidy in sperm and conventional seminal parameters. Furthermore, the presence of aneuploidy in sperm is associated with failed spermatogenesis, and may cause oligospermia or azoospermia. The study of semen aneuploidy can be performed quickly and sensitively by flow cytometry. This technique allows to determine sperm subpopulations with different DNA contents and, therefore, with different aneuploidy levels. This methodology analyzes a greater number of cells than in a conventional FISH and takes into account the entire DNA content of the cell.

Study design, size, duration: This is a prospective cohort study of 481 couples who have undergone a first IVF cycle with embryo transfer between 2014 and 2017. The patients underwent a semen analysis and a study of sperm DNA using propidium iodide staining (PI/RNase, BD Pharmingen) by flow cytometry (MACSQuant Analyzer, Miltenyi Biotec).

Participants/materials, setting, methods: Sperm populations were classified according to fluorescence intensity as: subhaploid, haploid, diploid and polyploid. A univariate analysis has been carried out in which the different results obtained from the sperm analysis and the study of ploidies have been compared according to the reproductive results (positive / negative): clinical pregnancy, ongoing pregnancy and live birth. The statistical analysis were carried out by Student's t-tests, considering $p < 0.05$ as statistically significant.

Main results and the role of chance: No statistically significant differences were observed in the levels of subhaploidies between patients with positive and negative reproductive results for clinical pregnancy (35.0% vs. 65.0%, $p = 0.77$), ongoing pregnancy (22.5% vs. 77.5%, $p = 0.79$), or live birth (22.2% vs. 77.8%, $p = 0.83$). There were also no differences in the haploidy rate (35.0% vs. 65.0%, $p = 0.45$, 22.5% vs. 77.5%, $p = 0.21$, 22.2% vs. 77.8%, $p = 0.25$); nor in the diploidy rate (35.0% vs. 65.0%, $p = 0.42$, 22.5% vs. 77.5%, $p = 0.29$, 22.2% vs. 77.8%, $p = 0.32$). However, in the polyploidy percentage, statistically significant differences were detected for ongoing pregnancy and live birth (35.0% vs. 65.0%, $p = 0.21$, 22.5% vs. 77.5%, $p = 0.01$, 22.2% vs. 77.8%, $p = 0.02$), as the percentage of polyploidies was somewhat higher in the group of pregnant patients, but without clinical relevance.

Limitations, reasons for caution: The population included in this study was part of infertile couples at their first IVF cycles; caution should be exerted when extending these results to other populations with a longer infertility history.

Wider implications of the findings: The degree of semen aneuploidy does not seem to be related to reproductive outcomes; a more conservative approach to semen analysis seems to be best suited for routine assessment before IVF.

Trial registration number: None.

P-068 Characterization of somatic testicular cells in fetal, prepuberal and adult testis. The role of StAR in Leydig cells

A. Garcia[1], L. Herrera[1], C. Rodriguez[1], M.A. Vesga[1], M. Diaz-Nuñez[2], A. Exposito[2], R. Matorras[2], B. Prieto[2], S. Chuva de Sousa Lopes[3], C. Eguizabal[1]

[1]Centro Vasco de Transfusiones y Tejidos Humanos Hospital de Galdakao, Cell Therapy and Stem Cells Group, Galdakao Bizkaia, Spain
[2]Cruces University Hospital, Human Reproduction Unit, Barakaldo, Spain
[3]Leiden University Medical Center, Department of Anatomy and Embryology, Leiden, The Netherlands

Study question: Is StAR protein present in somatic cells of male fetal gonads in the first trimester?

Summary answer: No StAR expression in Leydig cells from 9-10 weeks of gestation, whereas a weak expression at 12 weeks and high expression at 14 weeks.

What is known already: In humans, StAR protein is known to be express in adult Leydig cells, but also in Leydig cells of fetal testes from 14.5-19 gestational weeks, however there is no data about the expression of StAR in first trimester fetal male gonads.

Study design, size, duration: We collected fetal, prepuberal (Klinefelter Syndrome patients) and adult testis samples to perform immunofluorescence for studying the presence of specific testicular somatic cell markers as StAR, GATA4 and SOX9 during the human development of the male gonads.

Participants/materials, setting, methods: Human fetal samples from 9 to 21 weeks postconception (wpc) were obtained from Leiden Universitary Medical Center (LUMC) (The Netherlands). Human prepuberal patient samples diagnosed with Klinefelter Syndrome and human adult samples diagnosed with azoospermia were obtained from Cruces University Hospital (Spain). Oral and written information was given and informed consent was obtained from all patients. We performed immunofluorescence for detecting VASA,OCT4, SOX9, GATA4 and StAR markers on paraffin sections of the samples previously mentioned.

Main results and the role of chance: StAR expression in male fetal gonads, there was no presence of StAR at 9 and 10 weeks of gestation, however, a weak expression is observed at week 12, being very significant at week 14 up to 21 weeks. As expected, StAR expression only appeared between the seminiferous tubules, in the interstitial space, where Leydig cells are located. GATA4 was clearly present in the Sertoli cells but also in some interstitial cells. SOX9 expression, it was present only in the nucleus of Sertoli cells.

In testis of Klinefelter Syndrome prepuberal patients, StAR expression is in Leydig cells with a spotty pattern. GATA4 was express in somatic cells inside the seminiferous tubules, but also in cells between tubules.

SOX9 expression is present in the nucleus of somatic cells inside the tubules.

Adult patients were separated in two different groups, depending on the presence or lack of spermatozoa (azoospermia). In general there was no significant difference between both groups and was detected StAR protein in the interstitial cells with spotty pattern. GATA4 positive cells were inside seminiferous tubules and in the interstitial space. SOX9 expression was observed only nuclear staining in Sertoli cells.

Limitations, reasons for caution: Due to the limited and difficulty in the obtention of material used in this study, we used few samples of gonads from several gestational stage and few samples of prepuberal testis.

Wider implications of the findings: The results obtained in this study will help to understand the early development of the fetal somatic cells, especially the Leydig cells and the role of StAR protein in steroidogenesis during this fetal development.

Trial registration number: NONE.

P-069 Association of the sperm telomere length and telomerase activity with semen quality and fertilization in IVF

Y. Li, R. Li, S. Ou, K. Dai, W. Wang

Sun Yat-sen Memorial Hospital, Department of Obstetrics and Gynaecology, Guangzhou- Guangdong, China

Study question: Whether the sperm telomere length(STL) and sperm telomerase activity(STA) are related to semen quality and pregnancy outcomes in IVF?

Summary answer: The STA gradually decreased with age. Better semen quality and fertilization outcomes are observed in patients with longer STL or higher levels of STA.

What is known already: Telomeres are functional DNA-protein structures located at the end of the chromosome and maintain the chromosome stability as well as genome integrity. Telomerase is an critical enzyme for maintaining the telomere length(TL). The sperm TL(STL) has been reported to be associated with idiopathic male infertility and early embryo development in IVF.

Study design, size, duration: 42 samples from men with normal semen examination were collected and divided into the group A(≤36 years old, $n = 16$), group B(36-40 years old, $n = 12$), group C(41-45 years old, $n = 7$) and group D(≥45 years old, $n = 7$).

Participants/materials, setting, methods: The STL was measured using quantitative real-time PCR and STA was detected by a modified quantitative-telomeric repeat amplification protocol assay.

Main results and the role of chance: STA levels differed significantly among four groups($P = 0.010$). The STA was highest in group B(between 0.009 to 0.33) and decreased in group A(between 0.002 to 0.05), group C(between 0.005 to 0.029) and group D(between 0.001 to 0.011). No obvious differences were observed in the STL, sperm density, fertilization rate, normal fertilization rate, available embryos or good quality embryos among these groups($P > 0.05$). Sperm density was positively correlated to the STL($r = 0.325$, $P = 0.044$) in our study population($n = 42$). The non-progressive sperm motility was negatively correlated to STL(r=-0.361, $P = 0.024$) and STA(r=-0.318, $P = 0.033$). The normal IVF fertilization rate was positively correlated to STL($r = 0.365$, $P = 0.021$). There were no significant differences in STL or STA between the pregnant samples and non-pregnant samples($P > 0.05$).

Limitations, reasons for caution: Our sample size is not that large enough to see the significant differences of STL among four groups. Further studies with larger sample size are needed to explored the differences of STL as well as other clinical features among these groups.

Wider implications of the findings: Patients with longer STL or higher levels of STA might have better semen quality and fertilization outcomes in IVF. Men who aged over 46 are more likely to have a very low level of STA.

Trial registration number: Not applicable.

P-070 Effect of leucospermia on sperm parameters and Intracytoplasmic Sperm Injection outcomes

K. Kacem Berjeb[1], S. Mnallah[1], N. Ben Brik[1], M. Braham[2], M. Ben Mefteh[2], D. Wahbi[1], S. Chtourou[1], A. Fadhlaoui[2], F. Zhioua[2], A. Zhioua[1]

[1]Aziza Othmana Hospital, IVF Laboratory, Tunis, Tunisia
[2]Aziza Othmana Hospital, Departement of Gynecology and Obstetrics, Tunis, Tunisia

Study question: Is there an association between seminal leucocytes levels, sperm parameters and ICSI outcomes in a large population of infertile patients?

Summary answer: Leucocytospermia had a harmful effect on sperm parameters, including sperm concentration, morphology and chromatin maturity of spermatozoa, but do not influence ICSI outcomes.

What is known already: Leucospermia is highly prevalent among infertile patients even those with negative semen culture. The role played by leukocytes in the human sperm is not totally understood. Activated leucocytes generate excessive reactive oxygene species (ROS) which have been negatively correlated with fertility and semen quality. In fact, there is consensus that leucocytospermia, defined by leukocytes exceeding 1×10^6 cells/mL, impaires sperm quality. In the other hand, there is still much controversy about its correlation with ICSI outcomes.

Study design, size, duration: Prospective observational study including 157 patients who underwent ICSI cycles between February and May 2017, in a university hospital. Patients were divided into two groups according to sperm leucocytes levels: Group 1 ($n = 33$) ≥ 1×10^6/ml and Group 2 ($n = 124$) < 1×10^6/ml.

Participants/materials, setting, methods: Only patients with negative semen culture were included in our study. Patients with azoospermia or cryptozoospermia were excluded. Sperm parameters were evaluated according to World Health Organization 2010 guidelines. The peroxidase method was used to quantify leucocytes, when round cell concentration exceeded 1×10^6/ml on fresh semen. Sperm chromatine condenstation was assessed by aniline blue staining.

The main parameters compared between the two groups were sperm parameters(volume, concentration, motility, morphology and chromatin maturity) and ICSI outcomes.

Main results and the role of chance: The mean age of the patients was comparable in groups 1 and 2 respectively (39.21 years VS 40.86; p = 0.1445). The clinic and paraclinic characteristics, the stimulation parameters and the ovarian response, were similar in both groups.

The number of leucocytes had a statistically significant negative influence on sperm concentration, morphology and sperm maturity when comparing groups 1 and 2 respectively (30,5 ± 26,0 VS 40,5 ± 37,7; p = **0.02); (**3,3 ± 1,0 % VS 4,6 ± 1,7 % p = **0.00); (**57,6 % ± 14,1 % VS 73,2 ± 11,8%; p = **0.0001)**

In contrast, sperm volume and progressive motility were comparable in both groups.

In the other hand, leucospermia has not significantly influence ICSI outcomes. The fertilization rate and the cleavage rate were comparable between the two groups (81.22 VS 83.82%, p = 0.59); (91.37 vs 95.66%, p = 0.25). We also didn't found any significant difference in top embryo rate and blastulation rate. The pregnancy rate were also comparable (37.03 VS 44.76%; p = 0.51).

Limitations, reasons for caution: The observational character of the study, and the reduced size of the samples studied constitute major limitations. In addition, measurement of sperm leucocytes in routine semen analysis appears to be of little prognostic value with regard to male fertilizing potential.

Wider implications of the findings: Further studies are needed to define other factors that increase the risk of sperm damage through elevated number of leucocytes in semen.

Trial registration number: Not applicable.

P-071 Lifestyle and semen variables: a prospective cohort study of men referring to an Italian Fertility Clinic

S.A. Noli[1], E. Ricci[2], S. Ferrari[2], I. La Vecchia[1], S. Cipriani[2], V. De Cosmi[3], E. Somigliana[1], F. Parazzini[1]

[1]Università degli Studi di Milano- Milan- Italy, Department of Clinical Sciences and Community Health, Milan, Italy
[2]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Dipartimento Madre-Bambino-Neonato, Milan, Italy
[3]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Pediatric Intensive Care Unit, Milan, Italy

Study question: We designed a prospective cohort study to investigate the relation between lifestyle and semen quality in men of subfertile couples undergoing assisted reproductive procedures.

Summary answer: In our study moderate alcohol intake was related to a beneficial effect on semen quality in male partners of infertile couples undergoing ART cycles.

What is known already: Although the causal link between environmental factors and impaired male fertility is still weak, there is growing evidence

suggesting that semen quality may be influenced by lifestyle habits; in particular, smoking, overweight, physical activity, dietary factors and alcohol intake have been suggested to play an important role but evidence is not always consistent. According to a recent meta-analysis of 15 cross-sectional studies, an occasional consumption does not adversely affect semen parameters, whereas daily consumption has a negative association with semen volume and normal morphology. However, these findings could not be controlled for confounders such as smoking and age.

Study design, size, duration: From September 2014 subfertile couples, presenting for evaluation to the Fertility Unit of Fondazione IRCCS Ca' Granda, Ospedale Maggiore, Policlinico, Milan, and eligible for assisted reproduction technologies (ART), were invited to participate to an ongoing prospective cohort study on the role of lifestyle habits and diet on ART outcome. The present study reported exclusively on evidence obtained from the male partner. From September 2014 to December 2016, 327 men were enrolled.

Participants/materials, setting, methods: Men of couples who agreed to participate were interviewed to obtain information on: BMI, smoking, caffeine intake, occupational and leisure physical activity (PA) and usual alcohol intake. Information on diet were obtained using a validated food frequency questionnaire (FFQ). Couples were interviewed on the day of oocyte retrieval. On the same day, a semen sample was collected and analyzed to proceed with ART. Semen volume, total sperm count and sperm concentration and motility, were determined.

Main results and the role of chance: We distinguished 3 categories of alcohol intake: a low intake group, who drank ≤ 4.3 g of alcohol per day; an intermediate intake group, who drank 4.4-13.3 g per day; a high intake group, who consumed ≥13.3 g per day. At univariate analysis, sperm volume was significantly associated with age, alcohol intake and leisure PA; sperm concentration with a history of ROD (reproductive organ diseases); total sperm count with a history of ROD and alcohol intake; sperm motility with age, history of ROD and leisure PA. We analyzed the association between alcohol intake and semen variables in a general linear model including age, history of ROD, leisure PA (associated with at least 1 semen parameter), smoking status, caffeine consumption, calories intake (associated with alcohol intake). After accounting for these variables, alcohol intake showed a significant beneficial relation with semen volume, total sperm count and sperm concentration. In analyses performed in strata of age, ROD and leisure PA showed that the positive nonlinear association between alcohol and semen volume was consistently observed in all subgroups, whereas the significant effects on concentration, total count and motility were limited to men who performed less than 2 hours per week of leisure PA.

Limitations, reasons for caution: Study limitations: findings should be referred only to patients of infertile couples, information regarding alcohol use was self-reported. Study strengths: large sample size, analysis of the role of alcohol in men with or without other conditions associated with infertility, adjustment for potential biases reported to be associated with semen quality.

Wider implications of the findings: A moderate alcohol intake exerts a beneficial effect on semen quality. These findings are in line with results of a recent meta-analysis, supporting that opposite effects might be exerted by alcohol on semen parameters and according to the amount consumed. The mechanisms underlying these effects need to be further investigated.

Trial registration number: No trial registration number needed.

P-072 Clinical predictors for selection of surgical sperm retrieval techniques in non-obstructive azoospermia patients

A. Majzoub[1], M. Arafa[2], S. AlSaid[2], K. Khalafalla[2], H. Burjaq[3], M. Albader[3], T. Al-Marzooqi[4], H. Elbardisi[2]

[1]Hamad Madical Corporation, Urology, Doha, Qatar
[2]Hamad Medical Corporation, Urology, Doha, Qatar
[3]Hamad Medical Corporation, Assisted conception unit, Doha, Qatar
[4]Hamad Medical Corporation, Obstetrics and Gynecology, Doha, Qatar

Study question: Can the clinical findings of patients with non-obstructive azoospermia (NOA) aid in selecting the most appropriate surgical sperm retrieval (SSR) method prior to invitro fertilization (IVF)?

Summary answer: Clinical findings such as testicular size, initial and post-treatment hormone levels and testicular tissue histopathology can aid in selecting the sperm retrieval technique.

What is known already: Testicular sperm retrieval has been practiced over the past few decades as a mean of providing patients with NOA the chance to father their biologic children through IVF. While microsurgical testicular sperm extraction (mTESE) yields higher SSR rates when compared to testicular sperm extraction (TESA), it can also be considered a more invasive procedure with, at times, detrimental effects on testicular spermatogenic and endocrine functions.

Study design, size, duration: This was a retrospective study of 439 patients presenting with NOA who underwent surgical sperm retrieval at a tertiary medical center over a period of 5 years. Data regarding patient demographics, clinical findings, serum hormone levels before and after medical stimulation therapy, chromosomal abnormality, type/outcome of the sperm retrieval procedure and histopathology results was collected.

Participants/materials, setting, methods: All participants received hormonal stimulation prior to a staged SSR procedure starting with TESA (needle aspiration biopsy technique) and progressing to mTESE when no sperm were retrieved after 4 aspirations from each testicle. Collected variables were examined against the sperm retrieval outcome and the method of SSR utilized. X2 and Kruskal-Wallis tests were used to analyze categorical and numerical values, respectively. A p value < 0.05 was considered statically significant.

Main results and the role of chance: Overall, SSR rate was 42.1%. Sperm were retrieved through TESA and mTESE from 99(22.5%) and 140(42.6%) patients respectively. Patients with a positive SSR were divided into 2 groups according to the SSR method used. Testes size, initial LH and FSH levels, post-treatment LH, FSH and testosterone levels and histopathology results significantly varied between the study groups (table 1). Patients with a positive sperm retrieval through TESA had a statistically significant larger right and left testicular size, lower initial and posttreatment LH and FSH levels, and higher posttreatment testosterone levels. The SSR rate with mTESE was higher than TESA in all testicular histopathologies ($p < 0.001$). However, the highest SSR rate in patients who underwent TESA was found in hypospermatogenesis, followed by maturation arrest, tubular atrophy and Sertoli cell only syndrome.

Table I

	TESA +ve (n = 99)	mTESE +ve (n = 140)
Age	37.6 ± 0.8	36.6 ± 0.6
Left testis size	8.8 ± 0.5*	6.8 ± 0.4*
Right Testis Size	9.6 ± 0.6*	7.2 ± 0.4*
(i)Testosterone	15.9 ± 0.7	16.2 ± 0.8
(i)LH	4.4 ± 0.2**	7.5 ± 0.5**
(i)FSH	8.1 ± 0.7**	14.8 ± 1.1**
(i)Estradiol	104.1 ± 4.1	121.7 ± 5.4
(t)Testosterone	23.3 ± 3.6*	17.3 ± 1.04*
(t)LH	8.1 ± 1.4	10.8 ± 0.8
(t)FSH	11.4 ± 1.1	19.9 ± 1.5
(t)Estradiol	134.7 ± 10.8	213.8 ± 87.1
Histopathology		
Hypospermatogenesis	36.4%**	41.5%**
Maturation arrest	15.2%**	29.6%**
Sertoli cell only	4.6%**	30.2%**
Atrophy	14.8%**	51.8%**
Abnormal Karyotype	11.5%	34.6%
Y-chromosome microdeletion	8.3%	8.3%

(*pvalue<0.05, **pvalue<0.01); (i)initial, (t)post-treatment

Limitations, reasons for caution: This was a single center study. Results need to be validated across different centers and study population.

Wider implications of the findings: It is important to recognize the predictors for successful SSR in different SSR methods to aid in selecting the most appropriate technique that can be effective and at the same time least invasive.

Trial registration number: NA.

P-073 Association between blood metal concentrations and human semen quality: a cross-sectional study in Hong Kong

X. Shi, M. Zhao, C. David, L. Tin-Chiu

Department of Obstetrics and Gyneacology- Prince of Wales Hospital, The Chinese University of Hong Kong- Hong Kong., New Territories, Hong Kong

Study question: Does heavy metal exposure, including essential and non-essential heavy metals, associated with the decline of semen quality and sperm function?

Summary answer: Although high blood lead and mercury level may be associated with poor semen quality, heavy metal exposure may not affect the sperm fertilisation function significantly.

What is known already: Exposure to metals, including essential and non-essential elements, is widespread and may be associated with altered semen quality. However, evidence from previous reports was contradictive. Moreover, there was lack of investigation regarding the effect of heavy metal exposure on sperm function.

Study design, size, duration: This is a cross-sectional study, which included 298 men who underwent routine fertility assessment between November 2015 and June 2016 in Hong Kong.

Participants/materials, setting, methods: Blood and semen samples were collected from participants at the teaching hospital of the Chinese University of Hong Kong. Routine semen analysis and sperm functional test (sperm vitality, sperm DNA fragmentation and acrosome-reaction test) were performed. Thirteen metals (As, Cd, Co, Cr, Cu, Fe, Hg, Mn, Mo, Ni, Pb, Se, and Zn) were measured in whole blood samples by inductively coupled plasma mass spectrometry. Multivariable logistic regression models were employed in data analysis.

Main results and the role of chance: After adjusting for age, abstinence time, current cigarette smoking habits and alcohol drinking habits in the multiple logistic regression analyses, we found blood lead level was significantly and negatively associated with sperm motility (Ptrend = 0.048). Moreover, we found significant dose-dependent trends of blood lead and mercury quartiles with sperm DNA fragmentation (Lead: Ptrend = 0.006; Mercury: Ptrend = 0.009). Furthermore, we found significantly dose-dependent trends of increase blood selenium with increase sperm morphology (Ptrend = 0.001). There were no significant associations between blood metal level and sperm vitality and acrosome reaction after adjustment for multiple demographic and lifestyle factors.

Limitations, reasons for caution: Our study is a cross-sectional study, the association found in our study is not causation between heavy metal exposure and semen quality, which is a common limitation to cross-sectional studies.

Wider implications of the findings: Environmental exposure to lead may be associated with lower sperm motility, and exposure to lead and mercury may associate with higher sperm DNA fragmentation; whereas selenium may have a protective effect for sperm morology. However, heavy metal exposure may not significantly affect the sperm fertilisation function.

Trial registration number: N/A.

P-074 Assessment of the impact of CryoFlex tubing on sperm cryopreservation outcome

T. Said[1], I. Kuznyetsova[2], A. Rajput[1], A. Del Valle[1]

[1]*The Toronto Institute for Reproductive Medicine - ReproMed, Andrology Laboratory and Reproductive Tissue Bank, Toronto, Canada*

[2]*The Toronto Institute for Reproductive Medicine - ReproMed, IVF Laboratory, Toronto, Canada*

Study question: Does wrapping cryovials with CryoFlex tubing prior to immersion in liquid nitrogen (LN) impact sperm cryopreservation outcome and the post-thaw recovery of motile sperm?

Summary answer: The use of CryoFlex tubing can negatively impact the outcome of sperm cryopreservation. The tubing should be removed prior to thawing to prevent such outcome.

What is known already: Cryovials are widely used to store cryopreserved semen samples. Nevertheless, they are not considered to provide effective biocontainment. Thus, LN penetration in addition to contamination of samples and LN tanks remain a concern. It has been suggested that wrapping cryovials in heat-shrinkable tubing prior to immersion in LN could reduce these risks. The tubing is made of a safe plastic resin polymer, however it has a poor temperature capability, which could affect cryopreservation-thawing protocols. It is not yet known if the use of CryoFlex tubing will impact the outcome of sperm cryopreservation, specifically, cryosurvival rates.

Study design, size, duration: Semen samples (n = 34) were included in this cross-sectional study. Following dilution with cryoprotectant media, each sample was split into 2 equal aliquots: 1) sample with CryoFlex wrapping, and 2) control without CryoFlex wrapping. The CryoFlex tubing remained wrapped during the thawing in 20 samples; while it was removed prior to thawing in 14 samples. All trials were conducted over the course of 3 months.

Participants/materials, setting, methods: Samples were provided by healthy donors. All aliquots were cryopreserved in vials with internal threading and silicon gasket (Nunc CryoTubes, Thermo Scientific). Heat-sealable wrapping (Nunc CryoFlex, Thermo Scientific) was applied to the sample aliquots, vials without wrapping served as controls. Thereafter, aliquots were placed in liquid nitrogen vapor for 20 minutes followed by plunging in liquid nitrogen. Thawing was performed after a minimum of 24 hours by immersion in 37 C water bath for 4 minutes.

Main results and the role of chance: Cryosurvival rates were calculated by dividing total motile sperm post-thaw by total motile sperm pre-freeze X 100. Statistical analysis was conducted using paired t-test with two-tailed test of significance. In samples thawed with the CryoFlex wrapping, the post-thaw sperm percentage motility and cryosurvival rates were significantly lower compared to controls (26.4 ± 6.1 vs. 30.9 ± 8.2, P = 0.003 and 60.6 ± 11.7 vs. 70.2 ± 12.8, P = 0.007, respectively). In samples where CryoFlex wrapping was removed prior to the thawing, no significant differences were noted in post-thaw sperm percentage motility and cryosurvival rates (32.1 ± 12.9 vs. 32.9 ± 12.8 and 69.0 ± 20.4 vs. 71.0 ± 12.5, respectively). Overall, the results showed that whenever the CryoFlex tubing is kept wrapped around the vials during the thawing process, a significant decline in the recovery of cryopreserved spermatozoa post-thaw will occur. No such decline was seen when the CryoFlex tubing was removed prior to thawing.

Limitations, reasons for caution: Our results are solely based on the evaluation of semen samples from healthy donors with normal semen parameters using a single cryopreservation protocol. It cannot be assumed that semen samples with lower quality parameters or the use of other cryopreservation protocol will yield with the same results.

Wider implications of the findings: This pilot provides new insights into the impact on CryoFlex tubing on sperm cryopreservation outcome. While it may alleviate some of the safety concerns associated with the use cryovials in sperm cryopreservation, CryoFlex can also negatively impact the outcome of sperm cryopreservation unless removed prior to thawing.

Trial registration number: Not applicable.

P-075 Nrf2 signaling in experimental cryptorchid mice

M. Baazm[1], H. Fallah asl[1], F. Jalali Mashayekhi[2], A. Zendedel[3]

[1]*Arak University of Medical Sciences, Anatomy, Arak, Iran*

[2]*Arak University of Medical Sciences, Biochemistry and Genetics, Arak, Iran*

[3]*Institute of Neuroanatomy, RWTH Aachen University, Aachen, Germany*

Study question: Whether Nrf2 signaling activates in experimental cryptorchid mice?

Summary answer: The Nrf2 signaling fails to develop in the cryptorchid testis.

What is known already: The nuclear factor erythroid 2 (Nrf2), a transcription factor, involve in cellular protection against oxidative stress. During cryptorchidism, heat stress induces destructive oxidative stress in testis by following deleterious impact on gonadal function which finally can result in decreasing sperm quality and infertility. Several studies report that Nrf2 plays an important role in inhibition the progress of oxidative stress in spermatogenesis. It has shown that the expression level of Nrf2 target genes decrease in men which suffer from low sperm motility. These findings spurred our interest to investigate the role of Nrf2 signaling in experimental cryptorchidism mice.

Study design, size, duration: 48 male mice at the age of 6 weeks were used. Cryptorchidism was induced by pushing left testis via inguinal canal into the abdominal cavity and fixing the testis to the abdominal wall, then gubernaculum was cut and inguinal canal was closed. After cryptorchidism-induction, mice were scarified on one day, one, four and eight eight weeks post operation. Sperm parameters and the expression of Nrf2 target genes such as HO1 and NQO1 were assessed.

Participants/materials, setting, methods: Sperm parameters including count, motility, morphology and viability were analyzed. Total RNA was extracted from the left testis of each mouse. The cDNAs were synthesized. For real time PCR reactions, primers were adapted from other primers (designed by the NCBI website). The quality of each reaction was confirmed by melting curve analyses. Efficiency was determined for each gene using a standard curve. For each sample, the target genes were normalized to a reference gene.

Main results and the role of chance: According to our statistical analysis, in all groups sperm parameters were reduced after cryptorchidism induction. The expression levels of studied genes were time dependent. One day and one week after surgery had similar gene expression pattern, except about the Keap1 expression (no change one day after surgery and decrease one week after cryptorchidism). In the mentioned time, the expression levels of Nrf2 and NQO1 were raised significantly ($p \leq 0.05$), but the level of HO1 expression declined ($p \leq 0.05$). Two weeks after cryptorchidism induction, Nrf2 expression level increased significantly, but the expression of Keap1 and HO1 significantly decreased ($p \leq 0.05$) and the expression of NQO1 showed any changes. Four and eight weeks after surgery, we could not detect any changes at the level of mRNA expression of the studied genes.

Limitations, reasons for caution: The limitation of research is that only gene expression is not strong tool for assessing the signaling and it needs supplementary studies.

Wider implications of the findings: In this study for the first time we showed Nrf2 signaling is activated during cryptorchidism, but it is not enough strong to prevent deleterious effect on the testis tissue.

Trial registration number: N/A.

P-076 Prevalence of Mycoplasma genitalium among infertile men and sperm donors consulting in a French center for Assisted Reproduction

L. Ferreux[1], A. Chargui[1], J. Loubinoux[2], J. Raymond[2], C. Jean[3], C. Chalas[3], V. Drouineaud[3], C. Poyart[2], C. Patrat[1], J.P. Wolf[1], E. Dulioust[1]

[1]*Hopitaux Universitaires Paris-Centre CHU Cochin, Service d'Histologie Embryologie Biologie de la Reproduction, Paris, France*
[2]*Hopitaux Universitaires Paris-Centre CHU Cochin, Service de bactériologie, Paris, France*
[3]*Hopitaux Universitaires Paris-Centre CHU Cochin, Service d'Histologie Embryologie Biologie de la Reproduction CECOS, Paris, France*

Study question: Is the prevalence of *Mycoplasma genitalium* (MG) higher in infertile men than in sperm donors? Does MG affect semen parameters?

Summary answer: MG prevalence in infertile men is significantly lower than in fertile men. No significant impact of MG on sperm parameters was evidenced.

What is known already: *Mycoplasma genitalium* is a bacterium, hard to isolate. Its prevalence is estimated between 1% and 3% in the general population. It is likely to cause a sexually transmitted infection and is responsible for 10 to 25% of non gonoccocal urethritis. *Mycoplasma genitalium* infection is usually asymptomatic. The impact of this emerging bacterium on semen parameters is still unknown as well as its role in male infertility.

Study design, size, duration: This study included 5208 infertile men and 162 sperm donors consulting between March 2012 and December 2016 in our Reproduction Center (Cochin hospital, AP-HP). A systematic search for *Chlamydia trachomatis, Neisseria gonorrhoeae* and *Mycoplasma genitalium* was performed on the first urinary stream by a highly sensitive and specific PCR technique (Test Dx CT/NG/MG®, Bio-Rad). This testing was systematically associated to semen parameters analysis.

Participants/materials, setting, methods: Prevalence of MG was calculated for each sub-group. Concomitant ejaculated semen was analyzed according to the 2010 WHO references. Semen parameters (sperm numbers, vitality, progressive motility and leucospermia) of infertile infected with MG were compared to those of infertile men free of any infection and matched according to the age, the abstinence period and date of analysis, using a student test.

Main results and the role of chance: The prevalence of MG was significantly lower in men consulting for infertility than men willing for sperm donation, already fathers (58/5208 1.1%, versus 7/162 4.3% $p < 0.01$). This prevalence among infertile men is similar to that reported in literature among the general population. The proportion of Chlamydia trachomatis infection was comparable in both populations (2/162, 1,2% versus 26/5208, 0,5% $p > 0,5$). Four of the 56 men consulting for infertility with a positive detection of MG (7.1%) exhibited genital-urinary symptoms. No significant difference was found between the sperm parameters of infertile men with or without MG consulting in our university center considering total sperm count (M) 162.6 ± 182.0 for MG+ versus 188.7 ± 215.5, $p > 0.5$, progressive motility (%) 34.6 ± 15.0 versus 34.4 ± 16.5 in MG-, $p > 0.5$, vitality 56.8 ± 15.8 versus 58.4 ± 17.3, $p > 0.5$, or leucospermia (M/mL) 0.8 ± 2.4 versus 0.4 ± 1.1, $p > 0.5$.

Limitations, reasons for caution: The semen parameters of infertile men with a positive PCR for *Mycoplasma genitalium* were not systemically controlled after an efficient antibiotic treatment to evidence a possible improvement of the parameters and eventually the pathogenic role of *Mycoplasma genitalium* on male fertility.

Wider implications of the findings: These findings need to be confirmed taking into account the prevalence and impact of *Mycoplasma genitalium* among the female partners of these patients and the outcomes of Assisted Reproduction therapies in couples carrying MG.

Trial registration number: Not applicable.

P-077 Euploid rate of embryos derived from aspirated and ejaculated sperm

A. Miller[1], C. Rios[2], M. VerMilyea[3], K. Silverberg[4]

[1]*Texas Fertility Center, Embryology, Austin- Texas, U.S.A.*
[2]*Ovation Fertility, Genetics Laboratory, Henderson- Nevada, U.S.A.*
[3]*Ovation Fertility, Embryology, Austin- Texas, U.S.A.*
[4]*Texas Fertility Center, Physician, Austin- Texas, U.S.A.*

Study question: What is the euploid rate relationship between aspirated and ejaculated sperm-sourced embryos?

Summary answer: TESE sperm may be more effective to treat male patients with azoospermia.

What is known already: Micro-surgical sperm aspiration procedures TESE (testicular sperm aspiration) and PESA (Percutaneous Epididymal Sperm Aspiration) followed by ICSI and PGS are all suitable approaches for treating azoospermia (Weng, 2014). The choice of surgical procedure is based on the cause of azoospermia: non-obstructive azoospermia (NOA) or obstructive azoospermia (OA). NOA often requires extracting testicular spermatozoa, which are fragile, non-motile, and have not undergone chromatin condensation. OA can be treated with a less invasive procedure to extract sperm from the epididymis, which are more durable, mostly motile, and have completed or are currently undergoing meiotic maturation.

Study design, size, duration: This is a retrospective cohort study that spans from 1/2016 until 12/2017. Overall 992 embryos were biopsied and analyzed for this study. High quality blastocyst embryos exhibiting tightly bound inner

cellular mass (ICM) and good quality trophectoderm were subsequently biopsied. Trophectoderm biopsy and PGS screening were performed on Day 5, 6 and 7 embryos. Chi-square statistical analysis was performed to determine significant differences between groups.

Participants/materials, setting, methods: Trophectoderm biopsy and PGS screening were performed on Day 5, 6 and 7 of high quality blastocyst embryos. Overall 992 embryos were biopsied (751 ejaculated sperm, 114 TESE, and 127 PESA sperm-sourced embryos). Biopsied embryos were segregated into based on sperm source: ejaculated sperm, TESE, or PESA. Biopsied samples were analyzed using next generation sequencing (NGS) to determine euploid status. Embryos were vitrified using Vit Kit (Irvine Scientific) for subsequent transfer.

Main results and the role of chance: Euploid rates per group were 50% (374/751) for ejaculated sperm, 57% (65/114) for TESE and 43% (54/127) for PESA. Chi-square statistical analysis displayed that PESA sperm embryos resulted in significantly lower euploid rate when compared to TESE sperm rates ($p = 0.0246$). Ejaculated sperm euploid rate was not found to be significantly different between TESE and PESA. Complex abnormal rates were 9% (18/196) for ejaculated sperm, 7% (5/67) for TESE, 14% (15/104) and for PESA; these results were not significantly different from each other. Embryos sourced from testicular sperm resulted in a significantly higher euploid rate than those from epididymal sperm. These data suggest that, in some patients, maturation of sperm through the epididymis may alter DNA during chromatin condensation. This, in turn, can cause an abnormal random assortment during fertilization causing a potential higher propensity of aneuploidy in the developing embryo. Our findings suggest that sperm retrieved prior to further maturation in the epididymis may be more effective to treat male patients with azoospermia.

Limitations, reasons for caution: This study was limited by not grouping age of female patient providing the oocytes, which can impact euploid rate. It also does not provide specific reasons for requiring aspirated sperm.

Wider implications of the findings: Literature suggests that ejaculated sperm would have a higher euploid rate than that of aspirated sperm and no difference between TESE and PESA. This data completely contradicts published literature in that TESE sperm had a significantly higher euploid rate than that of PESA.

Trial registration number: not applicable.

P-078 Is human semen more sensitive than blood for assessing environmental impact on health? EcoFoodFertility Project

L. Montano[1], P. Bergamp[2], M.G. Volpe[3], M.G. Adreassi[4], C. Vecoli[4], S. Lorenzetti[5], A. Mantovani[6], T. Notari[7]

Study question: The aim of this study is to evaluate if human semen can be considered more than blood early biomarker of environmental pollution exposure and useful for innovative prevention program.

Summary answer: Semen RedOx status, motility, DFI and sperm telomere length (STL) can be considered as an early markers of environmental pollution, more sensitive than blood.

What is known already: High environmental pressure may impair male infertility by affecting semen quality, but the real effects remains controversial. Some studies have supposed that specific factors present in some areas, but not in other, might cause a reduction of semen quality. In a previous EcoFoodFertility study, we have demonstrated that sperm DNA fragmentation is significantly higher in men who live in high environmental polluted areas respect of those who live in low polluted areas and, others studies, have hypothesized that air pollution could be affects the length of sperm telomeres.

Study design, size, duration: Pilot biomonitoring study (EcoFoodFertility Project) conducted in Campania (Italy) on blood and semen of clinically healthy men living in the 'Land of Fires" (High Environmental Impact-HEI) and, as control group, in 'Alto-Medio Sele" (Low Environmental Impact-LEI), to assess environmental impact on fertility and human health. 220 men were recruited, from July to December 2015, for analysis of: 22 trace elements, sperm DNA fragmentation (DFI), total antioxidant capacity (TAC), antioxidant enzyme activity and telomere length (TL).

Participants/materials, setting, methods: Partecipants were divided into two groups:

Group A: 110 males from HEI ($n = 60$) and LEI ($n = 50$);

Group B: 112 males from HEI ($n = 57$) and LEI ($n = 55$).

In group A 22 trace elements were analyzed in blood and semen by optical emission spectrometry, DFI by Sperm Chromatin Dispersion test, TAC by Glutathione peroxidase/reductase (GPX-GSR).

In group B telomere length (TL) was assessed by quantitative Real-Time PCR on genomic extracted from leukocytes (LTL) and sperm (STL).

Main results and the role of chance: In Group A, HEI subjects showed significantly higher values ($p < 0.05$) for Al, Mn, Cr, Mg, Li, Co, Ca in blood, as well as for Cr, Cu, Zn in semen, while Fe was lower in semen ($p < 0.05$). Immotile sperms and DFI were both higher ($p < 0.026$ and $p < 0.01$ respectively) in HEI-group. TAC in blood showed no differences, while TAC, GPX and GSR in the seminal plasma were significantly lower in the HEI-group ($p < 0.05$). In group B, a significant negative correlation was found between age and LTL ($r=-0.024$, $p = 0.01$), as aspected, but no correlation was found between STL and age ($p = 0.7$). No significant LTL differences was observed between low and high exposure groups (0.99 ± 0.33vs 0.90 ± 0.38, $p = 0.2$), while STL was significantly higher in HEI-group compared to LEI-group (1.15 ± 0.51vs 0.90 ± 0.26, $p = 0.04$). Age-adjusted analysis confirmed a higher STL in HEI-group compared to control group LEI (1.10 ± 0.36vs 0.90 ± 0.32, $p = 0.05$). When STL was analyzed according to the 75th percentile distribution, HEI-group emerged as a significant risk predictor of longer STL (Odds Ratio: 3.1, 95% confidence intervals: 1.1-10.2; $p = 0.02$).

Limitations, reasons for caution: Several limitations need to be considered: no direct ambient measures of air pollution were available and some of the differences in the associations could be due to the relatively small sample size of the groups. Even if analysis were adjusted for potential covariates, we cannot exclude other unidentified confounding factors.

Wider implications of the findings: Semen RedOX status, DFI and STL can be considered as early markers of environmental pollution and human semen seemed a more early sensitive source of biomarkers than blood to monitor high environmental pressure on human health, hence useful for innovation prevention programs and health surveillance, especially in risk areas.

Trial registration number: This work was supported by institutional funds.

The authors declares.

Not required because it is a pilot biomonitoring observational study.

P-079 Oxytocin expression in spermatozoa is positively associated with their motility, whereas expression of oxytocin receptor is negatively associated with their morphology

E. Neofytou[1], S. Lymperi[2], C. Vaitsopoulou[3], M.G. Bazioti[2], K. Chatzimeletiou[3], A. Lambropoulos[3], E.Y. Kolibianakis[3], B. Tarlatzis[3]

[1]Newlife IVF, IVF Unit, Thessaloniki, Greece
[2]Private Diagnostic Laboratory Agias Sofias, Andrology Laboratory, Thessaloniki, Greece
[3]Aristotle University of Thessaloniki, 1st Department of Obstetrics and Gynecology, Thessaloniki, Greece

Study question: Is oxytocin (OXT) and oxytocin receptor (OXTR) mRNA expression in spermatozoa different between normal sperm samples and samples with at least one abnormal parameter?

Summary answer: Compared to normal sperm samples, OXT mRNA expression is significantly lower, whereas OXTR mRNA expression is significantly higher in abnormal samples (at least one parameter).

What is known already: OXT is synthesized in the penis, testis, epididymis and prostate, whereas its receptor has been detected throughout the male reproductive tract. Furthermore, OXT promotes the conversion of testosterone into dihydrotestosterone. During orgasm, a burst of OXT is released into the systematic circulation to stimulate contractions of the reproductive tract. Various studies have shown that exogenous administration of OXT increases the spermatozoa concentration of ejaculated sperm. OXT seminal plasma levels have been shown to be lower in fertile men compared to men with oligoasthnoteratozoospermia. However, OXT and OXTR has never been assessed in spermatozoa.

Study design, size, duration: A prospective study was performed in 2016-2017, including a total of 105 samples for OXT and 70 samples for OXTR. All samples had > $1*10^6$ spermatozoa/ml and <$1*10^6$ leukocytes/ml. Sperm samples' analysis was performed according to WHO 2010 criteria and mRNA was extracted to assess the mRNA expression levels of OXT and OXTR. mRNA expression levels were compared between different categories of sperm samples, classified according to their concentration, total number, motility and morphology.

Participants/materials, setting, methods: All sperm samples were subjected to mRNA extraction, cDNA synthesis and quantitative Real-Time PCR (RT-PCR) for the expression of the OXT and OXTR genes. The relative standard curve method was selected as the most appropriate due to the nature of human spermatozoa. Each sample was run in duplicate and normalized to β2-microtubulin. Differences in mRNA expression levels were analyzed between different sperm categories using the generalized linear model. Values are expressed as median (95% CI).

Main results and the role of chance: Compared to normal samples, samples with at least one abnormal sperm parameter had statistically significant lower OXT mRNA expression levels [5.27(1.69-13.98) vs. 0.93(0.53-1.64), p = 0.019] and higher OXTR mRNA expression levels [0.91(0.42-3.3) vs. 4.79(1.02-8.43), p = 0.000). Compared to samples with total number of spermatozoa >39 × 10^6/ml, oligozoospermic samples had statistically significant higher OXT mRNA expression levels [1.64(0.99-2.94) vs. 0.65(0.24-2), p = 0.002] and lower OXTR mRNA expression levels [3.3(0.86-4.71) vs. 16.03(0.07-63.89), p = 0.047). In addition, compared to samples with normal motility, asthenozoospermic samples had statistically significantly lower OXT mRNA expression levels [1.96(1.15-4.4) vs. 0.4(0.21-0.79), >60% immotile spermatozoa, p = 0.000 and 1.97(1.16-4.6) vs. 0.32(0.09-0.75), progressive motility <32%, p = 0.000]. Furthermore, teratozoospermic samples had statistically significant lower OXT mRNA expression levels [4.19(1.66-9.5) vs. 0.79(0.52-1.59), p = 0.049] and higher OXTR mRNA expression levels [0.94(0.44-3.3) vs. 5.46(1.22-10.16), p = 0.000]. Interestingly, OXT mRNA expression was positively associated with the rapid progressive (a) (spermatozoa with a speed >25μm/sec at 37°C, p = 0.008), the slow progressive (b) (spermatozoa with a speed <25μm/sec at 37°C, p = 0.021) and the total progressive (a + b) motility (p = 0.000), and negatively associated with the percentage of immotile spermatozoa (p = 0.001). On the contrary, OXTR mRNA expression was negatively associated with the percentage of normal forms (p = 0.000) and positively associated with the percentage of head defects (p = 0.01).

Limitations, reasons for caution: Given that the method used for the analysis was the relative standard curve method, it would be interesting to define the absolute levels of OXT and OXTR in spermatozoa and confirm the results with the protein expression of both genes.

Wider implications of the findings: We have shown for the first time that OXT mRNA is downregulated in samples with lower motility and OXTR is upregulated in samples with abnormal morphology compared to normal sperm samples. OXT and OXTR mRNA expression in spermatozoa could be used as novel and unbiased diagnostic tool of male infertility.

Trial registration number: NOT APPLICABLE.

P-080 Paternal age and semen quality: Does the association of those two factors affect the embryo development?

P.A. Monteleone[1,5], P. Peregrino[2,5], S. Gonçalves[2], P. Petersen[2], J. Miorin[2], D. Wajman[2,5], M. Fugii[3], H. Martin[3], T. Bonetti[4], A. Gomes[3]

[1]*Centro de Reproducao Humana Monteleone, Clinical director, Sao Paulo / SP, Brazil*
[2]*Monteleone Centro de Reproducao Humana, Clinical, Sao Paulo, Brazil*
[3]*Monteleone Centro de Reproducao Humana, Embriology, Sao Paulo, Brazil*
[4]*Universidade Federal de São Paulo – Escola Paulista de Medicina UNIFESP-EPM, Gynecology, Sao Paulo, Brazil*
[5]*Faculdade de Medicina da Universidade de São Paulo USP, Obstetrics and Gynecology Department - Discipline of Gynecology, São Paulo, Brazil*

Study question: Does the association of advanced paternal age and low sperm count affect the embryo development?

Summary answer: The paternal age, sperm count or association of them do not affect blastocyst formation rate or clinical pregnancy rate in ICSI cycles.

What is known already: Many studies exist on the impact of female age on fertility and success of ART. More recently, male age has been highlighted and there are reliable scientific data, which confirm decline of fertility related to advancing male age and in the risk of genetic diseases for the offspring. The age at which men are often classified as advanced age is commonly after age 50 years, although many of the risks continue to increase with age. Semen analysis remains a standard component of a male fertility evaluation, and several studies have reported general decline of semen parameters with advancing age.

Study design, size, duration: We hypothesized the association of advancing paternal age and decreased sperm count can affect the embryo development potential. Then, we developed a retrospective cohort study, which reviewed 3063 ICSI cycles using ejaculated sperm performed during the last 15 years in a private ART center. Semen analysis were performed following World Health Organization manual and controlled ovarian stimulation used standard protocols.

Participants/materials, setting, methods: Cycles were split into four groups according to paternal age and sperm count: (1) young men (age < 50 years) and normal sperm count (≥15 × 10^6 sperm/ml) (Group young-normal, n = 2101); (2) young men (age < 50 years) and low sperm count (<15 × 10^6 sperm/ml) (Group young-oligo, n = 796); (3) ageing men (age ≥50 years) and normal sperm count (≥15 × 10^6 sperm/ml) (Group old-normal, n = 87); and (4) old men (age ≥50 years) and low sperm count (<15 × 10^6 sperm/ml) (Group old-oligo, n = 79).

Main results and the role of chance: Men age varied from 21 to 84 years old (young-normal: 38.4 ± 4.8; young-oligo: 38.4 ± 5.1; old-normal: 54.4 ± 5.4; old-oligo: 56.7 ± 7.0; p < 0.001). Sperm concentration were similar for young-normal (50.0 ± 33.3 million/ml) versus old-normal (52.6 ± 37.6 million/ml; p = 0.490) and for young-oligo (5.9 ± 4.4 million/ml) versus old-oligo (5.4 ± 4.5 million/ml; p = 0.351). There was not a correlation between men age and sperm concentration (Pearson's correlation: r=-0.013, p = 0.469). For the 1127 cycles in which the embryos were cultured until blastocyst stage, the blastocyst formation rate was not affected by the men age (young-normal: 29.8%; young-oligo: 27.4%; old-normal: 32.8%; old-oligo: 28.3%; p = 0.457). The association of men age or sperm concentration or interaction of both on the clinical pregnancy was evaluated by multiple regression analysis adjusted to women age and we did not find any significant association (men age: OR = 0.995, p = 0.432; sperm count: OR0.998, p = 0.162; interaction of both: OR = 0.648, p = 0.254). The clinical pregnancy rates of groups were: young-normal: 32.7%; young-oligo: 34.8%; old-normal: 26.7%; old-oligo: 22.8% (p = 0.080).

Limitations, reasons for caution: Retrospective design is a limitation of this study. Despite of large casuistic of this study, the number of cycles included in the group of age ≥50 years is small. The multiple regression model was used to adjust the outcomes for the women age; however, other female factors were not considered.

Wider implications of the findings: We investigated the association of men age and sperm count in outcomes of ICSI cycles and showed no association. Our findings are in line with those authors presenting the paternal age is not a determinant factor of the ICSI cycles, even if the sperm count is declined.

Trial registration number: not applicable.

P-081 The impact of isolated teratozoospermia on the outcome of intrauterine insemination after ovarian stimulation with gonadotropin

M. Jeong[1], S. Kim[1], C.W. Choo[2], S.K. Kim[3], S.H. Kim[1]

[1]*Seoul National University Hospital, Obstetrics and Gynecology, Seoul, Korea- South*
[2]*Seoul Maria Fertility Hospital, Obstetrics and Gynecology, Seoul, Korea- South*

[3]Seoul National University Bundang Hospital, Obstetrics and Gynecology, Seoul, Korea- South

Study question: What are pregnancy outcomes after intrauterine insemination (IUI) in couples with isolated teratozoospermia (<4% of normal form with normal count and motility)?

Summary answer: Clinical pregnancy rate and abortion rate after IUI in couples with isolated teratozoospermia are comparable with those in couples with normozoospermia.

What is known already: Decreased sperm count and motility before and after sperm preparation are known to be associated with IUI outcomes, but the impact of sperm morphology on IUI outcomes are still controversial.

Study design, size, duration: A retrospective study was conducted using data from 466 couples who underwent 858 stimulated IUI cycles from January 2015 to December 2016.

Participants/materials, setting, methods: Couples with endometriosis and tubal factor infertility were excluded. All couples showed normal count and motility in the semen analysis. Ovarian stimulation was performed by gonadotropin injections. The couples were divided according to the percentage of normal form; group A(<1.0%), group B(1.0–1.9%), group C(2.0–2.9%), group D(3.0–3.9%), and group E(≥4.0%). Subgroup analysis was performed in women with normal ovarian reserve(serum AMH level 1.5–4.0 ng/mL, female age ≤40 years).

Main results and the role of chance: Overall clinical pregnancy rate was 15.3% (131/858). Clinical pregnancy rate was 13.0% (32/247) in group A, 24.0% (44/183) in group B, 13.0% (16/123) in group C, 10.4% (8/77) in group D, and 13.6% (31/228) in group E. Clinical pregnancy rate was significantly higher in group B compared with group E (P <.05). In women with normal ovarian reserve, clinical pregnancy rate was similar among five groups; 16.0% (13/81) in group A, 18.3% (11/60) in group B, 15.9% (7/44) in group C, 3.8% (1/26) in group D, and 11.1% (8/72) in group E.

Limitations, reasons for caution: Size and numbers of mature follicles at triggering day was not included.

Wider implications of the findings: These results suggest that IUI which is less invasive and cost-effective may be the first-line option in couples with isolated teratozoospermia before moving on to in vitro fertilization/ Intracytoplasmic sperm injection (IVF/ICSI).

Trial registration number: Not applicable.

P-082 Human sperm lipid profiling in men with asthenospermia

Y.S. Cho[1], S. Lobasso[2], R. Vitale[2], P. Lopalco[2], P. Totaro[1], A. Corcelli[2]

[1]Ospedale Santa Maria, Assisted Procreation Unit, Bari BA, Italy
[2]University of Bari Aldo Moro, Department of Basic Medical Sciences- Neuroscience and Sense Organs, Bari, Italy

Study question: Is sperm lipid profile in asthenospermia different from normozoospermia?

Summary answer: Asthenospermic semen samples showed an alteration in cholesterol sulphate/seminolipid ratio.

What is known already: Lipid composition of spermatozoa is important in determining the functional characteristics of the spermatozoa, in particular on motility, acrosomal exocytosis or fusogenic properties of the sperm.

Study design, size, duration: Sperm samples from 33 men undergoing IVF/ICSI treatment were collected of which **9** with normozoospermia (group A; control) and 11 with asthenospermia (group B) were included in this study. The total progressively motile sperm cells/ejaculate were 166.4 + 44.3 millions and 6.4 + 5.9 millions in group A and B respectively. Semen samples were collected, frozen, and stored at -80 °C until processed.

Participants/materials, setting, methods: We used Matrix Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF/MS) in the negative ion mode combined with Thin Layer Chromatography (TLC) to elucidate the lipid composition.

The signals of the MALDI mass spectra (3 replicates/sample) were exported in a final matrix in a compatible format for the multivariate analysis with *ClinProTools 3.0* software and *t*-test was used to confirm significant differences between the two lipid patterns. Peaks with $P < 0.05$ were considered statistically significant.

Main results and the role of chance: Our data on the lipid composition of whole ejaculate give novel information on lipid molecular species and components. In contrast to previous literature reports, we have found only traces of cardiolipin; the only cardiolipin species found in sperm has four palmitic acid chains (corresponding to the MS peak at m/z 1352.3). The mass spectrometry and chromatographic (TLC) comparative analyses of control and asthenospermic samples suggest an alteration in cholesterol sulphate/seminolipid ratio. As regards sulfolipids, TLC and MALDI-TOF mass spectra replicates showed that the content of the cholesterol sulphate (corresponding to the MS peak at m/z 465.4) and of the sulphoquinovosyl acylalkyl glycerol (namely S-QDG or seminolipid corresponding to the MS peak at 795.8) were significantly different between the two groups ($P < 0.05$). The mean intensity of the cholesterol sulphate MS peak and of the seminolipid MS peak were 40.0 ± 6.8 and 278.9 ± 70.6 in group A and 156.4 ± 53.9 and 59.7 ± 25.5 in group B respectively.

The specific lipid composition of seminal plasma and of spermatozoa is under investigation.

Limitations, reasons for caution: The seminolipid is exclusively present in the spermatozoa whereas the cholesterolsulphate is a component of the seminal fluid and of blood, too. In future studies, it may be interesting to measure the cholesterol levels as well as its derivative cholesterolsulphate in the blood in order to verify patient specific differences.

Wider implications of the findings: Our results suggest that the MALDI-TOF/MS lipid profile of sperm may represent a diagnostic tool for the assessment of asthenospermic conditions in the clinical practice.

Trial registration number: None.

P-083 Fibronectin and human sperm selection

M. Heidari, M. Darbandi, S. Darbandi, M.R. Sadeghi

Avicenna Research Institute Shahid Beheshti University- Evine, Endocrinology Reproductive & Embryology, Tehran, Iran

Study question: Does Fibronectin protein as a new biomarker can be used for human sperm selection in ART?

Summary answer: Fibronectin can be used for selection of sperm with suitable quality.

What is known already: Detection of these molecules on the sperm surface and separation of sperm according to them are dependent on the availability of a specific ligand for designing a commercial test. Todays, hyaluronic acid as the PICSI dish is the only specific ligand available for sperm selection. In addition specific antibodies, as powerful ligands for detection, separation and measurement of other suggested biomarkers were used in different studies. Fibronectin (FN) is a multifunctional diametric glycoprotein on the surface of sperm plays an important role in sperm-oocyte interaction and fertilization process.

Study design, size, duration: Amount of FN and the sperm quality were assessed in normozoospermia (N) (42 men) and asthenoteratozoospermia (AT) (72 men) groups through Sperm chromatin dispersion (SCD), sperm chromatin structure assay (SCSA) and chromatin maturation index (CMI). Semen samples were collected after 48–72 h of sexual abstinence and assessed according to World Health Organization guideline (WHO)

Participants/materials, setting, methods: Polyclonal antibody against human FN was produced in rabbit. Its quality, purity and immune reactivity were assessed by SDS-PAGE and western blotting (WB). Also presence of FN on sperm surface was assessed through immunocytochemistry (ICC) and flow cytometry (FCM).

Main results and the role of chance: The results showed the FN distribution on the equatorial region of human sperm. Statistically significant differences were found in the FN levels of sperm surface between two groups with 24.64 ± 9.08% in N and 16.90 ± 7.27% in AT ($p \leq 0.0001$). Also, FN level correlated negatively with SCD ($p \leq 0.0001$), SCSA ($p \leq 0.0001$), and CMI ($p \leq 0.001$). A threshold of FN level and DFI percentage respectively were 16 and 30, were identified as a cut-off value to determine N with specificity 83.3% and 81.0%, and sensitivity of 16.8% and 19.0%. A specificity and sensitivity of FN-DFI were 91.2% and 8.8%.

Limitations, reasons for caution: This study implied that the FN levels in sperm could be potentially used as a biomarker in sperm selection and assessing the quality of sperm in ART.

Wider implications of the findings: Our study suggests that FN can be used for selection of sperm with suitable quality although future studies are recommended.

Trial registration number: N.A.

P-084 Prognostic factors of ICSI-success rates in azoospermic male patients

J. Rehnitz[1], S. Roesner[1], J. Harsch[1], T. Bruckner[2], T. Strowitzki[1], A. Germeyer[1]

[1]*Universitäts-Frauenklinik, Gynecological Endocrinology and Fertily Disorders, Heidelberg, Germany*

[2]*University Hospital, Institute of Medical Biometry and Informatics, Heidelberg, Germany*

Study question: Identification of prognostic factors affecting success rates in infertile couples undergoing ICSI procedure after TESE (testicular sperm extraction).

Summary answer: High embryo quality and lower male BMI positively affect ICSI success rate after TESE. In case of tubular-atrophy ≥SIGG4 no pregnancy could be achieved.

What is known already: Azoospermia is defined as complete absence of sperms in male ejaculate leading to infertility. Azoospermia can be divided into obstructive azoospermia, where the vas deferens is affected and non obstructive azoospermia, where spermatogenesis itself is impaired. Testicular atrophy can be classified histologically after its severity into categories after SIGG. Azoospermic men are often recommended to undergo TESE to evaluate, if mature sperms can be found and ICSI-procedure is feasible. To our knowledge little is known about further clinical factors that can affect ICSI success rates in those couples undergoing ICSI treatment after sperm-positive testicular biopsie.

Study design, size, duration: Retrospective analysis of 118 cycles of ICSI-treatment after TESE-procedure because of male azoospermia. Clinical data were selected from our medical records. Statistical analysis including Wilcoxon, Fishers Exact and Chi-Square-Test were carried out with SAS statistic software; statistical significance was set as $p \leq 0.05$.

Participants/materials, setting, methods: 118 cycles of couples undergoing ICSI procedure after TESE with sperm-positive result were analyzed. Of those 66 cycles were the first, 35 the second and 17 the third ICSI attempt. To avoid statistical bias only the first 66 cycles of 66 different couples are demonstrated here. We evaluated, if potential prognostic factors, such as male/female age, male/female BMI, male/female nicotine abuse and histological result affect ICSI-pregnancy-rates (HCG-positivity 14 days after embryo transfer).

Main results and the role of chance: Pregnancy rate of couples with two good quality embryos were 47.62% and 38.1% with one good quality embryo, whereas only 14.29% in case of poor quality embryos. So embryo quality was positively associated with pregnancy chance ($p = 0.0278$), as seen in conventional IVF/ICSI. Males whose mates conceived after TESE/ICSI were significantly leaner than men whose partners did not get pregnant ($p = 0.023$). BMI of women and age of men and women had no effect on pregnancy rate in our population; as well as nonsmoking was not positively correlated in men and women with ICSI-success - maybe due to small numbers of smokers in both groups (only 12 men and 9 women in total). Women whose partners had tubular atrophy ≥ SIGG4 did not conceive in our population even if mature sperms were bioptically found, regardless of the number of cycles that were performed.

Limitations, reasons for caution: Analyzed cycle number (total 118) was low. Prospective analysis of more patients are needed to improve prognostic statements for couples undergoing ICSI procedure after TESE.

Wider implications of the findings: Similar to situation in conventional IVF/ICSI embryo quality is highly relevant for success-rate in ICSI/TESE. Additionally, men´s weight seems to have an effect and weight reduction in overweight men can be discussed before TESE. In case of tubular-atrophy ≥SIGG4 couples should be informed about their low chances conceiving with ICSI-procedure.

Trial registration number: not applicable.

P-085 Investigating the expression of sperm-specific microRNAs in a mouse model of obesity

M. Khalid Abdulkareem Al-Gazi[1], S. Bradburn[1], S. Sugden[2], M. Ahmed[2], A. Greenstein[2], C. Murgatroyd[1], M. Carroll[1]

[1]*Manchester Metropolitian University, School of Healthcare Science, Manchester, United Kingdom*

[2]*University of Manchester, Institute of Cardiovascular Sciences, Manchester, United Kingdom*

Study question: To investigate the relative expression and the epigenetic control of sperm-specific microRNAs in high fat diet (HFD) mice and aged matched controls (AMC).

Summary answer: Sperm-specific MicroRNAs from HFD mice are upregulated, with miR-21a-5p being highly significant. miR-21a-5p expression is regulated by methylation of CpG islands on VMP1 promoter.

What is known already: MicroRNAs (miRNAs) are small non-coding single-strand RNA molecules (17-26 nucleotides). miRNAs are encoded in the genome and transcribed by RNA polymerase II to form long primary miRNA transcripts. After post-transcriptional processing, the mature miRNAs can targets mRNA transcripts inhibiting gene expression through disruption of ribosomal attachment, or via degradation of the mRNA transcript. Sperm contain a unique family of miRNAs, which are responsible for spermatogenesis, sperm function and embryogenesis. Several reports have implicated dysregulation of sperm specific miRNAs in male infertility. High fat diet can alter the expression of miRNAs in sperm, which may impair sperm function and fertility.

Study design, size, duration: C57BL/6 mice were fed on rodent diet with 60% kcal% fat (HFD, n = 12) and rodent diet with 10% kcal% fat (AMC, n = 12) for 24-28 weeks post weaning. After sacrifice, the testes were removed and the sperm were extracted form the epididymis and processed for total DNA and RNA extraction. A panel of 84 sperm-specific microRNA was assessed in addition to the methylation status of the VMP1 promoter.

Participants/materials, setting, methods: Epididymal sperm were removed and isolated by the swim-up method. Total RNA was extracted using the Norgen biotek kit and used for qPCR for 84 sperm-specific miRNAs using custom miScript miRNA PCR array (Qiagen-UK). Sperm DNA was isolated by cell lysis and ethanol precipitation. The methylation status at two CpG sites on the VMP1 promoter region was carried out by bisulfite pyrosequencing using PyroMark Q24 system (Qiagen, UK).

Main results and the role of chance: This study revealed an increase in the relative expression of 28 miRNAs ($p = 0.05$) in the sperm of HFD mice. With miR-883a-3p expression been significantly lower in HFD nice ($p = 0.05$). The remaining miRNAs assessed on the miRNA PCR array showed no significant difference in relative expression in HFD and AMC mouse sperm. After applying a Bonferroni correction, it was demonstrated that miR-21a-5p relative expression was highly significant in the HFD mouse sperm relative to AMC ($p = 0.0006$). We were then interested in the epigenetic regulation of miR-21a-5p. The sequence responsible for the expressions of the pre-miR-21a-5p overlap with the upstream 3'UTR end of the VMP1 gene. Using bisulfite pyrosequencing we showed increased methylation at CpG sites in this region in AMC mice. These data indicate the epigenetic control of miR-21a-5p expression in sperm in relation to high fat diet.

Limitations, reasons for caution: A limited panel of miRNAs were analysed and only mature sperm were assessed.

Wider implications of the findings: This study links obesity with altered expression of sperm miRNAs in a mouse model. In addition, there was a change in the methylation status and expression of miR-21a-5p. These data indicate the impact that paternal high fat diet has on sperm miRNA expression and DNA methylation.

Trial registration number: None.

