Main results and the role of chance: Group 1 and 2 has no difference in blastocyst formation (50 ± 45% and 51 ± 44% to zygotes quantity, respectively, p = 0.82) but in the group with GF high quality blastocyst proportion was significant increased (morphological score was 3.6 ± 0.9 in group 1, and 4.0 ± 0.9 in group 2, p = 0.0035). In group 1 was 42 transfers (1.38 embryo on ET) and 56 ET were in group 2 (1.46 embryo on ET) inclusion of growth factors mix showed rising trends in implantation rate without significantly differences in groups (14 ± 5% and 22 ± 5% to the number of transferred embryos, respectively, p = 0.20). The ET success was evaluated at 8-9 gestation week by ultrasound screening with a heart rate examination. Two miscarriages cases were in group 1 (one frozen pregnancy and one trisomy 22) and an anembryonic pregnancy in group 2. All miscarriages were not included in success ET cases. All samples in groups were compared by T-test for Independent Samples, and values were showed in Mean±SD format.

Limitations, reasons for caution: Although this experimental design is based on the supplementation of recombinant growth factors diluted during embryo cultivation, future studies on the potential side effects of these factors on chromosomal numbers, genomic integrity, proteomic changes, and epigenetic modifications are essential for wide clinical use.

Wider implications of the findings: Though, growth factors not influence on the blastocyst formation rate, but increase proportion of high quality embryos. Probably GF using not evaluate on blastocyst quantity, but assist to grow and choose better morphological grade blastocyst for ET, this finding could potentially increase implantation chance for every one transferred embryo.

Trial registration number: Not applicable.

P-217 The effect of changing culture media on aneuploidy rates seen in preimplantation embryos

B. Behr[1], R. Lathi[2], C. Cinnioglu[3], J. Kort[4]

[1]*Stanford University, Reproductive endocrinology and infertiliity, Stanford, U.S.A.*
[2]*Stanford University, Reproductive endocrinology and infertility, Stanford, U.S.A.*
[3]*Ivigen, Genetics, Torrance, U.S.A.*
[4]*Stanford University, OB/GYN, Stanford, U.S.A.*

Study question: To examine the effect of two different embryo culture media, in the same clinic using the same reference lab, on blastocyst ploidy.

Summary answer: Aneuploidy rates vary with different culture media for specific patient populations. However, this may be a manifestation of different blastulation rates.

What is known already: Aneuploidy screening of embryos has been proposed to increase implantation rates and decrease miscarriage rates in women undergoing IVF. While maternal age is the strongest predictor of embryonic aneuploidy, these and mosaicism rates have been observed to vary between clinic and reference labs. These variations have been seen in donors and cannot be explained by maternal age alone. The embryo culture system was changed from sequential media to a single step medium in our lab in 2017.

Study design, size, duration: This was a retrospective cohort study comparing aneuploidy rates between two five month periods in a single clinical lab in which the culture system was different (Period I: Sage sequential plus 10% SPS, Period II: Sage 1-step media). All patients undergoing PGS during these periods were included, consisting of 212 patients and 465 blastocysts cultured in sequential media, and 176 patients and 476 blastocysts cultured in 1-step media.

Participants/materials, setting, methods: Patient age, blastocyst development rates and pre-implantation genetic screening results were compared between two periods during which different culture media were used. CO2 levels were adjusted to maintain the same media pH of both media and no other changes in culture SOP were made between these two periods. All biopsies were performed at the blastocyst stage on day 5-6 and sent to a single reference lab for aneuploidy testing using NGS.

Main results and the role of chance: A total of 212 patients and 465 blastocysts biopsied over a 5 month period after culture in sequential media. A total of 176 patients and the corresponding 476 blastocysts were biopsied after culture in single step media. Mosaicism rate was < 2% in all groups throughout the study period and therefore no statistical analysis was possible. There were significantly more usable blastocysts in the single step medium (Sequential Media 48 % usable Blast/2PN vs. Single Step: 56 % usable blastocysts/2PN, $p<0.05$). Euploid/Aneuploidy rates were similar between media groups for patients in age groups <30, 30-35, 36-37, 38-39. There were significantly higher euploidy rates for blastocysts cultured in single step media for patients age 40-41 (54% vs. 32%, $p<0.05$) than blastocysts cultured in sequential media, and a similar trend approaching significance for patients ≥42 (6% vs. 0%, $p<0.05$) favoring blastocysts cultured in single step media.