P-086 Sperm quality affects fertilization but not embryo cleavage and pregnancy rates after intracytoplasmic sperm injection

F. Imbimbo[1,3], G. Coticchio[2], G. Patria[1], G. Intra[1], M.R. Campitiello[3], A. Borini[1,2,3]

[1]Policlinico San Marco- 9puntobaby Family and Fertility Center Osio Sotto- Bergamo, Ospital, Osio di Sotto- Bergamo, Italy
[2]9puntobaby Family and Fertility Center Bologna - Medicine of reproduction - Via Dante, 15 - Bologna - Italy,
[3]Tortorella Clinic - 9puntobaby Family and Fertility Center Salerno - Via Nicola Aversano, 1 - Salerno - Italy,

Study question: This study deals with correlations between sperm quality and fertilization rate, early embryos development, pregnancy and implantation rates in patients undergoing Intra-Cytoplasmic Sperm Injection (ICSI).

Summary answer: Sperm quality significantly affects fertilization rate but not embryo cleavage in patients who underwent ICSI.

What is known already: Several studies have suggested that differences in sperm quality (i.e., azoospermic, sever oligoasthenoteratozoospermic and normozoospermic) reflect on oocyte fertilization, zygotes and embryos quality during cleavage stages. Also, pregnancy and implantation rates are believed to be independent from sperm quality.

Study design, size, duration: This study considered 1049 ICSI cycles between April 2016 and December 2017. The study excluded those cases with freeze-all embryos and couples with sever female factor (i.e., endometriosis and uterine factor). Sperm quality was classified into four groups according to WHO2010: Group1 - Normozoospermic (sperm/ml≥15 M); Group2 - Moderate Male Factor (5≤sperm/ml<15 M); Group3 - Severe Oligoasthenoteratozoospermia (0<sperm/ml≤5 M); Group4 – Azoospermia (sperm/ml = 0).

Participants/materials, setting, methods: Partner age for the four groups was respectively: Female - 34.71 ± 5.8; 37.72 ± 3.75; 36.73 ± 4.47; 36.38 ± 4.45. Male – 40.3 ± 5.8; 40.1 ± 5.75; 39.97 ± 5.73; 41.24 ± 8.57. A total of 5849 MII oocytes were inseminated. Average value of inseminated oocytes for each group was 5.16 ± 2.89, 5.14 ± 2.76, 5.50 ± 3.15, 6.45 ± 3.55 respectively. Data analysis was carried out using correlation study and ANOVA, which was set with a statistical significance threshold of $P < 0.05$. The statistical Matlab toolbox was adopted for the study.

Main results and the role of chance: Fertilization rate decreased with increasing severity of male factor across the groups. The difference was not statistically significant among Group1, 2 and 3 (77%, 73% and 73% respectively) but was significant (P-value 0.00043) between Group1-3 and Group4 (59%). Instead, no trend was observed for cleavage rate both on day 2 and 3. The difference was not statistically significant among groups (97%, 96%, 99%, 96%, P-value 0.07 on day 2) (87%, 86%, 84%, 85%, P-value 0.128 on day 3). Embryo quality, expressed as number of grade 1-2 and 4-cell embryos on day 2, was not affected by sperm quality. In fact, the difference was not statistically significant (P-value 0.507) among groups (90%, 86%, 87%, 84%). The same trend was observed for embryo quality on day 3 (78%, 75%, 80%, 73%, P-value 0.67). Finally, no significant differences were observed in the pregnancy and implantation rates (16%, 11%, 17%, 19%) (10%, 8%, 11%, 12%) (P-value 0.527) respectively.

Limitations, reasons for caution: Although a very large cohort of patients was enrolled, the study is retrospective. In addition, groups are different in size. Therefore, controlled, randomized and well-designed studies are needed to confirm data.

Wider implications of the findings: Sperm quality impacts fertilization but it does not affect ICSI outcome. Therefore, all measures should be taken to assure maximal performance of ICSI in cases of severely compromised sperm quality.

Trial registration number: Not applicable.

P-087 Peak retrograde flow in adolescents with varicoceles influences sperm DNA integrity

G. De Win[1], S. Stuer[2], E. Coeck[2], S. De Wachter[1], D. De Neubourg[3], U.R. Punjabi[3]

[1]Universitair Ziekenhuis Antwerpen, Department of Urology, Edegem, Belgium
[2]University of Antwerp, Faculty of Medicine and Health Sciences, Edegem, Belgium
[3]Universitair Ziekenhuis Antwerpen, Centre for Reproductive Medicine, Edegem, Belgium

Study question: Does varicocele diagnosed in adolescents using the peak retrograde flow influence sperm DNA integrity?

Summary answer: The presence of varicocele, particularly with a PRF ≥ 38 cm/sec, tends to increase both total and vital DNA fragmentation as compared to healthy adolescents.

What is known already: Correct indication for varicocele repair in adolescents remains a subject of ongoing debate. Some researchers advocate the use of a high peak retrograde blood flow (PRF > 38.4 cm/s) in combination with a 20% testicular atrophy index (TAI) as criteria for treatment. Currently, there is a growing interest in the measurement of the supine PRF in the varicocele vessels. Conventional semen parameters are evaluated in varicocele studies but the significance is weakened due to lack of standardization. However, the true significance of the presence of the harbinger regarding standard sperm parameters and sperm DNA fragmentation in adolescents is still unclear.

Study design, size, duration: This study was a prospective, cross-sectional observational study. Between February 2017 and January 2018, sixty seven volunteers (mean age 21.5 years) were recruited. A total of 62 participants met the inclusion criteria.

Participants/materials, setting, methods: Every participant had a scrotal ultrasound to calculate testicular volumes (using the Lambert formula) and TAI. If varicocele was present, the grade and PRF in supine position was measured. All participants provided semen samples. Standard semen parameters were analyzed according to the WHO 2010 guidelines, and sperm DNA fragmentation test was performed using TUNEL assay in total and vital fractions of the semen. For statistical analysis, primarily ANOVA, Kruskall-Wallis, t-tests and Mann-Whitney tests were performed.

Main results and the role of chance: Of the 62 participants included, 35 were without (56.5%) and 27 (43.5%) with a varicocele. There was no significant difference in the semen parameters (sperm concentration, motility and morphology) and sperm DNA integrity between these two groups. Taking into account the 20/38-harbinger criteria, progressive and total sperm motility was significantly ($p = 0.009$ and $p = 0.027$, respectively) lower than in those who did not meet the harbinger-criterium. Sperm concentration, morphology and sperm DNA were not significantly different. The varicocele group was subdivided into one with a low PRF (21/27, 77.7%) and those with a high PRF (6/27, 22.2%). The descriptive semen parameters were not significantly different in the healthy control and in the varicocele group with high/low PRF. Total sperm DNA fragmentation was significantly higher ($p = 0.021$) with high PRF than with low PRF as compared to the controls. Vital sperm DNA fragmentation was higher in high PRF group than in the low PRF group ($p = 0.029$). TAI and different grades of varicocele did not influence semen parameters and sperm chromatin integrity.

Limitations, reasons for caution: Study is still ongoing. Results are preliminary observations on a limited number of participants.

Wider implications of the findings: The findings in this study might have implications in proving the presence of the 20/38-harbinger in varicocele patients as a valid criterium for surgical treatment.

Trial registration number: B300201730926

P-088 Severe male factor infertility – is there a role for pre-implantation genetic screening (PGS)?

K.C. Mantravadi[1], D.R. Gedela[2]

[1]Oasis Centre for Reproductive Medicine, EMBRYOLOGY, Hyderabad, India
[2]Oasis Centre for Reproductive Medicine, Infertility, Hyderabad, India

Study question: Will male factor infertility bring about higher incidence of Embryo Aneuploidy? Will PGS help us pick euploid embryo and optimize reproductive outcome in cases with severe male factor infertility?

Summary answer: Severe male factor does'nt bring about higher incidence of embryo aneuploidy and there seems positive trend for use of PGS to optimize reproductive outcomes.

What is known already: Sperm has an equal contribution in reproductive outcomes. Severe male factor is shown to affect reproductive outcomes. There is an increasing concern that lower sperm counts, advancing paternal age and use of testicular sperm might increase embryo aneuploidy and negatively affect the reproductive outcomes. There is also a potential risk for epigenetic changes in the off spring with severe male factor infertility. Hence, we wanted to look for incidence of aneuploidy in severe male factor cases through PGS and justify the role of PGS to optimize reproductive outcomes in such cases.

Study design, size, duration: This was a retrospective study of all of couples in the year 2014-2016 with severe male factor infertility and undergoing PGS for failed implantation as an indication.

All couples during study period with two-failed IVF/ICSI attempts (fresh or frozen transfers) were offered PGS at our centre.

All couples were subjected to trophectoderm biopsy on day 5-post insemination. All embryos were vitrified post biopsy. Biopsied tissue was subjected to comprehensive chromosomal screening with Next Generation Sequencing.

Participants/materials, setting, methods: Male partners were divided into three groups based on age (<40 yrs (n = 43) and >40 yrs age (n = 20)), sperm counts (<5millions/ml (n = 14) & >5millions/ml (n = 31)) and source of sperm (Ejaculate (n = 31) &Testicular sperm (n = 33)).

Mean aneuploidy was calculated. Only couples with female age < 35years were included to ensure we do not have bias with advanced maternal age. Euploid embryos were transferred in a frozen embryo replacement cycle. Live birth rate in all groups were calculated.

Main results and the role of chance: Mean aneuploidy and Live birth rates in each group respectively were as follows:

<40 yrs age – 54.58% & 68.75%
>40 yrs age – 56.66% & 25% (p = 0.0013)
<5millions/ml -52.63% & 50%
>5millions/ml – 54.45% & 59%
Testicular sperm- 56.41% & 64%
Ejaculate sperm – 54% & 59%

All the groups of severe male factor infertility showed similar incidence of aneuploidy and there was no statistical significance. LBR across all groups was comparable except advanced paternal age group – 25% (p = 0.0013).

Young couples seem to have the highest LBR compared to advanced age. Though the advanced paternal age group had similar aneuploidy rates, still LBR were statistically low. Sperm counts and source of sperm for IVF/ICSI seem to have comparable aneuploidy rates and LBR.

Limitations, reasons for caution: Retrospective data, Small sample size.

Wider implications of the findings: Advanced Paternal age and reproductive outcomes needs further research. Use of testicular sperm for IVF/ICSI seems encouraging. Advanced techniques seem to offer better reproductive outcomes in severe male factor infertility. Third party reproduction using donor sperm should not be offered as a first line of treatment in such cases.

Trial registration number: Not Applicable.

P-089 Protective effects of Cinnamtannin B-1 (CINB-1) on human sperm cryostorage

P.J. Soria Meneses[1], J. Bartolomé García[1], L. Luque[2], I. Ochando[2], A.J. Soler[3], R. Bernabeu[2], F. Martinez-Pastor[4], J.J. Garde[3], M.R. Fernández-Santos[1]

[1]University of Castilla La Mancha, Faculty of Pharmacy, Albacete, Spain
[2]Instituto Bernabeu, Instituto Bernabeu, Alicante, Spain
[3]University of Castilla La Mancha, Ciencia y Tecnología Agroforestal y Genética, Albacete, Spain
[4]University of León, Bioquímica, León, Spain

Study question: Could the antioxidant CINB-1 protect sperm during cryopreservation and preserve its physiological parameters after thawing?

Summary answer: CIN B-1 at 100 μM preserves sperm viability and mitochondrial activity during sperm cryopreservation.

What is known already: The process of sperm freezing and thawing may be related to an excessive production of reactive oxygen species (ROS), resulting in adverse changes in membrane lipid composition, acrosomal status, motility and viability. Adding antioxidants to the freezing extender could reduce these negative effects. CINB-1 is a natural A-type of proanthocyanidin that is present in few plants, which has a large number of cellular actions, mostly derived from its antioxidant properties. The protective ability of CINB-1 in thawed sperm samples from deer has been demonstrated before.

Study design, size, duration: Forty four amples were evaluated from eleven sperm healthy young donors. Sperm was collected with a period of abstinence between 48-72 h. Samples were cryopreserved following the WHO manual (2010) guidelines, supplementing with 0, 10 and 100 μM of CNB-1. Samples were evaluated after thawing and after incubation (37 °C, 4 h). Motility was evaluated by CASA. Viability, mitochondrial membrane potential, acrosomal status, lipoperoxidation, intracellular ROS and DNA integrity were assessed by flow cytometry.

Participants/materials, setting, methods: Sperm donors were selected according to ESHRE guidelines for gamete donation. After liquefaction, we washed the sperm samples with PBS and diluted them in freezing medium (Irvine Scientific). Extended spermatozoa were loaded into 0.25-mL plastic straws and cooled down, equilibrated to 5 °C (40 min) and frozen in nitrogen vapours. The straws were thawed at 37 °C for 7 min. Data were analyzed by linear mixed-effects models using R (http://www.r-project.org).

Main results and the role of chance: CNB-1 did not affect sperm motility parameters. There were significant effects in sperm viability, CINB-1 100 μM showing a positive effect ($p < 0.05$) on the percentage of live sperm cells at 0 h (19.27% ± 1.26) comparing to the control (15.11% ± 1.38) and CNB-1 (10 μM) (16.23% ± 0.74). Our results also show that the highest concentration of CNB-1 (100 μM) preserved better the mitochondrial activity after 4 h of incubation (10.60% ± 0.48) than the control (8.27 ± 0.54) ($p < 0.05$). There were no effect of CINB-1 on the rest of sperm parameters evaluated ($p \geq 0.05$). There were no significant effects of CINB-1 on other sperm parameters, including DNA integrity, either after thawing or after 4 h of incubation ($p \geq 0.05$).

Limitations, reasons for caution: We believe that sample size might be a limitation of this study as well as the use of normozoospermic samples. Further studies should be carried out to verify CINB-1 protective effect during cryopreservation in samples of low seminal quality.

Wider implications of the findings: Given the beneficial effect of Cinnamtannin B-1 *in vitro*, its use could also be considered as a feeding supplement especially in infertile men.

Trial registration number: not applicable.

P-090 Ability of SOD1 and SOD3 in seminal plasma to distinguish between two different azoospermic subgroups (mixed testicular atrophy and Sertoli cell-only syndrome)

E. Savadi Shiraz[1], A. Pilatz[2], W. Weidner[2], D. Fietz[3], L. O'Donnell[4], M. Bergmann[3], T. Diemer[2], P. Stanton[4]

[1]Department of Urology- Pediatric Urology and Andrology- Justus Liebig University- Giessen- Germany, Department of Urology- Pediatric Urology and Andrology- Justus Liebig University- Giessen- Germany, Giessen, Germany
[2]Justus Liebig University, Department of Urology- Pediatric Urology and Andrology., Giessen, Germany
[3]Justus Liebig University, Institute for Veterinary Anatomy- Histology and Embryology., Giessen, Germany
[4]Monash University, Hudson Institute of Medical Research. Department of Molecular and Translational Science., Melbourne, Australia

Study question: Are there marker proteins in seminal plasma that can predict the presence of testicular sperm before an invasive surgery in men suffering from non-obstructive azoospermia?

Summary answer: SOD3 (Superoxide dismutase 3) protein in seminal plasma has potential to predict the success of micro-dissection sperm retrieval in non-obstructive azoospermia men (NOA).

What is known already: Men with NOA have zero sperm in the ejaculate.

Testicular sperm suitable for assisted reproductive technology (ART) could be present in NOA patients.

Sperm is collected by micro-testicular sperm extraction (M-TESE). However, no diagnostic test exists to predict the presence of sperm in the testis biopsy

before surgery. About 50% of azoospermic men are unable to have sperm retrieved at M-TESE and therefore have surgery unnecessarily. The ability to predict the presence of sperm in the testis prior to TESE would improve sperm retrieval rates and avoid unnecessary surgery.

Study design, size, duration: Identification of specific proteins related to spermatogenesis in seminal plasma(SP) could provide a novel proteomics assay for sperm presence prior to biopsy. SP is a rich, easily-accessible and promising source of spermatogenesis biomarkers. This study was designed to compare the SP proteomes of two different groups of NOA.

(1) Men with mixed-testicular atrophy(MA) with a positive sperm retrieval at M-TESE.
(2) Sertoli-cell-only(SCO) patients with a negative sperm retrieval at M-TESE.

Results also compared with the control-group.

Participants/materials, setting, methods: SP was collected from MA and SCO patients (n = 8/group). Samples were compared by label-free Liquid chromatography-mass spectrometry/MS proteomics. Differentially expressed proteins were defined as those with a fold-change >2.0 and a significant difference between the groups($p < 0.05$).

Among the significant proteins identified, SOD3 and SOD1 were selected for further validation by 3 different methods:Western blotting, immunohistochemistry and ELISA (n = 15/group). To compare with SP, the protein concentrations of SOD3 and SOD1 were measured in the blood-serum of participants.

Main results and the role of chance: SOD3 immunoreactivity (ELISA) in SP from SCO men was 2.3 fold lower than controls ($p < 0.05$), and SP from MA men was 4.6 fold lower than controls ($p < 0.0001$). The SOD3 MA/SCO protein ratio was 0.49 ($p < 0.05$) by ELISA and 0.16 ($p < 0.01$) by mass spectrometry. SOD3 gave the expected band of 30 kDa by Western blot of SP samples, but no significant difference between MA and SCO groups was observed.

In normal human testis, SOD3 staining was predominantly observed in Sertoli cells, while in the testis of azoospermic patients staining was more variable.

SOD1 immunoreactivity (ELISA) in SP from SCO and MA men was decreased significantly compared with controls ($p < 0.05$). The MA/SCO ratio of SOD1 was significantly different by mass spectrometry but not by ELISA or quantitative Western blot. In normal human testis, SOD1 was predominantly localized in spermatogonia, while in the testis of azoospermic patients variable SOD1 staining was noted.

There were no significant differences in the levels of SOD1 and SOD3 in the blood-serum of MA compared to SCO patients.

Limitations, reasons for caution: Two different antibodies were used for quantitation of protein (in both cases of SOD1 and SOD3) by Western-blotting compared to ELISA which may explain the variation in results. Moreover, the selected antibodies may not target the same sequence region that was detected by the mass spectrometry.

Wider implications of the findings: SOD3 was significantly different in SP from MA versus SCO azoospermic patients by at least 2 different proteomics-methods (mass spectrometry and ELISA), and thus has the potential to predict the presence of sperm in the testis prior to biopsy.

Trial registration number: The trial registration number for this project is IRTG-62280541.

P-091 Predictors of positive sperm retrieval in azoospermic men

M. Esbert Algam[1], J.M. Pomerol[2], A. Gimenez[1], M. Florensa[1], A. Ballesteros[3], N. Garrido[4]

[1]IVI Barcelona, IVF laboratory, Barcelona, Spain
[2]IVI Barcelona, Andrology, Barcelona, Spain
[3]IVI Barcelona, Gynecology, Barcelona, Spain
[4]IVI Foundation, Research/Innovation, Valencia, Spain

Study question: Are there reliable factors able to predict the sperm retrieval rate (SRR) after conventional testicular sperm extraction (c-TESE)?

Summary answer: Testicular volume and histopathological diagnosis are related with the SRR while age, months of infertility, FSH level and body mass index are not good predictors.

What is known already: Obtaining sperm from the testis in combination with ICSI has become a routine in the assisted reproduction technology. However, it is still controversial which is the most effective sperm retrieval technology, the accuracy of different factors in predicting the SRR and if uncoupled TESE/oocyte pick-up (OPU) should be considered to prevent possible unnecessary ovarian stimulation and OPU when no sperm cells are detected.

The ability to predict those patients with a high probability of achieving a successful sperm retrieval would be of great value in counselling the patient and his partner.

Study design, size, duration: This is a retrospective cohort study which includes 96 consecutive azoospermic patients, 17 with obstructive azoospermia (OA) and 79 with non-obstructive azoospermia (NOA) who underwent c-TESE between 2004 and 2017.

The origin of the obstructive azoospermia was epididimal obstruction (n = 13), vas deferens obstruction (n = 3) or vasectomy (n = 1).

Participants/materials, setting, methods: All patients, whose azoospermia was confirmed by two semen analyses, underwent c-TESE by the same surgeon. The specimens were examined by an embryologist, where all the tubules were teased and analysed for the presence of sperm. A histopathology specimen was sent for analysis.

Factors such as male age (years), duration of infertility (months), FSH level (mUI/mL), body mass index (BMI), testicular volume (mL) and the histopathological diagnosis were correlated with the presence of sperm.

Main results and the role of chance: OA patients were older than NOA males (39.5 (95%CI 34.3-43.8) vs. 36.03 (95%CI 35.0-37.0)) ($p = 0.015$). However, the infertility duration (27.5 (95% CI 20.5-34.4) vs. 32.35 (95%CI 27.2-37.5)) ($p = 0.028$) and FSH levels (5.6 (95%CI 4.2-7.1) vs. 16.8 (95%CI 14.0-19.7)) ($p = 0.001$) were lower.

The SRR was 100% in the OA patients and 29.1% in the NOA group. No complications after the surgery were seen.

In the NOA group, the area under the ROC curve of male age, months of infertility, FSH level and body mass index respect the chance of finding sperm after c-TESE were 0.59, 0.51, 0.36, 0.45, respectively.

In 45.6% of the NOA patients, the volume of the biopsied testicle was diminished (<14 mL). The chance of positive SRR was higher in normal vs. low volume testicles (73.9% vs. 26.1%, $p = 0.03$).

Histopathological findings included four patterns: hypospermatogenesis (reduced number of normal spermatogenetic cells), MA (maturation arrest, only spermatogonia, spermatocytes and spermatids were detected), SCO (Sertoli cell only) and tubular sclerosis. The incidence of each pattern in NOA patients with negative SRR was 7.1%, 39.3%, 44.6% and 9.3%, respectively. That means that in 92.9% of the cases where the embryologist did not found any spermatozoa, the histopathological diagnosis confirmed the absence.

Limitations, reasons for caution: A low number of patients were analyzed because most of the azoospermic males visiting in our center are foreigners and their diagnostic TESE is performed abroad.

Our SRR is in the low range of what has been published, but the absence of sperm was mostly confirmed with the testis histopathology.

Wider implications of the findings: Although the testicular size seems to be related to the SRR, the most reliable parameter predicting the presence of sperm is the histopathological examination of testicular fragments. Despite having higher predictive value, it would not prevent the patient from undergoing a testicular biopsy.

Trial registration number: Not available.

P-092 Impaired fertility in a rat model of spinal cord injury and the role of inflammasome complex

B. Nikmehr[1], F. Abolhassani[1], G. Hassanzadeh[1], A. Shahverdi[2], M. Bazrafkan[1], M. Hezavehei[2], S. Berenjian[1]

[1]Tehran University of Medical Sciences, Department of Anatomy, Tehran, Iran
[2]Royan Institute for Reproductive Biomedicine- ACECR, Department of Embryology-Reproductive Biomedicine Research Center, Tehran, Iran

Study question: Activation of inflammasome complex affects male fertility following spinal cord injury.

Summary answer: We found that there is a relationship between inflammasome activation in rat testis and low sperm parameters.

What is known already: Infertility is a common feature of men with spinal cord injury (SCI). Inflammation is one of the most important abnormalities in semen of these patients. Previous studies showed some inflammasome components in semen of SCI men. Inflammasome activation pattern was found in many tissues and disease but about testis is still unclear.

Study design, size, duration: There are 20 Wistar male rats in this study. They were divided into four groups (n = 5): spinal cord injury was induced at T10 level of the spine, at three groups and one group remained intact (control group). Rats in SCI groups were sacrificed at three different time points: one day, three days, and 7 days after surgery. Testes were removed and protein analysis was done.

Participants/materials, setting, methods: In this experiment, Male Wistar rats weighing 200-250 g were used. Testis sampling was done at three specific time points (1, 3 and 7 days after injury). Protein expression (Caspase-1 and ASC) was assessed by immunofluorescence (IF). Data were analyzed by a parametric test of One-way ANOVA, and the comparison between the groups was taken by the Tukey post hoc test ($p < 0.05$).

Main results and the role of chance: Immunofluorescence showed a significant increase of inflammasome complex components from day 1 after injury. The protein level of Caspase-1 increased significantly on day 1, 3 and 7 after injury in comparison to control ($p < 0.001$).The peak of Caspase-1 expression was on day 7. ASC protein was raised significantly on day 1, 3 and 7 after injury, versus the control group ($p < 0.001$). The highest level of ASC protein was on day 3

Limitations, reasons for caution: We had some ethical considerations about the number of rats used in the study. Our data are experimental and should be proven in human studies.

Wider implications of the findings: The reason of diminished sperm parameters in patients with spinal cord injury is not clearly defined. Our data revealed a pattern for inflammasome activation in the rat testis following spinal cord injury. In later step, Inflammasome antagonists should be used to eliminate inflammasome complex and improve sperm parameters.

Trial registration number: not applicable.

P-093 Novel mutations in the CFTR gene associated congenital absence of vas deferens in China

Y. Gao[1], Y. Xu[1], Y. Liu[1], C. Deng[2], Y. Xu[1], C. Zhou[1]

[1]The First Affiliated Hospital of Sun Yat-sen University, Reproductive Medicine Centre, Guangzhou, China

[2]The First Affiliated Hospital of Sun Yat-sen University, Department of Andrology, Guangzhou, China

Study question: What are the novel cystic fibrosis transmembrane conductance regulator (CFTR) gene mutations and mutation spectrum in Chinese patients with congenital bilateral absence of vas deferens (CBVAD)?

Summary answer: 23 novel CFTR mutations were detected in 192 Chinese patients with CBAVD. 66% (127/192) patients have CFTR mutations.

What is known already: CBAVD is an autosomal recessive disease and occurs in 1–2% of infertile men. CFTR mutations or IVS8-5T polymorphism were the most common causes of CBAVD. The most common CFTR mutation in many populations is a deletion named F508del. The 5 T variant in intron 8 (IVS8-5T) is common in the different populations, but a higher than normal frequency of this allele has been found in CBAVD patients.

Study design, size, duration: A total of 192 male probands of congenital bilateral absence of the vas deferens were collected from the Andrology Clinic of the Reproductive Medicine Center in the First Affiliated Hospital of Sun Yat-sen University between 2014 and 2016. Twenty males with normal vas deferens were included as a control.

Participants/materials, setting, methods: CFTR mutations were searched for using Sanger sequencing to analyze genomic DNA samples from 192 probands with CBAVD. The primers used to amplify the 27 coding exons, the adjacent intronic regions, and the promoter. Potential pathogenic variants were filtered by the multiple-step bioinformatics analysis and further evaluated in 20 normal controls by Sanger sequencing.

Main results and the role of chance: 66% (127/192) patients have CFTR mutations. 35% (67/192) patients have two or more mutations (common CFTR mutations or IVS8-5T polymorphism). 31% (60/192) have a single detectable CFTR mutation. Of these detected mutations, 23 mutations were novel. 7 novel mutations were detected in promoter. 11 of 16 novel mutations in exons were predicted to be pathogenic by bioinformatic analysis. 30 (16%) homozygous and 73 (38%) heterozygous IVS8-5T polymorphism were found. But it was not found in controls. The most common CFTR mutation (F508del) in many populations were not found in our subjects. This suggested the IVS8-5T polymorphism was the major effect for Chinese male patients with CBAVD. The other frequent mutation in the studied cohort, G970D, was found in 9 probands. This mutation was on shared haplotype and thus evidence of a founder effect in the population. Furthermore, the severity of phenotypes may affect by the number or type of CFTR mutations in those patients.

Limitations, reasons for caution: Over 34% (65/192) of the patients without identified mutations might carry other pathogenic variants in the intron of CFTR, or may be caused by mutations in novel genes yet to be identified.

Wider implications of the findings: This study analyzed the relation between genotype and phenotype in Chinese CBAVD patients with CFTR mutations. A comprehensive analysis of the CFTR gene expanded the mutation spectrum in Chinese patients with CBAVD, and supplied the clues for discovering novel causative CBAVD genes and the foundation for gene therapy.

Trial registration number: not applicable.

P-094 Improvement of ICSI outcome using sperm selection by thermotaxis

S. Perez-Cerezales, R. Fernandez-Gonzalez, A. Chacon de Castro, B. Rodriguez-Alonso, M.J. Sanchez-Calabuig, R. Laguna-Barraza, A. Gutierrez-Adan

INIA, Reproducción Animal, Madrid, Spain

Study question: We tested if human and mice spermatozoa selected by thermotaxis show higher quality than spermatozoa selected by swim-up.

Summary answer: We found that spermatozoa selected by thermotaxis show much higher quality than those selected by swim-up and that mice thermotaxis-selected spermatozoa improved ICSI outcome.

What is known already: Sperm selection occurring *in vivo* within the female reproductive tract is bypassed when some artificial reproductive techniques (ART) are used, such as *in vitro* fertilization or intracytoplasmic sperm injection (ICSI). This could be in part behind the relative low success of fertility treatments. Thus, improving sperm selection has been pointed as primary strategy in order to improve ARTs outcome. Processes operating within the oviduct to guide the spermatozoa to the fertilization site are candidates as mechanisms of selection. This is the case of thermotaxis that guides the spermatozoa in response to a temperature gradient stablished within the Fallopian tube.

Study design, size, duration: Mice and human spermatozoa were selected by swim-up or by thermotaxis and the DNA integrity of the spermatozoa after both selections was analyzed (n = 5 for mouse and n = 8 for human, 50-100 spermatozoa per determination). ICSI was conducted with mice spermatozoa selected by swim-up or by thermotaxis (260 total ICSIs per sperm type). Resultant embryo were cultured *in vitro* up to two cells or blastocyst stage and transferred to recipient females.

Participants/materials, setting, methods: Sperm samples from B6D2 mice and 15 normospermic patients were used. Swim-up was performed following a standard procedure and thermotaxis using a method of sperm migration between two drops of medium connected by a capillary. Between the two drops a temperature gradient was stablished in a way that one drop was at 35°C (were spermatozoa were loaded) and the other at 37°C (were spermatozoa were collected after 1 h). DNA quality was analyzed by comet assay.

Main results and the role of chance: In both species we clearly observed lower DNA fragmentation in spermatozoa selected by thermotaxis. Thus, mice swim-up showed 12 ± 0.6% and thermotaxis 3 ± 0.5% ($P = 0.0001$, Student's *t*-test) of DNA fragmentation and human swim-up showed 15 ± 3% and thermotaxis 5 ± 0.8% ($P = 0.001$, Student's *t*-test). Using spermatozoa selected

by thermotaxis for ICSI we produced higher percentage of embryo reaching to blastocysts stage (expanded and hatched) than using swim-up spermatozoa [73 ± 6% vs 40 ± 11% respectively ($P = 0.01$, Student's *t*-test)]. Furthermore, significantly higher implantation rates (analyzed 15 days after ICSI) were recorded for thermotaxis-derived than swim-up-derived embryos both when two cell embryos (75 ± 8% *vs* 27 ± 7%, $P = 0.01$, Student's *t*-test) or blastocysts (77 ± 9 *vs* 43 ± 18, $P = 0.03$, Student's *t*-test) were transferred. For transfers with 2-cell embryo, we also recorded higher rates of development to term for the spermatozoa selected by thermotaxis (5 and 13 pregnancies to term out of 24 transfers per group for swim-up–ICSI and thermotaxis–ICSI respectively) and higher rates of born pups for the thermotaxis-ICSI derived embryos (12 ± 2 and 29 ± 4% for swim-up- and thermotaxis separated spermatozoa respectively; $P = 0.027$ two-tailed Student's *t*-test).

Limitations, reasons for caution: Our results of ICSI are limited to mice and are a proof of concept. At this stage we cannot conclude that sperm selection by thermotaxis would improve ICSI outcome in humans. Clinical trials with human patients are being done now.

Wider implications of the findings: Sperm selection by thermotaxis represents the first approach available to isolate a specific subpopulation of capacitated spermatozoa for their characterization. This would allow to reveal basic aspects of sperm biology and seed light on the contribution of the spermatozoa in the process of fertilization and on early embryo development.

Trial registration number: not applicable.

P-095 Predictive value of static oxidation-reduction potential in detecting high levels of sperm DNA fragmentation in infertile men

A. Lee[1], B. Yee[1,2], A. Qu[1,3], S. Shahani[1], S. Moskovtsev[1,4], C. Librach[4,5,6]

[1]*CReATe Fertility Center, Andrology, Toronto, Canada*
[2]*University of Toronto, Physiology, Toronto, Canada*
[3]*University of Toronto, Medicine, Toronto, Canada*
[4]*University of Toronto, Obstetrics and Gynaecology, Toronto, Canada*
[5]*CReATe Fertility Center, Reproductive Endrocrinology, Toronto, Canada*
[6]*Women's College Hospital, Gynaecology, Toronto, Canada*

Study question: Can sperm oxidative stress, measured as static oxidation-reduction potential (sORP), predict high levels of sperm DNA damage?

Summary answer: sORP was positively correlated ($p = 0.002$) to DNA damage and a sORP cut-off of 2.37 mV/10^6 sperm/mL was predictive of high levels of DNA damage.

What is known already: High levels of sperm DNA damage have been associated with decreased pregnancy rates and an increased risk of miscarriage. While the causes are multifactorial, sperm oxidative stress has been shown to play a key role in the etiology of DNA damage. The MiOXSYS system uses sORP, a global measure of the balance between oxidants and reductants, to determine oxidative stress.

Study design, size, duration: This prospective, institutional REB approved cross-sectional study was performed on 52 male, infertile patients presenting to the Andrology laboratory for routine semen analysis after 2-5 days of abstinence at the CReATe Fertility Center between July 2017 and January 2018.

Participants/materials, setting, methods: Male infertility patients with leukocytospermia or sperm concentration <1 million/mL were excluded. Semen analysis was conducted as per WHO 2010 guidelines. sORP was measured using the MiOXSYS system. DNA damage was evaluated by standard flow cytometric acridine orange-based assay as DNA Fragmentation Index (DFI). sORP was compared between a high DFI (≥30%) and low DFI (<30%) group and correlated to semen parameters. Receiver Operator Curve (ROC) analysis determined the sORP cut-off predictive of high DFI.

Main results and the role of chance: The mean paternal age was 39.2 ± 6.1 years (age range: 28 – 54 years). The mean sperm concentration was 43.0 ± 37.2 M/mL, total motility was 55.2 ± 14.5 %, morphology was 6.5 ± 4.2 %, and DFI was 21.7 ± 10.1 %. A significant positive correlation was found between sORP and DFI ($r = 0.43$, $p = 0.002$). A significant negative correlation was found between sORP and concentration ($r=-0.46$, $p = 0.0006$) and between sORP and morphology ($r=-0.33$, $p = 0.02$). Mean sORP was significantly higher ($p = 0.03$) in the high DFI group (4.29 ± 2.52 mV/10^6 sperm/mL) compared to the low DFI group (1.87 ± 2.17 mV/10^6 sperm/mL). ROC analysis indicated that a sORP cut-off of 2.37 mV/10^6 sperm/mL had a sensitivity of 75.0%, a specificity of 77.2%, a positive predictive value (PPV) of 37.5% and a negative predictive value (NPV) 94.5%. The area under the ROC (AUROC) was 0.84 (95% CI: 0.72 – 0.96, $p = 0.003$) and the diagnostic accuracy was 76.9%.

Limitations, reasons for caution: No additional confirmatory DNA damage methodologies were assessed. The DNA damage assay used in this study is generally considered the gold standard, however several alternatives are also routinely used. Larger standardized studies are needed to confirm the performance characteristics of sORP in predicting high DFI.

Wider implications of the findings: Requiring as little as 5 minutes to complete and a drop (30 uL) of semen, the MiOXSYS system provides a rapid, cost-effective measure of global oxidative stress easily integrated into clinical workflows. It can be used to specifically identify patients with oxidative stress induced DNA damage for anti-oxidant therapy.

Trial registration number: not applicable.

P-096 Vitamin D levels and sperm parameters

P. Navarro[1], L. Luque[2], A. Fabregat[3], J.A. Ortíz[4], J.C. Castillo[5], B. Lledó[4], J. Llácer[5], R. Bernabeu[5]

[1]*Instituto Bernabeu Alicante, Endocrinology, Alicante, Spain*
[2]*Instituto Bernabeu Albacete, Reproductive Medicine, Albacete, Spain*
[3]*IB Bioctech Alicante, Andrology, Alicante, Spain*
[4]*IB Bioctech Alicante, Molecular Biology, Alicante, Spain*
[5]*Instituto Bernabeu Alicante, Reproductive Medicine, Alicante, Spain*

Study question: Is it possible to evaluate a potential impact of vitamin D on male fertility through the measurement of routine sperm parameters?.

Summary answer: Routine seminal parameters are not a good predictor of the possible deleterious effects of low levels of vitamin D on male fertility.

What is known already: Vitamin D has physiological functions beyond those related to bone metabolism. As far as male fertility is concerned, it has been shown that vitamin D receptors are expressed in germ cells, ejaculatory duct and mature sperm cells. Vitamin D deficit has been described to a greater or lesser extent in all human populations studied. Deleterious reproductive effects of such deficit have been shown in animals. There is, however, contradictory evidence in humans, which makes this a controversial issue.

Study design, size, duration: Prospective observational study carried out in males coming to our institute between April 2013 and May 2015, seeking subfertility testing, who accepted to participate in the study. Vitamin D levels were tested and routine sperm parameters were recorded from the same sample used in the fertilization cycle.

Participants/materials, setting, methods: Caucasian males were included in the study. Subjects with systemic diseases were excluded. Vitamin D serum levels were tested and routine semen quality parameters were recorded. Semen samples were obtained by masturbation after an abstinence of 2-5 days. They were analyzed following 2010 WHO criteria. Association among variables was analyzed using linear regression and a Student´s t-test.

Main results and the role of chance: The study included 175 subjects (18 were smokers), with an average age of 39,7 ± 5,8 years. Average BMI was 26,3 ± 3,6. Average vitamin D was 25,6 ± 8,9 ng/ml (51% of the samples were collected between May and September). All semen parameters (volume, concentration/count and % progressive motile) showed a trend towards values indicating better quality with higher vitamin D levels. However, when correlations among vitamin D and the different semen parameters were analyzed a significant positive correlation was found only with sperm counts ($p = 0,045$). This correlation was lost after adjusting for confounding factors (age, BMI, seasonality and smoking). From 122 subjects with vitamin D levels< 30 ng/ml, 43 (35%) had alterations in semen. This proportion diminished to 28% (14 out of 53) in males with vitamin D levels ≥ 30 ng/ml ($p = 0,25$).

Limitations, reasons for caution: Age was relatively high in our study subjects, so that results may not be extrapolated to younger populations.

Wider implications of the findings: Our population included a few males with vitamin D levels≥ 30 ng/ml, above which the pleiotropic effects are evident. Studies with comparable subject samples with adequate/deficient vitamin

D levels are needed. Longitudinal studies comparing sperm quality in males with vitamin D deficit before and after supplement ill be useful.

Trial registration number: Not applicable.

P-097 Levels of p53 protein in human spermatozoa, embryo quality and pregnancy rate. EcoFoodFertility project (preliminary data)

S. Raimondo[1], T. Notari[2], M. Gentile[3], M. Cirmeni[2], T. Gentile[1], L. Montano[4], G. Borsellino[2]

[1]°Gentile s.a.s°- Gragnano NA, Field of research of the Laboratory °Gentile s.a.s°, Gragnano, Italy
[2]Polydiagnostic Center Check Up - Day Surgery, Lab - GEA - Ginecology- Embryology - Andrology, Salerno, Italy
[3]°Gentile s.a.s°- Gragnano NA, Field of research of the Laboratory °Gentile s.a.s°, Gragnano, Italy
[4]ASL Salerno °San Francesco d°Assisi° Hospital, Andrology Unit, Oliveto Citra SA, Italy

Study question: The aim of this study is to evaluate if different concentrations of p53 protein in human spermatozoa could influence embryo quality and pregnancy rate.

Summary answer: High concentrations of p53 in human spermatozoa is associated to low percentage of embryos at 6-8 cells stage in third day and lower pregnancy rate.

What is known already: Frequently seminal fluids with normal parameters of evaluation, according to the WHO laboratory manual for examination and processing of human semen (2010), show variations on the capacity to fertilize oocytes and also the quality of obtained embryos is very variable.

Protein p53 is well known as "The guardian of genome"; it changes its concentration in human spermatozoa DNA in relation to the damage of the latter. It has been suggested that the role of the p53 ancestral gene was to ensure the integrity of the genomic germline and the fidelity of the development process.

Study design, size, duration: From July 2013 to June 2017 we have examinated retrospectively 79 couples with 2-5 years of infertility history.

We have divided the couples on the basis of p53 levels:

Group A: 0,35–1,65 ng/mil (21 males);

Group B: 1,66–3,57 ng/mil (32 males);

Group C: 3,58-14,53 ng/mil (26 males).

We have evaluated the number of embryos at stage of 6-8 cells, obtained at the third day of embryo development, in these three different groups.

Participants/materials, setting, methods: Male partners of examinated couples had an average age of 27 ± 7,5 years, sperm concentration of 33,8 ± 6,2 mil/ml, progressive motility of 41,4 ± 8,3% and a typical morphology of 16,5 ± 3,5% according to Kruger's method.

In order to evaluate the concentration of p53 protein, we first proceeded to a DNA extraction with forensic method and then to a quantification p53 protein with ELISA-immunoenzymatic assay, expressed in ng/million of spermatozoa.

Main results and the role of chance: We have observed different percentage of embryo development at stage of 6-8 cells in the third day and different pregnancy rate (PR):

Group A: 101 embryos at 6-8 cells/ 147 total number of obtained embryos in this group (68,4%) and PR = 52,38%

Group B: 128/240 (53,5%); PR = 37,50%;

Group C: 79/216 (36,1%); PR = 7,69%.

These results support the hypothesis that an high concentration of p53 in human sperm DNA is associated to a low percentage of embryos able to reach the stage of 6-8 cells in the third day of development and also to a lower pregnancy rate.

So p53 levels can be considered as a predictive value to embryo development and pregnancy rate.

Limitations, reasons for caution: This study is preliminary. The number of couples examinated is limited. Some unknown confounding factors could not be considered. Further data are necessary.

Wider implications of the findings: Protein p53 is a sequence-specific transcription factor that responds to a wide variety of stress signals. Particularly quantitative research of p53 could be considered as a novel biomarker of sperm quality, able to predict the success of ART techniques, and could open a new road for infertility diagnosis.

Trial registration number: JHRS-01-18

P-098 Redox potential in human semen: validation and qualification of a quantitative electrochemical assay for measurement of oxidative stress

S. Homa[1], A. Vassiliou[2], C. Martin[3], A. Killeen[3], A. Dawkins[3], T. Yap[4]

[1]Andrology Solutions, Andrology, London, United Kingdom
[2]University of Kent, Department of Biosciences, Canterbury, United Kingdom
[3]The Doctors Laboratory, Department of Andrology, London, United Kingdom
[4]Guy's Hospital, The Urology Centre, London, United Kingdom

Study question: Does an electrochemical assay using the MiOX^{sys} CE-marked analyser, consistently meet the requirements and specifications to reliably measure static oxidation reduction potential (sORP) in human semen?

Summary answer: The MiOX^{sys} assay is robust, performing according to expectations and has been standardised and validated to reliably and accurately measure sORP in human semen.

What is known already: Low levels of reactive oxygen species (ROS) are prerequisite for sperm function. Physiological levels of ROS are maintained by antioxidants (reductants) in the local environment. A disturbance in the balance between oxidants and antioxidants leads to oxidative stress (OS), impairing sperm function and genetic integrity. A novel method for assessing OS in semen involves measuring sORP using the MiOX^{sys} galvanostat-based technology analyser. ORP measures levels of oxidants and reductants, providing a more comprehensive measure of OS than measurement of ROS alone. Although the MiOX^{sys} assay effectively measures sORP in semen, it has yet to be fully validated.

Study design, size, duration: This study was a technical validation of an assay for measuring sORP using the MiOX^{sys} CE-marked analyser. It included 40 replicate measurements of control samples on different days and on two separate analysers. Intra- and inter-technician variability was determined from 40 replicates. The characteristics of sORP in semen and the effects of independent variables were measured in 6 replicate samples from 19 men. Variables included time from ejaculation, temperature, mechanical agitation and freeze-thaw action.

Participants/materials, setting, methods: The assay requires applying 30 µl sample onto a disposable sensor which is inserted into the MiOX^{sys} analyser and a current is applied. sORP is displayed in mV after 2-4 min. Values were recorded for different operators, days and analysers using multipurpose handling medium (Irvine Scientific, CA, USA) as a control. Semen samples were obtained from consenting men attending for routine semen analysis to determine the stability of seminal ORP under different conditions.

Main results and the role of chance: Measurement of sORP (mV) using the CE-marked MiOX^{sys} platform (Aytu Bioscience, CO, USA) demonstrated repeatability between 40 replicates of the same control sample with no significant difference between measurements (mean sORP (mV) ± SEM = 281.5 ± 4.8; CV = 0.1). Readings remained consistent across multiple operators ($p = 0.67$), separate analysers ($p = 0.95$) and on different days ($p = 0.09$). Additionally, there was no significant difference between sORP values for 40 replicates of a single semen sample (mean sORP (mV) ± SEM = 45.1 ± 1.0; CV = 0.1). Although readings remain relatively stable in semen up to 45 min post ejaculation ($p = 0.06$), there are significant variations in seminal sORP values across all samples by 60 min post ejaculation ($p < 0.005$). sORP in semen remains stable after freezing and thawing as values do not change significantly ($p = 0.47$). This was demonstrated across biological replicates ($n = 6$). There was a significant difference between sORP in semen after mechanical agitation using a bench-top vortex ($p = 0.005$) and between samples incubated at different temperatures (2-6°C, 20-24°C and 36 + 1°C; $p = 0.003$).

Limitations, reasons for caution: The validation of the MiOX^{sys} platform was carried out in one laboratory only. A multicentre validation would assist in confirming the reproducibility and reliability of the test.

Wider implications of the findings: This simple to use, cost effective assay could be implemented in conjunction with semen analysis providing a welcomed

addition to routine diagnostic testing for male infertility. It may be particularly relevant to men with unexplained infertility, whose partners experience a delay in conception, multiple assisted conception failures or miscarriages.

Trial registration number: Not applicable.

P-099 The addition of porcine oviductal fluid (OF) in swim-up media improves the selection and modifies motility patterns and capacitation potential of boar spermatozoa

S. Navarro-Serna, S. García-Martínez, E. Paris-Oller, P.O. Calderon, J. Gadea

University of Murcia., Physiology, Murcia, Spain

Study question: Could the OF improve the sperm selection in swim-up and modify sperm parameters?

Summary answer: Porcine OF improve sperm selection, modulates motility patterns and increase the percentage of spermatozoa with high calcium response after incubation in capacitated media.

What is known already: Previous studies have demonstrated that the use of porcine OF from late follicular phase or specific OF proteins provides sperm membrane changes modulating capacitation process and motility pattern (Coy et al, 2010 Theriogenology).

When OF was added to swim-up procedure and the oocytes were incubated in OF before IVF, embryo development was improved, DNA methylation and gene expression patterns were closer to *in vivo* embryos (Cánovas et al, 2017 eLife). However, the specific role of the OF addition in swim-up media on sperm parameter is not well known.

Study design, size, duration: NaturARTsPIG sperm swim-up media (Embryocloud, Murcia, Spain) were supplemented with different amounts of BSA and OF. As a control we used swim-up medium with 5 mg/ml of BSA (5BSA) and was compared to 1 mg/ml of BSA (1BSA), 1 mg/ml of BSA plus 1% of Porcine OF (NaturARTsPOF-LF, Embryocloud) (1BSAPOF) or 1% Porcine OF (POF). Then we analysed sperm recovery, morphology, motility and vitality and calcium levels as capacitation signal after samples were incubated in a capacitating media.

Participants/materials, setting, methods: Swim-up was prepared adding 1 ml of NaturARTsPIG sperm swim-up medium in a conical tube and 1 ml of sperm sample of boar with proven fertility at the bottom of the tube. After incubation 500 µl from the top were recovered. Sperm recovery rate and morphology were evaluated. Motility and motion parameters were assessed by CASA and simultaneously sperm vitality and calcium levels were measured by flow cytometer with propidium iodide and Fluo-3AM (14 replicates).

Main results and the role of chance: Swim-up resulted in a suitable sperm selection, increasing normal morphology from 83,5 ± 1,3% before swim-up to >90% after. Morphology selection was worse in 5BSA (90.6 ± 2.2%) than other groups (1BSA: 96.4 ± 1.5%; 1BSAPOF: 96.3 ± 0.9%; POF: 95.7 ± 1.1%, $p = 0.02$). In addition, changing BSA concentration and adding OF modified motility patterns and calcium response. These motility differences have been found in all motility parameters which were represented in a study of motility subpopulation, with lower values for OF groups than others (motility %, velocities). In this sense, after a subpopulation analysis, the POF group showed a lower percentage of high motility population than others (5BSA: 14.1%, 1BSA: 9.4%, 1BSAPOF: 9,9%, POF: 4,5%). On the other hand, sperm vitality (mean 68.1 ± 2.4%) was not affected by groups ($p = 0.50$). Regarding the calcium response after incubation in a capacitating medium, the percentage of spermatozoa with high calcium level was higher in groups with OF (1BSAPOF: 32.2 ± 3.3%; POF: 34.6 ± 3.4%) than without OF (5BSA: 20.8 ± 2.7%; 1BSA: 26.7 ± 2.4%) with significative differences ($p = 0.01$). These results confirmed OF can modulate sperm function, leading to a better status for fertilizing after the swim-up procedure.

Limitations, reasons for caution: Modulating capacity of the OF could be affected by concentration of some proteins in the system and further studies are necessary to optimize the sperm selection procedure, in terms of viably and healthy embryos after IVF.

Wider implications of the findings: Our results agree with other studies demonstrating that OF reduces motility parameters and protect spermatozoa from early capacitation. The control capacitation patterns could be involved in the improved embryo development. This information could be used as a model to improve fertilization rate and embryo quality in humans.

Trial registration number: not applicable.

P-100 The effects of melatonin on possible damage that will be occured on epididymis and sperm parameters with the coadministration of fructose and bisphenol a (BPA)

S.Ö. Akarca Dizakar[1], S. Ömeroğlu[1], D. Erdoğan[1], T. Peker[2], N. Coşkun[3], İ. Türkoğlu[1], M.A. Eşmekaya[4]

[1]*Medical Faculty of Gazi University, Histology and Embryology, Ankara, Turkey*
[2]*Medical Faculty of Gazi University, Anatomy, Ankara, Turkey*
[3]*Medical Faculty of Hacettepe University, Obstetrics and Gynecology, Ankara, Turkey*
[4]*Medical Faculty of Gazi University, Biophysics, Ankara, Turkey*

Study question: Does melatonin have effects on epididymis and sperm morphology with the coadministration of fructose and BPA?

Summary answer: Administration of BPA, fructose, and concurrently both of these causes damaged to epididymis and sperm samples and melatonin were partially successful in preventing this damage.

What is known already: Nowadays, it is notable that the increase in the incidence of metabolic syndrome (MetS) and related clinical cases correlated with the increased of fructose rich food consumption and environmental and oral exposure to chemical substances known as endocrine disruptors. Fructose feed has recently increased and higher fructose consumption has associated with the increased of diseases such as dyslipidemia, insulin resistance, hypertension, hyperuricemia and infertility. BPA exhibits estrogen-like activity that cause toxicity in reproductive organs suppresses spermatogenesis, decreases sperm production and fertility rates.

Study design, size, duration: We used 42 adults, Sprague Dawley rats that were divided into seven groups. The groups were arranged as follows, Group 1 (n = 6, Control), Group 2 (n = 6, 10 % fructose), Group 3 (n = 6, only with 25 mg/bw/day BPA), Group 4 (n = 6, fructose 10% + 25 mg/bw/day kg BPA), Group 5 (n = 6, fructose 10 % +20 mg/bw/day melatonin), Group 6 (n = 6, 25 mg/bw/day BPA + 20 mg/bw/day melatonin), Group 7 (n = 6, fructose 10 %+ 25 mg/bw/day BPA + 20 mg/kg/day melatonin.

Participants/materials, setting, methods: After 8 weeks epididymal tissue was removed and analyzed by using histochemical (Hematoxylen-eosin, Masson's Trichrome and Silver impregnation stain) immunohistochemical (Zonula occludens-1 (ZO-1), Occludin (Occ) and Claudin-1 (Cl-1)) procedure. Sperm samples were counted, sperm morphology, motility and viability were investigated with Diff-quick and Eosin-Nigrosin stains. The apoptotic sperm cells were determined by flow cytometry.

Main results and the role of chance: Histopathologic changes were observed on the epididymis in BPA and BPA + Fructose groups and it was observed that melatonin has a protective effect on the histologic structural and morphological alterations of epididymis and sperm. When we semi-quantitatively compared the groups, ZO-1, Occ and Cl-1 immunostaining were decreased in BPA and BPA+Fructose groups compared to the control group, and these expression increased after melatonin administration. The total sperm count was not significantly different between the all groups ($p = 0.069$). Sperm motility increased significantly in the BPA + melatonin group compared to the BPA group ($p = 0.049$). Viability percentage of BPA + Fructose group was significantly lower than the control group ($p = 0.001$). The percentage of apoptotic sperm with Annexin V-FITC/PI staining in the BPA+Fructose+Melatonin group was lower than BPA+Fructose group ($P = 0,04$). Moreover, BPA and BPA+Fructose induced anomalies of the head and tail of sperm ($p < 0.05$). The anomalies head and tail of sperm were significantly lower in the BPA+Fructose +Melatonin group than BPA+Fructose group ($p = 0.018$, $p = 0.02$, respectively).

Limitations, reasons for caution: The *limitations* of the *study* are being an experimental animal model and immunohistochemical results should be supported quantitatively by using advanced molecular techniques.

Wider implications of the findings: Fructose and BPA have adverse effects on epididymis and sperm parameters. The decreased in immunoreactivity on epididymal tight junction proteins suggests that BPA and fructose can disrupt

the regular mechanism of blood-epididymis barrier and affect sperm maturation. This study have shown that melatonin can reduce the negative effects.

Trial registration number: not applicable.

P-101 Identification of seminal plasma proteins as potential biomarkers in men with primary infertility

A.D. Martins[1,2], A. Agarwal[1], L. Samanta[3], R. Sharma[1], B. Gopalan[4], B. Willard[5], Z. Cui[6], D. Durairajanayagam[7], E. Sabanegh[8]

[8]Cleveland Clinic, Department of Urology, Cleveland, U.S.A.

Study question: To identify molecular mechanism(s) and potential biomarkers of male infertility by comparing the seminal plasma proteome profile of fertile donors and men with primary infertility.

Summary answer: Altered protein expression profile in the seminal plasma of men with primary infertility may affect spermatozoa function, its use as a biomarker can be explored.

What is known already: Male factor is estimated to contribute to approximately 50% of all infertility cases. Primary infertility is the inability to father a child after 12 months of regular unprotected sexual intercourse. Basic semen analysis is the first step in the assessment of male potential. However, men with normal semen parameters can be infertile. There is a need for advanced methods to evaluate male fertility. Seminal plasma is a unique biological fluid that contains secretions from sex accessory glands. Therefore, the analysis of seminal plasma can serve as a great source for identification of key biomarkers of primary infertility.

Study design, size, duration: This study included seminal plasma samples from 13 men with primary infertility (without any female factor) and 13 proven fertile men. Following the basic semen analysis, seminal plasma was separated from the spermatozoa by high-speed centrifugation. For the proteomic study a pooled sample (n = 5) for each group was analyzed, and differentially expressed proteins (DEPs) identified. Validation of 7 selected proteins was carried out by Western blot (n = 8).

Participants/materials, setting, methods: Seminal plasma proteins were extracted and quantified. Following LC-MS/MS, Mascot, SEQUEST and X! Tandem tools were used to search the human reference database for protein identification. DEPs were identified based on normalized spectral abundance factor. Functional annotations, pathways and enrichment analysis were performed using GO, UniProtKB, Reactome, Metacore™ and DAVID. Network analysis was performed using both IPA™ and Metacore™ software databases. DEPs were selected for validation by Western blot and compared with proteomic analysis.

Main results and the role of chance: A total of 515 proteins were identified in the two groups, 48 were differentially expressed in primary infertility compared with proven fertile donors. In the primary infertility group, proteins related to diseases such as male infertility ($p < 0.0001$), azoospermia ($p = 0.005$), and oligozoospermia ($p = 0.02$) were underexpressed. Cellular assembly and organization, cell morphology and cell-to-cell signaling and organization were the main biological functions identified as dysregulated in primary infertility group. Proteins involved in cellular movement, free radical scavenging and cell-to-cell signaling and interaction such as: annexin-A2 ($p = 0.02$), cell division control protein 42 ($p < 0.0001$), peroxiredoxin-2 ($p = 0.03$), CD63 ($p = 0.005$) and transferrin ($p < 0.0001$) were overexpressed in the primary infertility group. On the other hand, proteins such as semenogelin-1 ($p = 0.001$) and semenogelin-2 ($p < 0.00001$), implicated in liquefaction and regulation of flagellated sperm motility, were underexpressed in the primary infertility group. The aforementioned DEPs were chosen to be validated by Western blot, however only annexin-A2 ($p = 0.03$) showed overexpression in the primary infertility group. This protein is a calcium regulated membrane-binding protein with high affinity to calcium. Dysregulation of calcium levels can be detrimental for key sperm processes such as capacitation, hyperactivation, acrosome reaction, and motility, which in turn may result in a failure of fertilization.

Limitations, reasons for caution: The number of samples used in this study is a major limitation. The use of only 13 different samples for each group is not enough to overcome the biological variability seen in the fertile and infertile male population.

Wider implications of the findings: The different seminal plasma proteomic profile of proven fertile men versus men with primary infertility suggests the important role of these proteins in the impairment of fertility. These proteins could be developed as biomarkers for diagnostic purposes. However, larger cohort studies are needed to justify their value as biomarkers.

Trial registration number: 'not applicable'

P-102 Exosomes, a bio-compatible delivery platform for mammalian sperm cells: A non-invasive approach for the transfer of therapeutic compounds

T. Vilanova[1], C. Plow[2], C. Jones[3], R. Dragovic[2], K. Coward[2]

[1]PhD Student, Nuffield Department of Women's and Reproductive Health, Oxford, United Kingdom
[2]University of Oxford, Nuffield Department of Women's and Reproductive Health, Oxford, United Kingdom
[3]University of Oxford, Nuffield Departmen of Women's and Reproductive Health, Oxford, United Kingdom

Study question: Can naturally-synthesised exosomes rival the efficacy of engineered nanoparticles to mediate the delivery of compounds into gametes for potential clinical use?

Summary answer: In vitro exposure of sperm to in vivo-synthesised exosomes did not significantly affect motility. Thus, exosomes may represent an effective delivery-tool for compounds into sperm.

What is known already: Over recent years, exosomes have become widely utilised as an efficient tool to mediate directed delivery of nucleic acids, peptides, antibodies, fluorescent compounds and other small molecules into cells and tissue in a non-invasive manner. However, the potential application of exosomes for the delivery of therapeutic compounds to mammalian gametes has not yet been elucidated.

Study design, size, duration: This study aimed to develop a mammalian cell line (HEK293T cells) from which exosomes can be synthesised, isolated and characterised for their ability to deliver compounds to mammalian sperm. A fluorescent dye (BODIPY) was used to test the efficiency of association between exosomes and sperm and to evaluate internalisation and safety aspects.

Participants/materials, setting, methods: BODIPY-labelled exosomes were synthesised and characterised by Nanoparticle Tracking Analysis (NTA) and Western blotting. Different exposure times (1 h, 2 h and 4 h) were tested by incubation with pre-activated boar sperm (n = 3). Sperm motility was then assessed by Computer Assisted Sperm Analysis (CASA), sperm-exosome association was quantified by Metafer-4 analysis and localisation/internalisation was assessed by confocal microscopy.

Main results and the role of chance: NTA showed that synthesised exosomes had a mean diameter of 152.5 ± 5 nm and concentration of 4.55 × 108/mL. Furthermore, Western blotting showed bands of the expected sizes for the characteristic exosome markers: Alix, syntenin and CD9. The association rate of BODIPY-exosomes incubated with boar sperm increased in a time dependent manner (1 h, 19.0%; 2 h, 24.9%; 4 h, 26.8%). Moreover, a consistent trend was observed for both internalisation and multiple association to the sperm with increased incubation (internalisation: 1 h, 12.5%; 2 h, 18.0%; 4 h, 55.0%; multiple association: 1 h, 0.83%; 4 h, 1.63%). Association to the tail declined progressively (tail association: 1 h, 50%; 2 h, 46%; 4 h, 35%). Interestingly, no exosome-surface head attachment was observed after 4 h. Metafer-4 analysis indicated a relationship between association and the length of incubation (1 h, 5.33%; 2 h, 6.6%; 4 h, 7.38%). Finally, exposure to labelled-exosomes did not significantly influence sperm motility after 2 h of incubation ($p = 0.244$).

Limitations, reasons for caution: The data presented here is preliminary in nature and derived from only a small sample size, thus limiting statistical analysis. Furthermore, Metafer-4 analysis is unable to quantify sperm tail association, and association rates may have been under-represented.

Wider implications of the findings: Our preliminary data demonstrated the successful synthesis, labelling and characterisation of exosomes. *In vitro* exposure of labelled-exosomes to mammalian sperm showed encouraging patterns of association and did not affect sperm motility. An exosome delivery-platform represents a multifaceted tool for reproductive biology with which to investigate gamete structure, physiology and preservation.

Trial registration number: not applicable.

P-103 The diet quality of couples undergoing IVF

T. Boedt[1], E. Dancet[2], K. Peeraer[2], S. Lie Fong[2], C. Spiessens[2], C. Matthys[1]

[1]*KU Leuven, Department of Chronic Diseases- Metabolism and Ageing, Leuven, Belgium*
[2]*KU Leuven, Department of Development and Regeneration, Leuven, Belgium*

Study question: Is the diet quality of men and women undergoing IVF adequate and is it correlated between partners?

Summary answer: The average diet quality of couples undergoing IVF does not meet Belgian dietary recommendations and is highly correlated between partners.

What is known already: Evidence on the association between reproductive health and dietary patterns of infertile men or infertile women is increasing. Infertility is a couples' condition. Yet, little is known on the correlation between the diets of partners undergoing IVF. Multiple methods to evaluate diets exist. Using a diet quality index has the added value of considering the complexity of food consumption patterns. It is an overall index to assess compliance with food-based dietary recommendations based on the quality, balance and variety of foods consumed.

Study design, size, duration: A cross-sectional observational survey was conducted between October 2016 and October 2017. Valid and reliable food frequency questionnaires (FFQ's) were disseminated online through the hospital e-platform to 396 Dutch speaking heterosexual couples about to start an IVF-cycle at a Belgian University fertility clinic. A total of 105 couples visited the e-platform. No reminders for filling out the questionnaire were sent.

Participants/materials, setting, methods: A total of 57 couples fully completed the FFQ, assessing portions and frequencies of foods consumed and their quality, balance and variety. Diet quality was described with an overall score between 0-100 and a cut-off <70/100 warranting need for dietary advise. Spearman correlations described inter-partner correlations. Clinical pregnancy (with fetal heartbeat) after one IVF and corresponding cryo-cycles was registered. Logistic regressions evaluated if the diet quality of couples was associated with their clinical pregnancy rate.

Main results and the role of chance: Participating men had a mean age of 36 (±6.7) and mean body mass index (BMI) of 26.6 kg/m^2 (±4.8). Participating women had a mean age of 33 (±4.8) and mean BMI of 23.6 kg/m^2 (±4.3). The overall diet quality was 70.5/100 (±12.7) for men and 73.2/100 (±10.1) for women. The diet quality of partners was positively correlated ($r = .537$, $p = .001$). On food (group) level, subfertile men and women did not meet the Belgian dietary recommendations. The vegetable intake (recommendation of 300 g/day) was inadequate, respectively on average 154 g/day in men and 146 g/day in women. The intake of processed foods (i.e. cookies, soft drinks, fast food) exceeded the recommendation of 10% of daily food intake, respectively 23.4% in men and 20.4% in women. One in three couples achieved a clinical pregnancy. After controlling for BMI and age, the average couples' diet quality of this small sample was not associated with their clinical pregnancy rate (OR 1.12, 95% CI .88-1.57).

Limitations, reasons for caution: Selection bias by health conscious couples is likely, which means that the diet of the average couple might be even more suboptimal. The small sample size and cross-sectional nature of this study does not allow causal inference.

Wider implications of the findings: Subfertile couples are in need of dietary advise, as was already reported for the general Belgian population. It would be interesting to examine whether advise improves reproductive health in large scale randomized controlled trails, which should include couples as partner's diet quality is correlated.

Trial registration number: Not applicable.

P-104 Impact of male partner chlamydia trachomatis seropositivity on infertility in unselected subfertile population

P. Joki-Korpela[1], T. Rantsi[1], H. Öhman[2], M. Puolakkainen[3], J. Paavonen[4], H.M. Surcel[5], A. Tiitinen[1]

[1]*Helsinki University Central Hospital- Womens hospital, Reproductive medicine, Helsinki, Finland*
[2]*The National Institute for Health and Welfare- Oulu- Finland, Immunology, Oulu, Finland*
[3]*University of Helsinki, Department of Virology, Helsinki, Finland*
[4]*University of Helsinki, Department of Obstetrics and Gynecology, Helsinki, Finland*
[5]*University of Oulu, Faculty of Medicine, Oulu, Finland*

Study question: Does *C. trachomatis* infection affect male fertility and pregnancy outcome? Is there association in lifestyle factors of male partners and female fertility?