Limitations, reasons for caution: This studies retrospective design and the difference in blastulation rates between culture systems prevents concluding whether the media affects embryo ploidy rather than changing the number of embryos available for biopsy.

Wider implications of the findings: There was an increase in euploidy rate after culture in single step media compared to sequential media for women >40. This finding suggests that culture conditions may influence aneuploidy rates, directly or indirectly by increasing the number of blastocysts available for biopsy or other less understood mechanisms.

Trial registration number: Not applicable.

P-218 Investigating the efficacy of non-invasive pre-implantation genetic testing for aneuploidy (NI-PGT-A) using spent culture media as a source of embryonic DNA

D. Babariya[1], S. Sarda[2], A. Manoharan[2], A. Coates[3], M. Large[4], J. Barritt[5], T. Escudero[2], S. Sawarkar[2], S. Munne[2], D. Wells[2]

[1]*University of Oxford and Reprogenetics UK, Nuffield Department of Women's and Reproductive health, Oxford, United Kingdom*
[2]*CooperGenomics, CooperSurgical, New Jersey, U.S.A.*
[3]*Oregon Reproductive Medicine, Oregon Reproductive Medicine, Oregon, U.S.A.*
[4]*CooperGenomics, CooperSurgical, Houston, U.S.A.*
[5]*ART Reproductive Center, ART Reproductive Center, Beverly Hills, U.S.A.*

Study question: Are spent media samples, derived from different culture systems/ conditions, a reliable non-invasive source of embryonic DNA for the purpose of NI-PGT-A?

Summary answer: Spent media samples contain embryonic DNA but the nature and content of that DNA varies according to their corresponding culture conditions.

What is known already: Currently, analysis of DNA from trophectoderm biopsy is the gold standard for comprehensive chromosomal screening (CCS) as well as pre-implantation genetic diagnosis for monogenic disorders. However, this approach is invasive and necessitates highly skilled personnel along with expensive micromanipulators to perform the biopsies. In recent years, non-invasive sources of embryonic DNA such as blastocoel fluid and spent culture media have been explored with the ultimate aim of developing non-invasive chromosomal screening and genetic diagnosis methods.

Study design, size, duration: Standard DNA amplification methods, including Sureplex and multiple displacement amplification (MDA), along with a modified MDA method were used to explore genetic content of 84 spent culture media samples derived from either fresh embryo cultures (n = 51) or vitrified-warmed embryo cultures (n = 33).The samples were subjected to next generation sequencing (NGS) and subsequently analysed for chromosomal copy number. Results were compared to those obtained using well-established invasive methods involving trophectoderm (TE) biopsy followed by CCS.

Participants/materials, setting, methods: For spent media samples from fresh embryo cultures (n = 51), a changeover of media was performed on Day-3 post fertilisation to a new 3 µl culture droplet (Sage Quinn) and the samples were subsequently collected on Day5/6 post fertilisation. Previously vitrified blastocysts (n = 33) were warmed in ~3-5 µl of culture media and collected after overnight incubation. The samples were subjected to whole genome amplification (either Sureplex, MDA or modified MDA) and subsequently sequenced using Illumina's Miseq platform.

Main results and the role of chance: Overall, the DNA amplification rates were superior in the samples amplified with the modified MDA method compared to those amplified by Sureplex and MDA methods: 93.48% (43/46) versus 47.37% (9/19) and 15.78% (3/19) respectively ($P<0.05$). Of note, the media samples which failed to amplify mainly belonged to a cohort frozen (at -20°C) for over a month before amplification. The aneuploidy/euploidy concordance rate between spent media samples and the corresponding embryo biopsy was found to be 95.35% (42/43) for modified MDA samples, 88.8% (8/9) for Sureplex amplified samples and 33.34% (1/3) for MDA samples. There was 99.3% concordance at the individual chromosome level for modified MDA samples (over 1000 chromosomes assessed), 99.1% for Sureplex samples and 94.4% for MDA samples.