Summary answer: We found a link between male chlamydial seropositivity and tubal factor infertility (TFI) in the female partner but no significant association in male semen parameters.

What is known already: The study results on the role of *C. trachomatis* and male fertility have been variable. *C. trachomatis* persistent infection might cause scarring of the ejaculatory ducts and loss of stereocilia or induce an autoimmune reaction inducing antisperm antibodies or autoantibodies. DNA fragmentation in sperm caused by *C. trachomatis* could affect the quality of the embryo and implantation. Fragmented DNA is a common finding in couples having a history of recurrent miscarriage. It has been reported that *C. trahcomatis* IgA and IgG but not heat shock protein 60 antibodies in male serum correlate negatively with semen characteristics and lower pregnancy rates.

Study design, size, duration: Altogether 224 subfertile couples were recruited in the Department of Obstetrics and Gynecology, Helsinki University Hospital, Finland, between July 2007 and December 2010 and follow-up continued until June 2014. Infertility work-up was performed according to our standard protocol after at least one year of unprotected intercourse. Data on lifestyle factors (smoking, alcohol consumption), previous illnesses, and medication was collected.

Participants/materials, setting, methods: Humoral immune responses to *C. trachomatis* were studied by measuring *C. trachomatis* MOMP specific IgG and IgA and CHSP60 specific IgG antibodies using ELISA kits (Medac Diagnostika, Hamburg, Germany) according to manufacturer's instructions. Results were obtained as a mean absorbance of duplicated samples at 450 nm. Less than 10% variation was seen in doublets (OD > 0.2). Semen samples of the male partners were analyzed according the criteria of World Health Organization (WHO).

Main results and the role of chance: The age of all male participants ranged from 21 to 49 (median 32) years with no difference between *C. trachomatis* seropositive or seronegative males. The prevalence of *C. trachomatis* IgG in male population was 10.3% (23/224), IgA 8.5% (19/224) and CHSP60 IgG 16.1% (36/224). The duration of infertility was significantly longer in couples with IgA seropositive males ($p = 0.04$) when compared to seronegative males. History of miscarriage was more common in couples with CHSP60 and IgA antibody positive male partners than antibody negative male partners ($p = 0.04$ and $p = 0.05$, respectively. No significant difference on live birth rate or need for IVF occurred between couples of chlamydial seropositive and seronegative males. There was no significant association in male semen parameters and chlamydial seropositivity. Male seropositivity correlated with TFI in the female partner ($p = 0.007$), but not with male factor infertility ($p = 0.43$). Alcohol consumption by a male partner was associated with a history of *C. trachomatis* infection ($p < 0.001$) and with TFI of the female partner ($p = 0.003$), while male smoking was associated with unexplained infertility of the couple ($p = 0.01$).

Limitations, reasons for caution: The rate of *C. trachomatis* antibodies were low in our study population leading to small study groups. The results on semen parameters were based on one sample. Knowing that the quality of semen can vary within the same individual this can have effect on the results.

Wider implications of the findings: In our study, we found significant association between male lifestyle factors and TFI, thus couples should be informed on the effect of healthy lifestyle on fertility. According to our results, not only female but also male chlamydial infection has an important effect on fertility of the couple.

Trial registration number: not applicable.

P-105 Open testicular mapping: a new and less invasive testicular sperm extraction (TESE) procedure

M. Vieira[1], S. Glina[1], J. Leite Marques[2], F. Elia Mizrahi[2]

[1]*Aliança dos Laboratórios de Fertilização Assistida, Urology, São Paulo, Brazil*
[2]*Aliança dos Laboratórios de Fertilização Assistida, Embriology, São Paulo, Brazil*

Study question: The aim of this study was to evaluate the successful sperm recovery rate (SSR) of open testicular mapping (OTEM) in non-obstructive azoospermic men.

Summary answer: Testicular sperm viable for Intracitopalsmic Sperm Injection (ICSI) was found in 50 (54%) of 92 azoospermic men.

What is known already: In 1999, Schlegel *et al.* reported on novel microsurgical techniques for TESE.

In Schlegel's hands this technique of microdissection resulted in an improvement of sperm retrieval rates (SRR) from 45 to 63%

Despite initial good results, the wide opening of the tunica albuginea and potential vascular damage are the controversial aspects of this technique.

Testicular microdissection SSR range from 34% (Japanese Nationwide Survey) to 63% (initial Schlegel results)

Study design, size, duration: Retropective study of laboratory files from patients presenting with non obstructive azoospermia from 2008 to 2016 evaluating 92 patients submited to OTEM for ICSI or cryopreservation.

Participants/materials, setting, methods: After delivered, the testis were mapped for sperm production without albuginea opening.

Patients were divided in two groups according to sperm recovery for purpose of analysis: group 1 (G 1), men with sperm found, and group 0 (G 0), men with no sperm recovered.

Age, FSH level and testicular volume (TV) were compared between groups 1 and 0 using the Statistical Package for Social Sciences (SPSS), 21.0 version, with significant values below five percent ($p < 0.05$)

Main results and the role of chance: SSR was 54% (50/92). Statistical difference was found for male age, mean 38 years for G 1 and 34 for G 0. FSH and TV had no statistical difference between the groups.

Limitations, reasons for caution: Histologic evaluation and laboratory exams were done in different laboratories may leading to non uniform readings and a wide range of normal values.

Wider implications of the findings: We present a new and less invasive option for sperm retrieval for patients presenting with non obstructive azoospermia with similar results to testicular microdissection.

Trial registration number: not applicable.

P-106 Differential expression of exosome-associated proteins in seminal plasma of infertile men with unilateral varicocele

M.K. Panner Selvam[1], A. Agarwal[1], L. Samanta[2], R. Sharma[1], S. Gupta[1], D. Durairajanayagam[3], Z. Cui[4], A. Ayaz[5], B. Gopalan[6], B. Willard[7], E. Sabanegh[8]

[1]*Cleveland Clinic, American Center for Reproductive Medicine- Department of Urology, Cleveland, U.S.A.*
[2]*Ravenshaw University, Department of Zoology, Odisha, India*
[3]*Universiti Teknologi Mara, Discipline of Physiology- Faculty of Medicine, Selangor, Malaysia*
[4]*Southwest University, College of Pharmaceutical Sciences, Chongqing, China*
[5]*Tulane Medical Center, Department of Urology, New Orleans, U.S.A.*
[6]*Yorg Corporation, Bioinformatics, Plano, U.S.A.*
[7]*Cleveland Clinic, Research Core Services - Proteomics, Cleveland, U.S.A.*
[8]*Cleveland Clinic, Urology, Cleveland, U.S.A.*

Study question: Does compromised delivery of sperm maturation factors by defective seminal exosomes cause sperm dysfunction in infertile men presented with unilateral varicocele?

Summary answer: Altered expression of seminal plasma proteins involved in the exosome-sperm fusion pathway may be a contributory factor for infertility in patients with unilateral varicocele.

What is known already: Exosomes are cell-derived vesicles that are either released from the cell upon fusion of an intermediate endocytic compartment (the multivesicular bodies) with the plasma membrane or directly from the plasma membrane. Seminal plasma provides a favorable environment for spermatozoa and exosomes released from the epididymis, prostate and seminal vesicles. Seminal exosomes carry a distinctive repertoire of small non-coding RNAs with potential regulatory functions. Though proteins associated with exosome function are involved in energy pathways, protein metabolism, cell growth and maintenance, there is paucity of information on the role of seminal exosomes on sperm function in general and varicocele in particular.

Study design, size, duration: Semen samples were collected from 33 infertile patients with unilateral varicocele from March 2012 to April 2014 and from 10 proven fertile healthy male volunteers. Proteomic profiling of seminal plasma was carried out in Finnigan LTQ linear ion trap mass spectrometer LC-MS/MS system. Differentially expressed proteins (DEP) in the unilateral varicocele patients to that of the fertile controls were evaluated.

Participants/materials, setting, methods: We compared the proteome of seminal plasma from unilateral varicocele patients ($n = 5$) with that of fertile men ($n = 5$). Relative quantification of proteins was estimated by spectral counts (SC) and their abundance determined based on the normalized spectral abundance factor. In silico analysis was done using Cytoscape and Metacore platforms to identify the top-most enriched pathways and DEPs involved in regulating the upstream transcription receptors respectively. Exosome-associated DEPs were validated by Western blot (WB) analysis.

Main results and the role of chance: Of the 47 DEPs identified in the seminal plasma, three were unique to the unilateral varicocele group and one to the fertile donor group. Network analysis predicted 13 DEPs (APOD, SERPINF2, ORM1, TSPAN1, CRISPLD2, Rab-27A, CD13, MME, KLK11, TMPRSS2, DPP4, TGM4 and GLOI) to be under the regulation of Androgen receptor affecting normal sperm function. Other transcription factors YB-1 (associated with fertility), SP1 (related with reproductive processes) and NRF2 (antioxidant gene expression) were the principal upstream regulators of most DEPs. Bioinformatic analysis revealed the altered expression of vital proteins involved in regulation of vesicle fusion and positive regulation of endocytosis related to exosomes. We demonstrated the presence of exosomes in the seminal plasma of both, the patients and the control group by WB expression of CD63 (exosomal marker). Annexin A2 (ANXA2), a calcium-regulated binding protein responsible for fusion of exosomes was significantly upregulated (2.49-folds; $P = 0.0016$) and transferrin (TF), involved in positive regulation of endocytosis showed a 1.19-fold ($P = 0.1257$) increase indicating impaired fusion of exosomes with spermatozoa in varicocele patients. Therefore, it is suggested that exosomes were unable to deliver the regulatory factors/elements resulting in impaired maturation of spermatozoa in varicocele patients.

Limitations, reasons for caution:

- We did not purify the exosomes for proteomic studies, thus decreasing the specificity of the technique.
- Samples were pooled to overcome the biological variation in high-throughput experiments.

Wider implications of the findings: Aberrant expression of exosome function associated proteins hinders the transfer of exosomal elements/factors to the spermatozoa essential for maturation process. Validation of additional DEPs may further strengthen our hypothesis. These findings could help clinicians identify the exosomal dysfunction as one of the causes of infertility in patients with unilateral varicocele.

Trial registration number: Not Applicable.

P-107 Taste receptors expression in human sperm: possible chemosensors for sperm-oocyte attraction

A. Luddi, C. Marrocco, L. Governini, A. Capaldo, B. Semplici, V. Pavone, L. Boschi, V. De Leo, P. Piomboni

University of Siena, Molecular and Developmental Medicine, Siena, Italy

Study question: Are taste receptors (TAS) implicated in the capacitation and reprogramming of spermatozoa during their successful trip toward the oocyte?

Summary answer: Human spermatozoa express a number of taste receptors and their localization is modified by sperm capacitation and ligand interaction.

What is known already: Recent studies showed the expression of several TAS in mammalian testis and sperm, suggesting their possible role in fertility. The taste receptor ligands are single amino acids, nucleotides, sugars, proteins, acids and other molecules; their presence in the female genital tract imply a possible role for taste receptors as chemosensor during the journey of sperm towards the fertilization site. To this regard, it has been demonstrated that glutamate concentration is very high in the uterus but it decreases in the fallopian tube, thus suggesting the possibility that taste receptors may use this gradient to guide the sperm towards the oocyte.

Study design, size, duration: We enrolled for this study a total of 30 patients referring to our Centre for Couple Sterility (median age 36 years; range18–58) undergoing semen evaluation during an infertility diagnostic screening, from October 2016 to February 2017, at the Centre of Couple Sterility, Siena University Hospital.

Participants/materials, setting, methods: Patients have been enrolled after signing an informed consent. Ejaculated sperm were collected and seminal parameters were monitored according to WHO 2010 guidelines. Taste receptor expression/localization was confirmed at the protein level by western blot and immunofluorescence. We analysed, by quantitative RT-PCR, in ejaculated sperm the gene expression profile of the genes involved in the transduction cascade elicited by TAS. Finally, we also evaluated the TAS expression/localization after exposure to TAS ligands, agonist/antagonist.

Main results and the role of chance: In ejaculated human sperm we demonstrated the expression of several taste receptors: TAS1R1, TAS1R2, TAS2R3, TAS2R4, TAS2R14, TAS2R19 and TAS2R43. Immunofluorescence showed a different localization of these receptors in basal and capacitated conditions; the modification of their expression pattern seems to be compatible whit motility hyperactivation and predisposition to acrosomal reaction. Indeed, during their journey through the female genital tract, sperm are subjected to modifications that induce a functionally reprogramming or capacitating enabling the sperm to became able to fertilize. Western blot analysis confirmed these modifications in basal and capacitated conditions, with different protein isoforms detected. Since the molecules involved in sperm capacitation and chemoattraction are still widely unknown, we *in vitro* tested some TAS ligands selected from the literature, such as genistein, daidzein and trihydroxyflavone. Our data demonstrated a time and dose-dependent significant impact on sperm parameters, such as motility and vitality. Therefore, investigations on these molecular pathway could be interesting for increasing the outcome of ART procedures.

Limitations, reasons for caution: In this pilot study we analyzed only normozoospermic patients. The inclusion of patients with altered semen parameters (oligozoospermic, astenozoospermic) is mandatory in order to validate these findings.

Wider implications of the findings: Further studies might contribute in better understanding the physiologic role of taste receptors in sperm-oocyte attraction and recognition. This should be crucial to clarify the mechanism underlying fertilization, thus to provide a chance for ameliorating the in vitro conditions, in order to improve IVF outcome.

Trial registration number: Not applicable.

P-108 To evaluate outcome of methylxanthine theophylline in frozen thawed testicular sperm in intra cytoplasmic sperm injection cycles

G. Kant, K.D. Nayar, M. Singh, N. Sharma, R. Gahlot, K. Nayar

Akanksha IVF Centre, Reproductive Medicine, New Delhi, India

Study question: To evaluate whether methylxanthine theophylline can be used routinely in frozen thawed testicular sperm in intra cytoplasmic sperm injection (ICSI) cycles.

Summary answer: Theophylline increases sperm motility, which may contribute towards higher fertilization, improved embryo formation and better pregnancy rates.

What is known already: Cryopreserved thawed spermatozoa are used to avoid further damage to the testis. While reduced motility of extracted sperm and affect of cryopreservation represent a persistent problem in finding a viable sperm for ICSI. Over the years, many chemical agents have been tried to over come this problem like: caffeine and other methylxanthines. Pentoxifylline turned out to be an effective tool in stimulating motility in fresh and cryopreserved human sperm. Interestingly, theophylline, a closely related molecule, has been investigated for this purpose to a much lesser extent and no randomised control study is reported to its show benefit.

Study design, size, duration: A randomized controlled study was conducted from 1st January 2015 to 31st September 2017 where normal responder women undergoing frozen testicular sperm ICSI cycles were randomized using computer generated list and closed opaque envelops into 2 groups, group (A) sperm treated with theophylline and group (B) not treated with theophylline. All A grade embryos were vitrified at day 3 (7–9 cells) or day 5 (Blastocyst) and transferred in the subsequent frozen embryo transfer cycle.

Participants/materials, setting, methods: Eighty women were randomised in group A (n = 36) and B (n = 34),rest 10 women were excluded due to <4 oocyte retrieved or left the cycle. All A grade embryos in both groups were vitrified and warmed using same protocol by same embryologist on 7-9 cells and blastocyst stage.Primary outcome of the study was clinical pregnancy rate and secondary outcome was fertilization rate. Statistical analysis was performed using SPSS for Windows version 20.

Main results and the role of chance: Descriptive characteristics of the patient in group A and group B like Age, BMI, total dose of FSH, total dose of HMG, days of stimulation, Metaphase II oocytes were found to be comparable. The sperm selection was easier in the group A than group B due to increased motility in thawed testicular sperm. The fertilization rate in group A were 67.2% vs. group B 46.4% (95% CI 13.6–27.7%, $p < 0.001$) and mean Grade-A embryo formation rate in group A were 2.97 ± 1.424 vs. group B 2.24 ± 0.741 (95% CI 0.191–1.283, $p = 0.023$) were significantly higher in group A compared to group B. Results were comparable for both the groups for clinical pregnancy rate 44.4% vs. 29.4% (95% CI -7.4% - 35.4%, $p = 0.193$) however, it was higher in the group A than group B.

Limitations, reasons for caution: Need large sample size.

Wider implications of the findings: Theophylline increase selection of viable sperm due to increased motility. This may contribute towards higher fertilization, improved embryo formation and increased clinical pregnancy rate. This can also reduce the burden on embryologist for finding viable sperm. Further studies may be required for better understanding of potency of theophylline.

Trial registration number: MCDH/2015/7.

P-109 The relevance of Annexin A5 in male fertility

H. Lavorato[1], A. Markoff[2], N. Bogdanova[2], F. Tüttelmann[2], S. Schlatt[1]

[1]*Muenster University, Center of Reproductive Medicine and Andrology, Münster, Germany*

[2]*University Clinics Muenster, Institute of Human Genetics, Münster, Germany*

Study question: The study aimed to investigate the relationship of the haplotype M2/ANXA5 and male fertility parameters.

Summary answer: Our study does not show any biologically relevant effect of lower levels of annexin A5 on male fertility parameters.

What is known already: Annexin A5, which functions as an anticoagulation protein, is coded by the ANXA5 gene. The haplotype M2/ANXA5 decreases the ANXA5 gene promoter region activity and mRNA expression. The carrier status of the haplotype M2/ANXA5 is an important risk factor for recurrent pregnancy loss during the early stages of pregnancy.

In rabbits, annexin A5 is the main protein of the seminal plasma and influences all sperm parameters. Yet, the role of annexin A5 in men is currently underresearched.

Study design, size, duration: This study consists of a retrospective selection and analysis of the clinical data from our patient cohort (n = 340; 165 severe oligozoospermic and 175 normozoospermic), taking into consideration a new genetic diagnostic evaluation.

Participants/materials, setting, methods: Genomic DNA from blood was sequenced with Sanger sequencing. The frequency of the haplotype M2/ANXA5 was then compared between the groups and compared with the general population. The clinical data from the patient groups was evaluated according to their genetic variant of the promoter region for ANXA5. The hormonal parameters were FSH, LH, testosterone, SHBG, free-testosterone, prolactin and estradiol. Sperm parameters evaluated were ejaculated volume, concentration, total count, motility, morphology, vitality and accessory glands markers.

Main results and the role of chance: Association of M2 carrier status with oligozoospermia was first assessed in the two comparably sized groups of oligozoospermic and normozoospermic patients. Both groups were in HWE at $p = 0.773$ and $p = 1.000$, respectively. The M2 carrier rate was 24.2% for oligozoospermic and 17.7% for the normozoospermic patients (table 1). The comparison of both groups yielded an OR of 1.5 (95%CI 0.9 to 2.6), not achieving significance. When comparing the oligozoospermic patients with the general population control group, the OR was 1.8 (95% CI 1.1 to 2.8), $p = 0.009$. The only statistically significant differences between the carriers and non-carriers of the haplotype M2/ANXA5 could be observed in the prolactin and α-glucosidase levels when looked in the normozoospermic patients. The prolactin levels mean in the non-carriers and M2 carriers was 196 mU/l and 167 mU/l, respectively. The α-glucosidase levels mean was 78.3 mU and 113 mU in the non-carriers and M2 carriers group, respectively. In the oligozoospermic patients, there is also a decrease in prolactin levels and an increase in α-glucosidase levels. However, these variations are small and not statistically significant. Selection of patient cohorts may account for the observed differences or lack of them.

Limitations, reasons for caution: The study was carried out with patients attending a human reproduction service, thus the results may not reflect the differences present in the general population.

Wider implications of the findings: The patients carrying the haplotype M2/ANXA5 do not present a clinical profile, so genetic screening is advisable to avoid recurrent pregnancy loss.

Trial registration number: not applicable.

P-110 Timing of intrauterine insemination in relation to human chorionic gonadotropin trigger following superovulation with clomiphene citrate

P. Chung[1], M. Irani[2], S. Elder[3], V. Ramnarine[4], J. Wan[5], Z. Rosenwaks[2]

[1]*Weill Cornell Medical College, Reproductive Medicine, New York- N.Y., U.S.A.*
[2]*Weill Cornell Medicine, Center for Reproductive Medicine, New York, U.S.A.*
[3]*Cornell University, Weill Cornell Medicine, New York, U.S.A.*
[4]*Jamaica Hospital Medical Center, Obstetrics and Gynecology, New York, U.S.A.*
[5]*Columbia Universisty, Columbia University Medical Center, New York, U.S.A.*

Study question: Does the timing of intrauterine insemination in relation to ovulation trigger with human chorionic gonadotropin (hCG) affect the outcomes of clomiphene citrate cycles?

Summary answer: Intrauterine insemination (IUI) performed 19–23 hours after the administration of hCG has comparable clinical pregnancy rates with those performed 24–36 hours after trigger.

What is known already: Several factors affect IUI outcomes, including female age, total number of inseminated motile spermatozoa (TM), number of recruited follicles, and infertility diagnosis. The timing of IUI is also important given the limited fertilization window of the ovulated oocyte(s). Yet, the optimal insemination timing is not well defined.

Study design, size, duration: It is a retrospective cohort study at an academic medical center. All IUI cycles performed between 2004 and 2013 were reviewed. To control for female age and stimulation protocol, we included only clomiphene citrate cycles of women ≤35 years old with normal uterine cavity and patent fallopian tubes.

Participants/materials, setting, methods: A total of 741 clomiphene citrate/IUI cycles were included. Cycles were divided into two groups based on the number of motile inseminated spermatozoa ($<15 \times 10^6$ and $\geq 15 \times 10^6$). Within each group, the clinical pregnancy rates (CPRs) were compared between IUI performed within the first 23 hours after hCG to those who had their IUI ≥24 hours after hCG. χ^2 and Fisher's exact tests were used for categorical variables. Values were expressed as mean ± standard deviation.

Main results and the role of chance: Within the group of patients with an adequate number of motile inseminated spermatozoa ($\geq 15 \times 10^6$) (n = 618 cycles), the CPRs were comparable between those who underwent IUI within the first 23 hours after hCG (range: 19–23 hours) (n = 71 cycles) and those ≥24 hours (range: 24–36 hours) (n = 547 cycles) (15.5% vs. 20.2%, respectively, $P = 0.3$). There was no significant difference in terms of female age (32.4 ± 2.9 vs. 31.8 ± 2.7 years old, $P = 0.2$), number of dominant follicles larger than 18 mm at the time of trigger (1.7 ± 0.8 vs. 1.8 ± 0.1, $P = 0.1$), or peak endometrial thickness (7.9 ± 2.3 vs. 7.9 ± 2.3 mm, $P = 0.9$) between cycles of the two timing groups. Similarly, among the cycles in which the number of inseminated spermatozoa was $<15\times10^6$, IUI performed within the first 23 hours after hCG had comparable CPR with those ≥24 hours (7.6% vs. 14.4%, $P = 0.3$). Female age (31.7 ± 2.1 vs. 31.7 ± 2.7 years old), number of dominant follicles (1.8 ± 0.8 vs. 1.9 ± 0.9), and peak endometrial thickness (7.5 ± 2.1 vs. 7.8 ± 2.3 mm, $P = 0.6$) were not significantly different between the two timing groups.

Limitations, reasons for caution: Although this is a retrospective study, the adjustment for all potential confounding factors such as female age, number of dominant follicles, stimulation protocol, peak endometrial thickness, and number of inseminated motile spermatozoa strongly supports the accuracy of our findings in investigating the influence of IUI timing on pregnancy outcomes.

Wider implications of the findings: Timing the IUI as early as 19 hours after hCG administration yields comparable clinical pregnancy rates with IUI performed as late as 36 hours after ovulation trigger. This reassuring wide range of IUI timing grants providers and patients more flexibility when scheduling IUI without impairing the outcomes.

Trial registration number: N/A.

P-111 Differential sperm proteomic profile between sperm samples achieving pregnancy or not in intracytoplasmic sperm injection (ICSI) cycles in oocyte donation program

R. Rivera Egea[1], N. Sota[1], M. Meseguer[2], F. Dominguez[3], J. Remohi[4], N. Garrido[3]

[1]*IVIRMA, Andrology, Valencia, Spain*
[2]*IVIRMA, IVF laboratory, Valencia, Spain*
[3]*IVI Foundation, Research, Valencia, Spain*
[4]*IVIRMA, gynecologist, Valencia, Spain*

Study question: Are there any differences between sperm samples that failed vs. those achieving pregnancy regarding the sperm proteomic profile after ICSI cycles?

Summary answer: This study reveals a differential protein profile between sperm samples that failed vs. those achieving pregnancy, able to be used as sperm fertility biomarkers.

What is known already: There is a lack of sperm fertility markers, and several studies demonstrated that idiopathic male infertility is multifactorial. Although is believed that sperm are cells translational and transcriptionally silent, their functionality can be studied using proteomic approaches. Many proteins have been already identified having an important role in sperm motility, sperm-oocyte's zona pellucida interaction, metabolism, apoptosis, cellular cycle, meiosis, membrane transport, and ribonucleotide acid regulation.

Furthermore, some previous works from our group described differential molecular factors in sperm samples from which a pregnancy was obtained compared with those failing, defining molecular characteristics for physiologically competent sperm.

Study design, size, duration: Descriptive, prospective and non-randomized biomedicine study evaluating the proteomic profile of spermatozoa from patients' ejaculates where pregnancies were (Group pregnant (P), n = 4) or were not (Group non-pregnant (NP), n = 4) achieved after ICSI in an oocyte donation program aiming to standardize female factor. Aliquots from the same samples employed in ICSI procedures were collected, frozen until the reproductive results were known, and then assigned to their corresponding group and analysed.

Participants/materials, setting, methods: Eight sperm samples from infertile males undergoing ICSI cycles in oocyte donation program with normal sperm parameters and total progressive motility >5mill were included in our study, 4 of them failed to achieve pregnancy and 4 who succeeded. Proteins were separated and analysed by means of SWATH-MS (Sequential Windowed Acquisition of All Theoretical Fragment Ion Mass Spectra). Proteins are available via ProteomeXchange: identifier PXD006309. All proteins abundances were compared statistically between P and NP groups.

Main results and the role of chance: We identified 2228 proteins, 53 of them were found in different abundance between sperm samples, being 37 significantly more abundant in sperm samples in P group, and 16 less abundant in this same group compared with NP. We applied Elastic-Net statistic method to identify the 27 proteins best performing to differentiate both groups. Also, we use PLS-DA analysis (Partial Least Squares Discriminant Analysis) verifying that the samples are classified accordingly to their group. Finally, we applied a *VIP-score* test over Elastic-Net and PLS-DA, in order to determine which proteins have more importance in achieving pregnancy. We obtained 27 proteins with high *VIP-score* in Elastic-Net, and 300 in PLS-DA.

Then we applied functional analysis over the proteins obtained in the analysis PLS-DA+*vip-score*, obtaining 5 proteins more abundant in P group with reproduction functions (NME5, SPATA20, DNAI1, ARMC4 and AK7) and 10 less abundant in NP group (GNB2L1, PDIA4, YWHAZ, SYNGR1, FNTB, LCP1, NDUFS4, COG3, STOM and GIT1) with metabolic functions.

Finally, we identified 11 proteins present in PLS-DA+*VIP-score* analysis, located in membrane, susceptible to be selected by MACS (Magnetic-activated-cell-sorting) to develop a new system to select the best spermatozoon.

Limitations, reasons for caution: Other molecular factors not included within this analysis could be involved in sperm fertility given that sperm function has been demonstrated multifactorial.

The low number of samples studied make us be cautious about our findings, but lead us to design a focused research on the main findings with bigger sample-sizes.

Wider implications of the findings: The description of proteins linked to sperm fertility, open new possibilities regarding the development of male fertility diagnostic tools, culture media formulations, or, to design new sperm selection tools based on these molecular traits, using MACS of spermatozoa exhibiting specific proteins associated with the best reproductive results.

Trial registration number: This study is not considered as a trial study.

P-112 Sperm DNA fragmentation index (DFI) does not increase with increasing number of treatment cycles

A. Prahl[1], A. Giwercman[2], S. Malic Voncina[2], A. Stenqvist[2], Y. Lundberg Giwercman[1]

[1]*Molecular genetic reproductive medicine, Department of Translational Medicine, Malmo, Sweden*
[2]*Reproductive medicine, Department of Translational Medicine, Malmo, Sweden*

Study question: Do men undergoing numerous IVF cycles have higher amount of sperm DNA strand breaks than those who experience only one cycle?

Summary answer: Men in couples who have undergone numerous cycles do not have higher mean DFI then those who have undergone one.

What is known already: Sperm DNA strand breaks, measured as DNA fragmentation index (DFI) by sperm chromatin structure assay (SCSA) is a clinically useful marker of male infertility, and a couple's chance of pregnancy. However, it is still unclear if high DFI is more common in men going through many IVF treatment cycles compared to those achieving pregnancy in the first.

Study design, size, duration: Prospective, clinical study, in which n = 2968 men were consecutively enrolled during the period 2007–2018, at Reproductive Medicine Centre, Malmö, Sweden. Sperm samples were collected and analysed before each cycle. In total, DFI from 4894 fresh treatment cycles ranging from cycle number 1-7 were included.

Participants/materials, setting, methods: Approximately 5000-10 000 sperm cells were analyzed by SCSA. Analysis of the flow cytometric data was carried out using dedicated software.

Main results and the role of chance: In the first cycle there were 2460 DFI values, second cycle 1402 DFI values, third cycle 755 DFI values, fourth cycle 190 DFI values, and in cycles 5-7 87 DFI values were available. The mean DFI value for the first, second and third cycle was 16%, respectively, the fourth cycle 19%, and the 5^{th}-7^{th} 17%. There was no statistically significant difference in DFI between the cycles (p trend = 0.058).

Limitations, reasons for caution: The number of men was decreasing with numbers of IVF cycles completed.

Wider implications of the findings: Men who have undergone many IVF/ICSI are not presenting with higher DFI than those who enter the assisted reproduction treatment.

Trial registration number: Not applicable.

P-113 Intrauterine insemination: predictive factors regarding pregnancy outcomes for women aged 35 and over

M. Bendayan[1], N. Swierkowski-Blanchard[1], A. Oppenheimer[2], L. Alter[1], L. Caceres-Sanchez[1], J. Selva[1], A. Torre[1], G. Robin[3], F. Boitrelle[1]

[1]*CHI de Poissy-St-Germain-En-Laye, Service d'Assistance Médicale à la Procréation - Biologie de la Reproduction -, Poissy, France*
[2]*Hôpital Antoine Béclère, Service d'Assistance Médicale à la Procréation, Clamart, France*
[3]*CHRU de Lille, Service de Médecine de la Reproduction, Lille, France*

Study question: From what age pregnancy rates in intrauterine insemination (IUI) decrease? Among these women, what sperm parameters are necessary to get pregnancy in IUI?

Summary answer: There is an interest of IUI in women aged 35 and over when spermatic parameters allow to reach the needed thresholds.

What is known already: As women's age increases, specialists of assisted reproductive technologies (ART) tend to offer an in vitro fertilization (IVF) whereas the necessary conditions for an IUI were sometimes reunited. There is no threshold concerning women's age. Furthermore, the number of inseminated motile spermatozoa definitely has an impact on the pregnancy outcome after IUI, but with variable thresholds. The sperm morphology impact of is more questionable, and only the initial morphology (on total sperm) has been studied.

Study design, size, duration: We have performed a prospective study in Poissy Hospital Center, between January 2015 and June 2017. A multivariate logistic regression analysis was used to determine the predictive value of each parameter in clinical pregnancy outcome after 12 weeks. A p value of 0.05 was considered as statistically significant.

Participants/materials, setting, methods: We have studied couples with primary infertility and benefits from an IUI cycle after ovarian stimulation with follicle-stimulating hormone (FSH) and mono-follicular answer. For each IUI, sperms count and motility of post-wash sperm preparation (sperm preparation for IUI) were performed with computer-assisted method. A smear of this preparation was stained to establish percentage of typical spermatozoa (David classification). The number of inseminated motile spermatozoa (NIMS) and the number of inseminated normal spermatozoa (NINS) were calculated.

Main results and the role of chance: 433 couples with 990 IUI cycles were included in the study. The clinical pregnancy per cycle was 11.8%. According to a multivariate logistic regression analysis, women's age is the only predictive factor of clinical pregnancy (p <0.004) in this population. A 35-year threshold was shown to be predictive for success, with higher rates of pregnancy among women under 35 (14.1% vs. 8.1%, p = 0.0038).

The second part of the study focuses on women 35 years and older (383 cycles). According to the multivariate logistic regression analysis, the NIMS and the NINS are the only predictive factors of the occurrence of a clinical pregnancy in women over 35 years-old. In this population, regardless of women's age, women's body mass index (BMI), and the number of attempts, the rates of clinical pregnancies are statistically higher:

- if NIMS > 7.25 million (11.4% vs. 5.3%, OR adjusted 2.21 [1.04, 4.93], p = 0.04)
- or if NINS > 1.56 million (10.6% vs. 4.8%, OR adjusted 2.33 [1.05, 5.69], p = 0.04)
- and if NIMS and NINS are above the previously described thresholds (3.9% vs. 10.7%, OR adjusted 3.37 [1.22, 7.97], p = 0.02).

Limitations, reasons for caution: It's a monocentric study, and we only included mono-follicular cycles. Only a few centers use David classification to improve sperm morphology.

Wider implications of the findings: We demonstrated the value of IUI in women aged 35 and over when spermatic parameters allow to reach the thresholds previously found, with rates of progressive pregnancy per cycle higher than 10%, which is the equivalent of pregnancy rates, reported in the general population in IUI, regardless of the age.

Trial registration number: not applicable.

P-114 New computational approach for the analysis of quantitative proteomics: Identification of patient-specific altered pathways in seminal fluid from infertile men

D. Delgado-Dueñas[1], F. Barrachina[1], A. Soler-Ventura[1], J.L. Ballescà[2], R. Oliva[1], M. Jodar[1]

[1]Molecular Biology of Reproduction and Development Research Group- Department of Biomedical Sciences- Faculty of Medicine- University of Barcelona- Institut d'Investigacions Biomèdiques August Pi i Sunyer IDIBAPS- Barcelona- and Biochemistry and Molecul
[2]Hospital Clinic, Clinic Institute of Gynaecology- Obstetrics and Neonatology-, Barcelona, Spain

Study question: Could novel computational methods to analyze quantitative proteomic data be designed to seek for patient-specific altered pathways in seminal fluid?

Summary answer: Patient-specific altered protein pathways in seminal fluid were determined in individual infertile patients, by identifying deregulations in the stable-correlated proteins established in the control population.

What is known already: The current classification of infertile men is limited to the evaluation of seminal parameters. However, a wide range of factors alters both sperm and seminal fluid compositions, leading to a high heterogeneity within patients sharing the same phenotype. Quantitative proteomics analyses provide a valuable tool in the field of male reproduction to identify proteins in semen as biomarkers to better stratify the different subgroups of infertile patients. Nevertheless, no candidates were validated to date, probably due by the misclassification of the patient groups. Novel approaches for data analysis are demanded to overcome these limitations.

Study design, size, duration: Quantitative proteomic data derived from the TMT-10Plex isobaric labeling followed by mass spectrometry identification of 16 samples of seminal plasma were used for this computational methodology. The samples were separated in four groups according to the World Health Organization criteria: 4 normozoospermic patients with normal seminal parameters (NZ), 4 oligozoospermic patients with low sperm concentration (OZ), 4 asthenozoospermic patients with altered sperm motility (AS) and 4 azoospermic patients (AZ) without presence of sperm cells.

Participants/materials, setting, methods: Stable-correlated proteins were determined in each group of patients by applying the following statistical principle: 2 proteins (with more than 1 peptide quantified each) were highly-correlated when ≥90% of their peptides has a Pearson correlation coefficient ≥0.9. The repetition of this analysis with control group samples (NZ) by adding a case sample once a time allows determining changes on the control profile of stable-correlated proteins, leading to the identification of deregulated pathways in individual samples.

Main results and the role of chance: A total of 1175 correlations comprising 78 different proteins were identified in the control population (NZ). Interestingly, BASP1, a protein required for the activation of the oocyte, showed the highest number of correlations with other proteins (58). In contrast, the number of identified stable-correlated proteins was drastically reduced in patients presenting altered seminal parameters (126 in AS, 0 in OZ and 6 in AZ). These results reflect the high heterogeneity present in infertile patients, as well as the multiple causes that might be affecting to the seminal parameters. To overcome these limitations we used the methodology mentioned above to assess potential specific-altered pathways in individual patients. The repetition of the analysis after adding patient AS-2 to the control group resulted in few changes in the stable-correlated proteins profile. This suggests that AS-2 contains a seminal plasma protein signature similar to the control group. Interestingly, this patient was taking MACA, an herbal supplement considered to improve male fertility. In contrast, when this analysis is repeated by adding other patients one by one, deregulations in specific pathways are revealed: glycolysis for AS-1, OZ-1, AZ-1 and AZ-2, the response of oxygen reactive species for AS-4, and the complement system for OZ-3 and AZ-4.

Limitations, reasons for caution: This computational statistical study has been conducted with a small sample size. It is considered a first pilot study to design the algorithms that will be used in a wider sample population.

Wider implications of the findings: This study represents the first step for the generation of new methodologies leading to the identification of patient-specific molecular deregulations. This would contribute to an improvement in the classification of the infertile patients, as well as to the achievement of a personalized medical care in the treatment of infertility.

Trial registration number: N/A.

P-115 Comparison of ICSI outcomes with hypo-osmotic swelling (HOS) reactive sperm and motile sperm on sibling oocytes in patients with severe asthenospermia

C. Çakır[1], I. Kasapoglu[2], S. Saribal[1], G. Uncu[2], B. Avci[1]

[1]Uludag University Faculty of Medicine, Histology and Embryology, BURSA, Turkey
[2]Uludag University Faculty of Medicine, Obstetric and Gynecology, Bursa, Turkey

Study question: Is there any difference between motile sperm and immotile HOS reactive sperm from fresh/frozen and ejaculate/testicular sperm samples in terms of embryo development?

Summary answer: Since the effect of using HOS reactive or motile sperm on fertilization rates, HOS reactive sperm can be used in asthenospermic patients.

What is known already: Considering that the prevalence is approximately 18% for isolated asthenospermia and abouth 63% for asthenospermia associated with oligospermia or teratospermia; this cases have a great importance for ART centers. It is known that the motility and viability of spermatozoa and their origin from ejaculate or testicular biopsies are important predictors in terms of fertilization, pregnancy and live birth rates. In order to improve the outcome of ICSI in these cases, various methods have been described for the selection of the immotile but viable spermatozoa.

Study design, size, duration: A retrospective cohort study was performed using database of University affiliated Assisted Reproductive Technology Center from 2011 to 2017. The inclusion criteria were patients with isolated male infertility etiology (total motile sperm count<10% from ejaculate or testicular biopsies) under the age of 39 (male/female) and ICSI cycles in which the total number of oocytes was higher than the total motile sperm counts in order to compare both motile and immotile sperm results in sibling oocytes.

Participants/materials, setting, methods: 491 oocytes obtained from the 49 cycle were evaluated. Considering that the injected sperm was motile (Group 1) or immotile HOS reactive(Group 2) study groups were formed. Each groups divided in 4 subgroups according to sperm sample type (fresh or frozen) and origin (ejaculate or TESE). If the absence of motile sperm, HOS reactive sperm had to chosen for ICSI. Fertilization, implantation, live birth, cleavage (CQS) and blastocyst quality score (BQS) were compared throughout individual embryos.

Main results and the role of chance: The total fertilization rate was 43.1% (n = 211) and there was no differences in group 1 (47.5%, n = 105) compared with group 2 (39,4%, n = 106) including comparison between ejaculate and

TESE subgroups. When fresh or frozen sperm samples in Group 2 were considered, the fertilization rate of fresh ejaculate sperm was significantly higher than frozen ejaculate sperm (46.2% vs 10.0%, p = 0.02), while there was no significant difference in the fertilization rates between fresh and frozen testicular sperm (50.4% vs 43.3%, p = 0.42). When quality scores of embryos obtained by using motile or immotile HOS reactive sperm with randomized sibling oocytes were evaluated, there was no significant difference between day2 CQS, day3 CQS and day5 BQS between the two groups. According to the number of transferred embryos (n = 74), there was no difference between group 1 (51.4%, n = 38) and group 2 (48.6%, n = 36) (p = 0.26). The implantation and live birth were only achieved when fresh testicular sperm had been used. 4 live birth were achieved with fresh/immotile HOS reactive/TESE sperm and 1 pregnancy was achieved with fresh /motile /TESE sperm.

Limitations, reasons for caution: The limitations of the study were the small sample size and HOS test could not be confirmed with different methods of selecting viable sperm from among immotile sperms. The main disadvantages of HOS test is related to false positive as well as false negative results.

Wider implications of the findings: There is no difference between motile sperm and HOS reactive sperm in terms of clinical outcome in ICSI cycles. In contrast to testicular sperm, HOS test could not predict spermatozoa viability following freezing / thawing procedure of ejaculate sperm.

Trial registration number: The study is not a clinical trial.

P-116 Human sperm protein extraction for proteomic analysis: Effect of different lysis buffer on quality and quantity of extracted proteins

T. Rezaei Topraggaleh[1], S.M.J. Taher Mofrad[1], P. Rahimizadeh[1], S. Mirshahvaladi[2], N. Ziarati[1], A. Shahverdi[1], G. Hosseini Salekdeh[2]

[1]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR, Department of Embryology, Tehran, Iran
[2]Cell Science Research Center- Royan Institute for Stem Cell Biology and Technology- ACECR, Department of Molecular Systems Biology, Tehran, Iran

Study question: Are there quantities and qualities variation in human sperm proteins extracted with different lysis buffer?

Summary answer: Lysis buffer containing Urea/triton yielded higher levels of the proteins with better quality in human sperm cell.

What is known already: Molecular studies in protein level of sperm is increasing due to the crucial role of proteins in normal functions of spermatozoa. High purity and concentration of extracted protein is essential for protein analyses. Based on the types of the cells and intended proteomic approaches, proper lysis buffer must be selected. The specific lysis buffer should be considered for sperm protein extraction because of the special features of sperm such as high amounts of membrane associated proteins and intensive nuclear compaction.

Study design, size, duration: In this experimental study, the semen samples of 70 normozoospermic men who referred to Royan institute for assisted reproductive treatments were collected between April 2017 and November 2017.

Participants/materials, setting, methods: This study comprised two experiments. At the first, the pooled semen samples were divided to the seven equal groups and diluted in urea/ thiourea, urea/ nonidet P-40 (NP40), urea/ sodium dodecyl sulfate (SDS), urea/triton, RIPA, Trizol and Qiagen kit lysis buffers. The extracted proteins were quantified through the Bradford assay and SDS-PAGE. In second experiment, the subcellular localization of specific proteins which extracted with high yielded lysis buffers, were quantified by western blotting.

Main results and the role of chance: In the first experiment, the protein concentration was significantly high in urea/ thiourea, urea/ NP 40, urea/ SDS and urea/triton lysis buffers in compared to the others. The highest yield of the proteins was related to urea/triton which was not significantly different between four mentioned lysis buffers. In the second experiment, the expression of cytoplasmic (β actin, α tubulin, GAPDH, Lactate dehydrogenase C, heat shock protein 60) and mitochondrial (Malate dehydrogenases, and ATP synthetize 5 A) proteins were not significantly different, although the expression level of nuclear protein such as histone H3 and membrane associated protein like pan cadherin were higher in urea/SDS and urea/triton lysis buffers respectively.

Limitations, reasons for caution: Lower concentration of the extracted proteins in some lysis buffers such as urea/SDS, was a limited factor for the number of possible replicates in the western blot technique.

Wider implications of the findings: According to our results, urea/triton lysis buffer could be a proper suggestion for extraction of whole sperm proteins. However, other lysis buffers would be suitable for extraction of specific proteins that are localized in the particular subcellular regions.

Trial registration number: 0

P-117 Testicular sperm retrieval in azoospermic male cancer survivors

F. Adenubi, E. Williamson, M. Davies

University College London Hospital- UCLH, Reproductive Medicine Unit, London, United Kingdom

Study question: Can testicular sperm extraction offer azoospermic cancer survivors a chance for fertility and a possible route to biological fatherhood?

Summary answer: Successful sperm retrieval can be achieved in men who have received intensive chemotherapy treatment, however larger studies are required to determine predictors of success.

What is known already: Sperm cryopreservation is routinely offered to men with cancer prior to undergoing gonadotoxic treatments such as chemotherapy. For children, young adolescents and azoospermic men, cryopreservation prior to treatments may not be possible, and hopes for biological children rest on recovery of sperm following treatments. Azoospermia in adults following treatment modalities can be treated with surgical sperm retrieval techniques (TESE), however success rates in this patient group are unknown and there is not enough data to confirm patient selection for this invasive procedure. We present our experience.

Study design, size, duration: A retrospective case note analysis of 28 patients with a history of past cancer treatment who underwent surgical sperm retrieval for azoospermia at a tertiary fertility clinic within a 3 year period.

Participants/materials, setting, methods: Patients with a history of past cancer treatment who underwent TESE for azoospermia at a tertiary Fertility clinic.

Main results and the role of chance: 28 patients aged 22-66 years (median 37) underwent TESE. The diagnoses included 11 patients with testicular cancers, 6 patients with lymphomas, 3 patients with leukaemia and the remaining 8 patients had other types of cancers. 11/28 (39.2%) had mature sperm successfully retrieved, 16/28 (57.1%) were unsuccessful and 1/28 (3.6%) had partial success (2 grossly abnormal sperm seen). In the testicular cancer group 5/11 (45%) had successful TESE with 3 showing normal spermatogenesis, 1 showing maturation arrest and 1 showing sertoli cell only syndrome (SCOS) upon histological analysis. In lymphoma group, 2/6 (33%) had successful TESE, with histology showing 1 patient with SCOS and 1 with normal spermatogenesis. None of the 3 patients with history of acute leukaemia, total body irradiation and bone marrow transplant had successful TESE. However, 1 patient with history of rhabdomyosarcoma had a successful procedure, indicating the potential for fertility in men surviving intensive treatment modalities. Testicular histology in all unsuccessful TESE showed SCOS in all but 2 patients, the remaining having fibrotic or totally sclerosed tissue. 4 patients with normal spermatogenesis and 1 with maturation arrest indicates that azoospermia in the post-chemotherapy male may be attributed to complications of cancer treatment other than gonadotoxicity.

Limitations, reasons for caution: Although TESE is widely used for patients with cancer, there is little published research studying the outcome of TESE in azoospermic men following chemo/radiotherapy. Larger studies will be required to help in defining the determining predictors of success. Outcome data for use of retrieved sperm in fertility treatments were unavailable.

Wider implications of the findings: Our data shows 39.2% success with TESE for this patient group. This signals an opportunity for this patient group to achieve fertility, including those who have received intensive treatments.

Prospective patients should be counselled for the undetermined success rates, which may remain low in some groups.

Trial registration number: not applicable.

P-118 Adipokines expression in seminal fluid of normal-weight men

[8]Pôle Santé Léonard de Vinci, Centre AMP, Chambray-lès-Tours, France

Study question: The aim of the study was to investigate expression profile of adipokines in seminal fluid of normal-weight men and compare their seminal and plasmatic concentrations.

Summary answer: Adipokines profile expression in seminal and blood plasma is different: many adipokines, including some inflammatory markers, are present in seminal fluid in higher concentrations.

What is known already: Infertility affects 14% of childbearing-age couples and a male causal factor is involved in 20-50% of cases. Unlike women, little data is available about relation between body-mass index and spermatic parameters. It is however known that obesity is associated with impaired male fertility through a decrease of sperm quality. We hypothesized that adipokines, produced by adipose tissue, could interfere with gonadal function. Leptin's role in the interaction between energy metabolism and male reproductive system is well-known. Recently, some novel adipokines have been identified in seminal fluid and their seminal concentration is likely to be correlated with some morpho-functional spermatic parameters.

Study design, size, duration: Seminal and blood samples from 70 healthy men consulting for couple infertility were collected in two Assisted Reproductive Centers (Tours, FERTIPROTECT protocol, n = 32, and Paris, METASPERME protocol, n = 38) between 2015 and 2017. Subjects aged between 20 and 40 years, had normal BMI (20-24,5 kg/m^2) and normal semen analysis according to 2010 World Health Organization guidelines. Men with metabolic disorders were excluded. Informed consent was signed by each participant.

Participants/materials, setting, methods: Adipokines were analysed in seminal fluid and blood plasma using three different methods. First, human adipokine-arrays, testing simultaneously 58 adipokines, were performed on seminal and blood samples from 6 patients enrolled in Tours. The identified adipokines of interest were then quantified by enzyme-linked immunosorbent assay (ELISA) and Western-Blot analysis in the samples from Paris Centre (n = 38) and Tours Centre (n = 20), respectively.

Main results and the role of chance: Preliminary adipokine-arrays (n = 6) showed that blood concentrations of adiponectin, leptin, chemerin and resistin were significantly higher than seminal ones. Interestingly, others adipokines, such as visfatin, vaspin, fibrinogen, IL-8, CCL-2, FGF-19, calgranulin and angiopietin-1, were significantly more expressed in seminal fluid than in blood plasma. These results were confirmed by successive analyses. Western-Blot analysis evidenced that visfatin, FGF-19, VEGF, IL-8, HGF and CCL-2 concentrations were significantly higher in seminal fluid than in blood plasma ($p<0,0001$). Similarly, significantly higher visfatin and IL-6 concentrations in seminal fluid were confirmed by using ELISA assay ($p<0,0001$). On the other hand, adiponectin, leptin, chemerin and resistin were predominantly expressed in blood plasma ($p<0,0001$ for all adipokines, except for resistin, $p = 0,01$), then confirming different adipokines profile expression in seminal fluid and peripheral blood.

Limitations, reasons for caution: Our study shows that adipokine expression in seminal fluid is different from blood plasma. However, the meaning of a predominant expression of some adipokines in seminal fluid, notably including inflammatory markers, remains to be elucidated. We can only speculate that adipokines may play a role in male fertility.

Wider implications of the findings: Different adipokines profile expression in seminal and blood plasma suggests the possibility of a gonadal production or a compartment-specific regulation of adipokines in reproductive tract and peripheral blood. Immunohistochemistry characterisation of adipokines, currently in progress in spermatozoa and different testicular cellular types, could allow us to elucidate adipokines metabolism.

P-119 Association between sperm DNA damage extent, fertilisation and cumulative live birth rates among infertile couples undergoing assisted reproduction treatments

S. Malic Voncina[1], A. Stenqvist[1], M. Bungum[2], A. Giwercman[1]

[1]Lund University, Dept. of Translational Medicine, Malmö, Sweden
[2]Skåne University Hospital, Reproductive Medicine Centre, Malmö, Sweden

Study question: Is there any association between sperm DNA Fragmentation Index and cumulative live birth rate (CLBR) following up to three IVF/ICSI cycles?

Summary answer: If the first treatment was IVF, couples with DFI $\geq^3$20% at initiation of treatment had statistically significantly lower CLBR as compared to those with DFI<20%.

What is known already: Several studies have shown that high DFI is associated with lower chance of live birth, mainly in IVF and, to a less degree in ICSI cycles. However, these observations are made on single IVF/ICSI cycles. From a clinical point of view, it seems most relevant to look at the CLBR following all treatments offered to a couple. In many countries where the IVF/ICSI treatment is supported by the public health service, the couples are offered up to 3 fresh cycles and frozen embryo transfers emerging from these treatments.

Study design, size, duration: The study is a large cohort longitudinal analysis of retrospective data from August 2007 to August 2017 in a tertiary medical centre, at the Reproductive Medicine Centre at the Skåne University Hospital, Sweden. In total 5443 cycles in 2730 eligible consecutively included couples with 1280 children born were analysed.

Participants/materials, setting, methods: All IVF/ICSI treatments (up to 3 fresh plus frozen) offered by the public health care were included. DFI value used for analysis was, assessed by SCSA at the initiation of the treatment. The couples were divided into them starting with IVF and those with ICSI as first treatment. Switching between IVF and ICSI, during the treatment course, were based on standard laboratory parameters, sperm number after gradient centrifugation and fertilisation/good quality embryo in previous cycle(s).

Main results and the role of chance: Using linear regression we found negative association between DFI and fertilization rate for IVF ($p<0.0001$) but not for ICSI ($p = 0.89$).

Using Kaplan-Meier analysis with subsequent log rank test, adjusted for the female age, we found statistically significantly higher CLBR for those with DFI<20% at initiation of treatment as compared to couples with DFI^3 ≥20%, if

the first method used was IVF (56% vs 51%; p<0.02), whereas it was not case if the first treatment was ICSI (54% vs 53%, p = 0.97).

These calculations based on the assumption that patients who did not return for IVF/ICSI cycles would have the same chance of a pregnancy resulting in a live birth as patients who continued treatment. were confirmed by calculations based on assumption that none of the women who did not return for a subsequent cycle would have had a live birth.

Limitations, reasons for caution: Despite our robust methodological approach, the presence of biases related to retrospective design cannot be excluded.

Wider implications of the findings: Our results, demonstrate that selection of the first method for assisted reproduction, based on the results of SCSA analysis, has a statistically significant impact on the CLBR.

Trial registration number: Not relevant.

P-120 Is fertility preservation justified in male patients with congenital adrenal hyperplasia (CAH)?

Study question: Is sperm cryopreservation relevant in patients with congenital adrenal hyperplasia (CAH), especially in those having testicular adrenal rest tumours (TARTs)?

Summary answer: Men with CAH should benefit from a sperm cryopreservation at the onset of puberty, before the occurrence of TART and/or before alteration of sperm parameters.

What is known already: CAH is a genetic autosomal recessive defect in the adrenal steroidogenesis pathway. 21-hydroxylase deficiency is the most common form, leading to glucocorticoid and in more severe cases, mineralocorticoid deficiency associated with androgen excess. The clinical phenotype is classified classic (with or without salt-wasting) for the severe form or non-classic for the mild form. In men with CAH, infertility is an important complication in which (TARTs) are the most frequent cause. TARTs can strongly contribute to the occurrence of oligospermia or azoospermia through an obstructive or a deleterious paracrine effect. Therefore, several authors have recommended sperm cryopreservation in patients with CAH.

Study design, size, duration: This was a retrospective and observational study including CAH male patients, addressed to the CECOS (sperm bank) of Paris Cochin Hospital between 2008 and 2017 for sperm cryopreservation. Clinical, hormonal and testicular ultrasound data were collected as well as sperm parameters before freezing and after thawing.

Participants/materials, setting, methods: Twenty CAH patients between 15 and 37 years old, with or without TARTs were included. Initial sperm analysis was performed in all patients. Sperm cryopreservation was performed in 15 men and sperm parameters before and after freezing were analysed. Data were compared between the group of patients with TARTs or without TARTs. All samples were analysed according to the WHO 2010 recommendations. The potential use of straws in assisted reproductive technology (ART) was evaluated.

Main results and the role of chance: Mean age of the patients was 22.1 +/- 5.6 years old. 85[i1] % of them had a 21-hydroxylase deficiency, and 75% classified as salt-wasting TARTs were present in 65% of the patients. Median total sperm count (33.8×10^6) and sperm concentration (12.1×10^6 /ml) was low according to the WHO criteria. 25% (5/20) of the patients showed azoospermia and 25% (5/20) showed oligospermia while 50% (10/20) had normal sperm. All patients who were azoospermic had TARTs (5/5). Severe oligozoospermia (<5 M/ml) was significantly more frequently observed than moderate oligozoospermia (between 5 and 15 M/ml) or normozoospermia (>15 M/ml) in patients with TARTs compared to patients without TARTs (p = 0 .04). Sperm concentration and total sperm count were significantly lower in patients with TARTs than in patients without TART (respectively p = 0.02 and p = 0.03). The[DV2] post-thawing sperm progressive motility was significantly lower in all patients (p = 0.001) and particularly in patients with TARTs compared to sperm progressive motility before freezing (p = 0.01). The mean total number of motile spermatozoa per straw was low, at 0.7×10^6, allowing their use only in ICSI in 73% of the patients in case of a future fertility project and regardless to the fertility check-up in the female partner.

Limitations, reasons for caution: CAH is a rare disorder, explaining the low number of patients included. The same id observed in the scientific litterature. Our study was a retrospective observational study and a prospective longitudinal study with a larger sample would be necessary to confirm these first results about sperm cryopreservation in CAH patients.

Wider implications of the findings: We have confirmed that patients with CAH and especially those with TARTs, could have severe altered sperm parameters, with high rate of azoospermia. Sperm cryopreservation should be proposed as soon as possible, before the occurrence of TARTs and/or alteration of sperm parameters, in order to improve their chance to procreate.

Trial registration number: Not applicable.

POSTER VIEWING
Embryology

P-121 Effects of the oral oxytocin receptor antagonist nolasiban on early embryonic development

O. Pohl[1], D. Perks[2], R. Sisti[3], J.P. Gotteland[1]

[1]ObsEva SA, Research and Development, Plan-les-Ouates Geneva, Switzerland

[2]Covance Laboratories Ltd, Reproductive toxicology, Harrogate, United Kingdom

[3]Research Toxicology Centre S.p.A., Reproductive toxicology, Pomezia, Italy

Study question: Nolasiban, an oral oxytocin receptor antagonist, may increase rates of implantation and live-births among patients undergoing ART. The embryonic safety of nolasiban was demonstrated using rat and rabbit models.

Summary answer: Nolasiban showed no teratogenic or embryotoxic effects in rats and rabbits, nor effect on postnatal development and learning abilities of rats at the doses tested.

What is known already: Antagonism of oxytocin receptors may enhance uterine receptivity by decreasing uterine contractions and by improving endometrial perfusion. A meta-analysis of 7 studies showed significant improvements in clinical pregnancy rate after administration of oxytocin receptor antagonist (OTR) atosiban. To enable safe clinical testing of nolasiban, a novel, oral OTR, it is critical to evaluate its effects on early embryonic development.

Study design, size, duration: We administered nolasiban to rats and rabbits from implantation and throughout embryonic development at doses of 0, 37.5, 75 and 125 mg/kg/d and of 0, 125, 200 and 300 mg/kg/day, respectively, to assess fetal safety.

Participants/materials, setting, methods: Purpose-bred pregnant rats (50/group) and rabbits (20/group) were treated daily from gestation day (GD) 6-17 and 7-19, respectively. Females underwent cesarean section before term and external, visceral and skeletal examinations of fetuses were performed.

Additional rat groups were allowed to litter and offspring was assessed for mortality, behavior, learning abilities and reproductive performance.

Main results and the role of chance: Nolasiban had no effect on pregnancy parameters of pre- and post-implantation loss or the number of implantations or live fetuses per female. There were no effects on fetal weight or fetal sex ratio and no malformations. Treatment had also no effect on clinical observations including body weight, food intake developmental hallmarks such as vaginal opening and testes descent, behavior and learning abilities and mating and reproductive performance. The number of observed litters were sufficient to exclude nolasiban effects and in line with international testing guidelines.

Limitations, reasons for caution: The translation of animal findings to man should be made with caution.

Wider implications of the findings: In addition to previously reported peri-implantation safety data, these studies confirm the absence of harmful nolasiban effects on early fetal development, paving the way for developing nolasiban for use in ART. Our findings raise a potential to administer nolasiban beyond the current single-dose administration on the day of embryo transfer.

Trial registration number: N/A.

P-122 Time intervals from the hCG trigger: analysis of different checkpoints and their impact on embryo development, implantation and pregnancy

M. Papayannis[1], A. Demarco[2], G. Terrado Gil[2], C. Bisioli[1], J. Serna[1], M. Gomez Peña[1], M. Rocha[2], I. De Zuñiga[2], L. Kopcow[2], F. Sobral[2], A. Oubiña[2], M. Horton[2]

[1]Pregna Medicina Reproductiva, IVF Lab, Buenos Aires, Argentina
[2]Pregna Medicina Reproductiva, Department of Gynaecology and In Vitro Fertilisation Unit, Buenos Aires, Argentina

Study question: To analyse the impact on reproductive outcome of different time intervals at each stage of an ART procedure, from triggering of final oocyte maturation.

Summary answer: In ICSI cycles, we observed better pregnancy and implantation rates when interval between oocyte retrieval and denudation was < 2.5 hours.

What is known already: Previous reports have observed a greater number of available embryos and a significant increase in fertilization and clinical pregnancy rates when oocyte collection was close or even after 36 h from the hCG trigger. Other authors have also proposed delaying oocyte retrieval to optimize oocyte maturation.

Modifying oocyte incubation time could also affect reproductive outcomes and synchronise nuclear and cytoplasmic maturation. Some authors concluded that the incubation of oocytes approximately 1.5-2 hours between collection and denudation significantly influences the implantation rate.

Study design, size, duration: An initial set of 843 patients performing ART treatment with their own oocytes during a one-year period was reviewed. After exclusion of 145 patients with less than 3 oocytes retrieved, a cohort of 679 patients was analysed. Among them, 336 underwent ICSI and 343 conventional IVF insemination. We analysed the number of oocytes retrieved, the maturity rate, fertilisation rate, and blastulation rate, as well as implantation and clinical pregnancy rates at different time intervals.

Participants/materials, setting, methods: Patients were grouped into the following time-intervals:

(1) hCG trigger to oocyte retrieval (<35 and >35 h; early and late retrieval)
(2) oocyte retrieval to denudation (<2.30 and >2.30 h)
(3) denudation to ICSI (<10 and >10 min)
(4) oocyte retrieval to IVF (<2 and >2 h) and.
(5) administration of hCG to IVF or ICSI (<38 and >38 h).

Continuous variables were compared by T-test; categorical variables were compared by X^2 test.

Main results and the role of chance: One hundred and eighty seven patients (early retrieval group) and 492 (late retrieval group) were compared, showing similar age (37.7 ± 4.0 vs. 37.3 ± 3.8, p = 0.17) and total number of eggs retrieved (8.4 ± 6.2 vs. 9.2 ± 6.1, p = 0.12). In ICSI cycles, we observed a higher number of good quality embryos on day 3 (54.2% vs. 63.1% p = 0.002), and better blastocyst development (41.4% vs. 48.9% p = 0.0006) in the late retrieval group, which also showed a trend towards better oocyte maturity rate, although not significant (p = 0.06). Also in ICSI cycles, there was an increase in clinical pregnancy (42.3% *vs.* 23.2%, p = 0.005), ongoing pregnancy (34% *vs.* 19.6%, p = 0.03) and implantation rates (28% *vs.* 16%, p = 0.007) when time between oocyte collection and denudation was less than 2 h 30 min. These differences between groups were not present in IVF cycles, were both groups showed comparable outcomes. This could be related to the fact that the exact timing of fertilisation events and gamete fusion are difficult to evaluate and cannot be determined precisely.

Limitations, reasons for caution: This is an analysis of time intervals in an unselected population, where most retrievals were done in a narrow window between 35 and 36 hours of hCG trigger. Subtle differences between patients or undetected premature luteinization could affect these results.

Wider implications of the findings: Even a slight flexibilization of the trigger timing can have a substantial impact on treatment outcome because it has an influence on oocyte maturation and quality. Nonetheless, extending the culture of the oocytes prior to ICSI could have a negative effect, potentially linked to the premature ageing of the oocyte.

Trial registration number: Not applicable.

P-123 Comparing early embryo morphokinetics between patients with lower and normal ovarian response by using time-lapse microscopy in assisted reproductive technology

E. Alexopoulou[1], A. Bisgaard Pinborg[2], A. Zedeler[1]

[1]Hvidovre Hospital, 455 Fertility Clinic, Hvidovre, Denmark
[2]Hvidovre Hospital, Department of Obstetrics/Gynaecology, Hvidovre, Denmark

Study question: Are there differences on early embryo morphokinetic parameters and cleavage stage patterns between patients with a low and normal ovarian response to controlled ovarian stimulation?

Summary answer: We did not find any statistically significant difference in early morphokinetic parameters and cleavage patterns between the two patients groups.

What is known already: In the era of time-lapse microscopy (TLM) and elective single embryo transfer, early embryo morphokinetic parameters seem to play a significant role to select the embryo with the highest implantation potency. Patients with a low ovarian response have fewer fertilized oocytes hence fewer embryos for transfer than the normal responders. Little is known about embryo developmental patterns in low responders compared with patients with a normal ovarian response and if a similar morphokinetic model can be applied in both groups.

Study design, size, duration: Retrospective study on early embryo morphokinetics and cleavage patterns in 606 oocytes, where 435 oocytes derived from 47 patients with a normal ovarian response and 171 oocytes derived from 47 patients with a low ovarian response. Data were collected from May 2015 to November 2017 and extracted from our Embryoscope database.

Participants/materials, setting, methods: Number of aspirated oocytes and AMH were used to allocate patients into two groups. Low responders had AMH ≤ 7.8 pmol/L and less than 7 oocytes, while normal responders had AMH 10-35 pmol/L and 8-15 oocytes. Time of PN fading (tPnf), time to two cells (t2), three cells (t3), four cells (t4), asynchrony in 2nd cell cycle (S2), fragmentation, multinucleation, direct cleavages from 1-3 cells, reversed cleavage, rolling and non-tetrahedral shape were recorded.

Main results and the role of chance: Student's t-test was used to compare the timings between the groups and Chi-square test to compare proportions. The parameters that did not follow the normal distribution were analyzed with Mann- Whitney U-test. The timings of the early cell divisions did not differ statistically (p-value >0.05) between the low and normal responder group (t2: 29.0 h vs 28.1 h, t4: 40.4 h vs 39.6 h). Additionally, no statistically significant difference was observed for irregular cleavage patterns (26.5 % vs 35.1 %), multinucleation (53.8 % vs 53.4 %), fragmentation and non-tetrahedral shape rate at the 4-cell stage. The groups did not differ regarding fertilization and cleavage rate as well as the number of embryos that fulfill the ESHRE criteria for top quality characteristics on Day 2.

Limitations, reasons for caution: The retrospective nature of the study and the small number of patients limit the potential power. Prospective studies are required to confirm the validity of our results.

Wider implications of the findings: It is reassuring for patients with lower ovarian response and for clinicians to know that embryos derived from these patients are not prone to more prolonged and abnormal cleavages than the embryos from normal responders. Also, the use of a similar time-lapse morphokinetic model for both groups is possible.

Trial registration number: Not applicable.

P-124 Comparison of neonatal outcomes of births conceived from day 1 rescue ICSI and conventional ICSI cycles

M. Li, F. Xue

Peking University Third Hospital, Center of Reproductive Medicine, Beijing, China

Study question: Are the neonatal outcomes of births conceived from day 1 rescue ICSI different from births generated during conventional ICSI cycles?

Summary answer: neonatal outcomes of births conceived from day 1 rescue ICSI were comparable with the births generated during conventional ICSI treatment, including the incidence of abnormalities.

What is known already: A limited number of reports on day 1 rescue ICSI children are currently available; the available data and a systematic study are lacking.

Study design, size, duration: The study was a retrospective analysis of 74 singletons born from day 1 rescue ICSI cycles in fresh cleavage-stage embryos transfers, 38 singletons in frozen-thawed cleavage-stage embryo and 71 singletons in frozen-thawed blastocyst-stage embryo.To evaluate day 1 rescue ICSI on neonatal outcome, comparison groups (conventional ICSI) were used: 148 singletons born in fresh cleavage-stage embryos transfers 56 singletons in frozen-thawed cleavage-stage embryo and 142 singletons in frozen-thawed blastocyst-stage embryo.

Participants/materials, setting, methods: Conventional ICSI cycles were chosen as a control group to exclude possible influences of the insemination technique. To eliminate the effects of age, the female ages were matched between rescue ICSI cycles and conventional ICSI cycles (one rescue ICSI cycle was matched with two conventional ICSI cycles).

Main results and the role of chance: No significant differences were found between rescue ICSI cycles and conventional ICSI cycles with respect to the birth weight of singletons (3334.99 ± 338.59 g vs. 3331.52 ± 511.70 g) and gestational age (39.04 ± 1.44 vs. 38.61 ± 1.86 weeks) in fresh cleavage-stage transfers, and there were no significant differences with respect to the birth weight of singletons (3352.14 ± 599.33 g vs. 3406.21 ± 474.17 g) and gestational age (38.69 ± 1.47 vs. 39.09 ± 1.32 weeks) in frozen–thawed transfers and no significant differences with respect to the birth weight of singletons (3526.06 ± 434.15 g vs. 3505.90 ± 421.43 g) and gestational age (39.23 ± 1.54 vs. 38.88 ± 1.54 weeks) in blastocyst-stage transfers. Rate of congenital birth defects of the rescue ICSI group were similar to those in the conventional ICSI groups.

Limitations, reasons for caution: Additional cases are in need of study, especially with respect to the long-term health and development of day 1 rescue ICSI children.

Wider implications of the findings: The current study showed that the neonatal outcomes of births conceived from day 1 rescue ICSI are comparable with conventional ICSI treatment. Additional cases are in need of study, especially with respect to the long-term health and development of day 1 rescue ICSI children.

Trial registration number: The study was approved by the Ethics Committee of Peking University Third Hospital (reference no. 20080612) and all patients signed written informed consent.

P-125 Identifying general markers of human cumulus cells enables precise analysis for predicting human oocyte quality

M. Tsuneto, K. Yumoto, J. Yamauchi, S. Miyazaki, M. Nakaoka, I. Matsumoto, H. Moriwaki, Y. Kai, K. Iwata, Y. Mio

Mio Fertility Clinic, Reproductive centre, Yonago, Japan

Study question: Are flow cytometric analyses useful in detecting the biological features of cumulus cells relevant to predicting oocyte quality?

Summary answer: We successfully identified several general markers of human cumulus cells that could be used to sort and characterize these cells.

What is known already: Many studies have tried to predict oocyte quality by analyzing the surrounding human cumulus cells. For example, transcriptomic analyses identified candidate genes expressed in cumulus cells that were related to oocyte quality. However, the results of such studies remain controversial. As proposed by us in 2017 at the annual ESHRE meeting, several specific markers of cumulus cells must be identified for precise analysis and quality assessment of oocytes to avoid irrelevant information from contaminating peripheral blood cells and dead cells.

Study design, size, duration: From June 2016 to October 2017, cumulus cells were collected from intracytoplasmic sperm injection-treated patients who provided informed consent. The total number of patients was 26.

Participants/materials, setting, methods: The age of patients ranged from 30 to 47 years. After hyaluronidase treatment of the cumulus-oocyte complexes (COCs), cumulus cell samples were collected for staining with antibodies and analysis by flow cytometry (Gallios, Becton-Dickinson, USA). In cases where patients provided more than 2 COCs, the cumulus cells derived from the COCs were pooled. Alternatively, to compare the character of cumulus cells from individual COCs, cumulus samples from each COC were separately prepared.

Main results and the role of chance: The cumulus cell samples collected included 63.1% ± 15.95% dying/dead cells, indicated by staining with propidium iodide (PI). The PI-negative living cells contained10.7% ± 9.52% CD45-positive blood cells and CD235a-positive erythrocytes, suggesting contamination of the suspension by surrounding blood cells during oocyte retrieval. After screening out the blood cells by flow cytometry, the remaining non-hematopoietic cells expressed CD49a, activated leukocyte cell adhesion molecule, CD49f, and CD56 on the cell surface.

By further isolating the $PI^{-}CD45/CD235a^{-/dull}CD49f^{+}$ cells, cumulus cells were purified and confirmed by expression the Cyp19a1 gene using real time RT-PCR. Expression comparisons of these surface proteins on cumulus cells from individual COCs showed no remarkable differences, even in the presence of distinct oocyte developmental outcomes. Furthermore, by using JC-1 dye as a mitochondrial potential sensor, we could stain mitochondria in the cumulus cells.

These results suggest that flow cytometry and cell sorting are useful for precise analyses of cumulus cells.

Limitations, reasons for caution: The current work involves only a small number of samples, and large-scale analyses of cumulus cells should be done in the future.

Wider implications of the findings: Purification of human cumulus cells hold the promise of enabling precise transcriptomic analysis. In addition, flow cytometric analysis itself could provide simple screening of the condition of human cumulus cells associated with prediction of oocyte quality.

Trial registration number: Not applicable

P-126 Laboratory factors affecting the occurrence of multinucleated blastomeres

N. Aono[1,2], E. Sagara[2], Y. Ogura[2], N. Okuyama[2], N. Oka[2], R. Obata[2], T. Hashimoto[2], K. Kyono[1,2]

[1]Kyono ART Clinic, Obstetrics and Gynecology, Sendai, Japan
[2]Kyono ART Clinic Takanawa, Obstetrics and Gynecology, Tokyo, Japan

Study question: Do clinical and laboratory factors have an influence on the occurrence of multinucleation?

Summary answer: The occurrence of multinucleation among human embryos may be affected by laboratory factors such as culture media.

What is known already: Multinucleated blastomere (MNB) is a nuclear abnormality, and has been reported to be associated with poor embryo development and low implantation rates. Accordingly, embryos with MNB are usually not the first choice for embryo transfer. Furthermore, it has been reported that the frequency of MNB is high in human embryos cultured in vitro, and it

may have an effect on the development of aneuploidy among human embryos. However, it is unclear what kinds of factors have an impact on the development of MNB. We aimed to investigate whether clinical and laboratory factors may affect the occurrence of MNB embryos.

Study design, size, duration: This is a retrospective observational study conducted at Kyono ART clinic Takanawa in Japan from January 2015 to April 2017. A total of 1509 embryos from 302 cycles of 189 patients were included in this study. All embryos were monitored by time-lapse cinematography.

Participants/materials, setting, methods: We compared the backgrounds of the embryos which had at least one MNB between day 1 to day 3 embryo culture for age factor, fertilization method (c-IVF or ICSI), ovarian stimulation protocol (GnRH antagonist, agonist long, agonist short and others) and culture media (two different single culture media). Chi-squared and Fisher's test were used for statistical analysis. A P value of less than 0.05 was considered statistically significant.

Main results and the role of chance: The overall incidence of MNB was 33.7% (509 / 1509). MNB embryos showed lower blastulation rates (50.7%) compared to non-MNB embryos (55.9%), although this was not statistically significant ($P = 0.055$). The good morphology blastocyst (Gardner's grade 3BB or more) formation rate in the MNB embryos was significantly lower (18.3%) than that of the non-MNB embryos (25.1%) ($P = 0.003$). There was no significant difference in the MNB occurrence rate in terms of age factor (patients aged under 40 y.o. vs over 40 y.o.; 35.5% vs. 31.2%), and fertilization method (c-IVF vs ICSI; 33.6% vs. 33.8%). Also, there was no significant difference in MNB rate in terms of ovarian stimulation protocols. Culture media tended to have an impact on MNB incidence rate (media A vs B; 16.2% vs. 27.5%, $P = 0.067$) although this was not statistically significant.

Limitations, reasons for caution: The small sample size may have influenced these results. The details of culture media which have affected MNB is unclear.

Wider implications of the findings: MNB affects subsequent developmental potential of embryos, and these events may be affected by laboratory factors such as culture media. MNB formation may be related to an increase in aneuploidy rate and mosaic formation rate by using different culture media.

Trial registration number: not applicable.

P-127 Blastocyst development rates of embryos with morphokinetic variables and the effect of morphokinetic variables on clinical pregnancy rates in vitrified-warmed single blastocyst transfers

Y. Hur[1], E.K. Ryu[1], S.H. Yoon[2], K.S. Lim[1], W.D. Lee[1], J.H. Lim[1]

[1]Maria Fertility Hospital, IVF-ET Center 2, Seoul, Korea- South
[2]Maria Research Center, Research center, Seoul, Korea- South

Study question: How many embryos exhibiting morphokinetics variables could develop up to blastocyst stage? And how much the blastocysts were affected by morphokinetics variables on pregnancy?

Summary answer: The blastocyst development rates of embryos with morphokinetic variables were more than 40% and the clinical pregnancy rates of the blastocysts vitrified-warmed were adversely affected.

What is known already: In time-lapse cultures, morphokinetic variables are used to refer to two concepts; morphological assessment parameters and morphokinetic assessment parameters. Morphological assessment parameters include uneven pronuclei, blastomere, and multinucleation etc. Morphokinetic assessment parameters include direct division, reverse division, and rapid division etc. Morphokinetic variables generally have a fatal influence on the embryo development, implantation and pregnancy rates in fresh cycles. There are a few reports on the impact of various morphokinetic variables on blastocysts developments; and, there are a few reports on the effect of morphokinetic variables on vitrified-warmed blastocyst transfer cycles.

Study design, size, duration: Morphokinetic variables include uneven pronuclei, blastomere, multinucleation, and direct division, rapid and irregular division. Regularly developed embryos which are not observed in any kind of morphokinetic variables were compared with the embryos observed in morphokinetic variables. We conducted a review between January 2014 and November 2017. During the same period, the clinical pregnancy rates of the single blastocysts vitrified-warmed were determined and the effects of each type of morphokinetic variables on pregnancy rates were observed.

Participants/materials, setting, methods: Embryos were monitored in a time-lapse incubation system (embryoscope). Embryos were selected for transfers on day 3 or day 5, and surplus embryos were cultured for blastocyst development. The blastocysts were evaluated according to the blastocyst scoring system, and blastocysts graded 3BB or higher were cryopreserved. Vitrification and thawing processes were performed as lab protocols. In thawed blastocysts, they were graded CC or higher and were used for embryo transfers.

Main results and the role of chance: The blastocyst development rate and freezing rate of regularly developed embryos were 56.6% (2116/3739) and 45.1% (1687/3739) respectively. Uneven pronuclei were 43.4% (189/435) and 31.7% (138/435) respectively. Uneven blastomere were 55.9% (137/245) and 42.4% (104/245) respectively. Multinucleation were 53.5% (423/790) and 40.1% (317/790) respectively. Direct division were 40.2% (146/363) and 27.0% (98/363) respectively. Rapid division were 56.8% (162/285) and 39.3% (112/285) respectively. And, irregular division were 43.9% (94/214) and 24.3% (52/214) respectively. The blastocyst development rates of embryos with morphokinetic variables were lower than regularly developed embryos, but the blastocyst development rates of embryos with morphokinetis variables were more than 40%. The clinical pregnancy rate of regularly developed single blastocyst that vitrified-warmed was 37.7% (60/159). Uneven pronuclei were 20.0% (2/10). Uneven blastomeres were 10% (1/10). Multinucleation were 18.8% (6/32). Direct division was 6.3% (1/16). Rapid division was 0.0% (0/9). And, irregular division was 0.0% (0/5). The clinical pregnancy rates of single blastocyst with uneven pronuclei, blastomere and multinucleation were lower than a regularly developed single blastocyst. The clinical pregnancy rates of single blastocyst with direct, rapid and irregular divisions were much lower than a regularly developed single blastocyst.

Limitations, reasons for caution: In this study, it was possible to assess the effect of morphokinetic variables on pregnancy rates. However, further studies will be required to accumulate sufficient data to determine the effects of each type of morphokinetic variables on pregnancy, delivery, and congenital anomaly rates.

Wider implications of the findings: More than 40 percent of embryos exhibiting morphokinetic variables could develop up to blastocyst stages in the time-lapse system. Therefore, it was important that freezing the embryos were to be done carefully, because the embryos with morphokinetic variables were not easy to implant, even if morphology was good after thawing.

Trial registration number: not applicable.

P-128 A prediction model powered by a Group Method of Data Handling (GMDH) algorithm for selecting patients of a single frozen embryo

X. Zhang, T. Dineen, A. Kovacs, R. Mihart, J. O'Callaghan, J. Culligan, A. Tocado, N. Daly, R. Mendez-Vega, D. McAuliffe, M. Walsh, J. Waterstone

Waterstone Clinic, Laboratory, Cork, Ireland

Study question: As frozen embryo transfer (FET) cycles become more common, policies regarding the number of embryos to transfer need to be formulated for individual patients.

Summary answer: Using the most relevant factors relating to patients, embryos and fresh cycle outcomes, this GMDH predictive model can reasonably predict the occurrence of implantation.

What is known already: The introduction of vitrification has improved both embryo survival and FET success and has led to a large increase in routine embryo freezing. The improvement of embryo cryopreservation significantly increases the overall success for superovulation cycle. But a high proportion of twins results after transfer of 2 frozen embryos. Studies from fresh cycles suggested that acceptable pregnancy rates could be

achieved after transfer of a single frozen embryo in selected groups of patients.

Study design, size, duration: A retrospective analysis of all FET cycles carried out at Waterstone clinic between Feb 2012 and Dec 2017 was conducted.

Participants/materials, setting, methods: All embryos in the study had been vitrified on day 5 or day 6. Success rates were compared after transfer of either one or two embryos. SET cycle outcomes were also analysed with the factors which most strongly predicted success after FET. Two statistical models were used: the logistic regression and the GMDH algorithm.

Main results and the role of chance: From Feb 2012 to Dec 2017, a total of 1535 out of 1601 vitrified embryos survived after warming 95.9% and were transferred in 1205 cycles. Two embryos were transferred in 327 FET cycles and one embryo was transferred in 878 cycles. The clinical pregnancy (fetal heart activity at 8/40) rates were 41.9%/ transfer and 33.3%/ transfer for 2-ET vs. 1-ET cycles. The overall implantation rate was 31.4%. The proportion of pregnancies which were twins in the 2-ET group was 37.2%.

A logistic analysis was performed based on SET events to investigate the relationship between the implantation of embryos and different prognostic factors. We identified three prognostic factors that made the most significant contributions to the success of implantation: the woman's age, the quality of the inner cell mass (ICM) and the success or failure of the fresh cycle from which the frozen embryos derived. The predictive ability of the model measured by the area under the receiver operating characteristic (ROC) curve was 0.61 when using logistic analysis. Prediction ability was significantly improved by application of a GMHD algorithm which increased the ROC to 0.67 with the negative and positive predictive value of 70.5% and 76.9%.

Limitations, reasons for caution: This prediction model may be benefited by including uterine factors. Prospective studies are now required to confirm the clinical validity of the model.

Wider implications of the findings: Application of this GMHD algorithm may help in the decision making by accurately predicting success. It should identify patients for whom single embryo transfer is indicated and a smaller number of patients for whom a 2-embryo transfer would be wiser.

Trial registration number: na.

P-129 Polar body transfer in a mouse model to overcome transmission of mitochondrial diseases

M. Tang, R.R. Guggilla, P. Stamatiadis, M. Ferrer-Buitrago, V. Thys, M. Van der Jeught, P. De Sutter, B. Heindryckx

Ghent University Hospital Ghent Fertility and Stem cell Team, Department for Reproductive Medicine, Gent, Belgium

Study question: Can polar body transfer (PBT) serve as an efficient type of germline nuclear transfer (NT), to overcome mitochondrial diseases?

Summary answer: This mouse model study supports the efficient use of first (PB1) polar body transfer for overcoming mitochondrial DNA (mtDNA) disorders.

What is known already: Since mtDNA diseases are difficult to treat and manifest with life-threatening consequences, their prevention is a priority. Different germline NT have recently been proposed as novel technologies for preventing mtDNA mutations transmission, including germinal vesicle transfer (GVT), spindle transfer (ST), pronuclear transfer (PNT) and even PBT. Previous mouse studies have revealed full potential of PB1/2 genomes for embryonic development, by replacing female genome of oocytes/zygotes with PB1/2. However, PB2T requires female PN identification in zygotes, which is arduous in human. Therefore, we tested if MII oocytes can be used for both PB1/2T and compared its efficiency with ST and PNT.

Study design, size, duration: In a first set, PB1/2T were carried out in B6D2F1 mice, by introducing PB1/2 into enucleated oocytes (spindle removal, PB1T/novel PB2T) or zygote (female pronucleus removal, PB2T). For controls, ST, PNT and ICSI groups were implemented. In a second set, ST, PNT and routine PB2T were performed between NZB/OlaHsd and B6D2F1 mice for evaluating effect of heterologous NT on embryonic developmental potential. Oocytes/zygotes from B6D2F1 mice served as recipients, while karyoplasts originated from NZB/OlaHsd mice.

Participants/materials, setting, methods: Oocytes/zygotes were from superovulated B6D2F1 and NZB/OlaHsd female mice (6-8 weeks). NT was performed in KSOM-HEPES (2 µg/ml cytochalasin D, 1 µg/ml nocodazole). Karyoplasts were exposed to Sendai virus for fusion with enucleated oocytes/zygotes. One part of ST-, PB1T- and novel PB2T-oocytes were fertilized (ICSI) and exposed to cytochalasin D (only for novel PB2T) to prevent PB2 extrusion. Another part were examined for *de novo* spindle formation through polarized microscopy, and spindle morphology assessment via confocal analysis.

Main results and the role of chance: For homologous NT between B6D2F1 mice, after ICSI, novel PB2T-oocytes showed significantly lower two-cell formation rates compared to ST and PB1T groups (50.0%, 83.8% and 90.0%), but not different with ICSI control (70.6%). For routine PB2T, blastocyst rates (52.2%) were comparable with PB1T group and ICSI control (77.8% and 75.0%, respectively), but these were significant lower than ST- and PNT-embryos (80.6% and 100%, $p<0.05$ and $p<0.005$ respectively). Remarkably, no blastocyst formation could be achieved in the novel PB2T group. Polarized microscopy showed most reconstructed oocytes after novel PB2T contained a visible spindle (22/27, 81.5%) similar to PB1T-reconstructed oocytes (12/17, 70.6%). Confocal analysis, however, revealed that 61.5% of novel PB2T-oocytes displayed an abnormal spindle-chromosome-complex compared to 33.3% in PB1T-oocytes showing aberrant spindles. After heterologous NT from NZB/OlaHsd to B6D2F1 mice, following fertilization, 38.5% of ST-oocytes developed to blastocysts, significantly lower than ICSI control (B6D2F1-oocytes) (72.7%, $p<0.05$) and the homologous ST group (80.6%, $p<0.05$). In heterologous routine PB2T and PNT groups, two-cell rates were similar (69.2% and 83.3%, respectively), whereas PNT-embryos yielded higher blastocyst rates (27.8% vs 100%, $p<0.001$).

Limitations, reasons for caution: Further investigation is currently ongoing to determine whether these NT techniques would alter the genetic and transcriptomic landscape of resulting blastocysts and to assess the mitochondrial carry over level.

Wider implications of the findings: Intra-strain NT in B6D2F1 mice, routine PB1/2T, ST and PNT, did not compromise embryonic development. Novel PB2T could not support blastocyst formation, probably owing to embryonic aneuploidy. Inter-strain NT between NZB/OlaHsd and B6D2F1 mice resulted in declined development in routine PB2T and ST groups contrast with PNT and ICSI controls.

Trial registration number: Not applicable.

P-130 Predictive value of total number of normal morphology and progressively motile sperm on the fertilization failure of short-term insemination in in vitro fertilization

P. Chen, H. Zhang, G. Li, Q. Sun, F. Xiong, J. Huang, Y. Zeng, C. Wan

Shenzhen Zhongshan Urology Hospital, Fertility Center/Institute for Reproduction and Genetics/Shenzhen Key Laboratory for Reproductive Immunology of Preimplantation-, ShenZhen, China

Study question: To investigate the predictive value of total number of normal morphology and progressively motile sperm (TNNPS) on the fertilization failure of short-term insemination.

Summary answer: TNNPS may be considered as a potential parameter for predicting the failure of short-term insemination.

What is known already: Short-term insemination combined with early-rescued ICSI has some advantages in decreasing the incidence rate of fertilization failure. However, some studies suggested that short-term insemination can lead to increase the abnormal fertilization. For the patients treated by short-term insemination and early rescue ICSI, they had to withstand greater economic and mental stress. Therefore, it is necessary to predict the rate of fertilization failure of short-term insemination. TNNPS contains numerous information of semen and has shown to closely related with fertilization failure in IVF and IUI. Therefore, it is potential to be a parameter to predict the failure of short-term insemination.

Study design, size, duration: 2 768 cycles of short-term insemination in our fertility center from January 1, 2013 to March 31, 2016 were retrospectively analyzed. All cycles were divided into four groups by the 25th, 50th, and 75th percentiles of TNNPS, and then the cycles whose TNNPS≤3.0×10^6 were divided into six groups according to the difference of TNNPS and the intercept was 0.5×10^6.

Participants/materials, setting, methods: Comparing the differences of basic medical recording information (such as female age, male age, infertility years, average number of oocytes retrieved and female BMI) and fertilization failure rate among the different groups. Logistic regression was used to determine the influence of female age, male age, infertility years, average number of oocytes retrieved,female BMI and TNNPS≤1.0×10^6 on fertilization failure.

Main results and the role of chance: For all the cycles, no significant differences were found in the basic medical record information(P>0.05)among 4 groups. However, the insemination failure rate of group 1(23.27%, TNNPS:0~2.76×10^6) was significantly higher than that in group 2(9.83%, TNNPS:2.76~7.21×10^6), 3(9.83%, TNNPS:7.21~16.31×10^6), and 4(5.92%, TNNPS:16.31~149.61×10^6) (P<0.05). For the cycles that TNNPS≤3.0×10^6, no significant difference was found in the basic medical record information (P>0.05) among 6 groups. However, both the insemination failure rate of group I (43.31%, TNNPS:0~0.5×10^6, n = 157)and group II (28.79%, TNNPS:0.5~1.0×10^6, n = 132)were significantly higher than that in group III (12.84%, TNNPS:1.0~1.5×10^6, n = 148), IV (14.04%, TNNPS:1.5~2.0×10^6, n = 114), V (16.50%, TNNPS:2.0~2.5×10^6, n = 103) and VI (11.34%, TNNPS:2.5~3.0×10^6, n = 97)(P<0.05). Analysis of logistic regression demonstrated that TNNPS≤1.0×10^6(OR: 25.422; 95% CI: 17.702-36.508) had significance differences for predicting the fertilization failure of short-term insemination.

Limitations, reasons for caution: If patients with TNNPS≤1×10^6 treated by short-term insemination, they may have a higher risk of fertilization failure. Thus, it may be more favorable if those patients would be benefited by changing treatment program from IVF to ICSI. However, currently we lack the relevant data to support our conjecture.

Wider implications of the findings: TNNPS may be regarded as an index for predicting the failure of short-term insemination. For the patients treated by short-term insemination with TNNPS≤1.0×10^6, they have a higher risk of fertilization failure.

Trial registration number: None.

P-131 Comparative effectiveness of a universal warming/dilution approach to blastocyst vitrification using two different solutions: A randomized trial

M.C. Schiewe[1], S. Zozula[2], R. VanTol[2], A. Jones[3], R. Anderson[4]

[1]*Ovation Fertility, ART, Newport Beach, U.S.A.*
[2]*Ovation Fertility, Assisted Reproductive Technologies, Newport Beach, U.S.A.*
[3]*Ovation Fertility, Assisted Reproductive Technologies, Nashville, U.S.A.*
[4]*Southern California Center for Reproductive Medicine, Clinic, Newport Beach, U.S.A.*

Study question: Is the efficacy of vitrified human blastocyst post-warming dilution using a universal sucrose dilution approach comparable to standard manufacturer procedures?

Summary answer: Human blastocysts vitrification is equally effective using a simple sucrose step down dilution approach independent of the type of cryoprotective agent used.

What is known already: Blastocyst vitrification is a global standard in the IVF industry. Numerous vitrification systems are being marketed and successfully used. Each commercial company has its own recommended thawing solution. As more patients move their cryopreserved embryos between laboratories, it has become increasingly difficult and cost inefficient to maintain a stock of different thaw solutions. Although proprietary in formulation, it is safe to assume that all manufactured thaw solutions have one thing in common, declining sucrose concentrations. Sucrose is an effective non-permeating solute that safely removes intracellular cryoprotective agents (EG, DMSO, Glycerol) and allows for isotonic equilibration by gradual rehydrating dilution steps.

Study design, size, duration: Research consented, discard slow frozen (SF) embryos (N = 363; n = 328 cleavage stage, n = 35 blastocysts) were thawed, cultured and fair-good quality blastocysts were randomly assigned within batch groups to 1 of 2 vitrification treatments: 1) control Glycerol/EG solution, I.C.E. >7.9 M;or 2)15% DMSO/15% EG solution. All vitrified blastocysts were warmed rapidly according to standard operating procedures (SOP) then randomly assigned to either stepwise SOP dilution or universal sucrose step down dilution (n = 31 embryos/group; 2×2 factorial arrangement of treatments).

Participants/materials, setting, methods: All vitrified blastocysts were rapidly cooled (>1500°C/min) and warmed (>6000°C/min) in an aseptic closed system. All warmed embryos underwent stepwise dilutions by manufacturer SOP or a universal 4-step sucrose dilution (21°C) of 1.0 M for 5 min and 0.5 M, 0.25 M and 0.125 M for 3 min each before isotonic equilibration for 5 min at 37°C. Embryo survival and development was determined and differences in % survival and continued development were statistically compared by Chi-square analysis (p<0.05).

Main results and the role of chance: Sucrose diluted, SF embryos yielded 124 (34.2%) fair to good quality blastocysts for study revitrification, whether derived from cleaved embryos (n = 113, 34.5%) or blastocysts (n = 14; 40%). Day 5 SF blastocysts had superior sustained development (67%, n = 10 of 15) in contrast to Day 6 (20%, n = 4 of 20), as defined by blastocoele re-expansion and cellular fullness/growth. There were no differences in survival or sustained development of vitrified blastocysts between the combined dilution treatments, whether SOP thawing (93.5%) or standard sucrose dilutions (90.3%) was applied. Interestingly, cryoprotective agent treatments were significant, with 98.4% (n = 61) of the Glycerol/EG treated blastocysts being viable post-dilution and culture compared to 86.9% for DMSO/EG exposure (n = 53). Only a single I.C.E.-sucrose treated embryo degenerated, whereas degeneration occurred in 4 DMSO/EG-SOP and 5 DMSO/EG-sucrose dilution treated embryos. Although some DMSO/EG treated blastocysts appear to be more sensitive to osmotic injury, the overall viability of the intact blastocysts was excellent based on cellular fullness, clarity and growth/re-expansion.

Limitations, reasons for caution: Possible differences in blastocyst quality may have contributed to VTF survivability of blastocyst exposed to the EG/DMSO vitirification solutions, as DMSO exposure to the lipid bilayer of vulnerable trophectoderm cells may be more sensitive to osmotic stress. Alternatively, 30%EG/DMSO solutions may be unstable under closed vitrification/warming conditions, being less reliable.

Wider implications of the findings: This study has demonstrated that a cost-effective "universal" approach involving stepwise sucrose dilutions is an acceptable thawing method for vitrified blastocysts independent of the vitrification solution used. This standardized procedure allows for continuity of patient care within and between laboratories vitrifying embryos by different methods.

Trial registration number: none.

P-132 Effect of l-carnitine supplementation during vitrification of mouse oocytes: a RNA-seqtranscriptome profiling and validation

Y. Wang[1], H. Shen[2], M. Zhang[3], Y. Kuang[1]

[1]*Shanghai Ninth people's hospital affiliated Shanghai Jiao Tong University, Assisted reproduction department, Shanghai, China*

[3]*Renji Hospital affiliated Shanghai Jiao Tong University, Assisted reproduction, Shanghai, China*

Study question: To investigate the protedctive effects of L-carnitine on cell damage of oocytes following cryopreservation-warming

Summary answer: Our data are consistent with L-carinitine enhancing the developmental potential of when used as a supplement during the course of oocyte vitrification in murine model.

What is known already: Supplementation of L-carnitine(LC) during in vitro muturation (IVM) is reported to improve cryotolerance of mammalian oocytes. However, potential side effects of these supplements on transcriptional regulation during cryopreservation are not well understood.

Study design, size, duration: Oocytes collected from C57 female mice (8 to 10-week-old), were divided into 4 groups: LMXB-1 (n = 30, fresh and non-vitrified), LMXB-2 (27 oocytes, vitrified), LMXB-3 (29 oocytes, vitrified +1 mg/ml LC) and LMXB-4 (29 oocytes, vitrification +2 mg/ml LC).

Participants/materials, setting, methods: RNA sequencing and in silico pathway analysis were used to identify differentially expressed genes (DEGs) that

involved in oocyte viability after vitrification. DEGs were also analyzed by constructing regulatory networks and protein-protein interaction (PPI) networks, transcription factor (TF)-miRNA-target, and drug-gene interaction analysis.

Main results and the role of chance: Following parthenogenetic activation, a reduction in apoptosis marker expression in the L-carnitine treated group that was not observed in control groups. Protective effects of LC were also observed in RT-PCR mRNA studies, ATP measurements, and morphology confirming beneficial effects of LC indicated bioinformatics analyses.

Limitations, reasons for caution: The research is only in murine model. Female preservation finially need to be used on human being. The study got the data that L-carnitine could enhance the oocyte's devolopmental potential following cryopreservation-warming.

Wider implications of the findings: Next step, more discarded human oocytes could go through the silimar research to see whether it could be the same results or not. If L-carnitine could enhance human oocyte's developmental potential following cryopreservation-warming, this research could be really beneficial to human being, especially women.

Trial registration number: HKDL 2017-389 from trial experimental ethical inspection Shanghai Ninth people's Hospital affiliated to Shanghai Jiao Tong University, School of medicine.

P-133 Impact of vitrification on human oocytes before and after in vitro maturation (IVM): a systematic review and meta -analysis

M. Mohsenzadeh[1], M.A. Khalili[2], N. Tabibnejad[2], A. Salehi-Abargouei[3], M. Karimi-Zarchi[4]

[1]Gerash University of Medical Sciences, Gerash Research Center, Gerash, Iran [2]Research and Clinical Center for Infertility- Shahid Sadoughi University of Medical Sciences- Yazd- Iran., Research and Clinical Center for Infertility, Yazd, Iran [3]Department of Nutrition- Faculty of Health- Shahid Sadoughi University of Medical Sciences- Yazd- Iran, Department of Nutrition, Yazd, Iran [4]Department of Obstetrics and Gynecology- Faculty of Medicine- Shahid Sadoughi University of Medical Sciences- Yazd- Iran., Department of Obstetrics and Gynecology, Yazd, Iran

Study question: What is the impact of vitrification on human oocytes before and after in vitro maturation?

Summary answer: Oocyte vitrification neither before nor after in vitro maturation (IVM) has not a significant effect on matutration rate, survival rate, fertilization rate and cleavage rate.

What is known already: There are controversies regarding IVM procedure, the time of storing frozen oocytes and maturation stage of vitrified oocytes and its impact on oocytes fertilization capability.

Study design, size, duration: A systematic review with meta-analysis was undertaken. Main search terms were those related key words. We searched Medline, Embase, Scopus and ISI web of science to detect English-language studies. The final search was performed on 27 January 2018.

Participants/materials, setting, methods: The original articles which studied ART outcomes after vitrification of MII or GV oocytes before or after IVM were included. Studies that compared the combination of vitrification and IVM with fresh oocytes were also included. Exclusion criteria were animal trials and the studies that performed cryopreservation using slow-freeze method. Oocyte maturation, survival, fertilization and cleavage rates were assessed. Bias and quality assessments were applied.

Main results and the role of chance: 1102 articles and fifteen studies were included for analysis. Five studies compared laboratory outcomes between oocytes that vitrified at the GV stage and those firstly matured in vitro, and then vitrified. MA showed that vitrification of oocytes at GV stage had a negative impact on maturation rate (RR = 0.78, CI: 0.59-1.04); cleavage rate (RR = 0.93, 95% CI: 0.61-1.42); but not on fertilization rate(RR = 1.01, 95% CI: 0.88-1.18) and survival rate(RR = 0.99, 95% CI: 0.95-1.04). Eight studies compared outcomes between the oocytes that vitrified at GV stage before maturation and oocytes which were matured in vitro without vitrification. MA indicated that oocyte vitrification at GV stage had a significant negative impact on maturation rate (RR = 0.77, 95% CI: 0.65-0.91) and cleavage rate (RR = 0.65, 95% CI: 0.54-0.78). Fertilization rate did not differ between vitrified oocytes at GV stage and directly in vitro matured oocytes without vitrification (RR = 0.99, 95% CI: 0.87-1.11). Only one study compared vitrified in-vivo matured oocytes versus vitrified in-vitro matured oocytes. According to the results, survival rate (RR = 0.94, 95% CI: 0.81-1.09), fertilization rate (RR = 0.83, 95% CI: 0.70-0.98) and cleavage rate (RR = 0.91, 95% CI: 0.82-1.02) were significantly lower in vitrified IVM oocytes. No evidence of publication bias was seen using asymmetry tests with regards to outcomes.

Limitations, reasons for caution: However exact inclusion criteria were used in the design of the systematic review, the included studies are heterogeneous in culture media and laboratory technique.

Wider implications of the findings: In general, oocyte vitrification decreases the consequent maturation rate by 23%. However, maturation rate, survival rate and fertilization rate as well as cleavage rates did not significantly differ between the oocytes vitrified before IVM versus oocytes vitrified after IVM.

Trial registration number: CRD42017054372

P-134 Clinical utility of decorin in follicular fluid as a biomarker of oocyte potential

Y. Sawada, T. Sato, C. Saito, F. Ozawa, Y. Ozaki, M. Sugiura-Ogasawara

Nagoya City University Graduate School of Medical Sciences, Obstetrics and Gynecology, Nagoya city, Japan

Study question: This study investigated whether decorin (DCN) is useful as a biomarker for outcomes of assisted reproductive technology (ART).

Summary answer: The concentration of DCN in follicular fluid (F-DCN) has a possibility to be a biomarker indicating the quality of oocytes collected from the corresponding follicle.

What is known already: In the ovary, previous studies have shown that DCN presents in the connective tissue, follicular thecal compartments, follicular fluid (FF) of ovulatory follicles, and corpus luteum, and plays roles in some important processes such as follicle growth, ovulation, and keeping corpus luteum by regulating growth factors. However the association between DCN and the outcomes of infertility treatment has not been discussed.

Study design, size, duration: A retrospective cohort study involving 88 patients treated with ART because of unexplained infertility was performed at Nagoya City University Hospital between April 2010 and March 2016. Serum, FF and oocytes were collected at ovum pick-up (OPU). FF and oocytes were aspirated and collected from the first punctured follicle of each ovary. Some FF were layered over a Ficoll-Paque gradient. The cell samples in the mononuclear cell layer were cryopreserved as the granulosa cells (GCs).

Participants/materials, setting, methods: F-DCN and the concentration of DCN in serum (S-DCN) was measured by ELISA. The relation between F-DCN and patient's age, Perfusion Index (PI) of the blood flow around the follicle at OPU, the total dose of gonadotropin administered, S-DCN, the concentration of IGF-1 in FF, fertilization, and quality of embryo were analyzed. In addition, immunostaining and western blotting were performed using the granulosa cells to identify existence and localization of DCN.

Main results and the role of chance: A total of 130 oocytes and the corresponding FF and serum samples from 88 patients. F-DCN was 39.26 ng/ml (median value); it was higher than that in serum. Correlations were not observed between F-DCN and patient age, the total dose of gonadotropin administered, IGF-1 concentration in FF, and PI of the blood flow around the follicle. However, F-DCN showed a weak negative correlation with S-DCN ($R = -0.189$; $P = 0.031$). F-DCN of the oocytes fertilized by intracytoplasmic sperm injection (ICSI) was significantly lower than that of oocytes that were not fertilized (33.24 ng/ml vs 40.18 ng/ ml; $P = 0.043$). When a cut-off level of 34.5 ng/ml was set according to the receiver-operating characteristic curve, the fertilization rate of the oocytes from the follicles in which F-DCN was lower than the cut-off level tended to be good compared to that of the oocytes with F-DCN higher than the cut-off level ($P = 0.052$). S-DCN of the good embryos was significantly higher than that of the poor embryos only for those oocytes fertilized by ICSI. DCN is less likely to be produced by GCs, because it was not detected in GCs by immunostaining and western blot analysis.

Limitations, reasons for caution: The sample size was relatively small, which made it difficult to analyze the association between DCN and pregnancy

or birth rate. As the reason for that, our study was limited to patients treated with ART only because of unexplained infertility and FF samples were collected from the first punctured follicles.

Wider implications of the findings: The fertilization rate of oocytes from follicles in which F-DCN was less than 34.5 ng/ml was high, indicating that it is possible to predict the potential of oocytes to be fertilized by examining F-DCN of the corresponding follicle during ICSI. Therefore, it is useful for planning embryo transfer and cryopreservation.

Trial registration number: This study is not registered.

P-135 Morphologic status and angulation of meiotic spindle in vitrification-warmed oocytes of donor bank: effects on the ICSI outcomes

T.H. Chuang, Y.C. Huang, M.J. Lee, H.H. Lai, H.L. Wang, C.L. Hsieh

Stork Ladies Clinic, Stork Fertility Center, Hsinchu, Taiwan R.O.C.

Study question: Do the morphology and angulation of meiotic spindle correlate with the fertilization outcomes after ICSI in vitrification-warmed oocytes of donor bank?

Summary answer: The correlation exists between the spindle morphology and fertilization outcomes, while it does not show between the spindle angulation and fertilization outcomes in vitrification-warmed oocytes.

What is known already: The meiotic spindle is crucial for the fertilization process, including completion of meiosis, second polar body extrusion, formation of pronuclei, and the following mitosis. Since the structure of spindle is dynamic depending on the timeline of oocyte, temperature, and physical stress, characteristics of spindle in the vitrification-warmed oocytes may show different phenomenon with that in the fresh oocytes.

Study design, size, duration: Between June and September of 2017, five hundred and twenty-five oocytes from donor bank were included in the analysis. A total of 37 egg donors were involved: mean age 24.7 ± 3.5 years; body mass index (BMI) 19.7 ± 1.8 kg/m^2; anti-mullerian hormone (AMH) value 7.0 ± 4.2 ng/mL.

Participants/materials, setting, methods: All the metaphase II (MII) oocytes were cryopreserved by vitrification (Cryotech®, Japan) at the bank. Once being matched to the appropriate recipients, the oocytes were warmed and cultured in standard conditions for at least 2.5 hours following with image taken for spindle (Oosight®, Hamilton Thorne). The spindle presence, morphology, and angle to polar body (PB) were measured. The correlation between the outcomes of ICSI and post-warmed spindle status were estimated.

Main results and the role of chance: The overall survival rate of vitrification-warmed oocytes was 92.4% (485/525), and two-pronuclei (2PN) rate was 75.1%. The morphology of post-warmed spindle was classified into normal, translucent, no-visible, and telophase; the 2PN rate in each group was as below (p-value was compared to the normal group): normal = 79.4%, translucent = 73.2% ($p = 0.30$), no-visible = 48.6% ($p<0.05$), and telophase = 37.5% ($p<0.05$). Of the 2PN rates in oocytes with different angulation, no correlation was found: 0–30° = 79.8%; 31-60° = 76.1%; 61-90° = 82.1%; 91-120° = 80.0%; >120° = 90.0%.

Limitations, reasons for caution: Individual biases in manipulation of spindle microscopy cannot be completely avoided.

Wider implications of the findings: Unlike the biological representativeness of spindle angulation in fresh oocytes, the correlation between the spindle angulation and fertilization outcome was not observed in vitrification-warmed oocytes. The displacement of spindle in vitrification-warmed oocytes could be caused by the physical effects during the freezing-thawing procedures.

Trial registration number: Not applicable.

P-136 Antioxidants in IVF and culture media significantly improve human embryo development: A prospective randomised multi-centre trial

A. Yoshida[1], T. Kuramoto[2], M. Tanaka[3], S. Mitzumoto[4], M. Montag[5], D.K. Gardner[6]

[2]*Kuramoto Women's Clinic, Reproductive Medicine, Fukuoka, Japan*
[3]*Kiba Park Clinic, VF Laboratory, Tokyo, Japan*
[4]*Kuramoto Women's Clinic, IVF Laboratory, Fukuoka, Japan*
[5]*ilabcomm GmbH, Eisenachstr, Sankt Augustin, Germany*
[6]*University of Melbourne, School of BioSciences, Melbourne, Australia*

Study question: What is the effect of combined antioxidants Acetyl-L-Carnitine (ALC), N-Acetyl-L-Cysteine (NAC) and α-Lipoic Acid (ALA) on human embryo development, when present in IVF culture media?

Summary answer: Combined antioxidants present in G-Series media significantly increased the percentage of good quality embryos on day 3 and showed a trend to higher pregnancy rates.

What is known already: The combination of the antioxidants ALC, NAC and ALA in IVF media and/or culture media has a significant beneficial effect on mouse embryo development and viability.

Study design, size, duration: A sibling oocyte study, where oocytes were randomly distributed to the control or test group at the time of pick up. Day 3 embryo and day 5/6 blastocyst quality were assessed. Good embryo quality on day 3 was defined as 8 to 10-cells with even cells and low fragmentation; good quality blastocysts as equal or greater than 3BB. Clinical outcome was assessed on transfers of a single vitrified-warmed embryo on day 5.

Participants/materials, setting, methods: The study was conducted in 2 IVF centres in Japan. 115 patients were included in the study, generating a total of 1,350 MII oocytes. IVF/ICSI and embryo culture (G-1 and G-2 PLUS) were conducted in 5% oxygen in the presence or absence of antioxidants (10 μM ALC /10 μM NAC /5 μM ALA). Controls were oocytes and embryos that were not exposed to antioxidants in the medium.

Main results and the role of chance: The fertilization rate in the control and test group was 75% and 76% respectively. Of the resultant 2PN, 19.6% and 26.1% resulted in good quality embryos on day 3 ($P<0.05$). Good quality blastocyst rate was 25.4% vs 26.5% for the control and test group, respectively, and these results were not significant. 42 single embryo transfer cycles were performed in the control group and 45 in the test group. The ongoing clinical pregnancy rate, as determined by cycles with fetal heart beat was 52.4% vs 60.0%, however, the study was not powered for significance of clinical outcome data.

Limitations, reasons for caution: Transfers are mostly performed after vitrification/warming of embryos, which is why clinical outcome data are still not complete.

Wider implications of the findings: The presence of antioxidants during IVF and embryo culture imparts significant benefits on day 3 embryo quality. Hence, supplementation of antioxidants to IVF and culture media may improve the viability of human embryos in ART, plausibly through the reduction of oxidative stress.

Trial registration number: NCT02999958

P-137 Prolonged blastomere movement induced by the delay of pronuclear fading and first cytokinesis adversely affects pregnancy outcomes in human embryo

K. Ezoe[1], K. Ohata[1], A. Yabuuchi[1], S. Ueno[2], K. Uchiyama[2], T. Okimura[2], T. Kobayashi[3], K. Kato[3]

[1]*Kato Ladies Clinic, R&D division, Tokyo, Japan*
[2]*Kato Ladies Clinic, Embryology Laboratory, Tokyo, Japan*
[3]*Kato Ladies Clinic, Department of Gynecology, Tokyo, Japan*

Study question: Does the prolonged blastomere movement post first cytokinesis influence the pregnancy outcomes in human embryo?

Summary answer: The Prolongation of blastomere movement induced by the delay of pronuclear fading and first cytokinesis adversely affects pregnancy outcomes.

What is known already: Time-lapse monitoring systems allow consecutive observation of embryonic development and have been increasingly used for the selection of viable embryos. Morphokinetics during the first and second cytokinesis is an effective biomarker of developmental competence to high quality blastocysts in human. In a preliminary study using time-lapse imaging we characterized different patterns of blastomere movement between the first and second cytokinesis in human embryos. However, it is still unknown how

blastomere movement influences clinical pregnancy outcome and which factors influence the duration of blastomere movement.

Study design, size, duration: A total of 708 embryos from 708 patients (36.4 ± 0.2 years) were cultured in EmbryoScope+® time-lapse system and subjected to single fresh cleaved embryo transfer from April to July 2017 and retrospectively analyzed. Blastomere movement was observed between the first and second cytokinesis. First, the correlation between the duration of blastomere movement and clinical pregnancy was evaluated. Second, the association of the blastomere movement duration with patient characteristics and developmental speed until second cytokinesis was examined.

Participants/materials, setting, methods: Retrieved oocytes were inseminated either by conventional in vitro fertilization or intracytoplasmic sperm injection. Fertilized oocytes were cultured in time-lapse incubator and the time from insemination to pronuclear (PN) alignment (tPNa), PN fading (tPNf), first cytokinesis (t2), and second cytokinesis (t3) was annotated. Duration of blastomere movement (BMov) between t2 and t3 (dBMov) was monitored and the ratio of dBMov over the period of 2-cell stage (t3-t2) was calculated (dBMov/(t3-t2)).

Main results and the role of chance: The mean value of dBMov/(t3-t2) was 0.347 ± 0.008 (range: 0.033–1.000). Logistic regression analysis revealed that the increasing value of dBMov/(t3-t2) was statically associated with decreasing clinical pregnancy rate (Odds ratio: 0.193 [95% confidential interval: 0.081–0.480], P<0.01). The value of dBMov/(t3-t2) was not correlated with patient characteristics, including female age (P = 0.49), male age (P = 0.34), female body mass index (P = 0.68), number of previous cycles (P = 0.20), cause of infertility (P = 0.44), insemination methods (P = 0.73), total number of spermatozoa (P = 0.35), number of motile spermatozoa (P = 0.36), and number of abnormal spermatozoa (P = 0.19). No correlation between tPNa and the value of dBMov/(t3-t2) was found. On the other hand, the period of PN alignment (tPNf-tPNa) was positively associated with the value of dBMov/(t3-t2) (Spearman's rank correlation coefficient (SC): 0.097, P = 0.01). In addition, the period of PN fading (t2-tPNf) was significantly correlated with the dBMov/(t3-t2) value (SC: 0.178, P<0.01).

Limitations, reasons for caution: The limitation of this study was that the pregnancy outcomes after a single fresh cleaved embryo transfer were exclusively analyzed. Further studies are required to examine whether the blastomere movement affects the blastocyst development and subsequent pregnancy outcomes after blastocyst transfer.

Wider implications of the findings: The chance for a clinical pregnancy after single fresh cleaved embryo transfer is adversely affected by the prolonged blastomere movement which is associated with the delay of PN fading and first cytokinesis. These results support the possibility that blastomere movement can be used as a predictive parameter for pregnancy outcomes.

Trial registration number: None.

P-138 The proportion of monopronuclear zygote (1PN) after intracytoplasmic sperm injection (ICSI) is significantly higher in frozen-thawed oocytes than fresh oocytes

M.F. Chuang[1], Y.M. Peng[1], M.J. Lee[2], H.H. Lai[2], H.L. Wang[2], C.L. Hsieh[2], Y.C. Huang[1]

[1]Stork Fertility Center, Assisted Reproductive Technology, Hsinchu, Taiwan R.O.C.
[2]Stork Fertility Center, Reproductive Endocrinology & Infertility, Hsinchu, Taiwan R.O.C.

Study question: Is there different distribution of pronuclear types between fresh and frozen-thawed oocytes after ICSI?

Summary answer: The proportion of monopronuclear zygote (1PN) in frozen-thawed oocytes is significantly higher than fresh oocytes, irrespective of recipient or infertile group.

What is known already: In in vitro fertilization (IVF), the first check point is to confirm the appearance of pronuclei, including shape and number, around 16-18 hours after insemination. The formation of two pronuclei is defined as a successful and normal fertilization; however, the other pronuclear types such as more or less than two pronuclei or uneven pronuclei are considered as abnormal fertilization. Nevertheless, blastocysts derived from abnormal fertilized oocytes have been referred to have potential to develop into normal chromosomal status and produce a healthy baby.

Study design, size, duration: A retrospective cohort study was conducted at Stork Fertility Center, between January 2017 to December 2017. Total 1155 cycles were included in the study and divided into oocytes recipient (N = 458) and infertility (N = 697) groups. Total 14615 mature oocytes (MII) were collected from recipient (n = 7603) and infertility (n = 7012) groups. The further analysis including pronuclear types and embryo development were evaluated only against the MII fertilized by ICSI.

Participants/materials, setting, methods: The recipient and infertility groups were subsequently categorized into two subgroups: fresh (N = 166 and 569, respectively) and frozen-thawed oocytes (N = 292 and 128, respectively) inseminated cycles. Moreover, all frozen-thawed oocytes were preserved by vitrification in this study. Total 6039 fresh and 5589 frozen-thawed oocytes were performed by ICSI, and the proportion of pronuclear types and following embryo development were observed.

Main results and the role of chance: In the recipient group, the mean age of the fresh and frozen-thawed subgroups were 23.86 and 24.42 years old, and 2031 and 4582 MII were performed ICSI respectively; the fertilization rate (FR), good embryo rate (GER) and good blastocyst rate (GBR) of the fresh and the frozen-thawed subgroups were 82.32% vs. 77.48%, 62.14% vs. 55.80%, and 63.10% vs. 54.33%. In the infertility group, the mean age of the fresh and frozen-thawed subgroups were 36.36 and 36.80 years old, and 4008 and 1007 MII were performed ICSI respectively; the FR, GER and GBR of the fresh and the frozen-thawed subgroups were 79.89% vs. 70.04%, 64.08% vs. 55.52%, and 57.87% vs. 42.63%. The different proportion of pronuclear types was found between fresh and frozen-thawed oocytes. The 1PN rate in frozen-thawed was significant higher than the fresh oocytes, which was showed in both recipient (10.83% vs. 5.61%, p<0.01) and infertility (12.1% vs. 5.39%, p<0.01) groups. This phenomenon might be a clue to explore the effect of frozen-thawed process and fertilization mechanism.

Limitations, reasons for caution: The difference between fresh and frozen-thawed oocytes such as spindle structure, protein expression profile, chromosomal constitution, mitochondria activity and cytoskeleton conformation should be distinguished to illuminate the causes of the different distribution of pronuclear formation. This phenomenon is restricted to ICSI since frozen-thawed oocytes could not be performed conventional IVF.

Wider implications of the findings: The exact factors of abnormal fertilization and the impact of frozen-thawed process have not been elucidated yet. This study might provide an additional aspect to investigate the crucial part of these issues and rescue the abnormal fertilized oocytes for further clinical applications.

Trial registration number: N/A.

P-139 Irregular oocyte swelling time in thawing solution (TS) highly correlates with the subsequent survival rate

Y.M. Peng[1], M.F. Chuang[1], M.J. Lee[2], H.H. Lai[2], H.L. Wang[2], C.L. Hsieh[2], Y.C. Huang[1]

[1]Stork Fertility Centre, Assisted reproductive technology, Hsinchu, Taiwan R.O.C.
[2]Stork Fertility Centre, Reproductive Endocrinology & Infertility, Hsinchu, Taiwan R.O.C.

Study question: Whether irregular oocyte thawing time in thawing solution correlates with following oocyte survival rate?

Summary answer: Irregular oocyte swelling time in thawing solution (TS) highly correlates and dramatically increases the mortality after thawing.

What is known already: Vitrification is an optimal method employed for oocyte preservation to prevent intracellular and plasma membrane molecules such as enzymes, structural protein and mRNA damage from ice crystals. The critical process of oocyte vitrification is considered to exchange water and cryoprotectant between intracellular and extracellular environments. Membrane integrity is supposed to be one of the major reasons influencing water/cryoprotectant exchange rate and following survival rate after thawing.

Study design, size, duration: A retrospective cohort study throughout June 2017 to November 2017, total of 2144 oocytes in 162 cryopreservation/thawing cycles were included. The timing of swelling, flattening and recovering time

in thawing solution were recorded and analyzed to reveal the effects on the thawing outcomes.

Participants/materials, setting, methods: Every oocyte undergone thawing procedure were recorded with the individual timing of swelling, flattening and recovering (swelling combined with flattening). All the oocytes were classified according to the (1. thawing outcomes-survival or mortal to reveal the timing diversity; or (2. regular (>30 s) or irregular (≤30 s) swelling time in thawing solution (TS) to compare the mortality.

Main results and the role of chance: Based on the thawing outcome, firstly, oocytes were grouped into survival and mortal groups for comparing the swelling, flattening and recovering time of the two groups. The results indicated that the mean time of swelling (44.3 s vs. 28.9 s, $p<0.05$) and recovering (57.2 s vs. 39.9 s, $p<0.05$) in survival group was significantly higher than the mortal group. The primary disparity of recovering time were mainly derived from the swelling time, although the average flattening (12.9 s vs. 10.9 s, $p<0.05$) time of survival group was also significant higher than the mortal group. Secondly, in the contrary, thawed oocytes were classified according to swelling time (regular, >30 s or irregular, ≤30 s). Mortality of the regular group revealed significantly lower than the irregular group (2.97% vs. 26.9%, $p<0.05$). Taken together, the two aspects indicated that the swelling time is a critical indicator correlating to the mortality of oocyte thawing. These observations implicated that osmotic potential plays a critical role affecting the thawing survival rate. Furthermore, membrane permeability and surface molecular profile might influence cell resistant from osmotic potential, which accounts for the dramatically increasing mortality.

Limitations, reasons for caution: Vitrification strategy was adopted in all the frozen-thawed oocytes in this study. Vitrification Kit 101 (Cryotech) and Warming Kit 102 (Cryotech) were employed for performing frozen-thawed procedures. The phenomenon should be observed in other vitrification strategy but might fail to refer to other frozen-thawed methods such as slow freezing process.

Wider implications of the findings: The present study implies that swelling time in TS is correlated with oocyte mortality. The considerable increase of mortality in irregular group implies that membrane constitution such as inappropriate lipids/cholesterol ratio and suboptimal water/ion channels, might play a critical role in regulating the water/cryoprotectant exchange between intracellular and extracellular environments.

Trial registration number: N/A.

P-140 Revisiting a controversial topic: The vitrification-warming procedure does not induce zona pellucida hardening in human blastocysts

H. Iwayama[1], M. Ishiyama[1], M. Shimoda[1], A. Nakatani[1], A. Hayashi[2], M. Yamashita[2]

[1]Yamashita Ladies' Clinic, Section of Human Gamete & Embryo Manipulation, Kobe, Japan

[2]Yamashita Ladies' Clinic, Section of Human ART, Kobe, Japan

Study question: Should the variation in zona pellucida (ZP) thickness during blastocoel expansion be considered an important factor of ZP hardness in vitrified-warmed blastocysts?

Summary answer: Unlike during the vitrification warming procedure, a reduction in ZP thickness during the physiological expansion of the blastocoel is a potential confounder of ZP hardness.

What is known already: Previous studies have demonstrated ZP hardening in cryopreserved blastocysts, resulting from improved clinical outcomes following assisted hatching and small experiments focused on the enzymatic digestibility of the zonae. However, to date, the regulatory pathways such as cortical reaction during oocyte ZP hardening remain unclear. Moreover, the main point of discussion regarding the multivariate associations of ZP hardening with respect to the vitrification-warming procedure and ZP thinning during blastocyst expansion was not addressed by these studies.

Study design, size, duration: This experimental study included fresh (n = 61) and vitrified-warmed (n = 36) blastocysts that were discarded during the treatment of patients. These blastocysts were harvested from IVF or ICSI cycles (n = 50) between March 2010 and May 2011.

Participants/materials, setting, methods: Two types of ZP hardness were estimated based on the response to enzymatic digestion and elastic behavior of ZP. Dissolution time was assessed by ZP disappearance in 0.1% protease solution. Elasticity was calculated from the maximum expansion rate in a sham-expansion model, which was micro-injection of Fluorinert™ fluid below ZP layer. The mean ZP hardness indexes were compared between fresh and vitrified-warmed blastocysts of each ZP thickness categories (>15, ≤15 to >7.5, and ≤7.5 μm).

Main results and the role of chance: Regarding the response of ZP to enzymatic digestion, the digestion time negatively correlated ($r = 0.67$, $p < 0.01$) with the reduction of ZP thickness during blastocyst expansion. The mean digestion time of vitrified-warmed ZP was similar to that of fresh ZP (405 vs. 390 s). The mean digestion time derived for the >15, ≤15 to >7.5, and ≤7.5 μm categories, i.e., 493, 375, and 334 s, respectively, were significantly ($p < 0.05$) decreased depending on the ZP thickness.Regarding the elastic behavior of ZP, the maximum expansion rate negatively correlated ($r = 0.92$, $p < 0.01$) with the reduction of ZP thickness during blastocyst expansion. The mean maximum expansion rate of vitrified-warmed ZP was similar to that of fresh ZP (24 vs. 28%). The mean maximum expansion rate derived for the >15, ≤15 to >7.5, and ≤7.5 μm categories, i.e., 40, 28, and 11%, respectively, were significantly ($p < 0.05$) decreased depending on the ZP thickness.

Limitations, reasons for caution: In this study, the results of molecular biology are absent.

Wider implications of the findings: The present study indicates that ZP softening might be induced by the reduction of ZP thickness during blastocoel expansion. Failure to evaluate the ZP thickness as a potential confounder might have led to biased results and conclusions, i.e., the demonstration that the vitrification-warming procedure induces ZP hardening in blastocysts.

Trial registration number: The authors declare no potential.

P-141 Is there a difference in embryo morphokinetics between ejaculated and non-ejaculated spermatozoa?

G. Raad, C. Nader, J. Azoury, K. Rizk, E. Dahdouh, M.C. Zayat, R. Bader, J. Azoury, J. Azoury

Azoury IVF clinic, ivf, Beirut, Lebanon

Study question: Does sperm origin (ejaculated, epididymal, and testicular) affect pre-implantation embryo morphokinetics and morphodynamics?

Summary answer: Non-ejaculated spermatozoa negatively affect all developmental stages of preimplantation embryos.

What is known already: Spermatozoa undergo biochemical and physiological modifications during their transit in the epididymis. However, the influence of the testicular extracted spermatozoa on embryo developmental competence did not reach a firm consensus.

Study design, size, duration: A retrospective study was conducted at Azoury IVF clinic, from August 2013 until August 2017. It was performed on 86 couples, who have undergone only intracyoplasmic sperm injection (ICSI) cycles. The infertile couples were divided into four groups: normozoospermia group (n = 23 couples, n = 133 embryos); oligozoospermia group (n = 22 couples, n = 109 embryos); percutaneous epididymal sperm aspiration (P.E.S.A.) group (n = 21 couples, n = 119 embryos), and testicular biopsy group (n = 23 couples, n = 123 embryos).

Participants/materials, setting, methods: The couples where the females had 38 years old or less at the time of ICSI, were selected and divided into four study groups according to sperm quality and source. Only the data of the embryos with normal fertilization and cultured for 5 consecutive days without interruption was included. In addition, embryos that were subjected to embryo biopsy were excluded. Subsequently, embryo morphokinetics and morphodynamics were analysed through time-lapse microscopy (Embryoscope) using the Embryoviewer software.

Main results and the role of chance: During the pre-compaction stage, the embryos of the P.E.S.A and testicular biopsy groups showed a significant delay in the first embryonic cell cycle (ECC1) when compared to the embryos of the normozoospermia group ($p<0.05$ and $p<0.01$, respectively). In addition, the third embryonic cell cycle (ECC3) was significantly delayed in both non-ejaculated sperm groups compared to the normozoospermia group ($p<0.01$ and $p<0.001$, respectively). Interestingly, this delay in the development continued through the post-compaction stage. Particularly, the embryos of the testicular biopsy group had significant delay in the time of starting blastulation ($p<0.05$) and in the time to reach a full blastocyst ($p<0.001$) in comparison to those derived from the normozoospermia group. Regarding the morphodynamic parameters, a lower percentage of blastocysts showed blastocyst contraction in the P.E.S.A and testicular biopsy groups compared to the normozoospermia group ($p<0.05$ and $p<0.05$, respectively).

Limitations, reasons for caution: A very important limitation of this study is its retrospective nature itself. A randomized controlled trial (RCT) should be conducted to confirm the findings of this study.

Wider implications of the findings: The present study clearly shows a negative impact of non-ejaculated sperm on early embryo development. Hence, recommending the use of testicular sperm in case of repetitive IVF failure and high sperm DNA fragmentation should be taken with caution.

Trial registration number: Not applicable.

P-142 Characteristics of human single pronucleated zygotes derived from conventional in vitro fertilization, considering the genome composition, chromosomal distribution and morphological assessment

H. Moriwaki, Y. Kai, K. Yumoto, K. Iwata, Y. Mio

Mio Fertility Clinic, Reproductive Centre, Yonago, Japan

Study question: Do human single pronucleated (1PN) zygotes derived from conventional in vitro fertilization (c-IVF) have developmental potential as normal fertilized zygotes leading to newborns?

Summary answer: Although approximately 80% of 1PN zygotes in c-IVF procedures were diploid, not all distributed their genome normally during the 1st cleavage.

What is known already: Cytogenetic and genetic composition based on histone modification analysis has revealed that many 1PN zygotes are diploid in c-IVF procedures. Some of them are able to develop to the blastocyst stage and result in normal deliveries in humans.

Study design, size, duration: We used 1PN zygotes obtained from February 2015 to September 2017 from c-IVF procedures (n = 60). Fresh or frozen/thawed zygotes were provided for cell biological and morphological analysis. Three normal two-pronuclear zygotes were also used as controls.

Participants/materials, setting, methods: Donated and ethically-approved zygotes derived from c-IVF were used in this study. 1PN zygotes were obtained more than 22 hours post insemination. We analyzed the genome composition by DNA and histone methylation status, chromosome distribution, pronucleus diameter, and the time-course from syngamy to the 1st cleavage. Immunofluorescence was performed using antibodies against 5mC, 5hmC, H3K9me3, alpha-tubulin and pericentrin. Live-imaging analysis was performed using TagGFP2-H2B mRNA and FusionRed-MAP4 mRNA.

Main results and the role of chance: Analysis of DNA methylation status by immunofluorescence for 5mC and 5hmC revealed that 80% of the 1PN zygotes (n = 10) showed a mixed 5mC/5hmC-positive genome in a single pronucleus, and analysis of histone methylation by immunofluorescence for H3K9me3 revealed that 78% of zygotes (n = 9) had a non-uniform H3K9me3-positive pronucleus or chromosomes. Analyses of spindle formation and chromosome segregation by immunofluorescence revealed that 45% of zygotes (n = 20) formed bipolar spindles at metaphase. At telophase, one zygote showed an unequal distribution of paternal and maternal genomes. In live-imaging analysis which visualized histone H2B (chromosomes) and MAP4 (microtubules), one zygote showed a tripolar spindle formation leading to abnormal chromosomal distribution during the 1st cleavage, while 56% of zygotes (n = 9) showed bipolar spindles and even chromosomal distribution. The average pronucleus diameter of zygotes which showed pronucleus disappearance and 1st cleavage was slightly bigger than the defectively-developed zygotes (n = 14, overlapped with live-imaging data). The time-course from pronucleus disappearance to 1st cleavage was almost the same as in normally-fertilized zygotes (n = 6, overlapped with live-imaging data).