For spent media samples amplified using modified MDA, all the female embryos were correctly identified with respect to gender of the corresponding TE biopsy (female embryos concordance: 27/27; 100%). However, one male embryo was misidentified as a female embryo (male embryos concordance: 15/16; 94%).

Limitations, reasons for caution: The sample size for present study is relatively small and the results need to be verified on a larger sample population. The ploidy status of the spent media samples was compared with a TE biopsy from the corresponding embryo and not the entire embryo.

Wider implications of the findings: The results confirm that the analysis of spent media represents a promising strategy for non-invasive PGT-A, frequently yielding genetic material which is representative of the embryo when appropriately amplified. While further experiments need to be performed to verify this data on larger sample sizes, the preliminary results are encouraging.

Trial registration number: Not applicable.

P-219 Determination of c-Abl tyrosine kinase and mTERT catalytic subunit of telomerase expression level during mouse prenatal and postnatal gonadal development

E. Yıldırım, A. Yaba Ucar

Yeditepe University School of Medicine, Histology and Embryology, Istanbul, Turkey

Study question: Do c-Abl tyrosine kinase and mTERT catalytic subunit play an important role in a successfull gonadal development?

Summary answer: c-Abl tyrosine kinase and mTERT telomerase catalytic subunit may have curriciale role during mouse prenatal and postnatal gonadal development.

What is known already: c-Abl is a non-receptor tyrosine kinase that plays an important role including cell adhesion, cell proliferation, growth and development. Telomerase is a ribonucleoprotein complex and a part of this complex as telomerase catalytic subunit telomerase reverse transcriptase (TERT). The maintenance of telomerase activity is necessary for the survival of proliferating cells. c-Abl and mTERT have important role in regulation of telomerase function. We aimed to compare and demonstrate the localization of c-Abl tyrosine kinase and mTERT telomerase catalytic subunit during periods of known prenatal and postnatal ovary-testis development.

Study design, size, duration: Gonads were dissected from prenatal 10.5, 11.5, 12.5 and 13.5 embryonic days and dissection was performed on days determined from different mothers. Ovary and testis tissues from postnatal days 1, 3, 5 and 9 were dissected by accepting the day when the pups were born. Additionally, 12-week old adult ovary and testis were removed from female and male mice, respectively.

Participants/materials, setting, methods: Hematoxylin-eosin staining was performed to compare ovarian and testicular morphology in prenatal and postnatal developmental periods in mice. Subsequently, localization of c-Abl and mTERT were detected by immunofluorescence staining with confocal microscope. *c-Abl* and *mTERT* expressions were detected at the mRNA level by qRT-PCR.

Main results and the role of chance: The morphological evaluation was completed with hematoxylin and eosin staining and gonadal areas were detected under a light microscope. c-Abl and mTERT protein localization were observed in germ cells and somatic cells in gonads. In the embryonic 10.5, 11.5, 12.5 and 13.5 days, c-Abl and mTERT expression were observed in germ cells and follicular cells surrounding germ cells. c-Abl expression in postnatal day 1, 3, 5, and 9-day ovaries was observed in only oocyte cytoplasm while it was observed in both oocyte and granulosa cells in adult ovaries. mTERT expression was weakly observed on days 1, 3, and 5, whereas a significant increase expression was observed in granulosa cells on day 9 in testicular tissue. c-Abl immunoreactivity detected in Sertoli cells. PN 1, 3, 5 ve 9 days. c-Abl immunoreactivity seen in Leydig cells on day 5. mTERT expression was not observed on days 1 and 3 in the testes, whereas expression was observed in Sertoli cells and Leydig cells on days 5 and 9. In the adult testis, c-Abl and mTERT expression were seen in spermatid cells found in the seminiferous tubule lumen.