Limitations, reasons for caution: This study was confined only to the period from zygote stage to 1st cleavage, so further developmental stages need to be analyzed.

Wider implications of the findings: Although we showed it is possible to select the diploid 1PN zygotes with developmental potency based on pronucleus diameter assessment, not all have the ability to distribute chromosomes normally during the 1st cleavage. Our findings may help in the selection of useable 1PN zygotes for clinical applications.

Trial registration number: Not applicable.

P-143 High-resolution nuclear magnetic resonance based profiling of spent human embryo culture media for assessment of in vitro embryo quality

M. Vilches[1], F.D.L.N. Ignacio[2], R.D.A. Ana Cristina[3], G.G. Ana[4], A.S. Luis Manuel[2], A.C. Francisco Manuel[2], S.F. Encarnacion[1]

[1]Complejo Hospitalario Torrecardenas, Unidad de Reproduccion Asistida Humana, Almeria, Spain
[2]Universidad de Almería, Departamento de Física y Química, Almeria, Spain
[3]Universidad de Almeria, Departamento de Física y Química, Almeria, Spain
[4]Hospital Universitari Vall Hebron, Unidad de Reproducción Asistida Humana, Barcelona, Spain

Study question: Over recent years, there has been much interest in the use of metabolomics to detect biomarkers of embryo viability, which might help embryologists to successfully increase implantation rates.

Summary answer: The aim of this study was to identify biomarkers from embryo metabolome that would allow us to predict and differentiate embryos of the best quality.

What is known already: The metabolic profile in the culture media used can be investigated using non-invasive metabolic techniques, such ^{1}H-NMR. This noninvasive quantification of embryonic metabolism can be a useful predictor of pregnancy outcome after embryo transfer, a potential supported by recent clinical studies that work with specific classes of metabolites such as glycolytic intermediates and amino acids (Singh, 2007).

Study design, size, duration: Multidisciplinary_study of several institutions which compass a highly analytical component, with random selection and assignment of the samples. The sample size (Perduzzi's formula [$n = 10 * (k + 1)$] and prevalence of poor quality embryos of 54%, $p < 0.005$) included 185 embryo cultures, assuming losses of 20%, being the final size of 222. The chronogram has combined embryonic selection tasks with NMR measurement periods with the aim of obtaining metabolic profiles and identifying biomarkers.

Participants/materials, setting, methods: The inseminated MII oocytes and were individualized in G1-Plus_medium (Vitrolife) left in culture during 48 hours (D+3). After embryo selection and transfer, embryo culture medium was collected and cryopreserved at -80 °C. The media for NMR measurements were prepared in a solution of NaCl in D_2O and were carried out on a Bruker_Avance_III_600 spectrophotometer equipped with a cryoprobe. The spectra were acquired using a ^{1}H CPMG sequence and processed through the TOPSPIN 3.2 software.

Main results and the role of chance: Schematically, the experimental procedure was carried out as follows: a) Collection of the samples, b) Analysis of the samples by NMR, c) Application of multivariate analysis techniques to the ^{1}H NMR data to identify the biomarkers that were associated with a better morphological kinetics and embryonic implantation. The Principal Component Analysis (PCA) model obtained so far allowed to discriminate between the embryo culture samples of the embryos that had an optimal development of those that did not. At the same time, the quantification of the metabolites that contribute most to the discrimination of the model was obtained, observing that the embryos with optimal development showed a higher consumption of metabolites such as pyruvate, glutamate, citrate, tryptophan (which means that they are metabolically more active). The worst embryonic development was

associated mostly to a lower consumption of pyruvate, the energy source, and of tryptophan, used in protein biosynthesis. The formate/acetate ratio significantly decreased in media samples belonging to embryos of type A (according to ASEBIR classification criteria), while it increased in embryo medium samples with worst development (types C and D).

Limitations, reasons for caution: Limitations: 1) rate of embryo fertilization; 2) the high operational cost associated with NMR measurements could be a limitation for routine prediction; and 3) the possibility that the tool is not sensitive enough to detect differences in metabolic embryos and does not achieve sufficient differentiation power is another weak point.

Wider implications of the findings: A large population size (> 200, average 36 years) from different geographical areas, as well as the use of mass spectrometry and separation methods in parallel to NMR spectroscopy, will try to give solidity to the study, although the preliminary results agreement with previous studies found in the bibliography.

Trial registration number: not applicable.

P-144 Does blastocyst re-expansion one hour post-warming predict clinical pregnancies?

C. Shaw Jackson[1], A. Tubbing[2], L. Ameye[3], B. Becker[4], A.L. Thomas[2], S. Rozenberg[2], C. Autin[2]

[1]*CHU Saint-Pierre, FIV, Brussels, Belgium*
[2]*CHU St Pierre, Gynaecology, Brussels, Belgium*
[3]*Jules Bordet Institute, Data centre, Brussels, Belgium*
[4]*CHU Saint-Pierre, Gynaecology, Brussels, Belgium*

Study question: Is it possible to predict a clinical pregnancy based on early conventional warmed blastocyst re-expansion analysis?

Summary answer: We demonstrate statistically higher clinical pregnancy rates for blastocysts that displayed re-expansion in the first hour after warming, as opposed to those that did not.

What is known already: A few studies have demonstrated that post warming blastocyst expansion is a predictor of implantation. However, most studies focus on expansion at one time point several hours after warming with no information on the method of expansion evaluation. Moreover, the stage of blastocyst development is not always taken into account. Time lapse technology was very recently used in two studies and demonstrated that early onset of re-expansion and duration of re-expansion were predictors of pregnancy.

Study design, size, duration: A retrospective analysis of 264 single vitrified-warmed blastocyst transfers that took place between January 2014 and December 2016 were included in this study. Photographs of the warmed blastocysts were taken at 0 – 30 and 60 minutes post warming and were prospectively analyzed by two methods.

Participants/materials, setting, methods: Blastocyst post-warming behavior was evaluated by the means of morphological measurements taken by a computer program, as well as independently by three biologists based on photographs at 0-30 and 60 minutes post warming. Four main groups were established based on the ability of the blastocyst to compact and re-expand. Survival and clinical pregnancy rates were compared between groups for different stages of blastocyst development.

Main results and the role of chance: We observed different post-warming behavioral patterns depending on the stage of blastocyst development. Blastocysts (stage 3) showed a lesser amplitude of compaction/re-expansion by computer analysis and no significant difference was observed between expanding and non-expanding groups in terms of clinical pregnancy rates (23% versus 27% $p = 0.76$) despite increased survival for re-expanding blastocysts (93% versus 88% $p = 0.01$). For combined expanded and hatching blastocysts (stages 4 and 5) showing re-expansion within 30-60 minutes after warming, significantly higher survival (99% versus 79% $p<0.001$) and clinical pregnancy rates (33% versus 13% $p = 0.02$) were observed compared to embryos that did not show signs of re-expansion. No significant difference in clinical pregnancies was observed between embryos showing fast and slow re-expansion (35% versus 31%, $p = 0.064$). Nine percent of all vitrified-warmed blastocysts showed atypical behavior without any signs of compaction directly post warming, or during the 60-minute observation period. The overall clinical pregnancy rate for these embryos was 35%. Globally, the biologist's method confirmed the computer analyses though this method was better suited to detect a larger cavity without an overall increase of the size of the embryo.

Limitations, reasons for caution: Expanded and hatching blastocysts that did not re-expand post warming had reduced pregnancy rates. Nevertheless, the decision to discard them should be done with caution. Further investigation between slow and fast re-expansion groups need to be carried out, focusing on the method and timing of re-expansion analysis.

Wider implications of the findings: This study is the first to demonstrate different post-warming behavior depending on the stage of blastocyst development and to investigate various methods of blastocyst re-expansion analysis. Early decisions concerning the fate of the warmed embryos can be made without the need for sophisticated time-lapse technology.

Trial registration number: not applicable.

P-145 Correlation between euploid blastocysts expansion/morphology and clinical outcomes in cycles with single frozen embryo transfer

M. Nicolielo[1], M. Piccolomini[1], N. Nobrega[1], M. Fanelli[1], A.P. Reis[1], T. Bonetti[2], E. Motta[3], P. Serafini[4], J.R. Alegretti[1]

[4]*Huntington Medicina Reprodutiva/University of São Paulo, Clinical Medicine Department/Department of Gynecology and Obstetrics, Sao Paulo / SP, Brazil*

Study question: How much the morphology of euploid blastocyst determines the clinical outcomes in frozen-thawed transfers after preimplantation genetic screening (PGS)?

Summary answer: The morphology of frozen-thawed euploid blastocyst does not affect the clinical outcomes in single embryo transfer (SET) cycles.

What is known already: Blastocysts are routinely evaluated with regard to the expansion of the blastocoel and the number of cells in the Inner Cell Mass (ICM) and in the Trophoectoderm (TE). However, the literature is not clear in euploid blastocysts evaluated by PGS, how much the morphology affects clinical outcomes. While some authors suggested that morphology was not associated with the chance of ongoing pregnancy, and 'poor" quality euploid blastocysts fared just as well as higher graded blastocysts, others believe that blastocyst morphology grading and particularly ICM is a useful predictor of ongoing pregnancy rate per biopsied euploid embryos.

Study design, size, duration: This is a retrospective cohort study including data from 270 SET of frozen-thawed euploid blastocysts performed between January 2016 and July 2017. Blastocysts were morphologically classified according with Gardner for expansion grade (EG), ICM and TE. Blastocysts were biopsied for PGS analysis by using NGS and then vitrified. Euploid blastocysts were warmed and single embryo transfers were placed after endometrial preparation.

Participants/materials, setting, methods: Blastocyst were classified as grade 3, 4, 5 or 6 for EG. The ICM and TE were classified as A, B and C, as grade A is best grade and C is poorer grade. Clinical pregnancy rate was analyzed according with each morphological classification of blastocysts and the multivariate analysis was performed to evaluate the association of EG, ICM, TE and the interaction among then in the clinical pregnancy rates, adjusted for confounders.

Main results and the role of chance: Patients included were 37.8 ± 3.6 years of age and the indications for PGS were implantation failure, recurrent miscarriage, advanced maternal age, severe male factor or patients' choice. The most of blastocysts were classified as EG grades 4 (40.4%) or 5 (47.5%), ICM grades A (43.3%) or B (40.4%) and TE grades A (32.9%) and B (38.8%). In the univariate analysis, we observed the clinical pregnancy rates yielded no statistically difference when blastocysts were classified by EG (3: 33.3%; 4: 46.6%; 5: 44.4%; 6: 35.7%, p value = 0,438), by ICM (A: 43.8%; B: 34.5%; C: 29.7%, p value = 0,258). When blastocysts were classified by TE morphology, the clinical pregnancy rate (A: 39.8%; B: 48.3%; C: 27.3%) was higher when TE=B (48.3%) compared to TE=C (27.3%; $p = 0.008$). The multivariate analysis did not show any association of EG (OR = 1.19; $p = 0.250$), TE (OR = 1.24; $p = 0.190$) or

ICM (OR = 1.35; p = 0.106) individually or the interaction of them (OR = 0.984; p = 0.223) with clinical pregnancy rate, adjusted to confounders.

Limitations, reasons for caution: This is a retrospective study including a relatively low number of samples and higher cohorts of cycles should be studied to confirm the outcomes. All patients included received SET; however not all cycles were elective SET, as some of them had only one euploid blastocyst available.

Wider implications of the findings: Our findings suggested that once the blastocyst is euploid after PGS evaluation, it morphology does not affect the clinical pregnancy rates. Based on that, we can speculate that high morphology grade and low morphology grade euploid blastocysts have same implantation potential and can be transferred arbitrarily.

Trial registration number: Not applicable.

P-146 ICSI procedure impairs the development of embryos to the blastocyst stage in patients with a slight degree of teratozoospermia: a prospective study

M. Stimpfel, I. Verdenik, J. Kmecl, L. Bacer-Kermavner, J. Mivsek, B. Valentincic-Gruden, K. Ferk, E. Vrtacnik-Bokal, I. Virant-Klun

Univerzitetni Klinicni Center Ljubljana, Department of Obstetrics and Gynaecology, Ljubljana, Slovenia

Study question: Is intracytoplasmic sperm injection (ICSI) the wrong method of choice in infertile couples with a slight degree of teratozoospermia defined by the strict Kruger criteria?

Summary answer: Classical IVF insemination resulted in better embryo development than ICSI procedure in infertile couples with a slight degree of teratozoospermia.

What is known already: ICSI procedure enables the fertilization of oocytes with a low quality sperm or even, in extreme cases, with only a few spermatozoa available. Although, the overuse of ICSI is observed, since it is also performed in couples with normal sperm quality and female indications of infertility. It has already been shown that the overuse of ICSI does not improve or may even impair the outcome of IVF/ICSI cycles (Grimstad et al., 2016; Tannus et al., 2017) but it is still not clear at which percentage of normal spermatozoa ICSI is beneficial, if sperm concentration and motility are normal.

Study design, size, duration: Our prospective sibling-oocyte study included 27 couples who were treated in y. 2017 because of male infertility with a slight degree of teratozoospermia (7-14% of morphologically normal spermatozoa), defined by strict Kruger criteria, and with normal sperm concentration and motility. In each couple approx. half of oocytes were fertilized with ICSI (ICSI-group) and the remaining half of oocytes with classical IVF (IVF-group). The aim was to elucidate, which procedure results in a better clinical outcome.

Participants/materials, setting, methods: The female partners were aged 26-43 years and had at least 6 cumulus-oocyte complexes to express a normal ovarian reserve. Up to two optimal embryos were transferred into the uterus regardless the procedure. The IVF and ICSI-groups were compared in terms of fertilization rate, quality of day 3 and day 5 embryos, and pregnancy rate. To determine the differences between the two groups, a multivariate analysis was performed. Statistical significance was set at $P<0.05$.

Main results and the role of chance: The mean age of included patients was 35.6 ± 4.7 years for females and 36.0 ± 4.8 years for males. Mean numbers of oocytes included in each group were: 6.3 ± 3.6 for ICSI and 7.9 ± 6.1 for IVF- group. The fertilization (ICSI vs. IVF; 56.7% vs. 63.9%), cleavage (100% vs. 98.4%), and good quality day 3 embryo rates (55.0% vs. 63.9%) did not differ significantly between the two groups. Nevertheless, a significantly higher blastocyst (35.3% vs. 63.9%; P = 0.019) and good quality blastocyst rates (14.5% vs. 33.5%; P = 0.049) were observed in the IVF-group than in ICSI-group on day 5. The multivariate regression analysis showed that other factors such as female/male age and sperm quality parameters did not influence the difference between the two groups. The embryo transfer was performed in 24 cycles (without 2 cycles with 'freeze all" blastocyst freezing due to hyperstimulation). In 5 cycles embryos only from ICSI-group were transferred (number of ET embryos 1.0 ± 0) with 40% pregnancy rate and in 15 cycles embryos only from IVF-group were transferred (number of ET embryos 1.1 ± 0.3) with 66.7% pregnancy rate. None of these differences were significant.

Limitations, reasons for caution: The limitations of the study are in the relatively low number of included couples but the study is still in a progress. A further prospective study is needed. Achieved pregnancies need to be followed to evaluate the miscarriage and live birth rates according to the procedure (IVF, ICSI).

Wider implications of the findings: The results of this study show that the IVF procedure is optimal in couples with a slight degree of teratozoospermia along with normal sperm concentration and motility. In these couples the ICSI procedure may even impair the development of embryos to the blastocyst stage and a chance to get pregnant.

Trial registration number: not applicable.

P-147 Impact of embryo density on ICSI outcomes

S. Chtourou[1], K.F. Kacem[1], M. Braham[2], S. M'nallah[1], M. Ben Meftah[2], H. Bellil[1], F. Anis[2], F. Zhioua[2], A. Zhioua[1]

[1]Hôpital Aziza Othmana, Center of Reproductive Medecine, Tunis, Tunisia
[2]Hôpital Aziza Othmana, Gynecology and Obstetrics, Tunis, Tunisia

Study question: Does embryo density have an impact on embryo cleavage or development and does it enhance Intra-Cytoplasmic Sperm Injection (ICSI) outcomes?

Summary answer: The grouped cultured embryos with a density of 10 µl culture medium per embryo seems to promote embryo development and slightly improve ICSI outcomes.

What is known already: Among all culture methods, many authors agreed that group culture seemed to be beneficial to embryos through growth factors deposited in the droplet of culture medium. Though, not only growth factors but also toxic substances (such as ammonium and oxygen-derived free radicals) can be secreted by embryos in a group culture. Embryo density appears to be one of the most important settings in group culture to guarantee a better embryo development without exposing the embryos to an increased concentration of negative factors.

Study design, size, duration: It is a monocentric, prospective and randomized study, which lasted for one year, from June2015 to June2016.

Patients who had 2 or 3 fertilized oocytes were included in the study, which made a total number of 169 ICSI cycles.

Embryos were cultured either individually, or in a group of 2 or 3 embryos per droplet, which yielded to an embryo density of 30 µl, 15 µl, or 10 µl of culture medium per embryo for the three groups respectively.

Participants/materials, setting, methods: ICSI cycles were randomized, according to oocyte retrieval day, in three groups of different embryo density:

- Group A: Individual culture (1embryo per droplet: 30 µl of medium per embryo) (91 cycles)
- Group B: Group culture (2 embryos per droplet: 15 µl of medium per embryo) (43 cycles)
- Group C: Group culture (3 embryos per droplet: 10 µl of medium per embryo) (35 cycles)

Embryo transfer took place on day2 or day3, and sequential culture medium was used for the culture pursuit.

Main results and the role of chance: Group culture in an embryo density of 15 µl (GroupB) yielded to better cleavage rates than GroupA or C (96.% vs 95.2% vs 91% respectively, p = 0.08). Though, among the three groups, GroupC had the best embryo quality with a significant difference in the mean number of TOP quality embryos obtained (1.1 vs 0.73 vs 0.74 for GroupC, A and B respectively, **p = 0.023**).

Pregnancy rates were higher for GroupC compared with the two other groups (41.1% vs 33.3% vs 31.4% for GroupC, B and A respectively, p = 0.22). Implantation rates were also greater after transferring embryos cultured in a density of 10 µl than the two other groups (22% vs 21% vs 17.8% for GroupC, B and A respectively, p = 0.44). Nevertheless, those differences were not statistically significant.

Same findings were noticed for live birth rates from embryos of GroupC, which were greater than the two other groups with no statistical difference (18.6% vs 13% vs 10% for GroupC, A and B respectively, p = 0.29).

Our results suggest that embryo density of 10 µl seems to be suitable for obtaining a better embryo quality and for enhancing ICSI outcomes in terms of pregnancy, implantation and live birth rates after transfer of day2 or day 3 embryos.

Limitations, reasons for caution: Adopting day5 embryo transfer could provide more proofs of the benefits of culturing embryos with a 10 µl embryo density rather than other tested densities.

Wider implications of the findings: Culturing embryos in high density could generate some assessing and selection difficulties. That is why some authors brought the idea of culture systems, such as the Well-Of-the-Well system, in which embryos are cultured in a cone shape well to increase growth factor concentration while diluting negative ones.

Trial registration number:

P-148 Development of a chemically defined protein supplement for in vitro embryo culture

S. Lin, M.K. Villafuerte, H.T. Ni

Irvine Scientific, Research & Development, Santa Ana, U.S.A.

Study question: Development of an effective, improved chemically defined protein supplement for IVF by identifying functional proteins found in the female reproductive tract and commercially serum-derived supplements.

Summary answer: A chemically defined protein supplement containing recombinant proteins identified in the female reproductive tract, HSA, and globulins, improved mouse and bovine blastocyst development in vitro.

What is known already: Commercially available protein supplements for embryo culture are used worldwide to effectively promote blastocyst development in IVF clinics. However, they generally consist of plasma derived human serum albumin (HSA) and globulin fraction IV, which lead to lot-to-lot variation. As a result, there is a need for the development of a chemically defined protein supplement that eliminates variability and delivers high quality blastocysts consistently. Recent studies have reported various biologic, functional proteins, including growth factors not only found in the female reproductive tract, which is the natural environment where embryos develop, but also in serum-derived protein supplements used in IVF labs.

Study design, size, duration: ELISAs were used to determine the presence and concentration of candidate factors in multiple lots of HSA and globulins. Mouse and bovine embryo assay (MEA/BEA) experiments were conducted to evaluate the effect of the identified factors on blastocyst development. ≥25 embryos were used per test group in both embryo assays. Embryos were cultured continuously in microdroplets overlaid with light mineral oil, and blastocyst rates were graded after 5 (mouse) or 7 (bovine) days of incubation.

Participants/materials, setting, methods: Frozen mouse zygotes from EmbryoTech were thawed and cultured in Continuous Single Culture Medium (CSCM®-NX) complemented with chemically defined protein supplement prototypes containing different defined protein compositions. All embryos were cultured in 5% CO_2 incubators at 37°C in 98% humidity. BEA experiments were performed at Applied Reproductive Technology, and all test samples provided were blinded to prevent biased evaluation and an internal control was always performed using specific bovine embryo culture media.

Main results and the role of chance: ELISA results demonstrated the presence of biological protein regulators, such as insulin in both the HSA and globulin/fraction IV, and concentrations were consistently higher in the fraction IV than in the HSA. These growth factor (GF) proteins, as previously reported, were also found in the oviduct and the endometrium. Test media prototypes were developed containing different combinations of these proteins. Even under more stressful and stringent embryo culture conditions of one embryo per droplet, MEA results showed that medium containing only insulin, performed equally well as control medium containing 10% Serum Substitute Supplement (HSA + globulin/fraction IV). In addition, test medium containing insulin and selected factors consistently improved blastocyst rate (≥80%) when compared to the control. Additional studies were done using the more sensitive BEA system, and these experiments also demonstrated that presence of defined protein supplement improved blastocyst rate as well as rate of fertilization, in vitro. Replacement of serum-derived components with recombinant proteins in IVF culture supplements not only eliminated inconsistencies and demonstrated improved performance, but it also removes the negative factors in human biological samples that may present toxic effects to the cultured embryos.

Limitations, reasons for caution: Present study of the newly developed, chemically defined protein supplement does not include human embryo development data. Human studies are in progress for full evaluation of the GF benefits to human embryo growth.

Wider implications of the findings: GF were shown to exist in the female reproductive tract as well as commercially available supplements that IVF laboratories have used for years. Therefore, GF in the chemically defined protein supplement will bring consistency in blastocyst development and can be considered safe as GF were present in previously accepted products.

Trial registration number: Not Applicable.

P-149 Early rescue ICSI has good clinical results - Record of 14 years at our clinic

S. Watanabe[1], R. Matsunaga[1], M. Miura[1], Y. Kobayashi[1], N. Yamanaka[1], M. Kamihata[1], T. Maeda[1], H. Makino[1], M. Ochi[1], T. Horiuchi[2]

[1]Ochi Yume Clinic Nagoya, ART Lab., Nagoya, Japan
[2]Prefectural University of Hiroshima, Faculty of life and emvironmental science, Shobara, Japan

Study question: Long-term clinical performance of early rescue ICSI.

Summary answer: Early rescue ICSI can result in clinically valuable outcomes, producing normal rates of fertilization, blastocyst formation, pregnancy, and production.

What is known already: Although the outcome of early rescue ICSI has been reported in the past, there have been no reports that describe experiences over a prolonged period (14 years in this presentation).

Study design, size, duration: We performed a retrospective analysis of 5171 oocytes in which early rescue ICSI was performed, among 29,776 oocytes taken from 10,750 cases undergoing IVF in 2004-2017. The fertilization rate, blastocyst rate, pregnancy rate, and production rate were examined. As a control, we used 30,114 oocytes taken from 12,815 cases who underwent conventional ICSI during the same period. The stimulation methods used in this study were natural cycle, letrozole cycle, or clomiphene cycle.

Participants/materials, setting, methods: Cumulus cells were removed 5 hours after insemination, and oocytes were observed.

(1) After stripping, release of the second polar body was observed.
(2) Fertilization cone or cytoplasmic flare was observed.
(3) Although not applicable to 1-2, spindle body was not observed in the egg by observation with the spindle visualization system (PolScope).

Observations were carried out until 7 hours after insemination, and early rescue ICSI was performed when none of 1-3 was applicable.

Main results and the role of chance: The normal fertilization rate of early rescue ICSI was 81.8% (4232/5171), and the 3PN rate (which indicates the possibility of multisperm fertilization) was 4.8% (249/5171). The good blastocyst rate was 36.2% (1140/3149), the pregnancy rate was 56.3% (429/762), and the production rate was 67.9% (248/365).

The normal fertilization rate of conventional ICSI conducted during the same period was 80.9% (24344/30097) and the 3PN rate was 3.2% (972/30097). The good blastocyst rate was 33.0% (6879/20839), the pregnancy rate was 48.9% (2489/5088), and the production rate was 66.6% (1426/2141).

There was no significant difference in normal fertilization rate. The 3PN rate, the good blastocyst rate and the pregnancy rate were significantly higher in the early rescue ICSI group ($P < 0.05$). There was no significant difference in production rate.

Good blastocysts were defined as those with a diameter of 160 µm or more and a recognizable ICM. All embryo transfers were performed using the freeze-thaw single embryo transfer protocol, and production rates were based on embryo transfers up to 2016.

Limitations, reasons for caution: In Japan, some patients do not like ICSI (due to concerns over health of the resulting children), and there are institutions that perform IVF as much as possible and only carry out early rescue ICSI where fertilization fails.

Wider implications of the findings: The clinical outcome of embryos fertilized by early rescue ICSI is equal to or higher than that of conventional ICSI and is a useful technique for patients who do not like ICSI. Because the 3PN rate was higher than conventional ICSI, more effective multispermic fertilization prevention measures are necessary.

Trial registration number: Not applicable.

P-150 Clinical value of embryos with three or more blastomeres at the first division (direct cleavage embryos) but with nuclei in only two blastomeres

K. Isobe[1], S. Watanabe[1], M. Miura[1], Y. Kobayashi[1], R. Matsunaga[1], N. Yamanaka[1], M. Kamihata[1], T. Maeda[1], H. Makino[1], M. Ochi[1], T. Horiuchi[2]

[1]*Ochi Yume Clinic Nagoya, ART Lab., Nagoya, Japan*
[2]*Prefectural University of Hiroshima, Faculty of Life and Environment sciences, Shobara, Japan*

Study question: Does the clinical outcome differ between direct cleavage embryos with two and three or more nucleus-bearing blastomeres at the first division?

Summary answer: Direct cleavage embryos with two nucleus-bearing blastomeres had a significantly higher rate of blastocyst formation than embryos with three or more nucleus-bearing blastomeres.

What is known already: There are many reports that the rate of development to the blastocyst stage is markedly decreased in direct cleavage embryos, and that these embryos have an increased risk of aneuploidy during development into blastocysts. However, few reports have investigated whether the number of blastomeres with nuclei in direct cleavage embryos affects their developmental outcomes.

Study design, size, duration: We performed a retrospective analysis of embryos that were cultured in the period 2013 to 2015 and that had been recorded using a time lapse monitoring system (EmbryoScope, Vitlolife).

In total, 1135 embryos with three or more blastomeres at the first division were included in the study. Cells with a diameter of 40 μm or more were defined as blastomeres.

Participants/materials, setting, methods: The first division of embryos cultured within the target period was observed with a time lapse monitoring system. Embryos with a nucleus in only two blastomeres (two nucleus group) and embryos with a nucleus in three or more blastomeres (three or more nucleus group) were classified among 1135 direct cleavage embryos. The rates of good blastocyst formation (a diameter of 160 μm or more and a recognizable ICM), pregnancy, and production were compared.

Main results and the role of chance: The rates of formation of good blastocysts were 26.0% (159/611) for the two nucleus group and 5.2% (27/524) for the three or more nucleus group; the rate in the two nucleus group was significantly higher ($P < 0.05$). After freezing, thawing and transplantation by single embryo transplantation, a pregnancy rate of 46.9% (38/81) was achieved in the two nucleus group and of 40.0% (6/15) in the three or more nucleus group; production rates were 65.8% (25/38) and 83.3% (5/6), respectively, for the two groups, which was not significantly different.

Limitations, reasons for caution: In Japan, PGS has not been approved, and a method for confirming euploidy of the embryos on the basis of morphology and developmental kinetics during culture is required.

Wider implications of the findings: The two nucleus group is presumed to have a normal chromosome distribution (blastomeres without a nucleus may be fragments). Although an abnormal distribution of chromosomes is expected in embryos with three or more nuclei, these embryos can produce successful pregnancies. The reasons for this will be studied in the future.

Trial registration number: Not applicable.

P-151 Clinical outcomes of metaphase II oocytes with the presence of refractile bodies in patients undergoing intracytoplasmic sperm injection treatment

H. Takahashi[1], J. Otsuki[2], R. Hirata[1], H. Saito[1], T. Habara[3], N. Hayashi[3]

[1]*Okayama couple's clinic, laboratory, Okayama, Japan*
[2]*Okayama university, Assisted reproductive technology center, Okayama, Japan*
[3]*Okayama couple's clinic, Physician, Okayama, Japan*

Study question: Does the presence of refractile bodies (RF) negatively affect fertilization, embryo development and implantation rates following intracytoplasmic sperm injection (ICSI)?

Summary answer: Oocytes with RFs showed lower embryo development and implantation rates than those without RFs, however there were no significant negative effects on fertilization rates.

What is known already: RFs are a one of the main morphological abnormalities that can be observed in the cytoplasm of human oocytes. RFs consist of a mixture of lipids and dense granular materials, having a yellow autofluorescence which is consistent with the typical autofluorescence of lipofuscin. Lower fertilization rates and lower embryo development rates have been consistently reported among oocytes with RFs when compared with those without RFs. However, the implantation potential of embryos derived from oocytes with RFs still remains unclear.

Study design, size, duration: To have the background of patients comparable and know whether RFs have negative impact on clinical outcomes, RF positive cycles which had both RF positive (RF(+)) and negative (RF(-)) oocytes were subjected into this study. A total of 316 ICSI cycles performed between January 2013 and June 2016 were retrospectively analyzed regarding fertilization and embryo development rates and 438 single frozen embryo transfers performed prior to January 2017 were analyzed to compare the implantation rates.

Participants/materials, setting, methods: MII oocytes with the presence of RFs ≥5 μm in diameter were recorded as RF(+). Retrieved oocytes were morphologically classified into RF(+) and RF(-) oocytes at the time of ICSI. A comparison of the fertilization and the blastocyst formation rates on Day 5 was made between the two groups. Implantation rates were assessed in frozen-thawed single embryo transfer cycles. Statistical significance was determined by Chi-Square test.

Main results and the role of chance: A total of 3,085 oocytes were retrieved. Of these, 648 (21.0%) were RF(+). Fertilization rates in RF(+) and RF(-) were 76.5% and 77.2% respectively and no significant differences were detected (Odds Ratio (OR) = 0.96; 95% CI: 0.79-1.18, $P = 0.730$). The blastocyst formation rates on Day 5 in RF(+) and RF(-) were 45.8% and 52.2% respectively and were significantly lower in RF(+) oocytes than those in RF(-) oocytes (OR = 0.77, 95% CI: 0.63-0.94, $P = 0.011$). Implantation rates in RF(+) and RF(-) were 24.2% and 42.2% respectively and were also significantly lower in RF(+) oocytes than those in RF(-) oocytes (OR = 0.44, 95% CI: 0.26-0.73, $P = 0.001$). Furthermore, the implantation rates in RF(+) oocytes when high quality blastocysts were transferred was 28.6%, which was also significantly lower than that of 46.1% in RF(-) oocytes (OR = 0.47, 95% CI: 0.26-0.86, $P = 0.011$). However, no significant differences were found regarding miscarriage rates (16.7% vs. 30.1%) (OR = 0.47; 95% CI: 0.15-1.44, $P = 0.158$).

Limitations, reasons for caution: As the presence of RFs was only recorded at the time of ICSI, the presence of RFs in immature oocytes could not be analyzed. Since this study only focused on the differences between RF(+) and RF(-) oocytes from RF(+) cycles, comparisons with RF(-) cycles have yet to be done.

Wider implications of the findings: Our results suggest that oocytes with the presence of RFs have a lower potential to develop into blastocysts and even when they develop into high quality blastocysts, the chances of implantation are reduced. Further study is required to elucidate the causes of RF formation and thus improve implantation rates.

Trial registration number: Not applicable.

P-152 A higher incidence of smooth endoplasmic reticulum clusters in patients treated with a regimen of aromatase inhibitors

H. Saito[1], J. Otsuki[2], R. Hirata[1], H. Takahashi[1], T. Habara[3], N. Hayashi[3]

[1]*Okayama couple's clinic, laboratory, okayama, Japan*
[2]*Okayama university, Assisted reproductive technology center, Okayama, Japan*
[3]*Okayama couple's clinic, Physician, okayama, Japan*

Study question: Can a regimen of aromatase inhibitor (AI) reduce the occurrence of smooth endoplasmic reticulum clusters (sERCs) in oocytes?

Summary answer: Contrary to expectations, the occurrence of sERCs was significantly higher in oocytes from patients treated with AI than in those treated with clomiphene citrate (CC).

What is known already: sERC is one of the dysmorphic phenotypes found in human oocytes and significantly reduces pregnancy rates. A comparatively higher number of abnormities in live-births appear to be associated with the presence of sERCs in oocytes, although healthy babies can be born from embryos derived from sERC(+) oocytes. sERC formation is related to the higher levels of serum E2 detected in sERC(+) cycles. It has recently been reported that embryos derived from sERC(+) oocytes are prone to a higher frequency of aberrant spindle formation and mitotic cleavage. The levels of serum estradiol are known to be lower in patients with AI.

Study design, size, duration: This was a retrospective cohort study of patients whose AMH levels were ≦1.0 ng/ml, involving a total of 598 cycles between July 2014 and December 2016. The choice of ovarian stimulation protocol was dependent on serum AMH levels and age. Patients treated with AI and CC were in the same classification and the choice of AI or CC was according to the patients' preferences, therefore the two regimens, AI and CC are comparable.

Participants/materials, setting, methods: All of the participants were infertile women who were being treated by ICSI. When there was at least one sERC positive oocyte among the retrieved oocytes the cycle was defined as a sERC(+) cycle. The rates of sERC occurrence were calculated for each regimen of ovarian stimulation. The AI and CC regimens were compared regarding the sERC(+) rates and the serum estradiol and progesterone levels on the date of hCG administration.

Main results and the role of chance: The average age and AMH(ng/ml) level were 41.4 ± 3.5 and 0.38 ± 0.3 respectively for patients treated with AI and 41.3 ± 3.5 and 0.41 ± 0.29 for those with CC. The two regimens were comparable regarding age and AMH level (Age: OR 1.01, 95% CI 0.96-1.06, P = 0.79; AMH: OR 0.75, 95% CI 0.41-1.36, P = 0.35). The occurrence of sERCs was found to be 13.2% (23/174) in oocytes from patients treated with AI which was significantly higher than that of 3.8% (16/424) in oocytes from those treated with CC (OR 3.88, 95% CI 2.00-7.55, P<0.0001). Among the patients treated with AI, serum estradiol(pg/ml) and progesterone(ng/ml) levels on the date of hCG were 549.1 ± 388.2 and 1.20 ± 0.72 in sERC (+) and 366.0 ± 276.0 and 0.75 ± 0.55 in sERC(-) cycles. Both the estradiol and the progesterone levels were significantly higher in sERC(+) than in sERC(-) cycles (E2: OR 1.18, 95% CI 1.01-1.39, P = 0.033; P4: OR 3.10, 95% CI 1.57-6.37, P = 0.001). With regard to the CC cycles, the serum estradiol and progesterone levels on the date of hCG were 1305.4 ± 443.1 and 0.83 ± 0.51 in sERC(+) and 994.8 ± 491.6 and 0.71 ± 0.46 in sERC(-) cycles. Conversely, no significant differences were detected (E2: OR 1.12, 95% CI 0.97-1.27, P = 0.12; P4: OR 1.64, 95% CI 0.58-3.83, P = 0.32).

Limitations, reasons for caution: The comparison was limited to two ovarian stimulation protocols. Other stimulation protocols, such as long, short, and antagonist protocols, could not be compared with AI in this study, as the patients' backgrounds (age and levels of AMH) were all different.

Wider implications of the findings: As AI did not reduce the occurrence of sERCs, the elevation of estradiol may not be the cause of sERC occurrence, but a consequence. Considering the higher levels of progesterone in sERC(+) cycles, the negative effects of premature luteinization on oocytes, which frequently occur with AI protocol, require further study.

Trial registration number: Not applicable.

P-153 Male Factor is the most important factor influencing the frequency of unequal direct cleavage events as visualized by time-lapse during early embryo development

S. Davies[1], C. Karamolegos[2], A. Karagianni[2], P. Sisi[2], C. Mendorou[2], M. Mastrominas[3]

[1]c/o Embryogenesis, embryology, Maroussi- Athens, Greece
[2]embryogenesis, embryology, athens, Greece
[3]embryogenesis, Clinical, athens, Greece

Study question: To study Irregular Direct Cleave (DC) events under differing Infertility causes, IVF protocols and age groups to identify sub-groups with increased prevalence.

Summary answer: Irregular direct cleavage events were observed with a consistent regularity in all groups studied. Only male factor patients showed significant increase in occurrence.

What is known already: Irregular divisions during initial cleavage stage of embryo development generate low viability embryos which either arrest at cleavage stage or have elevated aneuploidies or mosaicism. The events are very specific, appear to occur at random, but with a consistent regularity, are not an artefact of stimulation, and the underlying mechanism is not clearly understood.

Study design, size, duration: A retrospective study over the period of 2012-2017 with all embryos incubated in Embryoscope and all annotations performed by the same person, and irregular direct cleavages defined as DC1, DC2 & DC3 (referring to direct cleave 1st cycle, 2nd cycle and 3rd cycle). Embryos were incubated for 3-5 days in Sage-1-step media. All embryos were sub characterised into Stimulated IVF cycle, Natural cycle, PGS (RIF, RM, Altered Karyotype), Age, & male factor (Ejaculated, TESE, Ionophore).

Participants/materials, setting, methods: A total of 7052 embryos were included. Patients included, (a) IVF with ICSI (2998 embryos); (b) PGD-AS: Implantation Failures RIF (n = 706), Recurrent Miscarriages (RM) (n = 894), & Translocations (n = 448); (c) Male: Ejaculated (n = 786), TESE (n = 278) & ionophore-enhanced fertilisation (n = 204); & (d) Natural Cycle IVF (n = 738).

Only 1-3 cell cleavages were included, all ambiguous cleavages excluded.

Setting, private IVF facility.

Main results and the role of chance: Irregular cleavages DC1, DC2 & DC3 occurred with regular frequency across all groups studied irrespective of age, aetiology, or if embryos were generated with ovarian stimulation or natural cycle. The overall proportion of embryos with irregular direct cleavage up to 8 cell stages were 1692 / 7052 (23.9%), with a distribution: DC1, 955/7052 (13,5%), DC2, 700 / 7052 (9,9%), & DC3, 37 / 7032 (0,5%). The proportion of embryos showing multiple direct cleavages DC1 + DC2, DC2 + DC2, DC1/2 + DC3 were only 40 / 7032 (0,5%).

Male factor patients showed a significant increase (p>0,01) in direct divisions DC1 with respect to all the other groups studied, and there was increasing frequency of DC1 with decrease in sperm quality (+ ionophore (37/204, 18,1%) > TESE (47/278, 16,9%) > Ejaculate (122/786, 15,5%). There were no significant differences in DC2 or DC3 for any of the groups studied.

All the DC1 embryos arrested at cell stages of development. DC2 embryos developed to blastocyst but with much lower frequency than non-DC embryos.

Limitations, reasons for caution: Great care was taken to standardise all timings and annotations to include any comparable irregular direct cleavage events and avoid pseudo-cleavage events. Natural cycles are primarily non-elective and include older patients (>40 years) and poor responders. DFI was not used as criteria for male factor.

Wider implications of the findings: Decoupling of visible events of time lapse analysis is an important task in trying to understand the underlying cause or mechanism. The observation that sperm quality can increase DC1 but not DC2/3 implies independent mechanisms. Multinucleation may play more important role in DC2/3.

Trial registration number: None.

P-154 Effectiveness of ≥170-µm diameter criterion for blastocyst cryopreservation

T. Kyoya, H. Watanabe, H. Hasegawa, R. Suzuki, K. Tsukamoto, M. Kobayashi, S. Saito, J. Kobayashi

Kanagawa Ladies Clinic, ivf, yokohama- kanagawa-, Japan

Study question: Does setting a ≥170-µm diameter criterion for blastocyst cryopreservation influence clinical outcomes following implantation of frozen-thawed embryos?

Summary answer: Pregnancy rates following frozen-thawed embryo transfer were constant, irrespective of blastocyst diameter.

What is known already: Frozen blastocyst transfer is known to yield higher pregnancy rates than fresh blastocyst transfer due to embryo–endometrium synchronization.

We previously froze good-quality blastocysts at stage 3, and then thawed them on the day before transfer. Blastocysts were developed to stage 4 on the

following day and then implanted, and we reported a resultant improvement in post-freeze-thaw pregnancy rate over thawing on the day of transfer.

Based on this, we changed our cryopreservation criterion to stage 4 (blastocyst diameter ≥170 μm) in 2017.

Study design, size, duration: We targeted 547 cycles subject to single frozen-thawed blastocyst transfer between January and October 2017 for analysis in this study. Only good-quality blastocysts with diameter ≥170 μm at days 5 and 6 were eligible for analysis. Blastocyst diameter was measured from images taken immediately prior to cryopreservation, using an EmbryoScope system.

Participants/materials, setting, methods: Blastocysts were classified by diameter into Categories A (170 to 179 μm), B (180 to 189 μm), C (190 to 199 μm), and D (≥ 200). We compared pregnancy rates between the four blastocyst categories after 5- and 6-day incubation periods.

Main results and the role of chance: Pregnancy rates achieved with transferred blastocysts after 5-day incubation showed no significant differences between the 4 diameter categories, at 41.8% (64/153) for Category A, 39.5% (45/114) for Category B, 47.6% (30/63) for Category C, and 41.6% (32/77) for Category D.

Pregnancy rates achieved with transferred blastocysts after 6-day incubation showed no significant differences between the 4 diameter categories, at 29.5% (13/44) in Category A, 21.4% (9/42) in Category B, 45.5% (10/22) in Category C, and 46.9% (15/32) in Category D; however, the rates in Categories C and D tended to be high.

Limitations, reasons for caution: This study is limited to its retrospective design and small sample size.

Wider implications of the findings: Pregnancy rates showed no significant difference between transferred blastocyst categories irrespective of incubation periods; therefore, we considered that the cryopreservation criterion setting investigated in this study did not influence pregnancy outcome. Accordingly, we suggest that a criterion of diameter ≥170 μm is effective for blastocyst cryopreservation.

Trial registration number: Not applicable.

P-155 SCF in follicular fluid and granulosa cells is positively associated with oocyte developmental potential in humans

J. Tan[1], Y. Zou[2], X.W. Wu[1], X.J. Wan[1], Q.F. Wu[1]

[1]*Jiangxi Provincial Maternal and Child Health Hospital, Reproductive Medicine Center, Nanchang, China*

[2]*Jiangxi Provincial Maternal and Child Health Hospital, Key Laboratory of Women's Reproductive Health of Jiangxi Province, nanchang, China*

Study question: To explore whether the levels of SCF in follicular fluid (FF) and GCs can be used as a potential marker for predicting oocyte developmental potential.

Summary answer: The levels of SCF in FF and GCs might be considered as a new marker for predicting oocyte developmental potential.

What is known already: Stem cell factor (SCF), which is derived from granulosa cells (GCs), plays a key role in the process of follicular development and oocyte maturation.

Study design, size, duration: Follicular fluid and GC samples from 150 female patients undergoing intracytoplasmic sperm injection were collected in this study.

Participants/materials, setting, methods: The SCF concentrations in FFs and SCF messenger RNA (mRNA) in GCs were evaluated by using enzyme-linked immunosorbent assay and real-time polymerase chain reaction, respectively.

Main results and the role of chance: The results showed that the levels of SCF protein and mRNA were significantly associated with oocyte maturation, normal fertilization, cleavage, and embryo quality. Moreover, the levels of SCF protein and mRNA in pregnancy group were also higher than those in the non-pregnancy group. The cutoff value of SCF in FF for predicting high-quality embryo was 1.346, with a sensitivity of 57.8% and a specificity of 72.4%, and the cutoff value of SCF in GCs for predicting high-quality embryo was 6.650, with a sensitivity of 64.4% and a specificity of 78.1%.

Limitations, reasons for caution: The number of samples is the limitation in this present. Further study need to comfired this results.

Wider implications of the findings: Our results showed a positive and statistically significant relationship between SCF level and oocyte maturation, normal fertilization, cleavage, embryo quality, and clinical pregnancy.

Trial registration number: not applicable.

P-156 A new meta-analysis about an unclear topic in ART: Fresh embryo versus freeze-all embryo transfer strategies

J.G. Franco Jr.[1,2], F. Dieamant[1,2], C.G. Petersen[1,2], A.L. Mauri[1,2], M.C. Mattila[1], V.A. Comar[1], L. Vagnini[2], A. Renzi[2], B. Petersen[2], C. Zamara[1], J.B.A. Oliveira[1,2], R.L.R. Baruffi[1,2]

[1]*Centre for Human Reproduction Prof. Franco Jr, Research, Ribeirao Preto, Brazil*

[2]*Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil*

Study question: Can cryopreservation of all embryos with subsequent embryo transfer (Freeze-all) promote improvements in the clinical ART outcomes compared with fresh embryo transfer (Fresh-ET)?

Summary answer: Freeze-all does not improve clinical outcomes when the mean number of oocytes retrieved is <15. It seems be useful when >15 oocytes are collected.

What is known already: Freeze-all has been hypothesized as the preferred way to avoid the potential deleterious effects of controlled ovarian stimulation (COS) on endometrial receptivity in fresh cycles of IVF/ICSI. It has been suggested that the supra-physiologic hormonal levels during COS promote a suboptimal uterine environment, impairing clinical outcomes in ART cycles. There are few randomized controlled trials demonstrating higher pregnancy rates with frozen-embryo transfer than with Fresh-ET. A previous meta-analysis has shown more favourable clinical outcomes with Freeze-all than with Fresh-ET. However, with the randomized trials published recently, a new meta-analysis is essential to guide the scientific community on this issue in reproductive medicine.

Study design, size, duration: A systematic review based on electronic searches of databases(PubMed, EMBASE, Web of Science, SCOPUS, and Cochrane Central Register of Controlled Trials; key-words:Freeze-all; Fresh-embryo; pregnancy rates; oocytes-retrieved) up to January 2018 was conducted to identify randomized controlled trials(RCTs) comparing the ART outcomes of fresh versus elective frozen-embryo transfer. The primary outcome was live birth rate (per woman randomized). Secondary outcomes included ongoing pregnancy rate(per woman randomized), clinical pregnancy rate(per patient randomized) and miscarriage rate(from clinical pregnancies).

Participants/materials, setting, methods: Six RCTs were included as targets for data extraction and meta-analysis. Most of the trials did not allow the clear identification of the study subjects(e.g,PCOS). Data were combined for meta-analysis using the StatsDirect statistical software. Dichotomous data are expressed as Relative Risk (RR) with a 95% confidence interval (CI). The amount of heterogeneity was evaluated using Cochran's Q and I^2. Study data were combined using a random-effects model. P-values <0.05 were considered statistically significant.

Main results and the role of chance: The results of this meta-analysis are divided into three parts, based on the mean number of oocytes retrieved.

Part I: mean number of oocytes retrieved >12 and < 21

1. Live birth rates(4-trials): Freeze-all: 46.9%(1081/2305) versus Fresh-ET:43.9%(1020/2321) with no statistical significant differences(RR = 1.13; 95%CI = 0.97-1.32; $P = 0.12$). Heterogeneity:$I^2 = 77.4\%$; CochranQ = 13.2, $P = 0.04$.
2. Ongoing pregnancy rates(6-trials): Freeze-all:49.7%(1209/2435) versus Fresh-ET:48.0%(1177/2450), with no significant differences(RR = 1.11; 95%CI = 0.98-1.25; $P = 0.1$). Heterogeneity: $I^2 = 67\%$; CochranQ = 15.1, $P = 0.01$.
3. Clinical pregnancy rates(5-trials): Freeze-all:54.5%(1278/2344) versus Fresh-ET: 53.7%(1269/2362), with no significant differences(RR = 1.04; 95%CI = 0.96-1.14; $P = 0.35$). Heterogeneity: $I^2 = 47.5\%$; CochranQ = 7.62, $P = 0.10$.
4. Miscarriage rates(5-trials): Freeze-all: 10.3%(132/1278) versus Fresh-ET: 12.1%(154/1269), with no significant differences(RR = 0.85; 95%CI =

0.65-1.12; $P = 0.25$). Heterogeneity:$I^2 = 23.8\%$; CochranQ = 5.25, $P = 0.26$.

Part II: mean number of oocytes-retrieved was >12 and <15

1. Live birth rates(3-trials): Freeze-all: 46.2%(1025/2214) versus Fresh-ET: 44.1%(985/2233), with no significant differences(RR = 1.07; 95%CI = 0.93-1.22; $P = 0.36$). Heterogeneity: $I^2 = 72.2\%$; CochranQ = 7.2, P = 0.03.
2. Ongoing pregnancy rates(4-trials): Freeze-all: 48.8%(1114/2284) versus Fresh-ET: 48.1%(1107/2300), with no significant differences(RR = 1.04; 95%CI = 0.93-1.16; $P = 0.47$). Heterogeneity: $I^2 = 59.3\%$; CochranQ = 7.30, $P = 0.07$.
3. Clinical pregnancy rates(4-trials): Freeze-all: 54.2%(1239/2284) versus Fresh-ET: 53.7%(1235/2300) with no significant differences(RR = 1.03; 95%CI = 0.94-1.13; $P = 0.50$). Heterogeneity: $I^2 = 53.8\%$; CochranQ = 6.5, $P = 0.09$.
4. Miscarriage rates(4-trials) Freeze-all: 10.3%(128/1239) versus Fresh-ET: 12.1%(149/1235), with no significant differences(RR = 0.87; 95%CI = 0.63-1.20; P = 0.39). Heterogeneity: $I^2 = 41.8\%$; CochranQ = 5.15, $P = 0.16$.

Part III: mean number was ≥15 and <21

1. Ongoing pregnancy rates(2-trials): Freeze-all: 62.9%(95/151) versus Fresh-ET: 46.7%(70/150), with statistical significant differences(RR = 1.33; 95%CI = 1.01-1.76; $P = 0.04$). Heterogeneity: CochranQ = 1.75, $P = 0.18$.

Limitations, reasons for caution: Most of the trials included did not define the population studied as PCOS/non-PCOS, so we cannot rule out the presence of ovulatory/anovulatory patients in the same study. Therefore, the mean number of oocytes retrieved was considered in the present meta-analysis. Some studies had high heterogeneity, thus high risk of bias.

Wider implications of the findings: Freeze-all could be favourable when a high number of oocyte is collected (≥15), suggesting an association between higher COS and impairment of endometrial receptivity. However, when the mean number of oocytes collected is <15, Freeze-all does not appear to be advantageous. RCTs on this topic are required.

Trial registration number: Not applicable.

P-157 Failure of cytokinesis and its higher incidence during ICSI procedures and in oocytes containing smooth endoplasmic reticulum clusters

J. Otsuki[1], T. Iwasaki[2], Y. Katada[2], Y. Tsutsumi[2], Y. Tsuji[2], K. Furuhashi[2], M. Yamamoto[3], S. Kokeguchi[2], M. Shiotani[2]

[1]Okayama University, ART Center, Okayama, Japan
[2]Hanabusa Women's Clinic, Reproductive Medicine, Kobe, Japan
[3]Okayama University, Graduate School of Environmental and Life Science, Okayama, Japan

Study question: Can the failure of cytokinesis be attributed to ICSI procedures and oocytes which contained smooth endoplasmic reticulum clusters (sERCs)?

Summary answer: Embryos fertilized by the ICSI have a higher incidence of meiotic failure and oocytes containing sERCs have a higher incidence of meiotic and mitotic failure.

What is known already: sERCs are one of the dysmorphic phenotypes that have been reported in human oocytes. Significantly reduced pregnancy rates and a comparatively higher number of abnormities in live births appear to be associated with the presence of sERCs in oocytes. However, some reports have shown that healthy babies can be born, without reduced pregnancy rates, from oocytes observed to contain sERCs. In ESHRE 2017 we reported a higher incidence of cleavage failure among embryos derived from sERC(+) oocytes in contrast to their sERC(-) siblings. However, the incidence of cleavage failure among embryos in sERC negative cycles has been under investigation.

Study design, size, duration: This was a retrospective observational cohort study, involving a total of 1,415 oocytes, evaluated between January 2011 and December 2015. Oocytes were obtained from 43 sERC(+) cycles, which had at least one sERC(+) oocyte among the retrieved oocytes, and 143 sERC(-) cycles. During the course of this study, time-lapse recording was restricted to patients aged between 30 and 40 years of age who yielded 4 or more oocytes.

Participants/materials, setting, methods: The presence of sERCs was evaluated by careful observation of 7 focal planes using an EmbryoScope®Time-lapse system while studying the dynamic changes within oocytes and embryos. Statistical analysis was carried out to explore the nature of the abnormalities. Logistic regression analysis was carried out to explore the independent variables for meiotic and mitotic cleavage failure. Independent variables included fertilization procedure (ICSI or IVF), cycle occurrence of sERCs and oocyte-based occurrence of sERCs.

Main results and the role of chance: Among 1,415 oocytes, sERCs were found in 5.7% of the oocytes (81/1415) using a time-lapse observation system. The occurrence of mitotic cleavage failure after the IVF procedure among sERC(+) oocytes in sERC(+) cycles, sERC(-) oocytes in sERC(+) cycles, and sERC(-) oocytes in sERC(-) cycles was 22.9% (8/35), 8.7% (10/115) and 7.7% (31/404) respectively. By comparison, the occurrence of mitotic failure after the ICSI procedure across the same categories was 33.3% (7/21), 20.4% (11/54) and 5.5% (15/274) respectively. The occurrence of meiotic cleavage failure after the IVF procedure among these categories was 8.9% (4/45), 0.7% (1/141) and 0.8% (4/506) respectively, while the occurrence of meiotic cleavage failure after the ICSI procedure across these categories was 4.0% (1/25), 3.0% (2/67) and 2.9% (10/340) respectively. The incidence of mitotic cleavage failure in oocytes with sERCs was found to be significantly higher than that in oocytes without sERCs (OR = 2.560, 95% CI: 1.210-5.410, P = 0.014). The incidence of meiotic cleavage failure during the second polar body extrusion in oocytes with sERCs was also significantly higher than that in oocytes without sERCs (OR = 5.140, 95% CI: 1.190-22.200, P = 0.028). Furthermore, ICSI was found to have a greater frequency of meiotic failure than IVF (OR = 0.413, 95% CI: 0.174-0.981, P = 0.045).

Limitations, reasons for caution: The mechanism of the frequent failure of cytokinesis in embryos derived from sERC(+) oocytes is still unknown. This requires further investigation, as the appearance of sERCs could be a consequence rather than a cause of cleavage failure.

Wider implications of the findings: Our current data, showing that aberrant cleavage frequently occurs in sERC(+) oocytes during meiosis and mitosis and in ICSI cases during meiosis, suggests that abnormal embryo development could be related to disturbed Ca^{2+} distribution patterns. Regarding cytokinetic failure, an embryonic cell could become tetraploid, which may induce abnormal chromosomal configurations.

Trial registration number: not applicable.

P-158 Annual variation in ICSI cycle outcome in temperate zones is related to weather-temperature not calendar - seasons nor day-light duration as proved by regression analysis

M.E. Ghanem[1], L.A.H. Al-Boghdady[1], A.G. El-Metwally[2], M. Emam[1], M. Hassan[2], A. Helal[2], A. Shababan[3], H. Abdel- Fattah[2], A. Zayed[2], M. Elzayaat[1]

[1]Mific, IVF, Mansoura, Egypt
[2]Mansoura faculty of medicine, ob/gyn, Mansoura, Egypt
[3]Al-Azhar faculty of medicine, ob/gyn, Cairo, Egypt

Study question: If the annual variation of ICSI outcome in our geolocality is related to meteorological year seasons (winter –spring-summer –autumn) or to weather temperature?

Summary answer: Weather temperature ≥ the 50th -centile, not calendar season in our geolocation independently predicts better IR and CPR in ICSI as shown by regression analysis.

What is known already: Whereas many studies reported significant seasonal variation in the outcome of IVF/ICSI cycles few studies denied the presence of such seasonality. The mechanisms underlying periodicity of human in vitro conception however are still unclear. While many authors attributed the annual variation in ICSI outcome to daylight length, others linked it to temperature changes. Peak natural fertility times vary from one latitude and climate to another and geographical discrepancies reflect differences in the mix of daylight

and temperature that most closely approximates ideal conditions for human conception. Are the same mechanisms apply to in vitro human conception?

Study design, size, duration: We retrospectively analyzed 3586 fresh first completed ICSI cycles performed in our center, geolocation -N 31.044183, E 31.378584300000057,by the same team of clinicians and embryologists over 6 years (2011-2016). We included all female ages and all ICSI indications. The cycles were assigned to one of 4 calendar- seasons (winter-spring-summer-autumn) then 2 temperature- centiles (November-_April) < & (May-October)≥ 50th centile: 20 °C) depending on date of ovum pick-up (OPU).

Participants/materials, setting, methods: We compared ages, infertility duration, eggs retrieved (ER), dose/ER, fertilization rate (FR), number of embryos-transferred (NET), blastocyst –ratios (RBL), clinical pregnancy rate (CPR) implantation rate (IR) in 4 calendar and 2 temperature seasons. Binomial logistic (BNLR) and multiple regression (MR) analysis were used to compare the predictive values of *age, NET, RBL, calendar-season, temperature-centile, day-light duration-centile*) for, IR, CPR.

Main results and the role of chance: No statistically significant differences were found between cycle features nor cycle outcome in the 4 calendar seasons: winter (888- ET), spring (843- ET),summer (840-ET), autumn (887 -ET) respectively (IR: 13.8, 13.1, 14.1, 13.2) (p = 0.68)**#**, CPR: 41.5, 40.6, 42.3, 40.5 (p = 0.86) **#**.Comparing the 2 temperature- centiles (November-April **temp < 20° C, 1747 ET) &** (May-October **temp ≥ 20 ° C – 1718 ET**) respectively): age **29.38 ± 5.6, 29.83 ± 5.6 (p = 0.02) *, Infertility-Duration 5.69 ± 4.26, 5.51 ± 3.975 (0.268) *, ER 11.16 ± 6.3, 11.02 ± 6.4 (p = 0.52) *, Amps/ER 3.92 ± 4.09, 3.94 ± 4.81(p = 0.92) *, FR 76.61 ± 22.02, 76.63.52 ± 22.0 (0.97) * mean NET 2.73 ± 0.83, 2.72 ± 0.85 (p = 0.9) *, RBL 36.2%, 38.9% (p = 0.11), total number of transferred embryos 4749, 4683, Total number of Sacs 601, 679, IR 12.7%, 14.5% (P = 0.0098) #, number of clinical pregnancies 690, 753, CPR 39.8% ,43.8% (P = 0.0026) #. (* T-test, # χ 2-test) Using MR for IR & BNLR for pregnant outcome employing the 6 variables significantly predicted both IR and CPR (p < .000) but, day- light duration, calendar-season did not significantly add to prediction (p>0.05). Absolute RR = 4 and Relative RR = 9.%, Number-Needed -to -Treat = 25**

Limitations, reasons for caution: The large sample size flagged minor differences in age (mean-29) and infertility duration (mean-5) as significant which is difficult to defend. The assignment to one calendar season or temperature centile by date of OPU does not exclude effects of other seasons when ET is done in subsequent season.

Wider implications of the findings: Patients in our geolocation should be counseled about the relatively better outcome in warmer weather compared to cold weather.This recommendation is only valid in locations which share us the weather temperature centiles.

Trial registration number: enter 'not applicable.

P-159 Re-biopsy combined with double vitrification during preimplantation-genetic-testing cycles: comprehensive description of blastocysts rescued after failing the first round of diagnosis

D. Cimadomo[1], L. Rienzi[1], F.M. Ubaldi[1], C. Patassini[2], V. Romanelli[2], E. Alviggi[3], L. Dusi[4], E. Albani[5], N. Barnocchi[6], F. Benini[7], P.E. Levi Setti[5], A. Capalbo[2]

[6]*G.en.e.r.a. Umbria, G.en.e.r.a. centers for reproductive medicine, Umbertide, Italy*
[7]*Demetra, Centro di procreazione medicalmente assistita, Firenze, Italy*

Study question: Which are the technical and clinical results of re-biopsied blastocysts that failed the first round of qPCR-based aneuploidy testing on trophectoderm biopsies?

Summary answer: The risk of inconclusive diagnoses is <3%.Re-biopsied blastocysts after double vitrification show similar survival, euploidy and implantation rates as blastocysts diagnosed at the first analysis.

What is known already: The implementation of multicellular trophectoderm biopsy approach has significantly reduced the risk for amplification failure and inconsistent results during preimplantation-genetic-testing cycles. Yet, to date few reports defined the rate of re-biopsy procedures required, as well as their related technical and clinical results. On average, 2-6% of the blastocysts were reported to result in an inconclusive diagnosis after comprehensive-chromosome-testing (CCT), of which 1-2% due to DNA amplification failure. The technical and clinical outcomes seem comparable to blastocysts with a conclusive result after the first biopsy.

Study design, size, duration: 8991 blastocyst biopsy procedures were conducted between April 2013 and September 2017 at 7 IVF centres in Italy and analysed by qPCR at a single genetic lab. 206 blastocysts were successfully re-biopsied after warming and re-expansion, and then re-vitrified. 41 frozen single-embryo-transfers (SETs) of blastocysts diagnosed euploid after trophectoderm re-biopsy were performed to date. Logistic regression analyses were performed to investigate the parameters associated with an inconclusive diagnosis.

Participants/materials, setting, methods: Only preimplantation-genetic-testing-for-aneuploidies (PGT-A) cycles with a freeze-all approach were included. Vitrification was performed within 30 min from trophectoderm biopsy on collapsed blastocysts. qPCR-based CCT method was adopted. Amplification failure or nonconcurrent molecular data resulted in an inconclusive diagnosis. Only frozen euploid SETs were performed ≈2 hr after warming. Clinical pregnancy, miscarriage (<20weeks) and ongoing pregnancy rates were monitored.

Main results and the role of chance: 8991 blastocysts were included (3244 PGT-A cycles conducted from 2687 couples, mean maternal age: 38.5 ± 3.9, 25-45). 2.6% of the trophectoderm biopsies resulted in an inconclusive diagnosis (n = 228/8991, 95%CI:2.2%-2.9%), of which 2% (n = 176/8991) due to amplification failure and 0.6% (n = 52/8991) due to nonconcurrent results. The only parameters significantly associated with the risk of obtaining an inconclusive diagnosis were the IVF centre (OR = 1.13, 95%CI:1.1-1.2 from the one performing the highest to the one performing the lowest number of procedures; p<0.01) and the day-of-biopsy (OR = 0.55, 95%CI:0.43-0.69 from day 5 to day7; p<0.01).

213 blastocysts were warmed to be re-analysed. The survival rate after warming was 98.1% (n = 209/213) and the survival rate after re-biopsy was 98.6% (n = 206/209). All the re-biopsied blastocysts resulted in a conclusive diagnosis, among them the euploidy rate was 51.9% (n = 107/206) (The euploidy rate of blastocysts biopsied only once was 45.7% (n = 4000/4778)).

41 blastocysts diagnosed euploid after re-biopsy have been warmed to date. All of them survived (100%, n = 41/41) and were transferred. 51.2% clinical pregnancy (n = 21/41), 9.5% miscarriage (n = 2/21) and 46.3% ongoing pregnancy (n = 19/41) rates were reported.

Limitations, reasons for caution: Only targeted-qPCR-based CCT method was adopted in this retrospective analysis. A more powered report of the clinical (and possibly obstetrical and perinatal) outcomes after frozen euploid SET of re-biopsied blastocysts requires a larger sample size. Ideally, these clinical data should be clustered also per blastocysts' quality and day of full-blastulation.

Wider implications of the findings: Trophectoderm biopsy approach is confirmed technically-consistent and clinically-secure. The residual risk for inconclusive diagnoses (2.6%) seems related to day-of-biopsy (possibly the number/volume of retrieved cells) and IVF centres' expertise. Yet, it is worth re-biopsying undiagnosed blastocysts since the survival, euploidy and ongoing implantation rates seem comparable to the control.

Trial registration number: None.

P-160 Blastocyst culture using G-TL single-step versus Origio sequential medium: a semi-randomized approach

M. Abraham, A. De Vos, I. Mateizel, H. Tournaye, G. Verheyen

UZ Brussel, Centre for Reproductive Medicine, Jette, Belgium

Study question: Does human blastocyst formation and clinical outcome after IVF differ when using a single-step medium or sequential culture media?

Summary answer: Significant differences were observed for fertilization and embryo development in favour of the sequential medium. However, clinical pregnancy rate was not different.

What is known already: Embryo culture conditions represent a key part of IVF success. The development of culture media is based on two distinct approaches. 1) "Back to nature" in which the embryos are exposed to stage-specific media, designed to reflect the physiological changes in nutrient concentrations in the fallopian tube and the uterus (sequential media). 2) "Let the embryo choose" in which the embryos select the nutrients they require from a medium that provides them all at once (single media). At present, insufficient evidence exists to prefer sequential or single-step media for the culture of human embryos to the blastocyst stage.

Study design, size, duration: A preliminary sibling oocyte study (50 ICSI cycles) did not reveal differences in fertilization and embryo quality between the single-step medium (G-TL, Vitrolife) and the sequential media (Origio Sequential, Origio). In order to focus on the clinical outcome, a semi-randomized controlled trial including unselected ICSI cycles was performed between July 2016 and December 2016. In total, 2012 ICSI cycles were assigned to G-TL single-step medium (n = 1007) or Origio sequential media (n = 1005) on alternate days.

Participants/materials, setting, methods: In the G-TL single-medium group, injected oocytes were individually cultured in the same 25 µl droplet until day 5/6. In the cycles with Origio sequential media, injected oocytes were individually cultured in 25 µl cleavage medium and replaced to 25 µl blastocyst medium on day 3 until day 5/6. Fertilization, embryo development, embryo utilization rate (embryos transferred and vitrified per fertilized oocyte) and clinical pregnancies (with FHB) per intended transfer were compared between the two media.

Main results and the role of chance: Mean female age was 35.1 (±4.9 SD) in the G-TL single-step medium group and 35.4 (±5.1 SD) years in the Origio sequential media group. On average, 7.0 (±0.2 SD) and 7.1 (±0.2 SD) mature oocytes were available for ICSI. Fertilization rates in G-TL single-step medium (67.5%) and Origio sequential media (71.9%) were significantly different ($p = 0.0006$). Embryo development (top and good quality embryos) was significantly in favour of Origio sequential media, both on day 3 (74.8% versus 69.8%, $p = 0.0008$) and on day 5 (47.6% versus 40.5%, $p = 0.0005$). Likewise, the embryo utilization rate in Origio sequential media (44.8%) was significantly higher than in G-TL single-step medium (40.1%, $p = 0.0013$). Nevertheless, no significant difference was observed in the clinical outcome between the two media. In some cycles, freeze all policy was applied (236 cycles in the G-TL single-step group and 256 cycles in the Origio sequential group). Clinical pregnancy rate with FHB per intended transfer was 25.4% in G-TL single-step medium and 24.5% in Origio sequential media ($p = 0.708$).

Limitations, reasons for caution: In the present comparison between a single-step and a sequential medium clinical pregnancy rate was used as endpoint. However, in view of the significant differences in embryo development and embryo utilization rate, it might be worthwhile to look at cumulative live births.

Wider implications of the findings: The present study contributes to evaluate the performance of single-step versus sequential media in terms of embryo development and clinical outcome. In a smaller sibling oocyte study the present findings remained unnoticed. Differences in embryo development between media might also depend on specific laboratory conditions.

Trial registration number: not applicable.

P-161 Correlation among pAKT, pERK1/2 and DNA fragmentation index in human cumulus cells to determine oocyte competence

L. Bosco[1], M.C. Roccheri[1], C. Luparello[1], D. Matranga[2], A. Ferrigno[1], S. Cuomo[3], G. Ruvolo[4]

[1]*University, Dip di Scienze e Tecnologie Biologiche- Chimiche e Farmaceutiche, Palermo, Italy*

[2]*University, Dip di Scienze per la Promozione della Salute e Materno Infantile "G.D'Alessandro" Via del Vespro- PALERMO, Palermo, Italy*

[3]*Centro Internazionale di Procreazione Assistita Via Clemente Maraini 8-, ProCrea, Lugano, Swaziland*

[4]*Centro di Biologia della Riproduzione- Via Villareale, Centro CBR, Palermo, Italy*

Study question: The aim was to correlate specific biological aspects of cumulus cells isolated from individual cumulus-oocyte complexes (COCs) with the clinical outcome of the related embryos.

Summary answer: In case of positive clinical outcome, pERK1/2 nuclear localization in cumulus cells was correlated positively with pAKT expression levels and negatively with the DFI value.

What is known already: It is widely acknowledged that the activated pERK1/2 and pAKT factors play a key role in supporting the survival pathway, exerting an anti-apoptotic effect; it is also known that pERK1/2 translocates into the nucleus to interact with transcription factors and the DNA itself to promote cell viability and proliferation. Previous results demonstrated that in the cumulus cells of the oocytes able to produce blastocysts, the pAKT/DFI ratio was higher than in cumulus cells of embryos arrested during the *in vitro* culture. In addition, a significant direct correlation was found between pAKT and pERK1/2, suggesting a cooperative action as survival factors.

Study design, size, duration: The study had the duration of 24 months and involved 26 patients after informed consent. For each follicle containing a mature oocyte, the levels of pAKT, the nuclear localization of pERK1/2 and the DNA fragmentation index (DFI) in cumulus cells of single COCs were evaluated and put in correlation with the positive or negative clinical outcome of the related embryos according to the ability to reach blastocyst stage and the results assessed for statistical significance.

Participants/materials, setting, methods: Normo-responder patients of ART procedures were selected. The cumulus cells were harvested after hyaluronidase treatment of the individual COCs and centrifugation. The oocytes were transferred to the culture medium until used for ICSI. The DFI was evaluated *via* TUNEL assay. The levels of pAKT and the nuclear localization of pERK1/2 were assessed via immunofluorescence microscopy and densitometric analysis of the images using the appropriate software. The statistical significance was evaluated *via* the non-parametric Kruskall-Wallis test.

Main results and the role of chance: Out of 126 MII oocytes, 91 were fertilized and the derived embryos had the following evolution: 53 were transferred "in utero", 8 were arrested during "in vitro" culture and 30 were cryopreserved. In case of the positive clinical outcome, we found that in cumulus cells of the corresponding COCs the nuclear localization of pERK1/2 showed a significant inverse correlation with the DFI value, which is an apoptosis hallmark, ($r_s = -0.39$, $p = 0.007$), and a significant direct correlation with the intracellular accumulation of pAKT ($r_s = 0.477$, $p < 0.001$). These results were not obtained with cumulus cells of COCs related to negative clinical outcome of the arrested embryos. In addition, all the cumulus cells examined showed a significant inverse correlation between the intracellular accumulation of pAKT and the DFI value ($r_s = -0.37$, $p < 0.001$), confirming its role as a survival factor also in this cell type. Therefore, our results suggest that high levels of nuclear pERK1/2 accumulation coupled with an increase of pAKT and a low DFI value in the cumulus cells of the corresponding COCs might be considered as a marker of oocyte competence leading to the development of embryos of presumed good quality.

Limitations, reasons for caution: The present results are preliminary and further investigation is needed to improve their significance level and to gain further insights into the involvement of the biological aspects under study in the acquisition of oocyte competence.

Wider implications of the findings: Our results suggest that the nuclear localization of pERK1/2 coupled to an enhanced intracellular accumulation of pAKT may play an anti-apoptotic role and increase cell viability thereby providing a novel marker tool to facilitate the choice of the best oocyte to be fertilized and submitted to an ICSI cycle.

Trial registration number: The trial is an observational study and no registration is needed.

P-162 Degree of blastocoel re-expansion is the single most determinant factor for enhanced live birth rates in vitrified-warmed single blastocyst transfer cycles

N. Shaikh[1], B. Chimote[2], N. Chimote[3]

[1]*Vaunshdhara Clinic and Assisted Conception Center, Biochemistry- Embryology and Endocrinology, Nagpur, India*

[2]Vaunshdhara Clinic and Assisted Conception Center, Embryology- Reproductive Endocrinology- Biochemistry, Nagpur, India
[3]Vaunshdhara Clinic and Assisted Conception Center, Embryology and Reproductive Endocrinology, Nagpur, India

Study question: To evaluate the independent effects of Inner-cell-mass (ICM), trophectoderm (TE), and degree of blastocoel re-expansion on live-birth rate in vitrified/ warmed single blastocyst transfer cycles.

Summary answer: Re-expansion of blastocoel with degree of 3-4 is imperious to ICM and TE cell gradation for better live-birth rates in vitrified-warmed single blastocyst transfer cycles.

What is known already: The relevance of blastocoel expansion for clinical outcomes in blastocyst transfer cycles has been documented. However recent studies have presented contradictory results regarding significance of ICM gradation, TE gradation and degree of blastocoel expansion/re-expansion for increased live-birth rates in fresh as well as vitrified-warmed blastocyst transfer cycles. There is no consensus yet on which of these is the most significant predictor for live-birth. Moreover, few studies have reported combined results from fresh/frozen and single/double transfer cycles. Therefore, we aimed at verifying the relevance of each of these three parameters in predicting live-birth rates exclusively in vitrified-warmed cycles involving single-blastocyst transfer.

Study design, size, duration: Retrospective study of vitrified-warmed cycles involving women (n = 216) undergoing elective / non elective single blastocyst transfer from February 2014 to November 2016 at our private ART centre. Oocyte donation, Embryo-donation, assisted hatching and preimplantation genetic diagnosis cycles were excluded. Ethics Committee of the centre approved this retrospective study. All blastocysts were graded as per Gardner and Schoolcraft method of classification as 1-6 for degree of expansion and grades A/B/C for ICM and TE.

Participants/materials, setting, methods: Natural-cycle endometrial preparation was done with hormone supplementation followed by luteal-phase support with micronized progesterone. Endometrial response (thickness and homogeneity) was noted by ultrasound. Elective/non-elective single blastocyst-transfer was done 3 hours after warming of vitrified blastocyst. Warmed blastocyst was compared with pre-vitrified blastocyst for degree of expansion, gradation of ICM/TE. β-hCG level measured on day8 of transfer indicated pregnancy. Positive cardiac activity at sixth week confirmed clinical pregnancy. Live-birth was the primary outcome measure.

Main results and the role of chance: Women were classified into Live-birth (LB; n = 74) and non-pregnant (NP; n = 142) groups. Age, BMI, infertility period as well as number of oocytes retrieved, rate of formation of good quality cleavage-stage and blastocyst-stage embryos and survival rates post-warming did not differ significantly between the two groups. Same brand of embryo-transfer catheter and same brand and volume of media was used for transfer. However, the degree of re-expansion was significantly higher in LB group than in NP group (Mean ± SD: 3.6 ± 1.0 v 3.2 ± 0.94, P = 0.0068). The Fisher-Exact test odds ratio for achieving a live-birth with 3-4 degree of re-expansion was 2.78 (p = 0.0016) whereas the odds ratio was much lower (0.36) with any other degree of re-expansion. Although ICM grade was higher/better in Live-birth group than in non-pregnant group, the difference remained statistically non-significant (Odds ratio 1.25, p = 0.82). No significant difference was observed in the TE grades between the two study groups (p = 0.17). A notable difference was also observed in the endometrial echopattern (p = 0.03) although the endometrial thickness remained comparable between the two groups. Thus, post-warming degree of re-expansion is the single most promising predictive factor for live birth rates in such cycles.

Limitations, reasons for caution: Although the results are promising, this is a retrospective study with a relatively small sample size. A multicentric/randomized trial with much larger sample size is essential to generate a strong power for degree of re-expansion to be predictive of live-birth.

Wider implications of the findings: A good experimental design catering exclusively to vitrified-warmed cycles involving single blastocyst transfer is a strong point of this study. Therefore, even a relatively small sample size leaves no ambiguity regarding the significance of selection of best blastocyst on the basis of degree of re-expansion in predicting live birth rates.

Trial registration number: Not Applicable.

P-163 Morphokinetic analysis of euploid blastocysts: searching for non-invasive criteria of embryo implantation additional to chromosomal assessment

R. Maggiulli[1], M. Stoppa[1], D. Cimadomo[1], G. Fabozzi[1], A. Glancani[1], L. Dovere[1], L. Albricci[1], A. Capalbo[2], F.M. Ubaldi[1], L. Rienzi[1]

[1]Clinica Valle Giulia, GENERA centers for reproductive medicine, Rome, Italy
[2]Igenomix, Italia, Marostica, Italy

Study question: Can we define any morphokinetic parameter able to increase our predictive power upon implantation potential of euploid blastocysts cultured in time-lapse?

Summary answer: Blastomeres' symmetry at 4 cell-stage and blastocyst morphological quality after full-expansion were significantly correlated with the implantation of euploid blastocysts.

What is known already: To date, the assessment of a normal chromosomal constitution through comprehensive-chromosome-testing techniques represents a powerful predictive parameter upon blastocyst's reproductive potential. However, ≈50% of euploid blastocysts fail to implant.

The study of preimplantation embryonic development, via morphokinetic parameters in time-lapse, do not provide to date solid evidence of correlation with the clinical outcomes after IVF. Although, the additional predictive value of morphokinetic in preimplantation-genetic-testing (PGT-A) cycles conducted in time-lapse is yet to be assessed.

Study design, size, duration: Retrospective exploratory study. All transferred euploid blastocysts obtained after consecutive PGT-A cycles conducted in a time-lapse system between March 2014-March 2017 were included (n = 320). All morphokinetic parameters of embryo evaluation were compared among implanted and not implanted euploid blastocysts. Logistic regression analyses and receiver operating curve (ROC) analysis were conducted. Power calculations for significant differences were performed with the software G*Power v3.1.

Participants/materials, setting, methods: 130 implanted and 190 not implanted euploid blastocysts were included and confronted for the following timings: tPB2(2ndPolar-Body extrusion), tPNf (pronuclei formation), t2,t3,t4,t5, t8 (2-,3-,4-,5- and 8-cell division), cc1(t3-t2), cc2(t4-t3), cc3(t5-t4), tM(morula), tSB(starting-blastulation), tB(full-expansion). Furthermore, blastomeres' symmetry and fragmentation at t4, and blastocyst's quality at tB were evaluated and blindly-confirmed by two independent operators. The results were corrected through univariable and multivariable logistic regression analyses for all putative confounders including maternal age.

Main results and the role of chance: Significant differences were reported between implanted and not implanted euploid blastocysts for cc2 (1.3 ± 2.3 h,0-12.6 h versus 2.5 h±4.3 h,0-26.5 h, p<0.01), cc3 (12.4 ± 5.2 h,0.3-45.5 h versus 10.7 ± 6.5 h,0-43.4 h, p = 0.02) and tM (88.7 ± 10.5 h,66.9-121.7 h versus 91.4 ± 10.0 h,61.3-123.1 h, p = 0.03). Furthermore, low-fragmentation (<10%; n = 111/243, 45.7%) at t4 resulted in higher ongoing implantation rates after euploid blastocyst transfer than high-fragmentation (≥10%; n = 9/77,24.7%; p<0.01 and power = 92%). Similarly, even blastomeres' symmetry (n = 114/241, 47.3%) at t4 resulted into a better reproductive outcome than uneven one (n = 16/79,20.3%; p<0.01 and power>99%). At last, blastocysts' quality at tB was also correlated with a positive ongoing implantation (excellent: n = 86/184,46.7%; good: n = 21/49,42.9%; average: n = 17/51,33.3% and poor: n = 6/36,16.7%; p<0.01 and power = 95%). The univariable logistic regressions confirmed these data. Conversely, the multivariable logistic model outlined only blastomeres' symmetry (even/uneven, OR = 0.36, 95%CI:0.19-0.67; p<0.01) and blastocyst's quality (excellent/good/average/poor, OR = 0.77, 95%CI:0.61-0.98; p = 0.04) as predictive of implantation success/failure. The ROC curve analysis defined an area under the curve (AUC) for this model of 0.65, 95%CI:0.60-0.71, p<0.01.

Limitations, reasons for caution: The main limitations of this study are its retrospective nature and the subjectivity of blastomeres' symmetry definition at t4. Possibly, these data should be confirmed through a computational/mathematical assessment. Moreover, the extension of the sample size may allow the evaluation also of anomalous patterns of development, such as direct/reverse cleavage.

Wider implications of the findings: A model including blastomeres' symmetry at 4cell-stage and blastocyst's quality at full-blastulation may represent a valuable selection tool to predict euploid blastocysts' reproductive competence for any PGT-A cycle, regardless the adoption of a time-lapse system. Nonetheless, these data should be confirmed from a prospective study.

Trial registration number: None.

P-164 Does embryonic culture environment affect ploidy rates

R. Ahmed-Odia[1], E. Drew[1], H. Exeter[1], X. Vinals-Gonzalez[1], W. Saab[2], P. Serhal[2], V. Seshadri[2]

[1]Center for Reproductive and Genetic Health CRGH, Embryology, London, United Kingdom
[2]Center for Reproductive and Genetic Health CRGH, Clinician, London, United Kingdom

Study question: Does culture condition affect the chances of detection of an euploid embryo in a benchtop incubator (BT) compared to Time lapse monitoring incubator (TLM)?

Summary answer: This study demonstrates that uninterrupted controlled culture environment (TLM) has an increased probability of detection of an euploid embryo in a PGT-A cycle.

What is known already: Most aneuploidies are meiotic in origin and maternal age related. Aneuploidies do not always impair embryo development and blastocyst formation can be achieved. Studies suggest several factors may adversely affect the incidence of chromosomal anomalies. Additionally, environment is known to affect outcome through epigenetic modulation. A recent study concluded that the incidence of mosaicism and euploid rates differed amongst labs, thought to be due to screening methods, culture conditions and biopsy stage and unknown indication for PGT-A. Our study explores the potential impact of culture environment on ploidy, evaluated by comparing two different incubator types in the same laboratory.

Study design, size, duration: Retrospective single centre cohort study, a total of 732 blastocysts were biopsied on D5/6 between May 2017 to December 2017. The genetic testing was performed using Next Generation Sequencing Technique (NGS) at a single reference centre (coopergenomics-UK). The euploid rate in embryos cultured in BT incubator, interrupted single-step medium (n = 349 blastocysts) vs those cultured in a TLM incubator, uninterrupted single-step medium (n = 383 blastocysts) were compared.

Participants/materials, setting, methods: Patients undergoing PGT-A cycle with at least two failed previous IVF attempts, advanced maternal age, recurrent miscarriage, or previous aneuploidy pregnancy. Study was conducted at a single centre IVF unit CRGH London. The average female age was 38.1 ± 4.3. Post ICSI, oocytes were either cultured in a BT incubator or TLM incubator. Trophectoderm biopsy was performed on D5/6 removing between 6-8 cells. The ploidy rates were subsequently compared between groups.

Main results and the role of chance: Age was normally distributed and comparable (p = 0.229) in both incubators. Fertilisation rate in the TLM was significantly higher (77 ± 17.3 vs 71 ± 14.9, p = 0.047) when compared to the BT Incubator. The blastulation rate was significantly higher in the TLM group versus BT group (64.8 ± 36.5 vs 63.4 ± 36.1, p = 0.000) respectively. The Euploid rate obtained from both groups showed a higher proportion of euploid embryos in the TLM incubator 25.5% (98/383) compared to those cultured in the BT incubator 20.6% (72/349) (p = 0.04).

Limitations, reasons for caution: Further PGT-A cycles resulting in increased number of biopsied blastocysts to be evaluated in a different centre to observe this findings in both culture environment.

Wider implications of the findings: First single centre study to directly compare euploid rates in two different culture conditions. Studying the algorithm patterns in euploid embryos could provide the means for non-invasive PGT-A screening. Further evaluate how culture conditions at a cellular level could affect epigenetic mechanism in embryo/s resulting in a higher aneuploid rate.

Trial registration number: not applicable.

P-165 The effects of 2-APB on the intracellular calcium concentration and ultra structure damage of vitrification oocyte

C. Junping[1], X. Wang[2], Y. Xue[2], W. Tan[1], B. He[1], X. Mao[1], J. Qin[1]

[1]The People's Hospital of Guangxi Zhuang Autonomous Region, The Center of Human Assisted Reproduction, Nanning, China
[2]Guangxi University, The department of animal's science and technology, Nanning, China

Study question: Can the change of calcium concentration of oocyte induced by cryoprotectant be regulated to reduce the damages of ultra structures?

Summary answer: IP3 receptor inhibitor 2-APB can effectively inhibit the increase of calcium concentration of oocytes and relieve the damages induced by freezing.

What is known already: Vitrification can effectively preserve human oocytes with high survival rate about 90-95%,Which was accompanied by compromised developmental potential and ultra structure damage of oocyte induced by cryoprotectants and low temperature. The increase of intracellular calcium concentration of oocyte induced by cryoprotectants was supposed mediating the injury happening in oocyte cryopreseving process. 2-APB which was known as IP3 receptor inhibitor can effectively inhibit calcium releasing from intracellular calcium store of endoplasmic reticulum for many different non excitatory cells.

Study design, size, duration: More than 500 cumulus-oocyte-complexes (COCs) were collected from 15 mice. The total of 478 MII oocytes with first polar body and normal morphology was used in subsequent calcium detection, vitrification and ultra structure analysis. The oocytes derived from the same mouse were allocated into 3 different groups at random: control, croprotectant without or with 2-APB. 60 oocytes were used for calcium labeling and other oocytes were vitrified and thawed with different treatment for subsequent analysis.

Participants/materials, setting, methods: A Total of 15 mice and 478 oocytes was included in present study. The oocytes were divided into 3 groups at random: control, croprotectant without or with 2-APB, in which the oocytes were treated with culture medium, cryoprotectants, and cryoprotectants with 0.1umol/l 2-APB respectively, following with analysis of intracellular calcium concentration by laser scan confocal microscope, ultra structures of freeze-thawing oocytes by transmission electron microscope.

Main results and the role of chance: Exploring the calcium transients demonstrated that cryoprotectant(n = 15) induced instantaneous increasing of Ca^{2+} in oocyte, and the concentration at steady state was also higher than that of fresh oocyte in control group(n = 15)(123.59 ± 4.73 vs.94.75 ± 3.54) (P<0.05); However the 2-APB treatment (n = 15) can effectively stabilize calcium level, the calcium transient peak and steady-state levels were lower than that cryoprotectants induced, and the concentration of calcium at steady-state was similar with that of the control group(92.76 ± 4 .22 vs.94.75 ± 3.54) (P>0.05). Undergoing freezing,the calcium concentration of 2-APB group was lower than that without 2-APB group(122.21 ± 4.33 vs.139.70 ± 6.00) (P<0.05). Examination by transmission electron microscope indicated that microvilli shortened and deficiency, cortical granule reduced in the cortex area in cryoprotectant, mitochondrial swelled, intermediate filament disassembled, edge of lipid drop blured, and a large number of vacuoles in matrix formed in vitrification group without 2-APB comparing with that in control group. Treatment with 2-APB relieved the injuries of the microvilli, cortical granule, mitochondria and lipid drops etc, which was partly resulted by vitrification. But the damages were still severer than that of control group.

Limitations, reasons for caution: More studies are needed to evaluate the developmental potential of oocytes treated by IP3 receptor inhibitor.

Wider implications of the findings: Our findings suggest a possibility to relieve the oocyte injuries induced by cryoprotectant and low temperature for oocytes which undergo cryopreservation.

Trial registration number: n/a.

P-166 High pressure freezing: A potential method for improving oocyte cryopreservation

K. Reader[1], J. Juengel[2], D. Morbeck[3]

[1]University of Otago, Department of Anatomy, Dunedin, New Zealand
[2]AgResearch, Reproduction, Mosgiel, New Zealand

[3]Fertility Associates, Department of Obstetrics and Gynaecology, Auckland, New Zealand

Study question: Do oocytes frozen under high pressure survive and exhibit better ultrastructural preservation than those frozen by standard vitrification methods?

Summary answer: Oocytes frozen under high pressure have improved ultrastructural preservation and survive freezing if cryoprotectants are used.

What is known already: Current vitrification methods are able to preserve oocyte viability but cause molecular and structural changes to both the nuclear and cytoplasmic compartments, which may compromise quality. Cortical granule release can occur during the cryopreservation process causing premature hardening of the zona pellucida (ZP) and necessitating the use of ICSI. High pressure freezing (HPF) is known to provide superior ultrastructural preservation, and potentially improved molecular preservation of cells. Some cell types survive this process. However, it is not known whether high pressure freezing can be used to preserve viability of oocytes or embryos.

Study design, size, duration: Grade 1 or 2 immature cumulus-oocyte complexes (COC) were collected from adult sheep ovaries. Groups of 16 to 24 COC or in vitro matured oocytes (MO) underwent HPF or vitrification, with or without cryoprotectants (CP) and were stored in liquid nitrogen for a minimum of one week. Three frozen oocytes from each group were examined by transmission electron microscopy following freeze substitution, embedding and sectioning. Thawed oocytes were matured, fertilised and cultured.

Participants/materials, setting, methods: COC and MO were frozen and thawed either without CP in H199 with 10% FBS or with CP as follows. Oocytes were equilibrated in base medium (H199 with 20% FBS; BM) with 7.5% each DMSO and ethylene glycol (5 to 15 min), then frozen within 60 sec in BM with 0.5 M sucrose and 15% each DMSO and ethylene glycol. Oocytes were thawed in BM with 1 M sucrose (1 min) then 0.5 M sucrose (3 min) and BM (5 min).

Main results and the role of chance: None of the HPF oocytes, without CP, survived thawing. However, the ultrastructure of these oocytes, following freeze substitution, was superior to those HPF or vitrified with CP, and conventionally fixed oocytes. 44% of the HPF and 21% of the vitrified COC, and 50% of the HPF and 43% of the vitrified MO underwent cleavage following IVF, though numbers were too low to perform meaningful statistics. None developed to morula stage. Oocytes vitrified with CP all had irregularly structured ZP containing pores of variable size. Oocytes frozen with HPF and CP had superior ultrastructural preservation of the ZP, with four out of the 6 oocytes examined having ZP with a uniform structure and no pores.

Limitations, reasons for caution: This was a pilot study to assess the potential of HPF for oocyte cryopreservation and low numbers of oocytes were examined. Polyspermy was not assessed in the fertilised oocytes.

Wider implications of the findings: High pressure freezing appears to provide improved ultrastructural preservation, particularly of the ZP, which may avoid the need for ICSI. The use of ICSI bypasses natural sperm selection processes and may also be associated with an increase in epigenetic defects in the resulting embryo.

Trial registration number: Not applicable.

P-167 Let-7b microRNA modulates attachment of trophoblastic cells and integrin β3 expression of endometrial cells

J. Kim[1], Y.E. Lee[2], Y.J. Choi[3], J.E. Park[2], E. Kim[1], J.W. Lee[4], J.H. Jun[2]

[1]Fertility Center of CHA Bundang Medical Center, Laboratory of Reproductive Medicine, Seongnam-si, Korea- South
[2]Graduated School- Eulji University, Dept. of Senior Healthcare- BK21 Plus Program, Seongnam-si, Korea- South
[3]Graduate School- Eulji University, Dept. of Senior Healthcare- BK21 Plus Program, Seongnam-si, Korea- South
[4]Eulji University, Dept. of Biomedical Laboratory Science, Seongnam-si, Korea- South

Study question: Does let-7b microRNA (miRNA) modulate attachment of trophoblastic cells and expression of integrin (ITG) family in endometrial cells?

Summary answer: Transfection of let-7b miRNA inhibitor decreases the attachment of trophoblastic spheroids, whereas transfection of let-7b miRNA mimic increases the expression of ITG-B3 in endometrial cells.

What is known already: Several miRNAs are known to be involved in regulating the implantation process, there is incomplete understanding of how let-7 family controls implantation. Expression of let-7b miRNA was significantly increased in outgrowth and peri-implantation embryos compared to pre-implantation embryos. ITG family expression levels in uterine biopsy samples suggested as a biomarker for evaluating uterine receptivity and determining the optimal time for embryo transfer. The ITG is an important molecule involved in attachment and invasion of trophoblasts and endometrial cells.

Study design, size, duration: Our previous studies have focused on the expression and function of let-7 family in blastocysts, outgrowth embryos and endometrial cells for successful implantation. This study was performed to evaluate the regulatory function of let-7b miRNA in human trophoblastic JAr cells and endometrial Ishikawa and ECC-1 cells.

Participants/materials, setting, methods: The expression profile of let-7b was clarified in a series of developing mouse embryos, and the target gene was confirmed by bioinformatics. Inhibitor or mimic of let-7b miRNA was transfected into human trophoblastic and endometrial cells, respectively. To investigate the effects of the let-7b on attachment and implantation process, transfected trophoblastic spheroids were co-cultured on endometrial cells. Expression patterns of integrin family after transfection of miRNAs were evaluated by immunoblot analysis in endometrial cells.

Main results and the role of chance: Expression of let-7b miRNA was significantly increased in outgrowth embryos on 7.5 days post coitum compared to pre-implantation embryos. When let-7b inhibitors were transfected into trophoblastic JAr cells, attachment rate of trophoblast spheroids onto endometrial cells was significantly decreased in both Ishikawa and ECC-1 cells. We found that ITG-B3 could be directly targeted by let-7b miRNA by in silico analysis. There were no significant differences of ITG-B4 and ITG-A5 expression after transfection of let-7b inhibitor and mimic transfection in endometrial cells. However, expression of ITGB3 was upregulated when mimic let-7b miRNA was transfected into Ishikawa endometrial cells.

Limitations, reasons for caution: Functional approaches were carried out by analyzing transient expressions of transfected microRNA modulators using *in vitro* model. The consequence of the let-7b miRNA on implantation process still remains to be determined in physiological *in vivo* model. Other target genes of let-7b in embryo implantation should be further elucidated.

Wider implications of the findings: Our findings indicate that the let-7b miRNA plays an important role in embryo implantation as a regulator of ITG-B3 expression. These results could provide a valuable understanding of the regulation involved in the miRNA-mediated implantation between trophoblastic and endometrial cells. It could subsequently improve outcome in human ART program.

Trial registration number: Not applicable.

P-168 Reproductive outcomes after vitrification of oocytes generated from human chorionic gonadotropin (hCG)-primed in vitro maturation cycles

Y. Cohen[1,2], A. St-Onge-St-Hilaire[1], S. Tannus[1], G. Younes[1], M. Dahan[1], W. Buckett[1], W.Y. Son[1]

[1]Reproductive Centre. McGill University Health Centre, Obstetrics and Gynecology, Montreal, Canada
[2]Tel Aviv Sourasky Medical Center, Obstetrics and Gynecology, Tel Aviv, Israel

Study question: What is the effect of cryopreservation of oocytes that matured in vitro (vIVM) on reproductive outcomes compared to fresh in vitro maturation (fIVM) cycles?

Summary answer: Lower fertilization, embryo cleavage and good embryo rates were found in vIVM cycles. Live birth rates were significantly lower in vIVM compared to fIVM.

What is known already: Although two successful live births and one ongoing pregnancy from cancer survivors were reported after cryopreservation of IVM embryos obtained, there is no report of a live birth from the cryopreservation

of oocytes produced by IVM of immature oocytes for cancer patients. In previous studies, lower reproductive potentials were found in vIVM cycles compared to oocyte vitrification in IVF cycles.

Study design, size, duration: This is a retrospective cohort study conducted at a university hospital affiliated IVF unit. Fifty-six cycles of vIVM and 263 fIVM cycles in women diagnosed with polycystic ovarian syndrome ovaries (PCOS) were included in the analysis. All women underwent a human chorionic gonadotropins (hCG) primed IVM cycle.

Participants/materials, setting, methods: The study group included PCOS patients who failed ovulation induction with intrauterine insemination and were offered IVM cycle followed by oocyte vitrification and warming. The embryological aspects and clinical outcomes of vitrification/warming were compared to controls undergoing fresh IVM cycles during the same period. The main outcome measure was the live birth rate.

Main results and the role of chance: From 1070 oocytes that were collected (56 patients) a total of 68 MII and 1,002 GV oocytes were retrieved; 645 oocytes (64.4%) matured in vitro and underwent vitrification/warming. In the fIVM group, 485 MII and 4,296 GV oocytes were retrieved; 2,630 (61.2%) matured to MII. Survival rate after warming was 59.8% (416/713). Fertilization and embryo cleavage rates per oocyte were significantly lower in the vIVM. Clinical pregnancy (10.7% vs. 36.1%) and live birth rates (8.9% vs. 25.9%) per cycle were significantly lower in the vIVM group than in the fIVM group ($P = 0.005$ and $P<0.001$, respectively). Five healthy singleton babies were born in the vIVM group, and 80 babies including 18 twins and 1 triplet were born following fIVM cycle. Furthermore, the association between live birth and vitrification, age, number of in vitro matured oocytes, AFC and number of embryo transferred was analyzed using a stepwise logistic regression analysis. Vitrification of IVM oocytes was associated with a lower likelihood of a live birth (adjusted odds ratio, 0.3 95% confidence interval 0.1 to 0.7).

In our fertility preservation program, 6 cancer survivors underwent a transfer of embryos from vitrified IVM oocytes that resulted in 2 chemical pregnancies.

Limitations, reasons for caution: The retrospective nature of this study.

Wider implications of the findings: Our results suggest that although vitrification of IVM oocytes is an alternative for women who cannot pursue IVF oocyte vitrification for fertility preservation, the reproductive potential of these oocytes is impaired.

Trial registration number: NA.

P-169 A new approach to reduce thermal and oxidative stress during vitrification procedure

M. Dashtizad[1], P. Kazemi[2], F. Sarmadi[1], S. Fayazi[1], E. Hashemi[1], S. Molaeiyan[1]

[1]National Institute of Genetic Engineering and Biotechnology, Department of Animal Biotechnology, Tehran, Iran
[2]Mcgill University, Biology, Montreal, Canada

Study question: Determine whether suspended graphene can be used instead of sucrose to reach higher thermal conductivity while maintaining the efficiency of vitrification solution.

Summary answer: Graphene can be proposed as a conductive cryoprotectant, leading to a more moderate expression of apoptosis, oxidative and thermal stress-related genes.

What is known already: The most effective characteristic of vitrification is high cooling/warming rate, which helps to reduce ice crystal formation and cellular damage. In recent years, the ultra-rapid cooling rate has been achieved using small volumes of vitrification solution along with various cryodevices. However, the heat conductivity of vitrification solutions as an effective parameter on the cooling/warming rate has received less attention.

Study design, size, duration: To determine the optimal concentration of graphene, 100 blastocysts in each group were vitrified using different graphene-based solutions (vitrification solution: 0.5, 1, 1.5, 3, 7 M; thawing solution: 2, 3, 4 M; dilution solution: 1, 1.5, 2 M), evaluated in terms of survival and hatching rate. The optimal solution was then compared with sucrose-based one in order to analyze all the aspects described below.

Participants/materials, setting, methods: In vivo produced mouse blastocysts were vitrified using Cryotop as described by Kuwayama (Kuwayama et al., 2005), with slight modifications. After 12 h, vitrified blastocysts were compared with fresh blastocysts in terms of survival, hatching and implantation rate, cellular peroxide levels and expression level of genes related to thermotolerance (*Hspa1a*) oxidative stress (*Sod1*, *Sod2*) and apoptosis (*Trp53*, *Bax*, *Bcl2*).

Main results and the role of chance: The optimum concentrations of 1.5, 2 and 4 M were first selected for vitrification, thawing and dilution solutions, respectively. According to our results, natural honey as a cryoprotectant could be as efficient as sucrose in terms of survival, hatching and implantation rate. The real-time RT-PCR analysis also revealed a reduction in the expression of *Hspa1a, Sod1*, *Sod2* and *Trp53* transcripts in the graphene group compared to the sucrose group; the abundance of *Bax* and *Bcl2*, however, did not change. Furthermore, there was a lower cellular peroxide level in the graphene-based group compared with sucrose-based one.

Limitations, reasons for caution: Further studies are necessary to evaluate development-related genes expression and live birth rate in blastocysts vitrified using graphene-based solution to assess long-term safety outcomes.

Wider implications of the findings: Our findings highlight the importance of heat conductivity of vitrification solutions, demonstrating that graphene can act as a cryoprotectant as well as a heat transfer agent.

Trial registration number: None.

P-170 Effects of resveratrol, GM-CSF, and DCA on the development of embryos in aged mice

K.M. Juhn[1], J. Yoon[1], E.H. Jung[1], H.J. Park[1], H.Y. Choi[2], J.Y. Kim[2], C.Y. Hur[2], S.H. Yoon[1], J.H. Lim[2]

[1]Maria Fertility Hospital, Maria research center, Seoul, Korea- South
[2]Maria Fertility Hospital, Maria Fertility Hospital, Seoul, Korea- South

Study question: To determine whether supplementation of culture media with resveratrol, GM-CSF, and DCA influence embryo development and pregnancy rates in aged mice.

Summary answer: Resveratrol significantly increased pregnancy and implantation rates even though there were no differences in fertilization and development rates.

What is known already: Major implications of older patients are low fertilization rate, poor embryonic development, and increased rate of chromosomal aberrations, which leads to an increased miscarriage and aneuploidy. It is associated with several molecular mechanisms contributing to ovarian aging such as alterations in gene expression and mitochondrial dysfunction. There were some reports that resveratrol has a positive effect on embryo development through improving mitochondria function. Moreover, addition of dichloroacetic acid (DCA) to culture media improved blastocyst development and mitochondrial output in embryos produced from aged mice. Granulocyte-macrophage colony-stimulating factor (GM-CSF) had significant effect on ongoing implantation rate in women with previous miscarriage.

Study design, size, duration: BD F1 female mice at 58-62 weeks of age were used for this study. MII oocytes obtained by super-ovulating mice were fertilized and cultured in MRC media with or without resveratrol (0.5 uM), GM-CSF (2 ng/ml), and DCA (1.0 mM). Blastocysts from each group were transferred into 2.5 days post-coitum (dpc) pseudo-pregnancy ICR mice using non-surgical embryo-transfer device.

Participants/materials, setting, methods: Fertilization and embryo development rates were monitored. To assess pregnancy and implantation rates, expanded or hatching blastocysts from each groups were transferred into pseudo-pregnant ICR mice. The pregnancy rate was measured as the number of pregnant mice as a proportion of the total transfer mice. Implantation rates were calculated as the number of live pups as a proportion of the total number of embryos transferred.

Main results and the role of chance: A total of 673 MII oocytes were fertilized in vitro (control: 186; Resveratrol: 177; GM-CSF: 158; DCA: 152). There were no statistically differences in fertilization rates among groups (control: 94.6%; Resveratrol: 97.2%; GM-CSF: 96.2%; DCA: 97.4%, respectively). The addition of resveratrol, GM-CSF, and DCA (92.4%, 92.1%, and 95.9%,

respectively) tended to increase the blastocyst rate, but only DCA group was significantly higher than control group (86.9%, *P<0.05*). After blastocyst transfer to recipient females, there was no significant increase in pregnancy and implantation rates when embryos were fertilized and cultured in the presence of GM-CSF (50.0% and 22.3%) and DCA (53.8% and 16.7%) as compare to the control (52.6% and 19.2%). However, supplement of resveratrol significantly increased pregnancy and implantation rates (75.0% and 33.8%) compared to the other three groups (P<0.05).

Limitations, reasons for caution: In this study, only development and pregnancy rates were measured in order to examine the effect of each factor in aged mice. Further investigations on the mechanism are needed to confirm the effect of each factor.

Wider implications of the findings: Resveratrol added to the media enhanced pregnancy and implantation rates, although there was no difference in fertilization and blastocyst rates. It suggests that the addition of resveratrol to embryo culture media for patient with advanced maternal age may potentially increase IVF outcomes.

Trial registration number: None.

P-171 Effect of resveratrol supplement during in vitro culture on the mitochondrial membrane potential and histone acetylation of embryos from aged mice

J. Yoon[1], K.M. Juhn[1], E.H. Jung[1], H.J. Park[1], H.Y. Choi[2], J.Y. Kim[2], C.Y. Hur[2], S.H. Yoon[1], J.H. Lim[2]

[1]Maria Fertility Hospital, Maria Research Center, Seoul, Korea- South
[2]Maria Fertility Hospital, Maria Fertility Hospital, Seoul, Korea- South

Study question: Does resveratrol supplementation of culture media affect mitochondrial membrane potential and histone acetylation of embryos from aged mice?

Summary answer: The addition of resveratrol to embryo culture media improves mitochondrial membrane potential and inhibits abnormal histone acetylation of embryos from aged mice.

What is known already: Advanced maternal age affects the quality of oocytes and blastocysts. Reproductive aging pathologies are frequently associated with mitochondrial dysfunction and gene expression of histone deacetylase, which may be involved in the process of epigenetic modification. There were some reports that resveratrol has the ability to prevent age-related diseases by improving mitochondria function. In addition, resveratrol activates sirtuin 1 (SIRT1), an NAD^+-dependent histone-deacetylase, which is able to remove the acetyl group from histone H4 at lysine 12 (H4K12) in somatic cell. It was reported that level of H4K12 acetylation in oocytes increased during the aging process in human and mouse.

Study design, size, duration: BD F1 female mice at 58-62 weeks of age were used for this study. As a control, 6-8 weeks old female mice were used for young group. MII oocytes obtained by super-ovulating mice were fertilized and cultured in MRC media with or without resveratrol (0.5 uM). Their embryonic development rates were monitored. On the other hand, mitochondrial membrane potential and level of histone acetylation were examined at different developmental stages (2-cell, 4-cell, morula, and blastocyst).

Participants/materials, setting, methods: Mitochondrial membrane potential throughout the pre-implantation embryo development was analyzed by 5,5′,6,6′-tetrachloro-1,1′,3,3′-tetraethylbenzimidazolyl-carbocyanine iodide (JC-1) staining. The acetylation pattern of H4K12 was examined by immunofluorescence staining using an anti-acetylated H4K12 antibody.

Main results and the role of chance: Fertilization rates were no statistically differences among three groups (Young: 98.1%, Old: 94.6%, Old-res: 97.2%, respectively). However, blastocyst rate in young group (99.4%) was significantly higher than that in old group (86.9%) (P<0.05). The addition of resveratrol (Old-res group) increased the blastocyst rate (92.4%), but there was no statistical differences compared to the other two groups. The average mitochondrial membrane potential in young group was higher than that in old groups, but there was a statistical significant difference at 2-cell and 4-cell stages (P<0.05). Resveratrol supplement increased the level of mitochondrial membrane potential throughout the stages of pre-implantation embryo in aged mice. These increases were significantly greater than either young or old groups (P<0.05). The acetylation levels of H4K12 were examined and compared among three groups. Immunocytochemistry with specific antibody against AcH4K12 showed that the fluorescence signal was statistically higher in old group than in young group throughout the pre-implantation embryo development. The acetylation levels of H4K12 tended to decrease with the addition of resveratrol and it was statistically significant only at the 4-cell stage.

Limitations, reasons for caution: In the preliminary study, 0.5 uM resveratrol enhanced embryo development and mitochondrial membrane potential of embryos from aged mice. Therefore, 0.5 uM resveratrol was used in this experiment. However, the dose of resveratrol should be determined carefully because the appropriate dosage reported by researchers were varied.

Wider implications of the findings: Poor development of embryo in aged mice was associated with mitochondrial dysfunction and abnormal histone acetylation. In addition, resveratrol added to the media may result in an improvement of mitochondria membrane potential and stabilization of histone acetylation. Addition of resveratrol to culture media for aged women may increase IVF outcomes.

Trial registration number: None.

P-172 Embryo culture medium based on the composition of human oviductal fluid contributes to improving the viability of mouse embryos

T. Yao[1], Y. Asayama[1], Y. Sugiyama[1], Y. Kumasako[2], T. Utsunomiya[3]

[1]Fuso Pharmaceutical Industries- Ltd., Research and Development Center, Osaka, Japan
[2]St. Luke Clinic, IVF Labolatory, Oita, Japan
[3]St. Luke Clinic, Dept. of Ob/Gyn, Oita, Japan

Study question: Does a culture medium reflecting the inorganic salts, carbohydrates, organic acids, and amino acid concentrations of human oviductal fluid improve the viability of mouse embryos?

Summary answer: Embryo culture media based on human oviductal fluid composition with modified potassium and phosphate concentrations improve the hatching rate and cell numbers of mouse blastocysts.

What is known already: Commercially available HTF medium based on six components of human oviductal fluid and sequential media based on three components of human oviductal/uterine fluid have been used clinically in human assisted reproductive technology. However, information on the composition of female reproductive tract fluids is far from complete because of the limited volumes available for analysis. There is no medium with almost all of the components (more than 30) similar to human oviductal fluid.

Study design, size, duration: We developed a high-sensitivity multicomponent analysis system and analyzed human oviduct fluid. In a prospective study, mouse embryo culture media based on this analysis were compared with conventional culture medium. In vitro fertilized 1-cell mouse embryos were cultured in the media and observed every day until day 4. Blastocysts were analyzed to assess their viability. In total, 780 fertilized oocytes and 725 blastocysts were examined.

Participants/materials, setting, methods: Human oviductal fluid samples aspirated laparoscopically from 28 women aged 26–39 years were analyzed to determine the concentrations of 31 components by liquid chromatography with tandem quadrupole mass spectrometry and ion chromatography. Zygotes from ICR strain mice were cultured in control medium, $KSOM^{AA}$, or test media for 4 days to assess blastocyst formation and hatching rates. Blastocysts were analyzed by TUNEL staining to measure total cell numbers and the percentages of apoptotic cells.

Main results and the role of chance: Because the apoptosis rate of blastomeres cultured in media based on human oviductal fluid was higher than in $KSOM^{AA}$ medium (3.8% vs 5.2%), the potassium and/or phosphate levels in the new media were reduced from the levels found in human oviductal fluid levels to levels in conventional media (potassium, from 15.3 to 5.5 mmol/L; phosphate, from 2.5 to 0.3 mmol/L). As a result, using a potassium-modified medium or a potassium- and phosphate-modified medium, the hatching rate was improved (from 73.1% to 86.5% and 88.5%, respectively; $p < 0.05$) and the numbers of blastomeres increased (from 80.2 ± 1.5 to 95.8 ± 2.0 and 90.2 ± 2.0; $p < 0.01$) compared with the $KSOM^{AA}$ medium. In the phosphate-

modified medium, the numbers of blastomeres increased (from 80.2 ± 1.5 to 90.7 ± 2.2, p < 0.01) compared with the KSOM^{AA} medium.

Limitations, reasons for caution: Oviductal fluid samples were collected from ampullae after ovulation from patients suspected of infertility. The analytical values might differ if the donor and collection times or sites differ. This was a study using mouse embryos and their performance in such defined culture media might differ from human embryos.

Wider implications of the findings: We analyzed more than 30 components of human oviductal fluid for the first time and clarified that it was effective in helping to formulate new embryo culture media. We believe that these results have the potential to lead to the development of an ideal culture environment for human embryos.

Trial registration number: Not applicable.

P-173 Are morphology of first polar body related to embryo quality and euploidy rate in couples?

H. Jang[1], J. Jung[1], T. Kim[1], J. Woo[1], J. Eum[1], D. Lee[2], J. Ko[2], H. Park[1], J. Kim[1], W. Lee[1]

[1]CHA fertility center, CHA Gangnam medical center, Seoul, Korea- South
[2]CHA University, Biomedical Science, Seoul, Korea- South

Study question: What is the parameter of an oocyte that indicates the embryo quality and euploidy rate?

Summary answer: Morphology of first polar body has a relationship with the euploidy rate especially in under 38 years old maternal group.

What is known already: Previous studies have reported that morphology of first polar body (1st PB) affects oocyte viability and embryo quality. Furthermore, it has been reported that morphology of 1st PB is correlated with chromosome abnormality of embryos.

Study design, size, duration: This retrospective study was carried out to investigate the difference of euploidy rate and embryo quality according to morphology types of 1st PB in couples with advanced maternal age. Morphological classifying of 1st PB was evaluated in 676 MII oocytes of 101 PGS cycles using array-CGH. During the period from January 2016 to November 2017, this study was performed in couples suffering from recurrent implantation failure or repeated spontaneous abortion over 2 times.

Participants/materials, setting, methods: Observation of 1stPB was performed using an inverted microscope during Intracytoplasmic Sperm Injection (ICSI). Morphology of 1st PB is classified into 4 different groups: Type 1: ovoid 1st PB with smooth surface; Type 2: ovoid 1st PB with rough surface; Type 3: fragmented 1st PB; Type 4: large 1st PB. All embryos were biopsied at day 3 and day 5, and then analyzed by array-CGH.

Main results and the role of chance: The highest day2 and day3 good quality embryo (GQE) rate is type1 among four types (70.6 % and 58.1 %), with no statistically significant difference. However, the euploidy rate of type1 was observed significant difference with among each type2 and type4 (33.1% vs. 23.3%, $p<0.05$ and 33.1% vs.3.8%, $p<0.05$). Groups were divided to under 38 and over 38 years old, type1 and type2 of under 38 years of age group have higher euploidy rate than over 38 years old group with statistically significant difference (40.5% vs. 22.8%, $p<0.05$ and 29.2% vs. 16.2%, $p = 0.05$).

Limitations, reasons for caution: This study has numerical differences with each type which needs to be further validated. More studies should be performed to demonstrate these significant differences.

Wider implications of the findings: We found a relationship between the morphology of 1st PB and the euploidy rate in PGS cycles. Study suggests that the morphology of 1st PB can be one of the indicators of embryo euploid.

Trial registration number: N/S.

P-174 Comparison of clinical pregnancy and live birth rates among fresh day 5 and frozen-thawed day 5, day 6 blastocyst transfer

A. Konkova, V. - Apryshko, E. Shalamova, A. Naumova, A. Klepukov, M. Kharitonova, A. Bolt, K. Kirienko, A. Mironova, I. Ermilova, S. Yakovanko

AltraVita IVF Clinic, Embryology, Moscow, Russia C.I.S.

Study question: Is there a significant difference in outcome of IVF programmes with fresh day 5(d5ET), frozen day 5(d5FET) and frozen day 6(d6FET) blastocyst transfer?

Summary answer: According to our data based on 9671 fresh and frozen blastocyst transfers the highest pregnancy and live birth rates are in IVF programmes with d5FET.

What is known already: Blastocyst cryopreservation in IVF cycles is used to accumulate embryos in poor-responder patients, allows time to perform genetic testing, provides the opportunity to postpone a transfer away from the non-physiologic endometrium, which occurs during a stimulation cycle, and may improve pregnancy rate (PR) and fetal outcome. Some studies show higher ongoing pregnancy and live birth rate (LBR) following d5FET compared with d6FET.

Study design, size, duration: We performed retrospective comparative study of PR and live birth rate/transfer among 3 groups of ICSI-ET cycles: 3254 with d5ET (average woman age 34 ± 4,5 years), 3969 with d5FET (average woman age 34 ± 4,0 years) and 2448 with d6FET (average woman age 34 ± 4,7 years). All patients underwent IVF and ET from 2009 to 2016 at AltraVita IVF clinic, Moscow. Cycles with a single ET of a good and high quality blastocyst were included in the study.

Participants/materials, setting, methods: Vitrification method by Cryotech and Kitazato, Japan, was used for vitrification/thawing of blastocysts. Embryos were evaluated before transfer and were assigned grades according to Gardner blastocyst grading scale. For our investigation analysis cases with blastocyst transfer grades (1-4) AA, AB, BA, BB were chosen. Ongoing pregnancy after ET was confirmed by one fetal sac and heart beat. PR and LBR were statistically analyzed using Chi-square test.

Main results and the role of chance: Outcome results in the group of d5FETwere 36.6 % PR and 26.3 % LBR, which is significantly higher compared to 26,5 % PR (P<0.01; OD 1.64, 95% CI, 1.49-1.82) and 18.5 % LBR (P<0.01, OD 1.12, 95% CI, 1.05-1.37) in the group with d5ET and 27,5 % PR (P<0.01, OD 1.53, 95% CI, 1.37-1.70) and 18.1 % LBR (P<0.01, OD1.2, 95% CI, 1.06-1.36) in the group with frozen d6FET. There were no significant differences in the pregnancy rate 26,5% versus 27,5 % (OD 0.95, 95% CI, 0.84-1.07) and LBR 18.5% versus 18.1% (OD 1.01; 95% CI, 0.88-1.18) between groups with fresh d5ET and frozen d6FET, respectively.

Limitations, reasons for caution: ICSI-ET cycles groups contain data on all types of stimulation protocols without exceptions.

Wider implications of the findings: We've analyzed a high number of ET cycles in our study. The pregnancy and life birth potential of good and high quality frozen-thawed day 5 blastocysts is higher than fresh day 5 blastocysts and frozen-thawed day 6 blastocysts. D5FET may be considered as a preferable strategy during the IVF treatment.

Trial registration number: N/A.

P-175 Moving towards individualized embryo transfer-Guidelines for number of embryos to be transferred based on key performance indicators

U.N. Jindal[1], S. Kumar[2], S. Maheshwari[3]

[1]Jindal IVF & Sant Memorial Nursing Home, ART, Chandigarh, India
[2]Jindal IVF & Want Memorial Nursing Home Chandigarh, Assisted Reproduction Techniques, Chandigarh, India
[3]Jindal IVF & Sant Memorial Nursing Home, Assisted Reproduction Techniques, Chandigarh, India

Study question: Can key performance indicators (KPIs) help in formulating guidelines for number of embryos to be transferred?

Summary answer: Single embryo transfer (SET) should be considered in donor oocyte cycles and in women < 30 years if cleavage rate (CR) is above 95%

What is known already: KPIs in the Assisted Reproduction Techniques (ART) laboratory act as early warning signs. The Vienna Consensus Statement of July, 2017 of the European Society of Human Reproduction and Embryology (ESHRE) defines competency (COMP) and benchmark (BENCH) levels of various KPIs. Globally, there is a recommendation to shift to SET to avoid

complications of multiple pregnancies. However, it is a common practice at most of the centres in several countries including in India to transfer two embryos in routine and three in poor prognosis cases to increase the pregnancy rate.

Study design, size, duration: This study reported an analysis of 3-year data of 699 in-vitro fertilization (IVF) cycles with fresh embryo transfer at a tertiary IVF centre. KPIs analysed included: metaphase II (MII), fertilization (FR), CR and embryo quality rates (EQR), which were compared with COMP and BENCH. Outcomes compared included clinical pregnancy rate (CPR) and implantation rate (IR). Statistical analysis was done with one way ANOVA and Chi Square test methods for comparison using SPSS-21.

Participants/materials, setting, methods: The IVF cycles were divided in four groups based on age: Group I, ≤ 30 years; group II, age 31-35 years; group III, age > 35 years; and group IV, donor oocyte irrespective of recipient's age. Each group was subdivided into two sub-groups based on CR: A with CR < 95% (COMP level) and B with CR > 95 %. The CPR, IR and multiple pregnancy rates were compared amongst groups and within sub groups.

Main results and the role of chance: The mean CPR and IR rates respectively: Group I were 36.92% & 22.31%; group II, 33.05% & 18.53%; group III; 21.57 % & 11.44 %,and group IV; 43.79% & 27.02%. The CPR and IR were the highest in donor oocyte group, decreased as the age increased. Women above 35 years' age performed worst. These differences were statistically significant amongst various groups. In sub groups, CPR and IR were higher with cleavage rate > 95 % than CR < 95%, but the difference was statistically insignificant. Multiple pregnancy rate was the 11.83 % in group IV, followed by group I with 9.23 %, group II 7.73% and in group III 3.92%. Thus, a clear recommendation for SET can therefore be made for Group-IV. Similarly in group I with CR >95%, a policy of SET can be preferred over double embryos transfer (DET). Group II with age 31-35 years should be given DET due to a lower IR. In group III, all cases should be transferred three embryos to improve CPR.

Limitations, reasons for caution: KPI like MII, FR and EQR, being above BENCH were not considered. Any dip in an individual case will affect decision. The other variables which may affect the IVF outcome like endometrium, day of ET, previous failures were not taken into consideration. Moreover patient's choice has also to be considered.

Wider implications of the findings: Mathematical modelling based on clinical and laboratory KPIs can help individualize the number of embryos to be transferred.

Trial registration number: Since it was a retrospective analysis of data, trial registration number was not sought.

P-176 Enhancing blastocyst quality by priming spermatozoa with cumulus mass fragments for human ICSI cases

R. Dunn[1], V. Pham[2], G. Grunert[1], E. Kovanci[1], S. Chauhan[1], L. Schenk[1], R. Mangal[1], Y. Anaya[1], W.S. Wun[2]

[1]Houston Fertility Specialists, Fertility Clinic, Houston, U.S.A.
[2]Houston Fertility Specialists, IVF lab, Houston, U.S.A.

Study question: Does priming spermatozoa with cumulus mass before ICSI enhance developmental speed and quality of blastocysts?

Summary answer: ICSI with cumulus primed sperm not only increases developmental speed but also enhance the quality of blastocysts.

What is known already: By using big data set from US Society of Assisted Reproductive Technology (SART), it has found that application of ICSI for non-male factor cases significantly decrease pregnancy outcomes. In mouse model, ICSI with acrosome intact sperm has severe negative impact upon egg survival. Induce acrosomal reaction before ICSI can prevent this negative impact.

Study design, size, duration: The study is a cross sectional -control vs. treatment design. Totally 1447 eggs from 97 ICSI cases during September 1 - December 23, 2017 included in the study.

Participants/materials, setting, methods: The study population was with mean age 33.5 and median age at 33 in a fertility clinic. All ICSI cases with at least 6 oocytes and 5 million motile sperm/sample included in the study. In each case, half number of mature eggs assigned as control (ICSI with swim up sperm; Standard ICSI) and the other half number of mature oocytes ICSIed with autologous cumulus primed sperm (Primed ICSI). Generalized Estimation Equation used for statistical analysis.

Main results and the role of chance: For convenience, Standard ICSI is brief as Standard. Primed ICSI is brief as Primed. For fertilization, Standard has 482 fertilized out of 713 ICSIed eggs (67%) vs. Primed ICSI 546/764 71%)(not significant); Day 5 blastocyst quality > = 3BB, Standard 61/482 (12.6%) vs Primed 102/546 (18.6%) p<0.01); Total good quality blastocyst (> = 3BB) rate: Standard 254/482 (52.6%) vs. Primed 324/546 (59.3%) p<0.05; Biopsiable rate (at exapnded blastocyst stage): Standard 193/254 (75.9%) vs. Primed 246/324 (75.9%) not significant; euploid rate: Standard 80/193 (41.4%) vs. Primed 103/246 (41.8%) not significant.

Limitations, reasons for caution: The statistical power is limited due to small sample size.

Wider implications of the findings: There are reasons for worldwide elevation of ICSI utilization. To alleviate the negative impact of ICSI, the couple's autologous cumulus mass fragments show promising improvement. If confirmed by big data power, the cumulus priming procedure may will be the standard ICSI protocol worldwide.

Trial registration number: not applicable.

P-177 Blastocyst diameter is an important parameter for predicting live birth in frozen single blastocyst transfer cycles

R. Hirata, S. Inoue, K. Taguchi, H. Toshihiro, H. Nobuyoshi

Okayama Couple's Clinic, Gynecology, Okayama, Japan

Study question: Which morphological parameter is most important to select the best blastocyst for transfer?

Summary answer: The blastocyst diameter on Day 5, rather than inner cell mass (ICM) or trophectoderm (TE) grade, is the most significant predictor of live birth.

What is known already: To assess the blastocyst, three morphological parameters have routinely been used: degree of blastocoele expansion, size and compactness of the ICM and number of TE. Although blastocysts with the highest scores for all three parameters achieve high implantation rates (IRs), there is controversy over which parameter is the strongest predictor of live birth. In addition, even for the same expansion grade, the range of embryo diameters is wide.

Study design, size, duration: This study is a retrospective analysis of 1107 vitrified/warmed Day 5 single embryo transfers of good morphology blastocysts (≥3BB) between 2012 and 2015. Exclusion criteria included patients with ≥38 years of age, repeated implantation failure (≥6 embryo transfer) and hatching/hatched blastocyst. Blastocysts were divided by their diameter, ICM and TE grade. Implantation and live birth rates (LBRs) were compared.

Participants/materials, setting, methods: The blastocysts were observed at 114-116 hours after insemination. The blastocyst diameter was measured between the outside borders of the TE. Blastocysts were classified according to their diameters (<140μm, 140-160μm, 160-180μm, ≥180 μm), ICM (A, B) and TE (A, B). Adjusted odds ratios (AOR) were calculated by multivariate logistic regression.

Main results and the role of chance: The mean patient age was 32.4 ± 3.4 years. Univariate regression analysis showed blastocyst diameter and TE grade to be correlated with IR and LBR. The IRs for blastocyst diameter groups (<140μm, 140-160μm, 160-180μm, ≥180μm) were 37.1%, 53.9%, 59.1% and 61.3% respectively; while the LBRs were 28.2%, 38.6%, 46.5% and 48.6%, respectively (P<0.05). The IRs for TE grade (A, B) were 56.9% and 50.0%, respectively (P<0.05); while the LBRs were 44.4% and 37.3%, respectively (P<0.05). However, there was no significant association between ICM grade and LBR. LBRs were 42.8% and 37.2% for ICM grades A and B, respectively.

Furthermore, multivariate logistic regression analysis showed that only blastocyst diameter was significantly associated with live birth (<140μm versus 140-160μm: AOR 1.56 95%CI 1.08-2.27; <140μm versus 160-180μm: AOR 2.12 95%CI 1.47-3.06; <140μm versus ≥180μm: AOR 2.26 95%CI 1.50-3.43).

Limitations, reasons for caution: Only high-quality embryos used in frozen transfer were considered in this study. In addition, hatching/hatched embryos were excluded because an accurate diameter was not measureable.

Wider implications of the findings: Our data show a strong correlation between blastocyst diameter on Day 5 and probability of live birth. More individualized timing of embryo transfer in frozen embryo cycles may be needed to improve implantation rates, especially for blastocysts that are <140µm.

Trial registration number: Not applicable.

P-178 What stage of in vitro embryo development is affected by oxygen tension? A randomized clinical trial (RCT)

P. Maurin[1], C. Herbemont[1], I. Cedrin-Durnerin[2], J. Boujenah[3], B. Dagher-Hayeck[2], S. Sarandi[1], J. Calvo[2], A. Seroka[2], M. Comtet[2], C. Vinolas[2], M. Grynberg[2], C. Sifer[1]

[1]*Hôpital Jean Verdier, Histologie-Embryologie-Cytogénétique-CECOS, Bondy, France*
[2]*Hôpital Jean Verdier, Médecine de la Reproduction, Bondy, France*
[3]*Hôpital Jean Verdier, Maternité-Gynécologie-Obstétrique, Bondy, France*

Study question: Is embryo development influenced by oxygen tension applied during culture? If yes, are both cleavage and blastocyst stages vulnerable to oxidative stress (OS)?

Summary answer: Hypoxia during embryo culture improves embryo quality and development ability. However, late pre-implantation embryo development seems to be less vulnerable to oxidative stress.

What is known already: In mammals, uterine environment is at low oxygen concentration (2-8% O_2). Thus, human embryo culture under 2-8% O_2 is recommended by ESHRE revised guidelines for good practices in IVF labs. Indeed, hypoxia (5% O_2) seems to improve embryo quality at cleavage and blastocyst stages, presumably by reducing damages of OS. Nevertheless, recent meta-analyses concluded with a very low evidence to a superiority of hypoxia on IVF/ICSI outcomes. Furthermore, a study on mouse embryos suggested a negative impact of OS only at cleavage stage. This hypothesis has still never been investigated in humans.

Study design, size, duration: From 01/2016 to 12/2017, 721 IVF/ICSI cycles were included in this RCT. At Day-0 (D0), cycles were randomized using a 1:2 allocation ratio: group "20%-O_2" (n = 241); group "5%-O_2" (n = 480). Extended culture (EC) was performed when ≥5 D2-good-quality-embryos were available (n = 83 in subgroup A ("20%-O_2")). In subgroup "5%- O_2", 175 EC cycles were randomized again at D3 (using 1:1 ratio): group B: 5%-O_2 until D6 (n = 88); or C: switch to 20%-O_2 from D3 to D6 (n = 87).

Participants/materials, setting, methods: Inclusion criteria were: intracouple IVF/ICSI using fresh/frozen ejaculate; female age <40 years; absence of hydrosalpinx; ≥8 cumulus-oocyte complexes retrieved. Oocytes were fertilized and cultured in similar benchtop incubators, under 5 or 20% O_2. Fertilization rate, cleavage-stage quality (D2-top-quality-embryo (D2-TQE): 4 blastomeres, <20% cytoplasmic fragmentation), blastocyst quality when necessary (D5-top-quality-blastocyst (D5-TQB): ≥B4AA/AB/BA (Gardner and Schoolcraft's classification)) and implantation rate (IR) were compared between groups "20%" and "5%" (=cleavage-stage analysis), or A(20%), B(5%) and C(5%-to-20%) (=EC analysis).

Main results and the role of chance: In cleavage-stage analysis, all characteristics were similar between groups "20%" and "5%" O_2. A total of 6 304 embryos were analyzed. A significantly higher number of early-cleaved embryos was obtained under 5%-O_2 (3.3 *vs.* 2.4 under 20%; p = 0.0009). A trend towards higher D2-TQE rate was achieved under 5%-O_2 (40.8% *vs.* 37.0%; p = 0.067). Then, overall IR was comparable whatever the culture condition applied from D0 to D3 ("5% O_2": 29.7% *vs.* "20% O_2": 27.8%). Considering EC analysis, both demographic and clinical parameters of the cycles were also comparable. Blastulation rates were similar in groups A, B and C (68.1%, 70.4% and 71.6%, respectively). Regarding blastocyst quality, embryo culture under 20%-O_2 from D0 to D6 (group A) resulted in significantly lower D5-TQB rates/blastocyst (15.2%), than in both groups B (23.4%; p = 0.0029) and C (20.1%, p = 0.04). Furthermore, blastocyst quality was statistically equivalent between groups B and C. Finally, blastocysts IR were similar in groups A, B and C (43.4% *vs.* 39.4% *vs.* 42.7%, respectively).