Limitations, reasons for caution: Additional studies related inhibition of *c-Abl* gene expression might confirm the association between c-Abl and mTERT during gonadal development.

Wider implications of the findings: Interaction between c-Abl and mTERT genes can contribute to the explanation of gonadal developmental abnormalities.

Trial registration number: not applicable.

P-220 Elective frozen over fresh blastocyst transfer highly increases pregnancy rate in patients over 35 years-old

R. Pella[1], F. Escudero[2], P. Orihuela[2], Y. Pérez[2], M. García[2], I. Zorrilla[3], P. Berrío[3], S. Romero[4]

[1]*Centro de Fertilidad y Reproducción Asistida CEFRA, Dirección de Laboratorios de Andrología y Embriología, Lima, Peru*
[2]*Centro de Fertilidad y Reproducción Asistida CEFRA, Dirección Médica, Lima, Peru*
[3]*Centro de Fertilidad y Reproducción Asistida CEFRA, Laboratorio de Embriología, Lima, Peru*
[4]*Centro de Fertilidad y Reproducción Asistida CEFRA, Dirección de Investigación, Lima, Peru*

Study question: Is elective frozen blastocyst transfer an advantageous strategy for patients of all ages?

Summary answer: Chance of pregnancy in female patients, over 35 years-old, is increased by performing frozen embryo transfer.

What is known already: Researchers have recently focused on understanding endometrial receptivity, providing tools that are meant to evidence the best moment to perform embryo transfer, however oocyte and embryo quality are key factors that are not to be disregarded.

Due to the success on embryo vitrification, discrepancy has been raised over the point of whether the strategy of freeze-all embryos and subsequent frozen embryo transfers are meant for all cases.

In this study, we analyze our data of the past 6 years, trying to provide an answer on which patients may benefit of a freeze-all policy and a subsequent frozen embryo transfer.

Study design, size, duration: This retrospective cohort study includes infertile patients aged 30 to 41 years old, without previous history of recurrent failure of ART (including recurrent miscarriages). Enrolments took place between January 2012 and December 2017 and cycles with oocyte donation were excluded. Patients were transferred with either 1) embryos from a fresh cycle (ET) or 2) embryos that were frozen in a freeze-all policy (FET).

Participants/materials, setting, methods: Only patients with transfer of 1 or 2 blastocysts were included. PGD cycles were excluded. Moreover, following a freeze-all policy, pregnancy rate of the first FETs was compared to the outcome of the ETs. Transfers of Top and/or good quality embryos were included in the study.

The number of patients complying with the inclusion criteria were: 391 patients in 403 ICSI cycles (ET); and 216 patients in 220 transfers of frozen embryos (FET).

Main results and the role of chance: Mean age of patients with ET or FET was similar (35.0 ± 3.9 years-old vs 35.7 ± 3.9; mean ± SD; respectively).

Pregnancy rate was 47.6% and 58.6% (ET and FET, respectively). Based on our own observations and what has been reported in literature, pregnancy rate, following ET, undergoes a progressive decline at 35 years-old, therefore our patient population was stratified in four age ranges (30-32, 33-35, 36-38, 39-41 years-old).

No differences between ET vs FET were observed among 30-32 and 33-35 groups (45.7% vs 60% and 58.0% vs% 58.5%, respectively). However, FET significantly increased pregnancy rate in the 36-38 group (68.5% vs 48.6%), non-significant in the 39-41 group (54.1% vs 41.7%). These contrasting results were attributed to the population size in the oldest group (n = 37 for FET).

This latter result led us to further re-stratify the population in two groups (30-35 & 36-41 years-old).

In the group 30-35, no difference was observed between ET and FET. However, pregnancy rate was significantly lower following ET vs FET for the 36-41 group (46.0% vs 62.6%, respectively) (odds ratio 1.97; 95% CI 1.19-3.27). This result translates into a 36% higher chance of pregnancy when choosing FET over ET for the 36-41 group.