Limitations, reasons for caution: Embryos were not analyzed using morphokinetic parameters, which could have made the interpretation less subjective.

Wider implications of the findings: If confirmed, these results would encourage to systematically culture embryos under hypoxia during only early development stages, since OS might be detrimental exclusively before embryonic genome activation.

Trial registration number: ID-RCB: 2015-A02019-40

P-179 Functionally active extracellular vesicles are released and taken up by zona-intact bovine embryos produced in vitro

K.C. Pavani[1], A. Hendrix[2], B. Leemans[1], A. Van Soom[1]

[1]*Ghent University, Department of Reproduction- Obstetrics and Herd Health, MERELBEKE, Belgium*
[2]*Ghent University, Department of Radiation Oncology and Experimental Cancer Research, Ghent, Belgium*

Study question: Are extracellular vesicles (EVs), as putative autocrine factors, released into the culture medium by bovine embryos and are they able to cross the zona pellucida?

Summary answer: Extracellular vesicles were isolated from EV-free media conditioned by bovine embryos and were, after fluorescent labeling, taken up and internalized by zona-intact embryos.

What is known already: Group culture of bovine embryos in medium containing bovine serum albumin (BSA) is currently the most successful method to produce embryos in vitro. Autocrine factors play a key role in group culture, with EVs being possibly important autocrine mediators. Moreover, EVs are present in various body fluids including serum, suggesting that BSA may support bovine embryo development by enriching medium with extracellular vesicles. Theoretically, EVs (50-300 nm) can pass through the pores of the bovine zona pellucida (mean diameter 200 nm). We hypothesize that EVs are released and taken up by embryonic cells, serving as positive mediators in group culture.

Study design, size, duration: In vitro maturation and fertilization was performed using routine methods. For in vitro culture, presumed zygotes were allocated to Synthetic Oviduct Fluid (SOF) containing insulin, transferrin and selenium (ITS) and supplemented with 0.4% BSA. To assess the presence of embryo secreted-EVs, both standard and ultracentrifuged (EV-depleted; centrifuged at 100,000 g for 18 h at 4°C) media were tested. At day 8, blastocysts were recorded and quality was evaluated by differential staining.

Participants/materials, setting, methods: One ml of embryo-conditioned medium was pooled at day 8 and subsequently subjected to Optiprep® density gradient ultracentrifugation and size exclusion chromatography to isolate EVs. Identification and characterization of EVs was performed by nanoparticle tracking analysis, transmission electron microscopy and western blotting (CD9, TSG101,CD63). Next, EVs were pre-labeled by PKH67 dye and subsequently co-incubated with day 6 embryos for 48 hours to assess EV passage through the zona pellucida. The uptake was analyzed by confocal microscopy.

Main results and the role of chance: Blastocyst development and hatching rates were not significantly different comparing standard and EV-depleted embryo culture medium (40 ± 3.43 % vs 38.88 ± 1.48 %; 25.20 ± 1.16 % vs 24.0 ± 0.83%; normal medium vs EVs free medium; P>0.05). In contrast, a significant difference between culture media was observed in total cell number of expanded and hatched blastocysts (151.0 ± 1.95 vs 126.8 ± 1.74; 209.6 ± 1.31 vs 162.12 ± 2.29; normal medium vs EV-depleted medium; P<0.05). Moreover, apoptotic cell ratio was significantly higher in expanded blastocysts cultured in EV-depleted compared to standard medium (8.7 ± 0.35 vs 6.1 ± 0.50; P<0.05). Based on this data, EV-depleted culture medium had an significant adverse effect on embryo quality. Moreover, embryos cultured in EV-depleted medium secreted EVs in the culture medium. At day 8, EVs sizing from 25 to 250 nm were isolated, which indicates the secretion of EVs through the pores of the zona pellucida. By nanoparticle tracking analysis, the concentration of EVs extracted from 1 ml of conditioned medium was 1.36×10^8 particles/ml. Western blotting analysis demonstrated the presence of CD9, TSG101, CD63 markers in embryo-derived EVs. Co-incubation of PKH67 prelabeled EVs and embryos demonstrated the uptake of embryo-derived EVs by zona-intact embryos. We conclude that functionally active EVs can cross the zona pellucida.

Limitations, reasons for caution: The major limitation in the current study was the collection of high volumes of embryo conditioned medium, as it requires 400-500 in vitro produced embryos to obtain 1 ml conditioned

medium. To counteract this limitation we were obliged to make use of pooled embryo conditioned medium.

Wider implications of the findings: Our data demonstrated that EVs are secreted by in vitro cultured bovine embryos in the medium, cross the zona pellucida and can be taken up by embryos. These facts indicate the potential role of EVs as mediators in embryo development, also with possible implications for human embryo culture.

Trial registration number: Not Applicable.

P-180 A role of E-cadherin-Wnt/β-catenin-lin28/let7 pathway in epithelial-mesenchymal transition (EMT) during extravillous trophoblast differentiation

Q. LI

The university of hong kong, obstetrics & gynaecology, hong kong, China

Study question: How dose E-cadherin change in embryo trans-activate canonical Wnt/β-catenin signaling pathway and its downstream target lin28(a/b)/let7 affect extra-villous trophoblast EMT during normal implantation.

Summary answer: E-cadherin bound β-catenin release feeds into Wnt signaling pathway and promote trophectoderm EMT through up-regulation lin28a/b as well as suppression mir-let-7.

What is known already: Wnt/β-catenin signaling is one of the several pathways that involve in EMT, E-cadherin associated with β-catenin on the cellular membrane to prevent β-catenin participate in signaling pathway. Our own data showed that up-regulation of lin28a is required for the activation of mouse blastocysts and mir-let 7 was up-regulated in dormant embryo but lower expressed in implantation competent embryo in our microarray analysis.

Study design, size, duration: The expression of EMT related marker, lin28a,b, mir-let-7 family was detected in Wnt/β-catenin activated and inhibited human trophectoderm cell line, HTR-8/SVneo and Jeg-3. The function of E-cadherin disassociation with β-catenin in activate Wnt pathway was confirmed. The in vivo and in vitro effect of Wnt/β-catenin-lin28/let7 on embryo EMT was examined.

Participants/materials, setting, methods: Human trophectoderm cell line HTR-8/SVneo and Jeg-3 was used for in vitro assay. Pregnancy was produced by natural mating between female and male ICR mice, and C57BL6/J mir-let-7g overexpression transgenic mouse for in vivo assay. The expression of active β-catenin, E-cadherin, EMT marker, lin28a,b, mir-let-7 was detected in both cell line and mouse embryo in Wnt induced EMT by QPCR, Western blot, and immunostaining.

Main results and the role of chance: E-cadherin dissociation from adhesion junction (AJ) with β-catenin cause β-catenin gain the ability to be translocated into nucleus and activate Wnt signaling in Jeg-3 cell. Wnt/β-catenin activation trans-activate lin28a/b in Jeg-3 and HTR-8/SVneo in E-cadherin dissociated cell. Lin28 functionally regulates the expression of mir-let-7 family in Jeg-3 and HTR-8/SVneo. E-cadherin dissociation from AJ, Wnt/β-catenin activation, Lin28 overexpression and mir-let-7 knockdown cause Jeg-3 and HTR-8/SVneo cell EMT in vitro and also increase the invasion and migration rate. In the embryo in vitro co-culture process, from 24 h attachment to 48 h invasion, E-cadherin was down-regulated in invasive trophectoderm but active-β-catenin was increased, mesenchymal related markers were upregulated. In vivo, the implantation rate and embryo EMT of let-7g overexpressed mouse was decreased.

Limitations, reasons for caution: E-cadherin dissociation from AJ with β-catenin cause β-catenin and E-cadherin both translocated into nucleus, and Wnt activation, how the specific regulatory mechanism of E-cadherin affect Wnt activation still do not know.

Wider implications of the findings: Our findings indicate that trophectoderm cell experience Wnt/β-catenin pathway activation as E-cadherin dissociation from AJ, and supression its down-stream target mir-let-7 by lin28, thus promote EMT. This information contribute to a better understanding of the mechanisms that the miRNA-mediated regulation of embryo implantation, and subsequently improve treatments for infertility.

Trial registration number: no.

P-181 Embryo cryopreservation is associated with significantly higher birth weight compared with sibling cohort fresh embryo transfer: a bicenter cohort

A. Margaux[1], S. Phillips[2], A. Ferrieres-Hoa[1], A. Gala[1], A. Fournier[1], C. Vincens[3], E. Vintejoux[3], F. Bissonnette[2], I.J. Kadoch[2], S. Hamamah[1]

[1]human reproductive biology, art/pgd, Montpellier, France
[2]Ovo fertilité, Department of Obstetrics and Gynecology, Montreal, Canada
[3]Gynecology and Obstetrics, art/pgd, Montpellier, France

Study question: To determine if the freeze-thaw procedure itself is involved in birth weight difference between singletons born after fresh embryo transfer and those born after frozen embryo transfer.

Summary answer: Birthweight after frozen embryo transfer (slow freezing or vitrification) was significantly higher (215.6 g) than after fresh embryo transfer (3487.4 g vs 3271.8 g, p = 0.0001).

What is known already: It is well established that the frozen embryo transfer (FET) is associated with a change of birth weight in comparison with fresh embryo replacement even after taking into consideration relevant confounding factors. However, no study has compared the birth weight of consecutive siblings conceived using the same oocyte/embryo cohort but different transfer procedures (fresh vs frozen embryos).

Study design, size, duration: Retrospective bicenter cohort study. The cohort included 145 sibling pairs where the older sibling was born after fresh embryo transfer and the second after embryos frozen-thawed replacement from the same in vitro fertilization (IVF) cycle.

Participants/materials, setting, methods: The cohort included all IVF cycles where fresh embryo transfer that resulted in a singleton live birth (fresh group n = 145) was followed by FET that led to a singleton live birth (FET group n = 145). Twin pregnancies and stillbirths were excluded. The embryos were frozen either by slow freezing or after vitrification. Birth weight were adjusted for gestational age and the mean adjusted birth weight in the two groups were compared with the Wilcoxon test.

Main results and the role of chance: The mean adjusted birth weight of the FET group was significantly higher (by 215.6 g) than that of the fresh group (3487.4 g vs 3271.8 g respectively, p = 0.0001). These result were also significant for transfer at the blastocyst stage (3513.5 g vs 3290 g, p = 0.0074) but not at the cleaved stage (3448.7 g vs 3258 g, p = 0.1074). Concerning the number of embryos transferred, when one embryo was transferred, the birth weight was, indeed higher after FET than after fresh embryo transfer (3494.2 g vs 3296.9 g, p = 0.0044) but the results were not significant when two embryos were transferred (3452.8 g vs 3186.7 g, p = 0.3123). A significantly higher risk of being large for gestational age (LGA) > 90ème percentile or >97ème percentile after FET versus fresh embryo transfer was revealed: RR, 1.13 (95% CI, 1.03-1.23) and RR, 1.1 (1.02-1.19) respectively. As both embryos (fresh and frozen) were from the same IVF cycle to avoid confounding factors and the only difference between groups was the absence/presence of the cryopreservation step, our results strongly suggest that the cryopreservation procedure affects the birth weight of sibling embryo cohort.

Limitations, reasons for caution: The main limitation of this study, is the retrospective design.

Wider implications of the findings: ART techniques, such as cryopreservation procedure, alter birth weight, possibly through epigenetic modifications in FET (freezing/thawing procedure, cryoprotectants).

Trial registration number: Not applicable.

P-182 Clinical validation of a non-invasive embryo selection algorithm combining time-lapse morphokinetics and the oxidative status of spent embryo culture media

R. Del Gallego Bonilla[1], L. Alegre[1], T. Cnaani[2], S. Shnizer[2], J. Remohí[1], M. Meseguer[1]

[1]IVI Valencia, IVF Laboratory, Valencia, Spain
[2]Carmel Diagnostics, Thermochemiluminiscence, Kiryat Tiv'on, Israel

Study question: Determine if novel embryo selection technique based on spent´s embryo culture media oxidative profile combined with time-lapse morphokinetic analysis could predict implantation potential.

Summary answer: Implanting transferred embryos showed a more extensive oxidative metabolism which, when combined with morphokinetic data, led to the development of a predictive algorithm.

What is known already: Despite IVF's (*in vitro* fertilisation) widening application and technological progress, it remains associated with two main weaknesses that derive partly from our inability to adequately assess embryo quality: low implantation rates and high multiple pregnancy rates. Novel non-invasive strategies based on spent culture media analysis provide additional valuable data to current morphology and morphokinetic analysis performed by time-lapse technology. In particular, the assessment of the embryo's oxidative profile with the Thermochemiluminescence (TCL) Analyzer™ (Carmel Diagnostics, Israel) suggests a new approach in determining embryo's quality or viability and subsequent implantation potential.

Study design, size, duration: A retrospective cohort study was performed with a total of 505 spent embryo culture media, including 205 single-embryo transfers (SET) with known implantation, from 390 IVF cycles. Embryos were cultured and monitored in independent-well slides in the time-lapse system incubator Embryoscope® (Vitrolife) and were subsequently transferred at blastocyst stage. Implantation potential and embryo quality at day 5 (Transferred+Vitrified vs. Discarded embryos) were considered, in terms of oxidation, to find a predictive profile of pregnancy success.

Participants/materials, setting, methods: Oxidative status of 15 µl/embryo of Blastocyst medium (Cook) samples were assessed by the Thermochemiluminescence (TCL) Analyzer™, based on the heat-induced oxidation of biological fluids, leading to the production of light energy counted as photons emitted per second (**cps**). TCL parameters recorded were **cps** amplitude after 55 seconds (**H1**), 155 seconds (**H2**) and 255 (**H3**), in a 300-second period. Oxidative data was normalized with a smoothing algorithm (**sm**) and analyzed by the statistical test ANOVA.

Main results and the role of chance: Regarding day 5 embryo quality, transferred and vitrified embryos showed significantly higher values (sig. <0.05) for the oxidative parameters **H1sm**, **H2sm** and **H3sm**. In addition, out of 205 transferred embryos, 54.1% succeeded at implantation showing again higher significant values (sig. <0.05) in the oxidative parameters. This therefore implies high quality embryos have a more extensive oxidative metabolism exerting an oxidative load on their surrounding media. A combined assessment algorithm, including morphology, morphokinetics and the embryo's culture media oxidative status was subsequently developed as a predictive clinical tool of embryo selection, prior to transfer. Motato et al. (2016) morphokinetic model based on blastocyst expansion (**tEB**; optimal range ≤ 112.9 hours) and timing of transition from 5-blastomere embryo until 8-blastomere embryo (**t8–t5**; optimal range ≤ 5.67) was combined with TCL parameter **H2sm** (optimal range ≤ 92.96). A hierarchical classification was generated with six embryo categories (A - F) according to their implantation potential (76.5–29.2%).

Limitations, reasons for caution: The present retrospective study and its developed selection algorithm require an additional prospective validation for its routine clinical use. Oxidative status database will increase while using TCL to pursue a more accurate **H2sm** optimal range.

Wider implications of the findings: The fair correlation between TCL oxidative results, embryo quality and implantation potential proves its application as a clinical biomarker. Its combination with morphokinetic data aims for the improvement of our current selection criteria. A more accurate selection of the best embryo, especially in good-quality embryo cohorts, would determine IVF success.

Trial registration number:

P-183 Detection of multinucleated trophectoderm cells by time-lapse microscopy: Implications for PGT-A biopsy results

Q. Zhan, Z. Rosenwaks, N. Zaninovic

Weill Cornell Medicine, Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Is the nuclear status of trophectoderm (TE) cells uniform? If multinuclear TE (MNT) cells are used for PGT-A analysis, will they impact the aneuploid results?

Summary answer: MNT cells can be identified in human blastocysts. Biopsy and analysis of these cells using current PGT-A techniques may yield invalid results.

What is known already: Detection of triploidy and polyploidy using current chromosomal testing techniques (NGS or PCR) is limited. Bovine embryos contain polyploidy cells in the TE. So far, multinuclear cells in the human TE of preimplantation-stage blastocysts have not been reported. In contrast, polyploid multinuclear cells have been identified in the human trophoblast and syncytiotrophoblast. Day 11 human embryos contain single nucleated TE cells in cells adjacent to the epiblast compared to those in peripheral TE, which contain multinucleated cells. The chromosomal status of single multinucleated blastomeres on day 3 indicated polyploidy and/or aneuploidy. The chromosomal status of MNT cells is unknown.

Study design, size, duration: This is an observational study of IVF embryos cultured under time-lapse microscopy (TLM) incubation until the blastocyst stage.

Participants/materials, setting, methods: Embryos were cultured and monitored in a TLM incubator (EmbryoScope, Vitrolife, Sweden). At the blastocyst stage, the embryos were carefully monitored for the presence of binucleated and/or multinucleated cells in the TE. If MNT cells were detected, a retrospective analysis of TLM videos was performed to identify their origin.

Main results and the role of chance: Multinuclear blastomeres were positively identified with high specificity during the first three embryo cleavages. In addition, we observed the existence of MN cells in the TE during blastocyst development. This novel observation can be easily identified by TLM in fully expanded blastocysts where TE cells are stretched out. We observed MNT cells at various stages of blastocyst development, usually as single cells, an observation which appeared to be independent of the quality of the blastocyst or density of TE cells. We observed that MNT cells can be formed de novo during TE development by the fusion of two or more single nucleated TE cells. Interestingly, these MNT cells can subsequently cleave to two daughter cells with single nuclei. The chromosomal analysis may be altered if MNT cells or their progeny are used during TE biopsy. The chromosomal status of a single MNT cell and its descendant cells is unknown. The occurrence of MNT cells can be a normal event during blastocyst development, and it may indicate the plasticity of TE formation. It is possible that the quantity, quality, and nuclear status of TE cells could have an impact on the accuracy of PGT-A.

Limitations, reasons for caution: This is an observational study. The chromosomal status of individual MNT cells cannot be performed.

Wider implications of the findings: During TE biopsy, it is imperative to assess the nuclear status of the TE. MNT cells should not be used for biopsy, as they might cause an incorrect diagnosis of the embryo.

Trial registration number: N/A.

P-184 Does the transfer of a poor quality embryo together with a good quality embryo affect the In Vitro Fertilization (IVF) outcome?

L. Yang[1,2], S. Zhang[2,3,4], C. Lu[2,4,5], J. Dai[2,6], F. Gong[2,4,6], G. Lu[2,4], G. Lin[2,4,6]

[3]*Central South University, Institute of Reproducitve and Stem Cell Engineering- Basic Medicine College, Changsha, China*
[4]*Reproductive and Genetic Hospital of CITIC-XIANGYA, Reproductive and Genetic Hospital of CITIC-XIANGYA, Changsha, China*
[5]*Central South University, Institute of Reproducitve and Stem Cell Engineering- Basic Medicine College-, Changsha, China*
[6]*Central South University, Institute of Reproducitve and Stem Cell Engineering- Basic Medicine College, Changsha, China*

Study question: Whether a poor quality embryo has a negative effect on a good quality embryo when transferred along with a good quality embryo.

Summary answer: A poor quality embryo does not negatively affect a good quality embryo, when transferred together in a double embryo transfer.

What is known already: Embryo quality is one of the main predictors of success in IVF cycles. Many studies have shown a strong association between embryo morphology, implantation, and clinical pregnancy rates. In theory, the poor quality embryo has potential for a successful pregnancy, and may lead to higher spontaneous abortions and overall decreased clinical pregnancies and live birth rates. IVF cycles which result in only one good quality embryo, and a second poor quality embryo present a dilemma when the decision involves transferring two embryos.

Study design, size, duration: This single-center, retrospective cohort study involved patient who had only one good quality embryo in fresh cleavage stage embryo transfer using non-donor oocytes at the Reproductive and Genetic Hospital of CITIC Xiangya in the years 2010–2016. The analysis involved 409 of 418 enrolled cycles in patients who were included in the study group and 409 control cycles in patients who were identified by propensity matching from a cohort of 1339 cycles.

Participants/materials, setting, methods: We enrolled patients who had only one good quality embryo in the cleavage stage(D3), and involving double embryo transfers(DET) with one good quality embryo and one poor quality embryo(study group) or single good quality embryo transfers(SET)(control group). Propensity matching was used to identify a propensity matched control group from a cohort of 1339 cycles based on age, BMI, basical FSH, endometrial thickness on the day of hCG, number of oocytes retrieved, and quality embryo.

Main results and the role of chance: 818 cycles were included in the study. 409 cycles in women who had DET with one good quality embryo and one poor quality embryo [study group (G + P)], and 409 cycles in women who had SET with one good quality embryo [control group (G)]. There was no difference in patient baseline and cycle characteristics between the two groups. The clinical pregnancy rate (39.9% vs. 34.2%, P > 0.05), implantation rate (21.3% vs. 17.5%, P > 0.05), and live birth rate (28.6% vs. 26.2%, P > 0.05) were no difference between study and control groups respectively. The early abortion rate (17.8% vs. 17.1%, P > 0.05) and ectopic pregnancy rate (0.6% vs. 1.4%, P > 0.05) were no difference between study and control groups respectively. The twin pregnancy rate of the study group (G + P) (6.7%) was slightly higher than that of the control group (G) (2.1%) (P = 0.096), without reaching statistical significance.

Limitations, reasons for caution: The extrapolation of the results is limited by the retrospective nature of the study.

Wider implications of the findings: A poor quality embryo does not negatively affect a good quality embryo, when transferred together in a double embryo transfer.

Trial registration number: No.

P-185 Double biopsy at the blastocyst stage by retrieving blastocoelic fluid and trophectoderm cells does not affect embryo viability

G. Terzuoli[1], M.C. Magli[1], A. Pomante[1], S. Mascaretti[2], M. Dell'Aquila[1], I. Camera[1], A.P. Ferraretti[1], L. Gianaroli[1]

[1]*S.I.S.Me.R., Reproductive Medicine Unit, Bologna, Italy*
[2]*S.I.S.Me.R. Servizi Abruzzo, Reproductive Medicine Unit, L'Aquila, Italy*

Study question: Does the procedure of double biopsy affect embryo viability?

Summary answer: The simultaneous biopsy of blastocoelic fluid (BF) and trophectoderm (TE) cells does not decrease embryo viability, whereas double biopsy at previous stages negatively affects implantation.

What is known already: The current trend in Preimplantation Genetic Testing (PGT) programs is to perform biopsy of TE cells. This gives several advantages including the high probability of having informative results when compared to cases in which genetic analysis is done on polar bodies (PBs) or blastomeres. Consequently, the need to perform re-biopsy is not a common event following TE biopsy, but it can be necessary when biopsy is done at previous stages.

Study design, size, duration: This retrospective study includes 450 PGT cycles from September 2009 to September 2017. According to the clinical indication, biopsy was performed on PBs (n = 131 cycles), blastomeres (n = 227 cycles) or TE cells (n = 80 cycles). In cases of non-informative results, re-biopsy was performed. Only single embryo transfer were included in the study to evaluate the effect of double biopsy on ongoing pregnancy rate (>16 weeks).

Participants/materials, setting, methods: Indications to PGT were monogenic diseases (PGT-M, n = 93) or aneuploidy (PGT-A, n = 357). Following biopsy, Whole Genomic Amplification (WGA) was immediately performed and, after positive amplification, embryos were cryopreserved at the blastocyst stage to complete the genetic analysis. In case of negative amplification, re-biopsy was performed at the cleavage stage after PB biopsy and after blastomere biopsy. For blastocysts, the BF was used as back-up sample.

Main results and the role of chance: PGT-M and PGT-A cycles were equally distributed in the three biopsy groups (PBs, blastomeres, TE cells). Re-biopsy was performed in 14.5% of PB cycles, 9.8% of blastomeres cycles and 5% of TE cycles. The ongoing pregnancy rate in PB group was 14.2% after re-biopsy and 29.5% after single biopsy, while after blastomere biopsy it was 14.2% and 25% respectively. When pooling these two groups, the difference between re-biopsy and controls was significantly different (14.3% vs. 27%, P<0.05). For blastocysts, the ongoing pregnancy rate was 50% after biopsy of both TE and BF compared with 39% after biopsy of TE only. A significant difference was found when relating the ongoing pregnancy rate after re-biopsy that was significantly lower when done at the cleavage stage and the double biopsy at the blastocyst stage (P<0.001). Finally, a difference was also found when comparing the controls of single biopsies done at earlier stages (PB and cleavage stage) with blastocyst biopsy (P<0.025) confirming the clinical advantage related to blastocyst transfer.

Limitations, reasons for caution: The limited number of cases in the three biopsy groups is probably softening differences that are suggested by the observed trend.

Wider implications of the findings: Biopsy at the blastocyst stage is the preferable option either alone or combined with removal and storage of the BF. The last approach could provide a back-up sample to be used in case of non-informative genetic results. In addition, artificial blastocyst collapsing could possibly improve the results after vitrification.

Trial registration number: Not applicable.

P-186 High oxygen tension during in vitro maturation of human oocytes improves developmental competence

M. Miura[1], R. Matsunaga[1], K. Isobe[1], Y. Ohnuki[1], W. Mita[1], Y. Kobayashi[1], N. Yamanaka[1], M. Kamihata[1], S. Watanabe[1], T. Maeda[1], H. Makino[1], M. Ochi[1], T. Horiuchi[2]

[1]*Ochi Yume Clinic Nagoya, IVF laboratory, Nagoya, Japan*
[2]*Prefectural University of Hiroshima, Department of Life Science-, Shobara, Japan*

Study question: Is it advantageous to culture cumulus-oocyte complexes (COCs) under high oxygen tension (20%) during in vitro maturation?

Summary answer: Culturing COCs under high oxygen tension (20%) during in vitro maturation increased the rate of blastocyst development.

What is known already: Previous studies have investigated whether oxygen tension during in vitro culture of oocytes affects clinical outcome. However, there are few reports on the optimum oxygen level for in vitro maturation. It has been suggested that oxygen concentration during in vitro maturation (IVM) affects murine blastocyst cell numbers and fetal development. It is thought that oxygen tension influences reactive oxygen species levels in oocytes matured in vitro and it is also known to influence the normal fertilization rates of bovine oocytes in IVF. However the influence of oxygen tension on embryo developmental competence after human oocytes maturation is unknown.

Study design, size, duration: The study was performed from March to December 2017. We collected immature COCs from IVF patients undergoing letrozole stimulation and divided them into two groups. 188 COCs from 59 patients were cultured with 5% O2 and 133 COCs from 47 patients were cultured with 20% O2.

Participants/materials, setting, methods: COCs were cultured in TCM199 supplemented with FSH and EGF in 5% O2 or 20% O2. ICSI was performed on these oocytes which where then cultured in a one step medium for six days in 5% O2, 6% CO2 and 89% N2. We measured oocytes maturation rate, normal fertilization rate and blastocyst formation rate.

Main results and the role of chance: Oocytes maturation rate in 5% O2 was 55.3% and in 20% O2 was 53.4% (P > 0.05). There was no significant difference in normal fertilization rate between the two groups (5% O2 = 73.8% vs. 20% O2 = 78.6%). The blastocyst development rate following oocyte maturation in the 20% O2 group (47.3%) was significantly higher than that in the 5% O2 group (25.2%, P < 0.05).

Limitations, reasons for caution: This study is limited to immature oocytes obtained from patients undergoing IVF.

Wider implications of the findings: This is the first study to demonstrate the effectiveness of high oxygen tension during IVM in human oocytes. Our results show that oocytes cultured in 20% O2 during IVM exhibit enhanced developmental competence.

Trial registration number: none.

P-188 Artificial oocyte activation improves pre- and post implantation development of ICSI embryos irrespectively of sperm origin

K. Sasamine[1], T. Takeuchi[2], S. Mizuta[1,2], K. Kitaya[1], H. Matsubayashi[1,2], T. Ishikawa[1,2]

[1]*Reproduction Clinic Osaka, Reproductive Medicine, Osaka, Japan*
[2]*Reproduction Clinic Tokyo, Reproductive Medicine, Tokyo, Japan*

Study question: Is the effect of artificial oocyte activation (AOA) on embryonic development and pregnancy outcome associated with sperm origin?

Summary answer: Regardless of sperm origin, AOA effectively improved fertilization and pre- and post-implantation development by increasing the quantity and the quality of blastocysts available for transfer.

What is known already: AOA has been a therapeutic option for patients with a history of ICSI fertilization failure.

In earlier studies, it has been shown that AOA is effective in improving not only the fertilization rate, but also the pregnancy rate in cases where impaired fertilization was observed in preceding cycles.

However, whether sperm origin has any impact on the development of AOA embryos is not well understood.

Study design, size, duration: In order to examine the effect of AOA on late embryonic development, we compared ICSI outcome between non-AOA and AOA cycles in patients with various fertilization rates and different sperm origin, ejaculated (EJ) and testicular spermatozoa (TESE).

Between October 2013 and November 2017, total of 153 infertile couples with EJ and 48 with TESE ICSI were involved in the study.

All patients gave written consent, and institutional review board approval was granted.

Participants/materials, setting, methods: Consenting patients were grouped according to the sperm origin as well as fertilization rates in initial non-AOA cycles.

For AOA, ICSI inseminated oocytes were exposed to 10 μM calcium ionophore (A23187) for 15 minutes.

Developed embryos were all vitrified, and warmed-replaced in subsequent embryo transfer cycles, while no fresh embryo transfers were elected.

The rates of fertilization, blastulation, good blastocyst, clinical pregnancy, and on-going pregnancy were compared between non-AOA and AOA cycles.

Main results and the role of chance: The couples initially underwent 341 non-AOA cycles (280 with EJ and 61 with TESE), followed by 427 AOA cycles (328 EJ and 99 TESE, respectively). Both EJ and TESE groups were further divided into three subgroups according to initial non-AOA fertilization rates, i.e., low (<30%), sub-optimal (30-60%), and satisfactory (>60%). Semen parameters were comparable among the three groups. In both EJ and TESE groups, the rates of fertilization after AOA were significantly improved from non-AOA cycles in all (P<0.001), but satisfactory group as expected. We defined good blastocyst rate as the proportion of blastocyst with good quality per embryo reached the blastocyst stage. Interestingly, AOA treatment remarkably increased blastulation and good blastocyst rates in sub-optimal group with EJ sperm (38.4 vs 62.0 and 14.0 vs 43.3%, P<0.01), and satisfactory group with TESE sperm (22.2 vs 40.0%, N.S. and 12.5 vs 62.5%, P<0.05). More importantly, overall clinical pregnancy rates and on-going pregnancy rates after AOA were obviously improved regardless of sperm origin (15.8 vs 31.5 and 12.1 vs 27.0% with EJ, 16.6 vs 52.3 and 11.4 vs 38.8% with TESE, respectively, P<0.01).

Limitations, reasons for caution: We included only cycles with motile sperm. Further investigations are needed to assess the effect of AOA in cases with severely compromised sperm quality. Long-term follow-up of children born after AOA with calcium ionophore has not been well studied yet.

Wider implications of the findings: AOA was effective for improving fertilization as well as late embryonic development irrespective of sperm maturity. Considering the beneficial effect observed in TESE cases with satisfactory fertilization, our findings indicate potential use of AOA even at first attempts once the safety is warranted.

Trial registration number: None.

P-189 Should we vitrify the early blastocyst? Retrospective study on 851 warming cycles with single embryo transfer

[3]*Eylau-La Muette, IVF Department, Paris, France*

Study question: To optimize the outcome of frozen-thawed cycles with single embryo transfer (SET), survival rate after thawing and ongoing pregnancy rates were compared between early and non collapsed full blastocysts.

Summary answer: Survival rate after thawing is not affected by the blastocyst expansion while early blastocyst transfers (B1-B2, Gardner classification) yield significantly less clinical pregnancies.

What is known already: Extended embryo culture to blastocyst stage allows better embryo selection and higher implantation rates. Since a couple of years SET policy is widely used to reduce the risk of multiple pregnancies and freeze all strategy is routinely performed in order to transfer embryos in a more physiological environment and to overcome ovarian hyperstimulation consequences. Studies have shown the superiotity of vitrification of blastocysts compared to cleavage stage.

Lately extensive research was done around the best vitrification/thawing protocol and techniques: closed vs open system, media, shrinkage prior to vitrification, blastocyst stage at vitrification, automation.

Study design, size, duration: Observational retrospective study on 851 frozen cycles with SET during 2016-2017. Blastocysts were divided in four groups based on Gardner's classification: 1 early (B1-B2, 251 embryos), 2 full (B3, 233 embryos), 3 expanded (B4, 301 embryos) and 4 hatching/hatched (B5-B6, 66 embryos). All blastocysts were transferred on monitored natural cycles under ultrasound control 6/7 days after LH surge. Survival rate after thawing (SR) and ongoing pregnancy rate (OPR) were compared between the groups.

Participants/materials, setting, methods: Study was performed in a private IVF center.

Blastocysts were scored at day 5 according to the classification of Gardner. No shrinkage was done before vitrification of expanded blastocysts.

Vitrification/thawing were performed using closed high security straws (CryoBioSystem) in combination with Irvine Scientific® Freeze/Thaw kit.

After thawing the blastocysts were cultured for two hours (Sage 1-Step®, Origio) in order to assess survival and reexpansion. Damaged and non-reexpanded blastocysts were discarded.

The transfer catheters were loaded with EmbryoGlue® (Vitrolife).

Main results and the role of chance: Patients mean age and infertility indications were comparable between the four groups (p>0.05). Ovarian stimulation protocols at retrieval (antagonist with recombinant FSH) were the same for all the patients.

Survival rates were similar between 4 groups (p>0.05): B1-B2 97.2%, B3 97.8%, B4 98.3%, B5-B6 96.9%.

OPR per transfer in B1-B2 (20.5%) was significantly lower compared individually to each group: B3 (32.0%, p = 0.029), B4 (38.2%, p = 0.001), B5-B6 (35.9%, p = 0.049). Furthermore, the OPR per transfer of full-expanded-hatched blastocysts were significantly higher than early blastocysts (37.8% vs 20.5%, p = 0.0008).

Limitations, reasons for caution: The study was undertaken to evaluate D5 blastocysts at vitrification. D6 blastocysts were not included. Blastocysts obtained at D6 must be evaluated in order to decide if one extra day of culture may benefit to early blastocysts before undergoing vitrification.

Wider implications of the findings: Our two years experience of blastocyst SET in frozen cycles shows that OPR are significantly lower with early blastocysts even if SR are comparable to late blastocysts. Therefore, our vitrification policy has been moved to one extra day of culture for blastocysts that are not expanded on D5.

Trial registration number: Not applicable.

P-190 Increased scrutiny of NGS profiles / ranking does not improve eSET implantation of euploid blastocysts: A randomized comparative trial

C.M. Rios[1], J.B. Whitney[2], M. VerMilyea[3], A.E. Jones[4], A. Picou[3], K. Balloch[2], N.L. Nugent[2], K. Silverberg[5], R.E. Anderson[6], M.C. Schiewe[2]

[1]*Ovation Fertility, Genetics, Henderson, U.S.A.*
[2]*Ovation Fertility, ART Lab, Newport Beach CA, U.S.A.*
[3]*Ovation Fertility, ART Lab, Austin TX, U.S.A.*
[4]*Ovation Fertility, Genetics, Nashville TN, U.S.A.*
[5]*Texas Fertility Center, ART Clinic, Austin TX, U.S.A.*
[6]*Southern California Center for Reproductive Medicine, ART Clinic, Newport Beach CA, U.S.A.*

Study question: Can NextGeneration sequencing (NGS) profile ranking of euploid embryos better predict eSET implantation potential of top quality blastocysts in contrast to morphological grading alone?

Summary answer: When blastocysts are both top quality and euploid, the lack of noise on a NGS profile adds no benefit for eSET compared to embryo grading.

What is known already: Blastocyst morphology assessment is the primary determinant for embryo transfer selection. Preimplantation genetic screening (PGS) now provides patients the ability to know the ploidy status of embryos before being transferred, which increases the implantation potential of eSETs. NGS provides every embryo a unique genetic profile which gives geneticists more information on genetic "noise" and low-level mosaicism that remains inconsistent between samples, patients, technicians and labs. Transferring mosaic embryos of differing profile levels has resulted in viable pregnancies, further questioning the clinical relevance of mosaic profiles. Furthermore, the risks to the offspring of a mosaic embryos is relatively unknown.

Study design, size, duration: Prospective randomized multicenter trial, initiated April 2016 and ended December 31, 2017. A total of 61 patients qualified for randomization by producing ≥ two top quality euploid day 5 or day 6 blastocysts. Upon enrollment, eSET selection was randomized between two pre-determined, double blinded ranking groups: Group 1 - embryologists ranked euploid blastocysts based on morphologic grade; and Group 2 - geneticists ranked transfer selection based on their interpretation of the NGS profiles.

Participants/materials, setting, methods: The study was performed at two locations (Clinic A: Newport Beach, CA; and Clinic B: Austin, TX) involving 6 physicians and differing embryology lab management and protocols. A single genetics lab performed NGS analysis using MiSeq (Illumina), with genetic noise/rank evaluated by a geneticist's interpretation. All embryos were cultured through day 6, and trophectoderm biopsy and vitrification performed according to individual lab procedures. Implantation was measured by a visual sac and all pregnancies documented.

Main results and the role of chance: Eighty patients agreed to participate in this IRB approved study, however 19 (23.8%) failed to achieve inclusion criteria. Fifty-seven eSET's have been performed to date. Group 1 (Morphology) achieved a 75.9% implantation and 62.1% ongoing pregnancy rate. Group 2 (Genetics) produced a 78.6% implantation and a 71.4 % ongoing pregnancy rate. There was no statistical difference ($p>0.05$) between either group for implantation, spontaneous abortion and/or ongoing pregnancy rate. Between clinics, clinic A accomplished a combined 96.7% implantation rate and 87.1% ongoing pregnancy, while clinic B had a 53.8% and 42.3% implantation and pregnancy rate, respectively. Clinic A exhibited no trends ($p<0.1$) between morphology and genetics, whereas clinic B revealed a preference for Group 2 (Genetics) for ongoing pregnancy. The latter finding that genetic profile ranking is associated with reduced miscarriage rates, warrants further investigation with a larger sample population. There were no significant differences between labs regarding fertilization rates, blastocyst yields or euploid rates. Patient age was not different between clinics, with a mean of 34 years old for qualifying participants. Clinic A had a single physician perform all stimulation and transfers, whereas Clinic B involved a rotation of 5 physicians for treatment.

Limitations, reasons for caution: Although sample size was low, it is important to note that patient selection was not biased, with study qualification requiring two top quality euploid blastocysts, not achievable for all IVF patients. Levels of mosaicism under 30% were classified as euploid and further scrutiny of extremely low levels was not performed.

Wider implications of the findings: Morphological grading has long been a standard for improving IVF success rates. With the adoption of NGS testing, more scrutiny of the PGS results has placed further importance on the role of the evaluating geneticist. This study indicates to the contrary, the embryologist is still vital for eSET embryo selection.

Trial registration number: None.

P-191 Development of a Mouse Embryo Assay with enhanced sensitivity for detection of peroxides in mineral oil samples

E. Mestres[1], M. Garcia-Jimenez[1], L. Faes[2], I. Vanrell[1], V. Bogaert[2], I. Jonckheere[2], A. Casals[1], C. Llop[1], N. Costa-Borges[1], G. Calderon[1]

[1]*Embryotools S.L., R&D, Barcelona, Spain*
[2]*FertiPro N.V., R&d, Beernem, Belgium*

Study question: How can culture conditions alter the sensitivity and reliability of the Mouse Embryo Assay (MEA), used for detection of toxicity in mineral oil samples?

Summary answer: Culture conditions can greatly alter the sensitivity of the MEA and must be carefully optimized to ensure a reliable detection of embryotoxic mineral oil samples.

What is known already: Mineral oil has been a key component in IVF since Brinster described its use for oocyte/embryo culture in 1963. Overlaying culture medium micro-droplets with mineral oil helps stabilizing temperature, pH and osmolarity during culture, as well as protecting against external contaminants. However, as a petroleum-derived product, mineral oil can harbor undesired components (e.g. peroxides) that may adversely affect fertilization and embryo development. Peroxides can originate during oil manufacturing, and its inadequate storage/handling can result in an increase of peroxides over time. Thus, it is essential to develop quality control assays with enhanced sensitivity to detect toxicity in mineral oil samples.

Study design, size, duration: Mineral oil samples, produced by an ART-medium manufacturer (FertiPro), were exposed to UV-light for different time-periods to induce peroxide formation. Peroxide levels after exposure were determined by potentiometric titration (detection limit <0.1mEq/kg), and samples were MEA tested in our laboratory (Embryotools). Different culture conditions (concentration and type of protein supplement, individual *vs.* group embryo culture, culture dish design) were tested on each oil sample, and results compared to establish optimal parameters for sensitive toxicity detection.

Participants/materials, setting, methods: Experiments were performed with one-cell freshly collected mouse embryos (n = 2066). Three replicates were performed on each oil sample with the different culture conditions established: medium protein supplement type (HSA+Globulins, HSA or BSA) and concentration (5 mg/ml, 0.5 mg/ml), embryo density (individual *vs.* group culture), and culture dish design (Petri vs. time-lapse dish). Embryo development was followed and registered daily until the end-points (Day 5 or Day 6). Blastocysts obtained were fixed and stained for total cell counts.

Main results and the role of chance: A minimum of 80% of expanded blastocysts was obtained in oil with peroxide levels <0.1mEq/kg, regardless of the type and concentration of protein used. By contrast, no blastocysts formed in oil samples with high peroxide concentrations (0.198, 0.503, 0.756mEq/kg).

Interestingly, when an oil sample with peroxide levels close to the detection limit was used (0.128mEq/kg), culture conditions showed a strong influence on

the assay's sensitivity. High embryo density (group culture) and medium supplementation with BSA resulted in higher blastocyst formation rates, indicating a lower capacity to detect embryotoxicity than individual culture and HSA or HSA+Globulins supplements. In HSA and HSA+Globulins groups, lower protein concentrations (0.5 mg/ml) also yielded more blastocysts ($p = 0.0013$) than higher protein concentrations (5 mg/ml), reducing the assay's sensitivity. By contrast, lower concentrations of BSA resulted in diminished blastocyst formation, compared to higher concentrations ($p = 0.0018$). Total cell number was significantly decreased in HSA and HSA+Globulins ($p<0.005$) groups, but not with BSA, once again demonstrating the reduced sensitivity of the latter.

Culturing in a time-lapse dish (Embryoslide®, Vitrolife) improved developmental rates in all protein groups ($p\leq0.005$), possibly because its design entails less contact surface between the culture medium and the oil overlay, hence reducing its sensitivity for mineral oil embryotoxicity detection.

Limitations, reasons for caution: This study confirms that culture conditions must be carefully optimized to successfully detect low concentrations of peroxides in mineral oil. Medium supplementation with BSA, as well as group embryo culture, significantly improved embryo development and can compromise the sensitivity of MEA testing, resulting in undetected embryotoxicity in mineral oil samples.

Wider implications of the findings: Culture conditions significantly modulate embryo development, hence playing a major role in quality control testing. Inappropriate testing of mineral oil derives in diminished sensitivity for embryotoxicity detection. As previously reported, even low traces of peroxides in mineral oil could dramatically affect clinical human IVF outcomes.

Trial registration number: N/A.

P-192 Systematic single embryo transfer after preimplantation genetic screening improves overall results (in terms of "normal" ongoing pregnancies) and should be widely implemented

G. Barrenetxea Ziarrusta[1], E. Martínez[2], M. De Las heras[2], G. Ohiane[2], J.I. Arambarri[3], J. Barrenetxea[4]

[1]*REPRODUCCION BILBAO, Gynecolgy & Assisted Reproduction, BILBAO, Spain*
[2]*Reproducción Bilbao, Lab. Embriology, Bilbao, Spain*
[3]*Reproducción Bilbao, Gynecology & Obstetrics, Bilbao, Spain*
[4]*Complejo Hospitalario de Navarra, Gynecology & Obstetrics, Pamplona, Spain*

Study question: Why do most of specialists transfer 2 (or more) embryos in most of the assisted reproduction procedures, even knowing that multiple pregnancies constitute a real (and sometimes hazardous) complication?

Summary answer: The transfer of a genetically screened embryo after systematic application of blastocyst culture allows the achievement of high pregnancy rates and reduction of multiple pregnancies.

What is known already: Even knowing the complications of multiple pregnancies (MP), 2 (even 3) embryos are transferred in most assisted reproduction procedures in many countries. The main reason for such a policy is to try to achieve high pregnancy rates per transfer even though multiple pregnancies represent a risk both for women and offspring. PGS along with the blastocyst culture allows the selection of the embryo with the highest odds to implant and to become an ongoing, normal and successful.

Study design, size, duration: Retrospective cohort analysis of a total of 530 embryos genetically screened from 117 successive PGS cycles performed during one year period (June,2016-May,2017) at a University associated ART center were analyzed.

Cycles involving PGD for monogenic disease or chromosomal abnormalities were excluded. Also, cycles in donor eggs were used were not included.

Participants/materials, setting, methods: Due to previously reported results (ESHRE Geneva) systematic single embryo transfer (SET) is offered to all patients at our center. After being informed, each patient gave informed consent form for the procedure.

Rates of euploidy depending on the day of embryo biopsy and age of patients were assessed. Efficiency of treatment was defined as the ongoing pregnancy rate (OPR) per transferred embryo and was analyzed depending on age of patients.

Main results and the role of chance: The mean number of microinjected MII microinjected was 12,99. After the fertilization of 766 oocytes, a total of 530 embryos were genetically screened (4,53 per cycle). Euploidy rates were different depending on the day of embryo biopsy: 17,78%, 44,68% and 21,69% of the assessed embryos were genetically normal after embryo biopsies performed on days 3, 5 and 6 respectively ($p = 0,032$). As expected, aneuploidy rates increased with advanced age of patients. Almost half of the embryos (46,94%) from women aged 30-35 were genetically normal, whereas only 26,32% and 8,82% of embryos from women aged 36-40 and 41-45 respectively were euploidic ($p = 0,021$).

Irrespective of the day of the biopsy, the OPR after single embryo transfer of genetically selected embryos was high either among fresh or frozen-thawed embryo transfers. Overall ongoing pregnancy rate per transfer was 67,09%. In the cleavage stage biopsy setting, 12 out of 22 fresh embryo transfers (54,55%) and 8 out 12 frozen-thawed embryo transfers (66,67%) resulted in ongoing pregnancies. Among embryos biopsied at blastocyst stage, the ongoing pregnancy rate was 73,33% (33 out of 45 transferred embryos).

No multiple pregnancy was suffered during the study period.

Limitations, reasons for caution: The number of patients included and the retrospective nature of the study should make us cautious regarding the results.

Randomized trials would be needed to corroborate the results shown in the present study.

Wider implications of the findings: As specialists, we should not accept multiple pregnancies as an "unavoidable" side effect of assisted reproduction in the 21st Century. Furthermore, improvements in embryo culture systems, freezing-thawing procedures and genetic assessment of embryos, among others, should be fully (and really) incorporated into practice.

Trial registration number: Not applicable.

P-193 Safety of fluorescence lifetime imaging microscopy (FLIM) as a non-invasive assessment of embryo metabolism

M. Venturas Pedro[1], T. Sanchez[1], E. Seidler[2], D. Sakkas[2], D. Needleman[1]

[1]*Harvard University, Molecular and Cellular Biology, Cambridge, U.S.A.*
[2]*Boston IVF, Reproductive Endocrinology and Infertility, Waltham, U.S.A.*

Study question: Is the illumination from FLIM-based metabolic imaging safe for embryos?

Summary answer: Using two assays, we found that excessive FLIM illumination dosages caused a transient perturbation to embryos, whereas a limited clinical dosage had no measurable effect.

What is known already: Embryo mitochondrial health is known to be essential for viability. Metabolic imaging uses FLIM to measure autofluorescence of the endogenous molecules, NADH and FAD, which are essential for cellular respiration. We have show that this technique is an effective tool for quantitatively measuring metabolic state; but in order to develop it into a clinical application, we must understand the effects of the technique's illumination on embryos. The primary cause for potential damage using FLIM illumination is the generation of ROS due to the photochemical absorption of light, hence we investigated whether FLIM produced elevated ROS levels.

Study design, size, duration: We conducted a prospective observational study. Mouse embryos were illuminated using carrying degrees of photo dosages (intended clinical dose and varying excessive dosages) and were compared to control groups that received no illumination. We tested four illumination conditions with a total of 155 illuminated embryos and 122 non-illuminated control embryos. Embryo ROS levels were then measured, and metabolic measurements using FLIM were also taken to determine whether illumination had affected metabolic state.

Participants/materials, setting, methods: We used an on-stage incubation system to culture embryos from the 2-cell stage until blastoscyt. During this period, we took metabolic measurements of the embryos at regular intervals. To vary photodosage, we performed this experiment with varying intervals of illumination, from 2 hours to 24 hours. Control embryos were cultured in the same chambers but were not illuminated. After FLIM illuminations, we used an ROS reporter dye (HC-DCFDA) to measure intracellular ROS levels.

Main results and the role of chance: ROS levels were quantified by taking a simple measure of HC-DCFDA intensity, using custom units. According this measure, none of the illumination conditions resulted in significant differences

compared to non-illuminated control groups of embryos (p values < 0.05). The following dosages produced these mean values (± SD). For 44 metabolic measurements: 6.65 ± 1.81 (n = 39) for control and 6.59 ± 1.83 (n = 37) for experimental group; 24 measurements: 5.69 ± 1.22 (n = 32) for control and 5.58 ± 0.7(n = 36) for the experimental; 3 measurements: 4.42 ± 1.07 (n = 33) for control and 4.18 ± 0.80 (n = 33) for experimental group; 1 measurement: 4.42 ± 0.71 (n = 33) for control and 4.18 ± 0.80 (n = 33) for experimental group. We validated our assay by comparing to the positive control of adding H_2O_2 to embryos, which produced a mean value of 11.76 ± 1.97.

Additionally, we performed several experiments in which we took a single metabolic measurement of illuminated and non-illuminated groups. Interestingly, we found our method performed with superior sensitivity, as there were significant, yet transient, shifts for the metabolic parameters for excessive dosages between the illuminated and the control group. These effects where reversed after 24 hours.

Limitations, reasons for caution: Although we did not observe significant increases in ROS levels, our data showed large variations in ROS measurements. We concluded that this popular assay has limited sensitivity to subtle ROS differences. Also, safety data must be obtained using human embryos to further validate this technique for clinical application.

Wider implications of the findings: These data complement previous safety studies showing that FLIM illumination affects neither blastocyst development nor live birth rates in mouse. Together, these results support the safety of using metabolic imaging as a potential embryo selection tool. Future experiments on human embryo samples are planned in the clinic.

Trial registration number: Not aplicable.

P-194 Reproductive outcomes in patients with severe oligospermia undergoing intracytoplasmic sperm injection using testicular versus ejaculated sperms

S. Hebisha[1], H. Saleh[2], B. Aboelazm[1], M. Sakr[3], N. Abdellatif[4], S. Zakaria[5]

[1]*Faculty of Medicine-Alexandria University, OBGYN, Alexandria, Egypt*
[2]*Faculty of medicine-Alexandria Uinversity, obgyn, Alexandria, Egypt*
[3]*Faculty of Medicine-Alexandria University, urosurgery, Alexandria, Egypt*
[4]*Medical Research Institute- Alexandria University, pathology, Alexandria, Egypt*
[5]*Pharos University, science, Alexandria, Egypt*

Study question: To compare intracytoplasmic sperm injection (ICSI) outcome in patients with severe oligospermia using testicular versus ejaculated sperms.

Summary answer: In patients with severe oligospermia,TESE should be considered as it offers higher pregnancy rates.

What is known already: In infertile men with severe oligospermia (sperm concentration <5 million/mL) undergoing ICSI the choice between using repeatedly ejaculated sperm or recommending use of testicular sperm remains controversial.

Testicular sperm have shown lower levels of DNA damage compared with ejaculated spermatozoa from the same individuals, however testicular sperm exhibit higher rates of chromosomal abnormalities.

Study design, size, duration: Retrospective cohort study.

Patients with severe oligospermia who underwent ICSI cycles with either testicular or ejaculated sperm between January 2014 and December 2016 were included in this study.

205 couples met the study criteria after exclusion of cycles with mixed sperm sources.

Participants/materials, setting, methods: Patients were divided into 2 groups (Group A) included 104 patients in which ejaculated sperms were obtained while (Group B) included 101 patients where fresh testicular sperms were extracted (TESE).

The medical records of the included couples were reviewed and tabulated regarding demographic data, hormonal profiles and different semen parameters.

After micro injection; fertilization rate, cleavage rates, embryo quality, implantation and pregnancy rates were evaluated and compared in both groups.

Main results and the role of chance: There was no significant difference in the fertilization rate between the two subgroups (group A 67.93%, group B 68.01%, p = 0.960), however the cleavage rate of day 2 embryos was significantly higher when testicular sperm cells were used (47.37% vs 42.77%, p = 0.024*).

Implantation rate was slightly lower in group A compared to group B but without statistical significance (25.23% and 29.77% respectively, p = 0.292).

There were no statistically significant differences between both subgroups regarding number and quality of day 3 and day 5 embryos.

Pregnancy rate was significantly higher in group B where testicular sperm cells were used (54.45% vs 40.38, p = 0.044*).

Limitations, reasons for caution: Prospective randomized studies involving larger number of cases are needed to establish whether TESE should be performed as a routine step in infertile males with severe oligospermia or should it be limited to cases with previous ICSI failure.

TESE remains a surgical intervention with possible associated risk.

Wider implications of the findings: Sperm source can lead to better ICSI outcome in this certain group of patients; such finding may extend to include infertile males with abnormal DNA fragmentation testing.

Trial registration number: The study was revised and approved by the official ethical committee of Faculty of Medicine, Alexandria University, Egypt.

P-195 Sequential low oxygen culture improves blastocyst rate and morphokinetics in a randomised controlled study on mouse embryo assays (MEA)

T.N.Q. Nguyen[1], B. Greene[2], I. Bardua[3], C. Wrenzycki[4], U. Wagner[3], M. Kalffsuske[3], V. Ziller[3]

[1]*Universitätsklinikum Gießen und Marburg GmbH, Klinik für Frauenheilkunde und Geburtshilfe, Marburg, Germany*
[2]*Philipps University Marburg, Institut of medical biometry and epidemiology, Marburg, Germany*
[3]*University hospital Giessen and Marburg, Department of gyn. endocrinology and reproductive medicine, Marburg, Germany*
[4]*Jutus-Liebig-University Giessen, Clinic for obstetrics- gynecology and andrology of large and small animals, Giessen, Germany*

Study question: Does the sequential low oxygen concentration have better results in embryo development and morphokinetics than the commonly used cell culture condition on mouse model?

Summary answer: Sequential low oxygen concentration significantly improves blastocyst rate and morphokinetics compared to constant low and high oxygen tension on mouse model.

What is known already: Mammalian fertilization and early embryonic development occur in oviduct and uterus. In both organs, oxygen tension rises from day 1 to 3 between the eight-cell-morula stage and blastocyst formation, and then drops when the blastocysts are fully developed and implantation begins. Therefore, this study used time-lapse technique as a tool to investigate the effects of this sequential low oxygen concentration (7% from day 1 to day 2, 2% from day 3 to day 5) in mouse embryo development and morphokinetic analysis of cell division compared to low (5%) and high (20%) oxygen tension, giving insight into potential improvement in ART.

Study design, size, duration: To determine the best oxygen concentrations which have the most beneficial results in ART, we designed a randomized study employing mouse embryos. 314 zygotes were arranged randomly into three parallel groups consisted of high atmospheric oxygen concentration (20%) (n = 93), low oxygen (5%) (n = 129), and mixed (7% from day 1 to 2 and 2% from day 3 to 5) (n = 92). Blastocyst rate and morphokinetic analysis of cell division were recorded using a Primovision-System.

Participants/materials, setting, methods: Hybrid Bl6/CBAca MEA was used to identify morphokinetic cleavage parameters derived from time-lapse imaging. Female mice were sacrificed and zygotes were isolated 20-hours post-insemination. They were cultured in Primovision micro-well culture dishes using GTL Medium (Vitrolife) and observed in the Primovision system that integrates a digital inverted microscope into a standard high volume Memmert IVF incubator. Pictures of embryos were taken at 10 minute intervals for 5 days. Statistical analyses were performed using R program.

Main results and the role of chance: Blastocyst rate at 120 hours in mixed group (91,3%) was significantly increased compared to high (76,34%) and low group (74,42%), p = 0.009 and 0.001, respectively. Moreover, cell division of mixed group was significant faster in almost every cleavage stages comparing to the other groups, including p = 0.014 at 2 pronuclei stage (2PN) (mixed vs high), p = 0.002 at 2-cells stage (2 C) (mixed vs low), p = 0.005 at 5-cell stage (5 C) (mixed vs high), p = 0.009 at 8-cell stage (8 C) (mixed vs high), p = 0.031 and p = 0.034 at morula stage (mixed vs low, and mixed vs high, respectively), p = 0.001 at early blastocyst formation (mixed vs high), p = 0.005 at hatching stage (mixed vs low). Notably, the interim events was also significantly different between the groups, such as p = 0.022 (mixed vs low) and p = 0.002 (mixed vs high) from 3 C to 4 C, p = 0.001 (mixed vs low) and p < 0.001 (mixed vs high) from 3 C to 5 C, p = 0.032 (mixed vs low) and p < 0.001 (mixed vs high) from 4 C to 5 C, and p < 0.001 (mixed vs high) from 2 C to 5 C.

Limitations, reasons for caution: This in-vitro study used surrogate parameters as morphokinetics and blastocyst rates. No data on pregnancy or birth rates can be provided as blastocysts were not transferred due to German law restrictions. The results may differ on embryo development in different laboratory settings such as types of incubator and laboratory procedures.

Wider implications of the findings: If further research shows improved ART outcome in sequential low oxygen culturing, this should enter clinical ART management.

Trial registration number: N/A.

P-196 Female age affects DNA repair gene expression in mouse GV oocytes from stimulated and unstimulated cycles and in MII oocytes matured in-vivo and in-vitro

A. Ravichandran[1], F. Horta[1], S. Catt[1], B. Vollenhoven[1,2], P. Temple-Smith[1]

[1]Monash University, Obstetrics and Gynaecology, Melbourne, Australia
[2]Monash IVF, Reproductive Medicine, Melbourne, Australia

Study question: Does female age affect DNA repair gene expression in GV oocytes from stimulated and unstimulated mice and MII oocytes matured in-vivo and in-vitro?

Summary answer: Age has a major impact on DNA repair genes during the GV-MII transition in stimulated and unstimulated cycles.

What is known already: Gene expression patterns in germinal vesicles (GV) and metaphase II (MII) oocytes change with age. Oocyte maturation involves extensive degradation of maternal transcripts suggesting that GVs would have a larger number of mRNA transcripts than MII oocytes. Nevertheless, GVs from aged females show a decrease in numbers of transcripts compared to young GVs, and likewise in old MII oocytes compared to young MII oocytes. DNA repair gene expression patterns may give clearer links to repair competency during early embryo development. Understanding molecular signatures that predict genetically stable oocytes with higher developmental competency may result in better prognosis for reproductive treatments.

Study design, size, duration: GVs were collected from 4 stimulated and 4 unstimulated young (5-8 weeks) and old (42-45 weeks) mice respectively. From the stimulated cycles 20 GVs (stim-GVs) and 20 MIIs (*in vivo*-MII) were collected for each age groups. For unstimulated cycles 20 GVs (unstim-GVs) were used for analysis and a further cohort were matured in order to collect 20 MIIs for analysis (IVM-MIIs). Expression profiles were determined in all 4 groups per female age.

Participants/materials, setting, methods: C57BL6 female mice were used. Unstimulated GVs were *in vitro* matured in culture for 18hrs, and resulting MIIs collected. Oocytes for each treatment were pooled (n = 5), snap frozen and stored at -80C for later cDNA synthesis. cDNA synthesis was performed using the Single Cell-to-Ct Kit (Ambion, Life technologies) and cDNA samples were tested for DNA repair gene expression of 90 DNA repair genes using the Fluidigm Biomark HD system GE 96×96 Standard v2 Biomark Protocol.

Main results and the role of chance: Comparing MII oocytes to GV oocytes in both age groups, significant differences in gene expression were observed between *in vivo*-MII and IVM-MII oocytes (95% Confidence Interval, 95%-IC). The number of significantly down-regulated genes in IVM-MIIs from younger females, were greater than *in vivo*-MII (Young IVM-MII: 38 genes; Young in vivo-MII: 25 genes, 95%-IC). In aged oocytes, the expression pattern was reversed, with more DNA repair genes significantly up-regulated in IVM-MII and *in vivo*-MII oocytes than GVs (Old IVM-MII: 22 genes; Old *in vivo*-MII: 12 genes, 95%-IC). Also, in older females more DNA repair genes were down-regulated in IVM-MII oocytes than in *in-vivo*-MIIs (Old IVM-MII: 13 genes; Old *in-vivo*-MII: 4 genes, 95%-IC), suggesting that IVM has a different effect on MII repair genes than in vivo maturation in stimulated oocytes, with potential repercussions on oocyte quality. The key DNA damage response gene, H2AFX, was always down-regulated in MII oocytes compared to GV oocytes irrespective of maturation type (95%-IC). Confidence intervals were used to establish differential expression in DeltaDeltaCt analysis while Mann-Whitney was used to test relative expression of DeltaCt analysis.

Limitations, reasons for caution: The two age groups in this study were selected to represent women at either end of their reproductive lives, but clinical studies are required to confirm this effect in women. However, challenges in obtaining either unstimulated and/or stimulated MII oocytes for research may limit studies to human GVs.

Wider implications of the findings: Our results show DNA repair gene expression in oocytes is affected in older females, suggesting that this may also be linked with decreased DNA repair capacity in both GV and MII oocytes. These findings will direct future research to develop novel methods to assess the effects of aging on fertility.

Trial registration number: N/A.

P-197 Embryos derived from late maturing oocytes show no increased risk of chromosomal aneuploidy as assessed by Next Generation Sequencing (NGS) and can achieve clinical pregnancies

M. Cooney, J. Mullen

Monash IVF, Embryology, Clayton, Australia

Study question: Are oocytes that are immature at cumulus removal but mature by the time of insemination capable of normal fertilization and development into chromosomally euploid embryos?

Summary answer: Late maturing oocytes, inseminated by intraplasmic sperm injection (ICSI), if fertilized, can form chromosomally euploid embryos and are capable of establishing clinical pregnancies.

What is known already: Approximately 20% of retrieved oocytes from controlled ovarian stimulation cycles are found to be immature as either metaphase I (MI) or germinal vesicle (GV) stage at the time of cumulus cell removal. Debate exists as to whether these immature oocytes should be utilised if, after further evaluation, they are observed to extrude a polar body during the period of in vitro culture prior to insemination. The chromosomal constitution and developmental competence of these in vitro matured oocytes has not been adequately explored, with conflicting views on the rates of multinucleation and aneuploidy in the resulting embryos.

Study design, size, duration: A retrospective study was undertaken for 1902 autologous ICSI cycles performed between January-August 2017. Fresh or frozen spermatozoa were used for ICSI insemination.

Participants/materials, setting, methods: Autologous ICSI cycles that had one or more MI oocyte at the time of cumulus cell removal (38 hours post trigger) were included in the study. Embryos were cultured in Vitrolife sequential media and COOK mini-incubators. After laser ablation of the zona on day 3, 5-10 trophectoderm cells were biopsied on day 5 or 6 and embryos immediately vitrified. Genetically euploid embryos were warmed and transferred individually. PGS cycles were performed only at patient request.

Main results and the role of chance: In total 21,138 oocytes were collected from 1902 ICSI cycles. Of these, 75.2% were mature (metaphase II, MII) at the time of cumulus removal and 14.4% were MI. Of the MI oocytes, 42.6% progressed to mature to MII 4-6 hours after oocyte collection and were inseminated via ICSI. Overall, the fertilisation rate after ICSI of the late maturing oocytes was lower than those that were MII at the time of initial cumulus cells removal (41.9% v 64.8%, p<0.05). In total 80 transfers were performed (34 at day 3, 46 at day 5/6) with 51 fresh and 28 frozen embryos resulting in 18 ongoing pregnancies with to date, 2 live births.

A sub-group of embryos resulting from late maturing oocytes were analysed by NGS to assess their chromosomal composition. Thirty one

blastocysts were biopsied and vitrified. Seventeen of the thirty-one embryos (54.8%) were found to be euploid and deemed suitable for embryo transfer in future frozen embryo transfer cycles. To date, six singleton embryo transfers have occurred resulting in four ongoing pregnancies (4/6, 66.7%) in patients aged 44, 43, 39 and 34. These results refute previous reports that suggest late maturing oocytes are more likely to produce embryos with chromosomal aneuploidies.

Limitations, reasons for caution: This study looks at patients of all ages and aetiology. Genetic testing was limited to patients who had selected to undergo a PGS cycle.

Wider implications of the findings: The maturation status of oocytes at the time of cumulus removal does not indicate an increased risk of chromosomal aneuploidy in the resulting embryos. Late maturing oocytes should be utilised for patients undergoing ICSI as they can result in genetically tested euploid embryos and clinical pregnancies.

Trial registration number: Not applicable.

P-198 Optimal timing of trophectoderm biopsy for preimplantation genetic screening (PGS)

E.A. Park[1], R. Kim[2], B.Y. Kim[1], J.Y. Lee[1], S.Y. Moon[1], K.H. Choi[1], H.H. Kang[1], J.I. Baek[1], H.J. Jeong[1], J.J. Ko[3], J.H. Lee[1,3], Y.S. Kim[2], M.K. Koong[2], I.S. Kang[2], T.K. Yoon[2]

[1]CHA Fertility Center Seoul Station, Research, Seoul, Korea- South
[2]CHA Fertility Center Seoul Station-CHA University, Department of Obstetrics and Gynecology, Seoul, Korea- South
[3]CHA University, Department of Biomedical Science- College of Life Science, Pocheon, Korea- South

Study question: Is the timing of trophectoderm biopsy associated with successful pregnancy after the embryo transfer of blastocyst subjected to preimplantation genetic screening (PGS)?

Summary answer: Trophectoderm biopsy(PGS) before or after the cryopreservation may be the optimal strategy for the better clinical outcomes compared to the fresh trophectoderm biopsy without cryopreservation.

What is known already: Embryo biopsy and fresh embryo transfer are traditionally performed in the PGS cycle. However, before embryo transfer, the time allowed for genetic analysis of the specimens is restricted, particularly after blastocyst biopsy. Cryopreservation of blastocysts after biopsy instead of fresh transfer permits more sufficient time for performance of molecular diagnosis. The effect of cryopreservation and thawing/warming procedures on clinical outcomes in PGS cycle has not been effectively studied.

Study design, size, duration: This retrospective study included women that underwent IVF with PGS from January 2016 to December 2017. 1469 blastocyst from 306cycles were subjected to trophectoderm biopsy for performing array comparative genomic hybridization (CGH) test. Embryos were cultured to expanded blastocyst stage and underwent trophectoderm biopsy on day 5 to day 6 of embryo development.Cycles with complete PGS diagnosis were 306, 161 of which had embryo transfer. The performance of different groups of PGS patients was evaluated.

Participants/materials, setting, methods: The groups were divided into three; first group (n = 46 transfer/168 cases) contained fresh blastocysts that biopsied for PGS without cryopreservation followed by embryo transfer. In the second group (n = 34 transfer/56 cases), the cryopreserved blastocysts were warmed and biopsied prior to ET. The last group (n = 81 transfer/82 cases), the blastocysts were initially biopsied then proceeded with vitrification and warming before the embryo transfer.

Main results and the role of chance: The total pregnancy rate of fresh blastocyst biopsied group was 47.8% (22/46), the cryopreserved-warmed-biopsied blastocyst group showed 70.6% (24/34) and finally biopsied and cryopreserved-warmed group showed 55.6% (45/81), respectively. First group is significant higher pregnancy rate than second group.(p = 0.043). Also, The second(cryopreserved-warmed –biopsied) group showed slightly higher numerical pregnancy rate than third (biopsied and cryopreserved-warmed) group.

Limitations, reasons for caution: This is a retrospective study and had some limited case numbers for analysis.

Wider implications of the findings: Using currently available data, when faced with the option of fresh embryos, before or after trophectoderm biopsy for PGS, our result supported performing the biopsy before or after embryo cryopreservation and thawing.

Trial registration number: not applicable.

P-199 Synchrony or morphology: embryo-endometrial synchrony is more important than embryo morphology as a predictor of in vitro fertilization outcomes

I. Park[1], H. Sun[1], J. Kim[1], K. Lee[2], C. Sim[2], Y. Jeung[2], H. Chi[2], S. Kim[2], J. Park[2], S. Kwak[2], C. Yoo[2]

[1]Liora fertility center, Busan, Korea- South
[2]Mamapapa & baby Hospital, obstetrics and gynecology, Ulsan, Korea- South

Study question: Which one is better as a predictor of in vitro fertilization (IVF) outcomes, synchrony or morphology?

Summary answer: Embryo-endometrial synchronization, represented by proper embryo developmental speed, could be a better predictor of IVF success than good morphology.

What is known already: Embryo morphology including blastomere symmetry and fragmentation is well-known and most commonly used as a predictor of IVF outcomes. Therefore, transferred embryos are usually selected by morphological assessment. Embryo-endometrial synchronization which is represented by developmental speed coincident with embryo stage is also an important predictor of IVF outcomes.

Study design, size, duration: This was retrospective study with fresh embryo transfer on day 3 between January 2015 and December 2016. This study included 428 women who had two transferred embryos of same blastomere number.

Participants/materials, setting, methods: Women transferred two slowly developing day 3 embryos with good morphology embryo were divided into 2 groups by blastomere number.

S1 – two 4 cell embryos with good morphology.
S2 – two 6 cell embryos with good morphology.

Women transferred two properly developed 8 cell day 3 embryos were divided into 3 groups by grade.

G1 – two grade 1 8cell embryos.
G2 – two grade 2 8cell embryos.
G3 – two grade 3 8cell embryos.

Main results and the role of chance: In each group, age and AMH level reflected no differences. Pregnancy rate (PR) of S1 [7.4%(2/27)] was significantly lower than PR of G1[69.3%(138/199), P<0.01] and G2[54.0%(81/150), P<0.01]. It was also significantly lower that of G3[35.7%(10/28), P = 0.02]. PR of S2 [37.5%(9/24)] was significantly lower than PR of G1[69.3%(138/199), P<0.01]. However, it did not show significant difference as compared with that of G2[54.0%(81/150), P = 0.198] or G3[35.7%(10/28), P = 0.876].

Limitations, reasons for caution: This is a retrospective study. The sample size of each group shows difference among groups.

Wider implications of the findings: Implantation potential of slowly developing embryos with good morphology is lower than properly developed low grade embryos. It is probably that slowly developing embryos do not synchronize endometrial implantation window. Therefore, properly developed low grade embryos rather than slowly developing good morphology embryos should be selected for fresh embryo transfer.

Trial registration number: None.

P-200 Testicular sperm of severe oligo-cryptozoospermia patient may expect to improve clinical outcomes compared with ejaculated sperm

K.Y. Kang[1], B.Y. Kim[1], J.W. Park[1], E.B. Joe[1], K.H. Choi[1], H.H. Kang[1], E.A. Park[1], J.H. Lee[1,2], J.J. Ko[2], Y.J. Hur[3], D.K. Kim[4], Y.S. Kim[3], M.K. Koong[3], I.S. Kang[3], T.K. Yoon[3]

[1]CHA Fertility Center Seoul Station, Fertility laboratory, Seoul, Korea- South

[2]CHA University, Department of Biomedical Science- College of Life Science, Pocheon, Korea- South
[3]CHA Fertility Center Seoul Station- CHA University, Department of Obstetrics and Gynecology, Seoul, Korea- South
[4]CHA Fertility Center Seoul Station- CHA University, Department of Urology, Seoul, Korea- South

Study question: The purpose was to compare clinical outcomes of in vitro fertilization-intracytoplasmic injection (IVF-ICSI) between sperm retrieved from severe male factor (oligozoospermia, cryptozoospermia, TESE -sperm) patients.

Summary answer: In case of severe male factors, patients with cryptozoospermia showed low fertilization and significantly low clinical pregnancy rates compare to patients with oligozoospermia and TESE-sperm.

What is known already: Sperm from severe male factor contains more DNA damage than sperm from fertile patients as this is due to Reactive Oxygen Species. Several studies reported that sperm are susceptible to damage during passage through the male reproductive tract. When increased DNA damaged sperm is used for assisted reproduction, this sperm may be able to fertilize an oocyte, however, this may result in poor embryo development, implantation and pregnancy rates. The sperm quality may be related to unexplained recurrent pregnancy loss. Some reports states that patients using testicular sperm showed higher implantation and pregnancy rates than patients with severe oligoasthenoteratozoospermia syndrome.

Study design, size, duration: From January 2016 to December 2017, our IVF center performed 9707 IVF-ICSI cycles. Among them, only 299 cycles with severe male factor were analyzed in this retrospective study. The clinical outcomes including fertilization and pregnancy rate were compared and the age of couple was also evaluated in severe male factor groups. Statistical analysis was performed using ANOVA and chi-squared tests.

Participants/materials, setting, methods: Oligozoospermia was defined as spermatozoa under 15×10^6/cc; and cryptozoospermia was defined as spermatozoa observed only in the pellet with sperm concentration under 10^4 after centrifugation (WHO 2010). However, in this study, we considered oligozoospermia as over 0.1×10^6/cc to under 15×10^6/cc. TESE sperm was considered as sperm retrieved from azoospermia patients. In the study, the IVF-ICSI cycles were divided into three groups. Group 1: Oligozoospermia, Group 2: Cryptozoospermia, Group 3: TESE sperm.

Main results and the role of chance: This study showed a significant low fertilization rate in patients with cryptozoospermia (Group 2) compare to other groups (Group 1: 81.67%(820/1004), Group 2: 74.45%(303/407), Group 3: 79.02%(1134/1435); $p = 0.009$). Furthermore, pregnancy rate was also significantly low in cryptozoospermia patients (Group 1: 40.19% (43/107), Group 2: 17.78%(8/45), Group 3: 46.27%(62/134); $p = 0.003$) than others. However, there was no significant difference in fertilization rate and pregnancy rate between Group 1 and Group 3. In addition, there was no significant difference in both the wife's age (Group 1: 36.14 ± 4.09 ($n = 107$), Group 2: 35.04 ± 4.08($n = 45$), Group 3: 35.37 ± 4.35($n = 134$); $p>0.05$), and the husband's age (Group 1: 38.25 ± 5.10($n = 107$), Group 2: 37.60 ± 5.73($n = 45$), Group 3: 37.54 ± 5.66($n = 134$); $p>0.05$) in all three groups.

Limitations, reasons for caution: This is a retrospective study and a limited number of severe male factor in IVF-ICSI cycles were used for analysis.

Wider implications of the findings: The findings of this study indicate that cryptozoospermia patients, using several cryo-sperms with repetitive IVF-ICSI cycle failure and pregnancy failure may need to consider an alternative strategy of using TESE sperm for improved clinical outcomes.

Trial registration number: Not applicable.

P-201 The influence of blastocyst formation time on the pregnancy outcomes of vitrified-warmed blastocyst transfer according to the number of embryo transferred

S.H. Shin, J.H. Cha, J.W. Lee, Y.J. Kim, S.K. Lee, H.J. Cha, J.H. Kim, D.H. Kim, E.H. Kang, J.H. Ahn, H.Y. Kim, K.A. Pak, J.S. Yoon, S.Y. Park

Agaon Fertility Clinic, IVF center, Seoul, Korea- South

Study question: Does the blastocyst formation time before vitrification affect the pregnancy outcomes in single or double vitrified-warmed blastocyst transfer (SET or DET)?

Summary answer: Day 5-DET resulted in similar the pregnancy outcomes compared to day 6-DET while day 5-SET yielded significantly higher the pregnancy outcomes compared to day 6-SET.

What is known already: Zygotes can reach the blastocyst on day 5 or day 6 after insemination. Many studies on fresh IVF cycles have reported higher the pregnancy outcomes with the transfer of day 5 blastocyst compared with day 6. However, it is still unclear whether the blastocyst formation time in vitrified-warmed blastocyst transfer with studies yielding conflicting results affects the pregnancy outcomes.

Study design, size, duration: A retrospective cohort study of 405 SET or DET cycles was performed from January 2013 to September 2017. The cycles with frozen sperm, surgical retrieved sperm, genetic diagnosis, oocyte donation, poor responder, and advanced maternal age (≥38 years) were excluded. We compared the rates of good-quality embryos, clinical pregnancy, ongoing pregnancy, and implantation between day 5 and day 6 vitrified-warmed blastocyst transfer according to the number of embryo transferred.

Participants/materials, setting, methods: The cycles were divided into 4 groups based on the blastocyst formation time and the number of embryo transferred (SET: day 5, n = 107 vs. day 6, n = 104 and DET: day 5, n = 128 vs. day 6, n = 66). The classification of warmed blastocysts quality was evaluated refer to the criteria for classification by Gardner and Schoolcraft.

Main results and the role of chance: Characteristics of the cycles had no statistically significant difference in the female age, male age, infertility diagnosis, number of embryo thawed, survival rate, good quality (≥BB) embryos rate, with the exception of male factor infertility, which was significantly more common in the DET (14.1% vs. 25.8%, p = 0.045). Rates of clinical pregnancy, ongoing pregnancy, and implantation in day 5-SET was higher than those of day 6-SET (Table 1). However, the pregnancy outcomes were not significantly different between day 5-DET and day 6-DET.

Table 1 Comparison of the pregnancy outcomes between day 5 and day 6 vitrified-warmed blastocyst transfer according to the number of embryo transferred.

	Day 5-SET	Day 6-SET	P-value	Day 5-DET	Day 6-DET	P-value
Cycles (n)	107	104		128	66	
Clinical pregnancy rate (%)	43.0	20.2	0.000	50.8	43.9	0.366
Ongoing pregnancy rate (%)	36.4	17.3	0.002	45.3	37.9	0.321
Implantation rate (%)	43.9	22.1	0.001	35.2	29.5	0.266

Limitations, reasons for caution: This is a retrospective study. The number of day 6-DET group was smaller than day 5-DET group. Prospective, further studies are needed in order to support our results.

Wider implications of the findings: The blastocyst formation time could be an independent predictor of the pregnancy outcomes. Although the transfer of blastocyst derived from day 6 remains a viable treatment option, giving precedence to blastocyst derived from day 5 could allow opportunity to successful pregnancy outcomes in SET.

Trial registration number: Not applicable.

P-202 Morphokinetic differences of human embryo development according to the type of morphological defects of sperm

M. Ryu, S. Jeong, S. Bark, J. Kim, M. Kim, M. Chung

Seoul Rachel Fertility Center, Fertility Center, Seoul, Korea- South

Study question: Does type of morphological defects of sperm and fertilization method have an impact on morphokinetics of embryo development?

Summary answer: Morphokinetics of embryo development showed various difference according to the type of morphological defects of sperm and fertilization method, such as IVF and ICSI.

What is known already: Sperm morphology is the important parameter for evaluation in predicting male fertility potential. Time-lapse monitoring system offers evaluation criteria of embryo development that can chance to select embryos with higher implantation. In recent years, many studies have been reported that sperm affected in embryo development. But, not well known about the relation between morphokinetics of embryo development and type of morphological defects of sperm according to fertilization method.

Study design, size, duration: We performed a retrospective cohort study on patients undergoing IVF and ICSI cycle from October 2013 to May 2017. A total of 422 zygotes obtained from 60 patients. Exclusion criteria; A women who was over 40 years old or an anti-Mullerian hormone (AMH) less than 1.0 ng/㎖. Sperm parameters were evaluated according to 2010 WHO criteria. Correlation between type of morphological defects of sperm and morphokinetics of embryo development were analyzed.

Participants/materials, setting, methods: Patients were divided into three categories; normozoospermatozoa (≥15 million/㎖, motility ≥40% and normal morphology ≥4%) (Group1), teratozoospermatozoa (normal morphology <4%) with head defects (Group 2), and teratozoospermatozoa with head and tail defects (Group 3). Zygotes were cultured with the time-lapse monitoring system (Primo vision). Morphokinetics were evaluated as below; time of cell division (tS-t8) and interval of cell cycle (tS-tSC, cc1: tSC-t2, cc2; t2-t3, cc3; t3-t5, t2-t5 and s2; t4-t3).

Main results and the role of chance: Time points and durations of cell cycle in the ICSI embryos were similar in Group1 (n = 76) and Group2 (n = 73) except the times of syngamy to first division (tS-tSC) (2.1 ± 0.6, 2.0 ± 0.4, p = 0.0476) and Group1 and Group3 (n = 55) except synchrony in division from 3 to 4 cells (s2) (2.0 ± 3.1, 4.3 ± 5.3, p = 0.0143). There were no significant differences between Group2 and Group3. In IVF embryos, there were significant differences between Group 1 (n = 119) and Group 2 (n = 62) embryos; tS (27.7 ± 3.6, 30.1 ± 4.9, p = 0.0002), tSC (29.5 ± 3.7, 32.2 ± 5.4, p = 0.0001), t4 (41.4 ± 5.0, 43.6 ± 6.2, p = 0.0230) and t8 (57.1 ± 6.8, 61.1 ± 8.9, p = 0.0099). Significant differences were shown between Group 1 and Group 3 (n = 32) embryos; t8 (57.1 ± 6.8, 62.6 ± 9.9, p = 0.0012) and cc3 (11.9 ± 4.1, 14.1 ± 3.3, p = 0.0093). Also, there were significant differences between Group 2 and Group 3 embryos; tS (30.1 ± 4.9, 27.6 ± 3.7, p = 0.0135), tSC (32.3 ± 5.4, 29.5 ± 3.7, p = 0.0122) and t2 (31.6 ± 3.5, 29.9 ± 3.8, p = 0.0466).

Limitations, reasons for caution: This study was conducted with using cleavage stage embryos. Because the remaining embryos after transfer were cultured to blastocyst stage, we excluded it from this study. Based on the this study, more data will be collected in future prospective studies.

Wider implications of the findings: We found that type of morphological defects of sperm affected embryo development in IVF than ICSI. This is probably due to the high probability that ICSI will select the normal sperm. Our results suggest that morphological defects is may be an important factor to consider in the morphokinetics of embryo.

Trial registration number: None.

P-203 Effects of tocotrienol-rich fraction supplementation on the expression of DNA damage response genes in ovary and oocytes quality in mice exposed to corticosterone-induced oxidative damage

A.S. Nuraliza[1], W.A.R. Zaid[2], A. Norrabiatul Adawiyah[2], A. Nasibah[1], M. Mudiana[3]

[1]Faculty of Medicine- UiTM- Sg Buloh Campus, Physiology, Sg Buloh, Malaysia

[2]Faculty of Medicine- UiTM- Sg Buloh Campus, Institute of Medical Molecular Biotechnology, Sg Buloh, Malaysia

[3]Faculty of Medicine- UiTM- Sg Buloh Campus, Biochemistry & Molecular Medicine, Sg Buloh, Malaysia

Study question: Does tocotrienol-rich fraction (TRF) supplementation activate the DNA damage response genes in ovary and improves the quality of oocytes in mice exposed to exogenous corticosterone that induced oxidative damage.

Summary answer: Expression of CHEK1 gene that detects DNA damage in ovary is low and oocytes quality improves following TRF supplementation in mice exposed to exogenous corticosterone.

What is known already: Chronic exposure to exogenous corticosterone (CORT) induced-oxidative DNA damage in cells. Female reproductive system is susceptible to the detrimental effects of oxidative DNA damage leading to a decline in biological function of ovaries, deteriorate oocytes quality and eventually contributes to infertility. Tocotrienol-rich fraction (TRF), an antioxidant plays a protective role in oxidative stress-induced damage thus prevent infertility in female. The proposed mechanism of action TRF in protecting female reproductive system from various oxidative damage is by lowering plasma levels of malondialdehyde (an oxidative stress biomarker), reducing DNA damage in embryos and upregulating the expression of anti-aging gene in mouse ovary.

Study design, size, duration: Thirty-two (six-week-old) female mice (Mus musculus) were equally divided into four groups. Group 1: vehicle control was given via intraperitoneal (i.p) injection, Group 2: CORT (10 mg/kg body weight (BW) was administered intraperitoneally, Group 3: vehicle controls were given via i.p injection and oral gavage while Group 4 were administered with CORT (10 mg/kg BW, i.p injection) and concurrently supplemented with TRF (oral gavage) at the dose of 150 mg/kg BW for two weeks.

Participants/materials, setting, methods: At the end of the supplementation period, mice were superovulated and euthanized. The ovaries were collected for total cellular RNA isolation and oocytes were collected for zona pellucida (ZP) thickness measurement to assess its quality. The gene expression analysis of ATM, MPG, CHEK 1, CHEK 2 and MLH3 genes was performed using QuantiGene Plex 2.0 Assay kit.

Main results and the role of chance: Expression of CHEK1, the gene responsible for the detection of DNA damage was significantly higher in the ovary of mice exposed to exogenous CORT as compared to the control group. The expression level of CHEK1 gene in CORT group supplemented with TRF on the other hand was found to be normalized towards control value. However, expression of other DNA damage response genes was not significantly different in all groups as compared to its respective control. The ZP thickness of oocytes in mice exposed to exogenous CORT increased significantly as compared to its control. Conversely, TRF supplementation reduced ZP thickness of oocytes in mice exposed to exogenous CORT towards control. Upregulation of DNA damage response genes play a significant role in the maintenance of cell by activating various signalling network that detect and repair the oxidative stress induced-DNA damage in mice ovary exposed to exogenous CORT thus protect the ovary and maintain the production of good quality oocytes.

Limitations, reasons for caution: Gene expression analysis can only be done using ovarian tissue and not using oocytes as large quantity of oocytes is required for gene expression analysis.

Wider implications of the findings: Tocotrienol-rich fraction supplementation blocks the adverse effect of exogenous CORT in inducing oxidative DNA damage, as indicated by the low expression of CHEK1 gene that detects DNA damage in mice ovary. Consequently, by protecting ovary from oxidative damage, TRF maintain the quality of oocytes and hopefully will potentially improve fertility.

Trial registration number: N/A.

P-204 Is vitrification-warming of embryos developed from vitrified oocytes (double vitrification) an effective procedure for heterologous IVF program with egg donation?

R. Picone, F. Bertocci, P. Evangelisti, R. Fucci, C. Giachini, E. Borrani, P. Falcone, L. Badolato, F. Rizzello, C. Cozzi, C. Romanelli, M.G. Servidio, L. Criscuoli, M.E. Coccia

Careggi University Hospital, assisted reproduction technology, Florence, Italy

Study question: To evaluate the efficacy of transfer of *vitrified-warmed (V-W) embryo* derived from V-W oocyte (double vitrification) in heterologous IVF programs with egg donation.

Summary answer: Transfer of V-W embryo derived from V-W oocyte allows to obtain results statistically comparable to those obtained with fresh embryo derived by V-W oocytes.

What is known already: Advances in reproductive techniques, i.e. the introduction of oocytes vitrification, have provided opportunity to conceive from oocytes banks. The vitrification of oocytes and embryos is the gold standard method used worldwide for cryopreservation in infertility management and fertility preservation. The IVF outcome, in terms of pregnancy and implantation rate, are comparable with those obtained with fresh oocytes/embryos.

Study design, size, duration: This is a prospective study aimed to evaluate the efficacy of double vitrification in heterologous IVF cycles with oocytes donation at the IVF clinic of Careggi University Hospital of Florence, from 2016 to 2017. We compared pregnancy and implantation rates of transfer of V-W embryos derived from V-W oocytes (double vitrification) with transfer of fresh embryos derived from V-W oocyte (single vitrification), that represent our control population.

Participants/materials, setting, methods: From January 2016 to December 2017 we performed 49 transfer of V-W embryos derived from V-W oocytes; as controls we included 329 transfer of fresh embryos obtained from V-W oocytes within our egg donation program. We used the Kitazato vitrification-warming protocol; embryo transfers were performed in day 3 or day 5.

Main results and the role of chance: The pregnancy rate per ET cycle was 40,0% in the double vitrification group and 37,0% in the control group ($p = 0,751$). The implantation rate was similar in the double vitrification group and in the control population (29,7% and 24,7% respectively; $p = 0,562$).

Limitations, reasons for caution: The age of recipients in our oocytes donation program is usually advanced (even if less than 50 years old), so this could influence uterine receptivity due to several age-related pathologies (such as fibroids, menopause, endometritis).

Wider implications of the findings: Our findings confirmed the efficacy of the double vitrification-warming procedure (at oocytes and embryos stage) that could be used for supernumerary embryos or to postpone embryo transfer when the endometrial pattern is suboptimal.

Trial registration number: Not Applicable.

P-205 Cell-lineage specific effects of granulocyte macrophage colony-stimulating factor (GM-CSF) in mouse blastocysts

T. Pock[1], K. Schulte[2], S. Schlatt[1], M. Boiani[3], V. Nordhoff[1]

[1]*Centre of Reproductive Medicine and Andrology, Experimental embryology, Münster, Germany*
[2]*Central Animal Facility of the Faculty of Medicine, Experimental embryology, Münster, Germany*
[3]*Max Planck Institute for Molecular Biomedicine, Mouse embryology, Münster, Germany*

Study question: Does GM-CSF induce cell lineage specific differences during pre-implantation development?

Summary answer: Embryos cultured in medium supplemented with GM-CSF show significantly increased numbers of cells in the pre-implantation state. The effect is strongest in the trophectoderm.

What is known already: GM-CSF is a cytokine influencing the maternal-fetal interface and supporting placental development in mouse and human. It is expressed in epithelial cells of the endometrium under regulation of estrogens. A large clinical trial showed that GM-CSF supplemented medium leads to an increased survival of transferred embryos up to week 12. Especially in women with previous miscarriages GM-CSF supplementation of culture medium may improve ongoing implantation rates. However, a research study in mice found that high concentrations of GM-CSF may have a negative impact on blastocyst development and total cell numbers of the preimplantation embryo.

Study design, size, duration: Thirty female mice (5-10 weeks pp) were stimulated for zygote isolation. After 4.5 days of culture in defined concentrations (1, 2 or 5 ng/ml) of GM-CSF a total of 277 embryos were collected and subjected to immunohistochemical staining. Markers against the three cell lines trophectoderm (CDX2), epiblast (NANOG) and primitive endoderm (SOX17) enabled selective counting of cell numbers. 244 embryos were eligible for further analysis.

Participants/materials, setting, methods: Female mice (B6C3F1) were superovulated by injection of 5 IU PMSG and 10 IU hCG and mated to males (C57BL/6J). Zygotes were isolated on day 0.5 post coitum, pooled and randomly distributed to KSOM(aa) without GM-CSF and medium supplemented with increasing concentrations of GM-CSF. Zygotes were cultivated until blastocyst stage with a medium refreshment step at day 2.5.

Main results and the role of chance: Total cell numbers of blastocysts showed significant differences between KSOM(aa) without GM-CSF and KSOM (aa) containing 2 or 5 ng/mL GM-CSF (mean: KSOM(aa): 81.7 cells; KSOM(aa) +1 ng/mL GM-CSF: 84.5 cells; KSOM(aa)+2 ng/mL GM-CSF: 90.9 cells; KSOM(aa)+5 ng/mL GM-CSF: 91.4 cells). These differences were mainly due to changes in trophectoderm cell numbers; we found significant differences in the number of CDX2 positive cells between embryos cultured without GM-CSF and the two groups containing 2 and 5 ng/mL GM-CSF (mean: KSOM(aa): 65.6 cells; KSOM(aa)+1 ng/mL GM-CSF: 69.5 cells; KSOM(aa)+2 ng/mL GM-SCF: 74.1 cells; KSOM(aa)+5 ng/mL GM-SCF: 73.8 cells; $p \leq 0.01$). Additionally, more positive primitive endoderm (SOX17) cells were found at higher concentrations of GM-CSF (mean: KSOM(aa): 9.21 cells; KSOM(aa) +5 ng/mL GM-CSF: 11 cells $p>0.5$).The amount of epiblast (NANOG positive) cells showed almost no variance at different concentrations of GM-SCF. However, the proportion of trophectoderm, epiblast and primitive endoderm cell numbers did not change among the embryos of the different groups (80-82% trophectoderm; 11-12% primitive endoderm; 7-8% epiblast).

Limitations, reasons for caution: This study was performed in a mouse model and would need further investigation in other animal models or experiments with human embryos to elucidate and validate the influence of GM-CSF on trophectoderm cell numbers during preimplantation development.

Wider implications of the findings: GM-CSF increases the number of trophectoderm cells which may lead to an improvement in the implantation process and embryo or placental development and also may increase survival rates of transferred embryos in a clinical application.

Trial registration number: DFG NO 413/3-3 and BO2540/4-3

P-206 A prospective sibling oocyte study; do sequential and single step media perform comparably

K. Rennison, P. Knaggs, A. Storey, F. Heath

Abertawe Bro Morgannwg University Health Board, Wales Fertility Institute, Cardiff, United Kingdom

Study question: Do sequential and single step media perform comparably in terms of blastocyst formation, quality and pregnancy rates when using sibling oocytes?

Summary answer: There is an increase in blastocyst formation with single step media, however this does not appear to translate to an increase in clinical pregnancy rate.

What is known already: Recent years have seen the increased utilisation of culture in time lapse systems. Associated with this is the rise in the use of Single Step media for IVF culture. Using sibling oocytes we are validating the use of Sage Single Step (SS) media alongside Sage Sequential (SQ) media, with the eventual aim of introducing SS with the use of time lapse culture.

Study design, size, duration: From August 2017 until Decmeber 2017 103 patients who were being treated with IVF or ICSI who had 4> normally fertilised oocytes were included in the study. 85 patients reached transfer (the remainder had freeze all). Embryo selection for transfer is based on development and quality only not on media type. Decision to transfer on day 3 or culture on is based on embryo development and quality on the morning of day 3.

Participants/materials, setting, methods: The fertilised oocytes are divided between Sage Single Step (SS) media and Sage Sequential (SQ) media; Cleavage media, that is changed to Blastocyst media at approximately 68 hours post insemination. 50% that are cultured in Sage SS media that is refreshed at approximatley 68 hours post insemination. Our programme aimed to transfer a

single embryo unless patient history or embryo quality indicate a benefit from double embryo transfer.

Main results and the role of chance: Our inital analysis of the data suggests an increase of blastocyst formtion rate in SS embryos compared to SQ (68% vs 54% $P<0.05$). This is reflected in the increase seen in SS cultured embryos being selected for transfer over SQ derived embryos (50.5% vs 44.7%) the remaining 4.8% of transfers reflects a mix of SQ and SS embryos. Top quality blastocyst rates (SS 44% vs SQ 47%) and number of embryos frozen (SS 40% vs SQ 42%) are comparable. An increase is seen in positive pregnancy test for SQ transfers (53% vs 60% per embryo transfer), on going clinical pregnancy rates are comparable (SS 44% vs SQ 45%) and per embryo transferred (SS 34% vs SQ 32%).

Limitations, reasons for caution: The limitations of this study are the numbers of patients who have so far been recruited. As this is an ongoing study we hope to provide more data to increase its power.

Wider implications of the findings: This ongoing study indicates an increase in blastocyst formation for embryos cultured in SS media over SQ media. This increase does not currently translate into an increase in quality or clinical pregnancy outcome or increase in the number of embryos frozen.

Trial registration number: not applicable.

P-207 Embryo secretome profile from infertile patients undergoing assisted reproductive techniques can be affected by infertility factors

T. Bonetti[1], D. Hadad[2], T. Domingues[1,3], J.R. Alegretti[4], E. Motta[1,3], K. Seeley[5], I. Silva[1]

[1]Universidade Federal de Sao Paulo - Escola Paulista de Medicina UNIFESP-EPM, Gynecology, São Paulo- SP, Brazil
[2]Universidade Federal de Sao Paulo - Escola Paulista de Medicina UNIFESP-EPM, Urology, São Paulo- SP, Brazil
[3]Huntington Centro de Medicina Reprodutiva, Clinical, Sao Paulo, Brazil
[4]Huntington Centro de Medicina Reprodutiva, Embryology, Sao Paulo, Brazil
[5]University of South Florida, Proteomics and Mass Spectrometry Facility- Center for Drug Discovery and Innovation CDDI, Tampa, U.S.A.

Study question: Does the embryo secretome vary in according with infertility factor of women undergoing assisted reproductive techniques (ART), as endometriosis, polycystic ovarian syndrome or tubal factor?

Summary answer: Embryonic secretome from patients presenting deep infiltrating endometriosis (DIE), polycystic ovarian syndrome (PCOS), and tubal factor (TF) presented divergent protein profiles evaluated through proteomics approach.

What is known already: The field of human ART would benefit from more quantitative methods of determining embryo viability and implantation potential. It is known that soluble ligands and it receptors mediate human preimplantation embryo development and implantation. A number of researchers has been used proteomics approach related to human reproduction in several subareas. Various proteins has been investigated as embryo biomarker in the spent culture media, given the embryo culture medium secretome reflect the embryo development. We hypothesize that protein profiles are affected according with infertility factors, which can be responsible for detrimental oocyte and embryonic developmental, ensuing on lower IVF success rates.

Study design, size, duration: We studied embryo culture media from patients presenting DIE (n = 14) and PCOS (n = 7), which are the most frequent female factors of infertility. The control group was constituted by TF (n = 6) patients. It were included in the study embryo culture media samples obtained from patients submitted to IVF cycle. Patients underwent IVF treatment as routine and oocytes were fertilized by ICSI. The embryos were group cultured until D3 and after transfer, the culture media were collected.

Participants/materials, setting, methods: For the proteomics analysis, two pools of samples were prepared for groups CONTROL and PCOS, and 4 pools for group DIE. Samples were prepared to deplete high abundant proteins and followed evaluated by high throughput proteomics approach. Raw data acquired were searched against the European Bioinformatics Institute's (EBI) universal protein resource database (UniProt) using Mascot (version 2.2). Peptide and protein validations were performed using the Scaffold platform (version 3.00.08).

Main results and the role of chance: From 2904 proteins identified, decoy proteins that are considered false identification were excluded. Two sets of analysis were carried out with remaining proteins using the Ingenuity Pathway Analysis Software. In the DIE group, 17 proteins were exclusively expressed, and two were over expressed compared to CONTROL. The canonical pathways identified were associated with calcium metabolism (calcium signaling and transport and calcium induced T –lymphocyte apoptosis) and EGF signaling. The PCOS group presented 284 proteins exclusively expressed and one overexpressed compared to CONTROL, which were associated with the following canonical pathways: Protein Kinase A signaling and calcium signaling were downregulated, and GADD45 signaling, hydrocarbon receptor signaling and GDP-L fucose biosynthesis II were upregulated. Based on proteins identified, the CONTROL group had the following cellular and molecular function highlighted: cellular development, cellular movement, amino acid metabolism, small molecule biochemistry, cellular assembly and organization, which were function associated to general cellular development. Also, the embryonic, organ and tissue development were physiological functions activated based on proteins identified in the three study groups.

Limitations, reasons for caution: We did not correlate proteins with the embryo characteristics, as samples come from group cultured embryos. Also, due to high concentration of contaminants in the culture media, samples were submitted to a number of process which might depleted other less abundant proteins. The validation of proteins found is necessary.

Wider implications of the findings: The DIE group present a high calcium activity while PCOS showed a decreased calcium action, which may be related to embryo developmental competence or plasticityEmbryonic secretome will advance our knowledge and could lead to improved selection of embryos for transfer warrants further investigation.

Trial registration number: not applicable.

P-208 Oviduct-embryo interaction in cattle: Effect of asynchrony between the embryo and the oviduct on subsequent embryo development

B. Rodriguez Alonso[1], J.M. Sánchez[1], M. Hamdi[2], U. Besenfelder[3], V. Havlicek[3], P. Lonergan[1], D. Rizos[2]

[1]University College Dublin UCD, School of Agriculture and Food Science, Dublin, Ireland
[2]National Institute for Agriculture and Food Research and Technology INIA, Animal Reproduction, Madrid, Spain
[3]University of Veterinary Medicine, Biomedical Sciences, Vienna, Austria

Study question: Does maternal-embryonic asynchrony in the oviduct have an impact on subsequent development?

Summary answer: Asynchrony between the developing embryo and the oviduct has a negative impact on embryo survival and development.

What is known already: In cattle, which share a similar chronology of early embryo development with humans, while fertilisation of the oocyte occurs successfully in the majority of cases, a large proportion of embryos die subsequently, mostly in the first 2-3 weeks. Using state-of-the-art assisted reproduction techniques, this study aims to determine the influence of maternal-embryonic asynchrony in the oviduct on embryo development using the bovine model. Specifically, we investigated how the oviductal environment affects early development up to 8- to 16-cell stage embryos (Day 4, embryonic genome activation), blastocyst stage (Day 7, cell differentiation) and Day 15 conceptus stage (maternal recognition of pregnancy).

Study design, size, duration: Day 1 in vitro-produced bovine zygotes (IVF=Day 0) were endoscopically transferred to the oviducts of heifers (40 cross-bred beef heifers) which were either (i) synchronous with the embryos (i.e., at Day 1 after ovulation) or asynchronous and ahead of the embryo (i.e., at Day 3 after ovulation). A proportion of the heifers were slaughtered in a commercial abattoir 3, 6 and 14 days after transfer to assess embryo development at key embryo developmental stages.

Participants/materials, setting, methods: Fifty presumptive zygotes were transferred endoscopically into the oviduct ipsilateral to the corpus-luteum of heifers (n = 40, total of 2000 zygotes) which were synchronous or asynchronous with the embryo. Embryos on Day 4, 7 and 15 were recovered and

assessed; location within the reproductive tract, survival (based on morphology) and developmental stage (cell count by fluorescence microscopy or conceptus size in Day 15 embryos) were recorded. Data were analysed by Chi square and Student's t-test analysis.

Main results and the role of chance: Overall recovery rates were: Day 4 (83.5% vs 57.0%; p<0.05), Day 7 (70.0% vs 71.3%) and Day 15 (4.0% vs 12.0%) for asynchronous vs synchronous transfer, respectively. Transfer of an embryo to an advanced oviduct (asynchrony) resulted, on Day 4, in fewer embryos at the expected location (oviduct) (6.0% vs 42.2%), more degenerated (95.2% vs 74.4%) and less developed (8- to 16-cells: 9.7% vs 22.7%) embryos with a lower total cell number (10.8 ± 0.8 vs 13.7 ± 0.8) compared to synchrony group (P<0.05).

On Day 7, the recovery rate at the expected location (uterus) was lower following asynchronous transfer (86.7% vs 98.1%) with more degenerated (96.7% vs 84.1%) and less developed embryos (morula/ blastocyst stage: 14.8% vs 33.2%) compared to the synchrony group (p<0.05). However, in terms of quality the total embryo cell number was similar among asynchrony (78.3 ± 5.9) and synchrony (77.3 ± 3.6) groups.

On Day 15, only 50% of the asynchronous heifers yielded conceptuses vs 100% in the synchrony group. Day 15 conceptuses were longer following asynchronous tranfers (33.7 ± 4.4 vs 17.2 ± 1.9 mm, P <0.01), likely due to a progesterone-mediated effect in the uterus rather than an oviduct effect.

Limitations, reasons for caution: While the transfer of multiple embryos has been successfully used to study early embryo-maternal communication in the past, it should be noted that the presence of 50 embryos in the bovine oviduct is not the physiological norm.

Wider implications of the findings: Understanding how the early embryo interacts with the the oviduct will improve our knowledge of the factors regulating embryo development and survival and may lead to improved *in vitro* culture systems. Also, results may provide valuable information regarding the correct timing for embryo transfer.

Trial registration number: Project authorised by the Health Products Regulatory Authority (www.hpra.ie). Project Authorisation Number: AE18982/P120.

P-209 Laboratory and clinical outcome with embryos cultured in continuous single step media containing reduced lactate: A prospective sibling oocyte study

T. Aksoy[1], N. Findikli[1], B. Ozturk[1], I.O. Olcay[1], F.K. Boynukalin[2], E. Oral[3], M. Bahceci[2]

[1]Bahceci Fulya IVF Centre, IVF Laboratory, Istanbul, Turkey
[2]Bahceci Fulya IVF Centre, Infertility Clinic, Istanbul, Turkey
[3]Istanbul University Cerrahpasa School of Medicine, Obstetrics and Gyneocology, Istanbul, Turkey

Study question: Does embryo culture media with reduced lactate create any disturbances/benefits in terms of human embryo development and clinical outcome in comparison to conventional single step media?

Summary answer: Simultaneous comparison of two single step embryo culture media containing control and low lactate on sibling oocytes shows comparable and acceptable laboratory and clinical outcomes.

What is known already: Pyruvate, lactate and glucose are the primary energy substrates for human preimplantation embryos. Although its concentration greatly varies in vivo during the course of preimplantation embryo development, lactate concentration in commercially available human single step embryo culture media is usually kept between 4-10 mM. Recent studies indicate that blastocyst development and viability can be improved in environments having low lactate concentrations (<5 mM). Also, high lactate concentration in the culture media has previously been shown to change pyruvate uptake and may cause metabolic disturbances during zygote and early cleavage stages.

Study design, size, duration: This study is a prospective sibling oocyte study, performed between February – November 2017, including 1101 mII oocytes of 55 freeze-only ICSI cycles. After hyaluronidase treatment, mII oocytes of each case were equally (where available) allocated in two commercially available complete culture media, namely Continuous Single Culture Media (CSCM) and CSCM-NX (Low lactate) from the same producer (Irvine Scientific). They were individually cultured before and after vitrification/warming under 6% CO_2 and low O_2 (5%) conditions.

Participants/materials, setting, methods: Mean female age and oocytes collected per case were 31,6 ± 5,6 and 22,8 ± 6,1 respectively. A total of 546 and 555 mII sibling oocytes were inseminated by ICSI and cultured in either CSCM or CSCM-NX. In all cycles, developing embryos were cryopreserved by vitrification on either day 3 or day 5 of embryo development and subsequently warmed/cultured until ET. Fertilization, early embryo cleavage, blastocyst development as well as clinical pregnancy/delivery outcomes were compared between the groups.

Main results and the role of chance: Data regarding main laboratory KPIs such as fertilization rate, percentage of slow (<6 cells) and fast (>8 cells) developing embryos on day 3 as well as blastocyst development on day 5 were 76.9%, 19.5%, 19.0% and 44.0% for CSCM Group and 78.4%, 16.1%, 24.3% and 46.9% for embryos in CSCM-NX Group respectively. Although a slight increase in cleavage rates towards blastocyst stage was observed in CSCM-NX Group, no statistically significant differences were observed for all laboratory variables documented and compared in the current study (p>0.5). Of 55 freeze-only cycles, a subsequent FET was performed in 47 cycles by utilizing embryos from either CSCM Group (n = 21) or CSCM-NX Group (n = 26). Clinical pregnancy, ongoing pregnancy and implantation rates in each group were 66,6%, 57,1% and 64% for CSCM Group and 69,2%, 65,4% and 69,7% for CSCM-NX Group respectively.

Limitations, reasons for caution: Since this study mostly included good responder patients, our preliminary results should not be generalized for other patient groups with varying degree and spectrum of infertility indications. More studies with larger sample sizes are needed to compare these results in general patient population.

Wider implications of the findings: Lowering the lactate concentration in routine single step culture media displays similar embryo cleavage and developmental kinetics during early as well as post-compaction embryo development on embryos generated from sibling oocytes of good responder patients.

Trial registration number: None.

P-210 Spindle transfer can enhance the potential of developmentally compromised human oocytes to reach the blastocyst stage: proof of concept with donor oocytes

N. Costa-Borges[1], E. Nikitos[2], I. Miguel-Escalada K. Rink[1], K. Spath[3], D. Wells[4], I. Zervomanolakis[2], I. Vasilopoulos[2], D. De Ziegler S Grigorakis[2], G. Kontopoulos[2], T. Prokopakis[2], K. Dimitropoulos[2], P. Polyzos N. Vlachos[2], K. Kostaras[2], P. Psathas[2], G. Calderón[1]

[1]Embryotools S.L., Embryotools, Barcelona, Spain
[2]Institute of Life, IVF center, Athens, Greece
[3]CooperGenomics, CooperGenomics, Oxford, United Kingdom
[4]University of Oxford, Nuffield Department of Women's and Reproductive Health, Oxford, United Kingdom

Study question: Can spindle transfer represent a valuable strategy to enhance the potential of developmentally compromised human oocytes?

Summary answer: Spindle transfer can overcome embryo development arrest and enhance the potential of human oocytes with compromised quality to reach the blastocyst stage.

What is known already: Spindle transfer (ST) is a mitochondrial replacement therapy that has been proposed to prevent the transmission of maternally inherited mitochondrial diseases. In a recent study, we showed that ST could also be successfully used to overcome embryo development arrest and improve implantation rates in a mouse model with an intrinsic poor reproductive performance. The feasibility of using this technique for the purpose of treating infertility problems should be further explored, as it could offer patients with poor oocyte quality a last chance of having a child genetically related to them.

Study design, size, duration: Experiments were authorized by the Greek National Authority of Assisted Reproduction and approved by the IRB of the IASO Maternity Hospital. Informed consent was obtained from the 18 donors participating in the study, which was carried out at the Institute of Life (Athens) between June and December 2017. Experimental design aimed to compare the

efficiency of two membrane fusion methods and explore the feasibility of the technique using donor oocytes with different developmental competence.

Participants/materials, setting, methods: Micromanipulation procedures were performed on a heated stage under an inverted microscope (Olympus-IX73) equipped with an image birefringence system to confirm spindle removal. Karyoplast-cytoplast fusion was induced by exposure of the reconstructed oocytes to either a chemical solution or an inactivated protein extract (HVJ-E). Manipulated and non-manipulated control oocytes were inseminated by ICSI with a donor's sperm sample and cultured (Embryoscope$^+$, Vitrolife) in single medium (LifeGlobal) until Day6. Blastocysts were used for molecular analysis.

Main results and the role of chance: After careful optimization, enucleation of MII-oocytes was 100% in all oocytes presenting a birefringent spindle. The volume of cytoplasm removed was estimated in <1%(judged by microscopic measurements). In the first set of experiments, aimed at comparing two fusion methods, a total of 54 oocytes were used. HVJ-E-mediated fusion rates were significantly higher (98.2%) than those in the chemical method (71.7%, p<0.01). Fertilization rates were similar between the control (70%), HVJ-E (75%) and chemical-fusion (66.7%) groups. No differences (p>0.05) were found in blastocyst rates between controls (85.7%), HVJ-E (73.3%) and chemical-fusion (60.2%) groups. In the second set of experiments, ST was performed in 104 donor oocytes with differing developmental competence collected from normal and high responder donors, which included: fresh, vitrified, 'PCO-like"-morphology and in vitro matured oocytes. Overall, fertilization and blastocyst formation rates varied greatly depending on the quality of the recipient cytoplasm. When spindles were transferred from in vitro matured or PCO-like morphology oocytes into good quality cytoplasts, fertilization (66.7%-71.4%) and blastocyst (75.0%-60.0%) rates were significantly (p<0.05) improved compared to those of the corresponding non-manipulated controls (50.0%-33.3% and 0.0%-0.0%, respectively) or the reciprocally reconstructed (25.0%-0.0% and 37.5%-33.3%, respectively) oocytes. Preliminary molecular analyses from 8 ST-reconstructed blastocysts resulted in euploidy rates >60%.

Limitations, reasons for caution: Spindle transfer is a technically demanding procedure with multiple steps that need to be carefully optimized and validated to ensure its effectiveness. Genetic analyses are currently being performed to determine the aneuploidy rates and mtDNA carryover levels in a larger number of blastocysts.

Wider implications of the findings: This study shows the feasibility of ST to enhance the potential of compromised oocytes to develop up to the blastocyst stage. These promising preliminary results prompt further investigation under regulated controlled trials to confirm the effectiveness of the technique and identify groups of patients that could benefit from its application.

Trial registration number: Not applicable.

P-211 Embryonic exposure to Mono-2-ethylhexyl phthalate (MEHP) inhibits invasion and alters metabolism in mouse blastocysts

Y.Y. Ma[1], L. Guan Lin[2], C. Xiao Pan[3], S. Jing[3], C. Ya Ching[4], T. Chii Reuy[4]

[1]Center for Reproductive Medicine & Sciences, Department of Obstetrics & Gynecology, Taipei City, Taiwan R.O.C.
[2]College of Medicine- Taipei Medical University Taipei- Taiwan, Department of Obstetrics & Gynecology, Taipei City, Taiwan R.O.C.
[3]Department of Reproductive Endocrinology- Zhejiang Provincial People's Hospital-158 Shangtang Road- Hangzhou- Zhejiang- 310014- China., Department of Reproductive Endocrinology, Zhejiang, China
[4]Taipei medical university hospital Taipei- Taiwan, Department of Obstetrics & Gynecology, Taipei City, Taiwan R.O.C.

Study question: MEHP is lipophilic, tends to accumulate in adipose tissue and disturbs energy metabolism. Here we aim to investigate the influence of MEHP on embryonic metabolism and mitochondrial function.

Summary answer: Exposing to MEHP could negatively affect embryo implantation potential and viability by inhibits invasion and alters metabolism, suggesting possible risks for female reproductive health.

What is known already: In Human studies and animal exposure experiments, there is increasing evidence showing that exposure to PAEs elicits adverse effects on female reproduction.

Study design, size, duration: A prospective RCT of experimental animal study in a university hospital.

Participants/materials, setting, methods: The 2-cell mouse embryos were cultured in HTF supplemented with MEHP at range levels (0-50 μM) for 48 h (blastocyst stage) then blastocysts were collected from each groups. The expression levels of proteins involved in antioxidant enzyme (MnSOD), implantation (MMP-2 and MMP-9) and metabolism (lipin 1 and Glut3) were validated by Immunofluorescence analysis. The Lipid droplet abundance, ATP content and mitochondrial activity also assessed by sting BODIPY and MitoTracker, respectively.

Main results and the role of chance: Lipid droplet and antioxidant enzyme (MnSOD) was significantly increased ($P< 0.05$) in blastocyst by exposure MEHP (50 μM) than control. Moreover, MEHP were up- regulation of lipin 1 expression in dose-dependent manner (in 25 and 50 μM, $P< 0.05$). Meanwhile, ATP content and MMP-9 were significantly decreased in MEHP-treated blastocysts ($P< 0.05$).

Limitations, reasons for caution: Our study was based in mouse model and further studies on implantation or birth rate are required to confirm our findings.

Wider implications of the findings: This study provided new evidence of PEAs negative impact on embryo implantation and metabolism. It may contribute to early pregnancy loss in women.

Trial registration number: NA.

P-212 Aberrant expression of ribosomal proteins results in the developmental failure of human preimplantation embryo

C.Q. Zhang[1], L.Z. Leng[1], S.P. Zhang[1], L. Zhao[2], P.Y. Xie[1,3], C.F. Lu[1,2], F. Gong[1,2], G. Lin[1,2,3]

[1]Institute of Reproduction and Stem Cell Engineering, School of Basic Medical Science- Central South University, Changsha, China
[2]Reproductive and Genetic Hospital of CITIC-Xiangya, Reproductive center, Changsha, China
[3]National Engineering and Research Center of Human Stem Cells, National Engineering and Research Center of Human Stem Cells, Changsha, China

Study question: To investigate the underlying molecular mechanism of 8-cell arrested embryos without chromosomal abnormalities and morphokinetic abnormalities.

Summary answer: The decreased expression of ribosomal proteins (RPs) genes activate p53 pathway by nucleolar stress, which induced human embryo arrest at 8-cell stage.

What is known already: During in vitro fertilization (IVF) treatment, about 50-70% of normally fertilized human embryos cannot form blastocyst. Chromosomal abnormalities including uniformly aneuploid, polyploid, haploid, mosaicism chaotic chromosomal complement, and morphological abnormalities, such as multinucleation, cytoplasmic fragmentation, and unequal cleavage are the main causes of early embryonic development block. However, a small number of embryos with normal chromosome and morphological features still cannot reach the blastocyst stage.

Study design, size, duration: A total of 26 in-vitro matured metaphase (MII) oocytes were collected to perform ICSI. Then 8-cell embryos with normal cleavage in the first three times cleavages were collected, and single blastomere from 8-cell embryos was biopsied for transcriptome sequencing. According to whether the 8-cell embryos form blastocyst, they were divided into two groups, the blastocyst and the arrested embryo. Test the chromosomal constitution and compare the gene expression differences between the two groups.

Participants/materials, setting, methods: Monitor the morphological features and kinetic parameters of the two groups embryos via time-lapse technology, and analyze gene expression of single blastomere from 8-cell embryos by single-cell RNA-SEQ. Trophectoderm (TE) of the blastocysts and the arrested embryos were biopsied and detected the chromosomal makeup by next-

generation sequencing. And then the remaining of blastocyst were stained by immunoflurescence for SOX17 and NANOG.

Main results and the role of chance: A total of 3 embryos were collected in the blastocyst and the arrested group, respectively. 6 embryos are high-quality embryo at day 3 which graded 8cell-I or 8cell-II, and they had normal chromosome compositions at day 5. In the blastocyst group, all embryos had a significant expansion blastocoelic cavity and inner cell mass (ICM), and the average cell number of TE and ICM are 226 and 33, respectively. In the arrested group, 3 embryos arrested at 8-cell stage, with compaction of a few of cells and embryo fragmentation.

The average of total gene number for the blastocyst and arrested group were 15785 and 13907, respectively. 420 genes of 675 differentially expressed genes (DEGs) were identified as downregulated genes, and 255 DEGs were upregulated. The majority of 420 downregulated genes had a low level of expression, except RPs. And KEGG pathway analysis showed the most apparent enriched pathway was ribosome, including 80 genes, 23 of which were RPs. Likewise, the PRAME family genes were the higher expression among the 255 upregulated genes. Meanwhile, MDM2 related to nucleolar stress was upregulated. This indicates the decreased expression of RPs induces nucleolar stress indispensable for p53 activation, resulting in human embryo arrest.

Limitations, reasons for caution: A limitation is the sample size of this study. In addition, the preliminary results of the analysis will need to be further investigated by the more arrested embryos experiment.

Wider implications of the findings: During IVF/ICSI, 8-cell high-quality embryo without morphokinetic abnormalities may not have a capable of implantation at day 3 and it is necessary to perform more studies for accurate evaluation. And that besides the primary ribosome biogenesis, ribosomal proteins could regulate early human embryo development.

Trial registration number: NA.

P-213 Editing of the coatomer protein complex subunit alpha gene in bovine blastocysts using CRISPR/Cas9

M. Poirier, D. Miskel, F. Rings, M. Hoelker, K. Schellander

Institute of Animal Science, Animal Breeding and Husbandry, Bonn, Germany

Study question: Is CRISPR/Cas9-mediated editing of the coatomer protein complex subunit alpha (COPA) gene possible in bovine zygotes?

Summary answer: Microinjection of CRISPR/Cas9 in presumptive zygotes led to gene edited bovine blastocyst stage embryos.

What is known already: Successful genome editing to term has been accomplished in cattle by somatic cell nuclear transfer (SCNT). CRISPR/Cas9 microinjection of zygotes has been done in a limited number of attempts in ruminant species, mostly using RNA. Here we report successful editing of the COPA gene through plasmid delivery of CRISPR/Cas9 in bovine zygotes.

Study design, size, duration: Presumptive zygotes (n = 350) were microinjected with a CRISPR/Cas9 plasmid. Injected embryos were put in *in vitro* culture until blastocyst stage. At day 8, embryos were selected based on GFP fluorescence and frozen individually for sequence analysis. A separate IVF run with identical parameters was used as negative control without microinjection to compare development rates.

Participants/materials, setting, methods: Presumptive zygotes derived from slaughterhouse oocytes by *in vitro* maturation and fertilization were microinjected with the pX458 plasmid (Addgene #48138) containing a guide RNA recognition sequence for the 6th exon of the COPA gene. GFP positive structures at day 8 were selected as candidates for successful editing. Editing was assessed through T7 endonuclease assay, subsequently followed by Sanger sequencing.

Main results and the role of chance: Compared to the control (32.3%), the injected group showed a day 8 blastocyst rate of 27.7%. Fluorescence rate at day 8 was 7.6%. GFP positive blastocyst rate was 2.5%, totaling 7 blastocysts. T7 endonuclease assay revealed editing in blastocysts and morulae as well. Structures that were selected for editing through T7 assay showed a high variability of editing events neighboring the guide RNA target site. Deletions as long as 94 base pairs were found in blastocysts, as well as the absence of editing. Multiple editions found in structures as well as wild-type sequences suggest mosaic editing of blastocysts. This implies that editing of the COPA gene is possible in bovine zygotes and did not affect embryo development *in vitro*.

Limitations, reasons for caution: Editing of the COPA gene in bovine embryos is possible with plasmids but limited because of mosaic editing. Observation of genome editing without wild-type sequences persisting through development is crucial to imply that complete editing of COPA is not lethal.

Wider implications of the findings: This research sheds light on how CRISPR-Cas9 plasmid delivery in zygotes behaves and how it could circumvent cloning of edited cells. Results also indicate that the COPA gene may not be required for early embryo development.

Trial registration number: This study was funded by project number 309-70102 of the University of Bonn. The authors declare.

P-214 Effects of sperm direction (head first injection, tail first injection) in Piezo-ICSI on oocyte survival, fertilization and embryo morphokinetics in humans

Study question: Does the sperm direction (head first injection, tail firstinjection) in Piezo-ICSI have an effect on oocytes survival, fertilization and embryo morphokinetics in humans?

Summary answer: Sperm's tail first injected oocytes showed significantly higher fertilization as compared to the sperm's head first injected oocytes, but the fertilized embryo morphokinetics were similar.

What is known already: For the application of ICSI to human oocytes, it is believed that the sperm should be injected head first into the cytoplasm for fertilization because the internalization of sperm in the cytoplasm is initiated from the sperm head during natural fertilization. However, in the ICSI procedure, sperm are directly injected, bypassing the internalization of the sperm head in the cytoplasm; accordingly, oocytes could be fertilized if the sperm is injected tail first into the cytoplasm. However, little is known about the effect of the sperm direction on ICSI results, including embryo morphokinetics.

Study design, size, duration: We retrospectively investigated 75 mature oocytes retrieved from 26 patients were microinjected from sperm's head first (H-first) and 145 mature oocytes retrieved from 40 patients were microinjected from sperm's tail first (T-first) between May 2016 and April 2017. Of these. Only metaphase II oocytes with a visible meiotic spindle at the time of ICSI were microinjected to minimize the potential influence for fertilization (Heindryckx B et al. Hum Reprod. 2011: 26: 535-44).

Participants/materials, setting, methods: The survival, fertilization and good-quality day-3 embryo rates after Piezo-ICSI by H-first injection group and tail T-first injection group were compared. In addition, the time of second polar body emission, vanishing the two pronucleus and the first cleavage of fertilized oocytes were monitored by a time-lapse microscopy system (CCM-iBIS). Times were expressed as mean ± SD hours post-insemination and analyzed, where appropriate, by Unpaired T Student or Fisher's exact tests.

Main results and the role of chance: The survival rates of H-first and T-first groups were 97% (73/75) and 99% (143/145). No significant difference was observed. The fertilization rates of H-first and T-first groups were 85% (64/75) and 95% (137/145). A significantly higher fertilization rate was achieving in T-first group (P = 0.0397). The 0PN (no pronucleus) rates of H-first and T-first groups were 11% (8/75) and 2% (3/145). A significantly lower 0PN rate was achieved in T-first group (P = 0.0087). The 1PN (mono pronucleus) rates of H-first and T-first groups were 0% (0/75) and 1% (1/145). No significant difference was observed. The 3PN (three pronucleus) rates of H-first and T-first group were 1% (1/75) and 1% (2/145). No significant difference was observed. The good quality day-3 embryo rates per microinjected oocytes of H-first and T-first groups were 52% (39/75) and 68% (98/145). A significantly higher good quality day-3 embryo rate was achieving in T-first group (P = 0.0280). Among the H-first and T-first groups, there were no significant differences when comparing the time of second polar body emission (2.6 ± 0.8 vs. 2.8 ± 0.7 h), two

pronucleus vanishing (23.0 ± 2.9 vs. 22.5 ± 2.7 h) and first cleavage (25.4 ± 2.9 vs. 25.1 ± 2.8 h) of fertilized oocytes.

Limitations, reasons for caution: The morphokinetic parameter of first cleavage assessed in this study may require better definition to reduce inter-operator annotation variability.

Wider implications of the findings: Sperm tail first injection associated with higher fertilization and good quality day-3 embryo rates as compared to sperm head first injection without detrimental effect on embryo morphokinetics. Interestingly, sperm tail first injection might be used as a new technique for human ICSI to improve the effective utilization rate of oocytes.

Trial registration number: Not applicable.

P-215 A prospective study of oocyte Zona Pellucida mechanics as a predictor of embryo implantation: a novel tool for embryo selection

[3]Shamoon College of Engineering and Rotem Industries LTD, Department of mechanical engineering, Beer-Sheva, Israel

Study question: Does the zona pellucida's ability to resist shape change (shear modulus) predict embryo implantation potential?

Summary answer: Zona pellucida (ZP) shear modulus can predict implantation rate, regardless of ZP thickness, embryo diameter or patient's age.

What is known already: The ZP undergoes extensive mechanical deformation at the time of blastocyst expansion and hatching. To the best of our knowledge, no study examined the effect of mechanics properties of the ZP on embryo hatching and implantation ability. Furthermore, most studies assume that the ZP can be described as a linear elastic material and employ analytical models that mimic the oocyte deformation. This assumption may be applicable to small deformations but not to extensive ones when ICSI is performed. Although ZP hatching is at least partly a mechanical phenomenon, oocyte mechanics is not taken into consideration during embryo selection.

Study design, size, duration: A non-randomize prospective study performed during 2015 – 2017 designed to examine the deformation of the ZP during the ICSI procedure. One hundred and sixty-four oocytes were aspirated from 28 IVF patients. The patients were tested for ZP mechanical properties. Thirty nine embryos were transferred and the implantation rate was measured.

Participants/materials, setting, methods: The study was conducted at an IVF unit and the mechanical engineering department. Images from ICSI procedures were used to construct computational models using a non-linear model applicable to large deformations. The computed ZP deformation was compared to deformation observed in ICSI during oocyte suction. This comparison enabled the determination of ZP-shear modulus which represents the ability to resist shape change. Implanted embryos were compared to non-implanted embryos regarding the shear modulus using chi-square test.

Main results and the role of chance: The data show that a great variance exists in the shear modulus of oocytes aspirated from the same patient (0.0001-0.00065 Mega Pascale-MPa). A significant correlation was found between the value of the ZP shear modulus and implantation rate. The total implantation rate of the transferred embryos in the study was 30.7% (12/39). A significant difference was found when comparing implantation rate inside and outside of a specific shear modulus range (0.0002-0.0004 MPa). Ten out of the 16 (62.5%) implanted embryos, displayed shear modulus values in the specific range, with only 2 implanted embryos out of 23 were outside the range (8.7%) P = 0.037. No correlation was found between ZP shear modulus and embryo quality regarding blastomere's number and morphological index. The age of the patients inside and outside the range of the ZP shear modulus was comparable. Other mechanical properties such as the thickness of the ZP and oocyte diameter were not associated with implantation rate.

Limitations, reasons for caution: The limitations of the study: a small sample size.

Wider implications of the findings: The ZP shear modulus which is determined early at the time of sperm injection can be used as a novel method for embryo selection, consequently leading to a higher embryo implantation rate. Our methodology can be implemented with no major changes in the current ICSI procedure.

P-216 Human blastocyst development and implantation rate with human recombinant growth factors supplementation of culture media

V. Kazarinov, T.V. Ovsyannikova

Center of New Medical Technologies CNMT Institute of Chemical Biology and Fundamental Medicine Siberian Branch of the Russian Academy of Sciences, Laboratory of Reproductive Problems, Novosibirsk, Russia C.I.S.

Study question: Could growth factors promote early embryonic development and implantation in IVF treatment?

Summary answer: Growth factors promote blastocyst quality; this may help choosing embryo for transfer and improve implantation chance.

What is known already: Early studies using animal models demonstrated enhanced early embryonic development and survival when culture media were supplemented with individual growth factors (GF), including insulin-like growth factor-I (IGF-I), granulocyte-macrophage colony-stimulating factor (GM-CSF), epidermal growth factor (EGF) and others. Supplementation of culture media with key autocrine/paracrine growth factors promoted the development of tripronuclear human zygotes to blastocyst, promoted blastocyst formation of day 3 cryopreserved embryos and increased the proportion of high quality blastocyst. Also, growth factors could improve normally fertilized hatching blastocysts outgrowth *in vitro*.

Study design, size, duration: Patients undergoing IVF treatment were randomly divided into two groups (Group 1, n = 44, 34.2 ± 4.4 years; Group 2, n = 58, 34.1 ± 4.0 years). All obtained two-pronuclear zygotes were cultivated without GF (group 1, 196 embryos) or with recombinant human growth factors mix (group 2, 247 embryos) to blastocyst stage. Received good and high quality embryos were transferred or cryopreserved on fifth day. Both groups treatment, cultivation and embryo transfer (ET) were used with informed consent of the patients.

Participants/materials, setting, methods: After fertilization embryos were cultivated in one-step media with human serum albumin (Global total, LifeGlobal, US) individually in 30 ml microdrops without or with IGF-I and GM-CSF mix (each at 5 ng/ml) at equal conditions (37°C, 6.5% CO_2, pH 7.2-7.25). Blastocyst were assigned scoring based on the Gardner blastocyst grading scale (AA blastocyst were scored 5; AB, BA and BB - 4; CB, BC, CC - 3; and arrested blastocyst were scored 2) for statistical analysis.