Limitations, reasons for caution: Although the authors consider that the patient population is of optimal size, a detailed analysis of the stimulation protocol and hormonal values (estradiol and progesterone) during treatment, and its potential relation to the outcomes, should follow.

Wider implications of the findings: Considering the discrepancy on whether applying a freeze-all policy to all patients or not, our data suggests that elective frozen embryo over fresh transfer is advantageous for the older patient population (advanced maternal age); enhancing the chances to pregnancy in 36%.

Trial registration number: not applicable.

P-221 Spectroscopic characterization of Granulosa Cells correlates with oocyte fate

G. Gioacchini[1], V. Notarstefano[1], E. Sereni[2], C. Zaca[2], E. Giorgini[1], L. Vaccari[3], O. Carnevali[1], A. Borini[2]

[1]*Università Politecnica delle Marche, Department of Life and Environmental Sciences, Ancona, Italy*
[2]*9.baby, Family and Fertility Center, Bologna, Italy*
[3]*Elettra Syncrhotron, SISSI Beamline, Trieste, Italy*

Study question: Is it possible to outline the fate of an oocyte by analysing the corresponding granulosa cells?

Summary answer: By evaluating spectral Granulosa Cells biomarkers, here identified and validated, it is possible to outline the fate of the corresponding oocyte.

What is known already: In ART, oocyte selection is mainly based on the subjective observation of its morphological features; however, the success rate of this practice is still unsatisfactory.

Granulosa Cells (GCs) play a key role in regulating oocyte development and in maintaining the appropriate microenvironment for the acquisition of its competence. GCs produce estradiol and progesterone, together with essential nutrients for oocyte development.

Fourier Transform Infrared (FTIR) spectroscopy is a well-established vibrational technique, applied in life sciences for the study of the biomolecular building and composition of cells. Recently, FTIR was applied to evaluation of oocyte quality in several experimental models including human.

Study design, size, duration: The study has been conducted between March 2016 and September 2017 on 55 women undergoing a COH for IVF treatment at 9.baby, Bologna Italy. Inclusion criteria: age <40 years; no ovarian infertility diagnosis (only tubal, idiopathic and male infertility); regular ovulatory menstrual cycles (25-30 days) with FSH < 10 IU/l on day 3 of the menstrual cycle; sperm sample with a total motility count after treatment ≥ 300.000; number of oocytes retrieved ≥ 8; non-smokers.

Participants/materials, setting, methods: GCs from single-follicle aspirates were classified based on the clinical outcome of the corresponding oocyte: clinical pregnancy(A), fertilization failure(B), embryo development failure(C), and implantation failure(D). FTIR analysis provided a set of macromolecular data characterising GCs; then, feature selection procedures were applied to derive the spectral biomarker signature for different oocyte fates. ANOVA, PERMANOVA, Factorial Discriminant Analysis, FDA, and Canonical Analysis of Principal Coordinates, CAP statistical tools were applied to validate the identified spectral biomarker signature.

Main results and the role of chance: An innovative FTIRM-based method was developed to characterize GCs macromolecular fingerprint and to retrospectively relate this FTIR information to the corresponding oocyte clinical outcome. Several feature selection procedures ('Leave-one-out' method on FDA, Variable Characterization method, and Logistic Regression method; significance set P<0.0001) let identify 17 FTIR-biomarkers, singularly analyzed by univariate statistics and validated by multivariate tools.

ANOVA (P<0.05) analysis pinpointed that each experimental group showed specific macromolecular traits, ascribable to different biological and metabolic characteristics of GCs, and that not only the correct amount of macromolecule supplied by the GCs but also the quality could make the difference for the fate of the surrounding oocyte.

By applying multivariate tools, we validated the ability of the 17 FTIR-biomarkers to segregate GCs samples in the four experimental groups. FDA showed a clear separation along F1-axis (62.75% of discrimination) between GCs from oocytes able (A,Dgroups) or not (B,Cgroups) to develop into embryos; F2-axis (24.14% of discrimination) segregated the embryos that gave pregnancy (A) from those that failed implantation (D). The confusion matrix (total percentage of correctness = 80.25%) obtained from this analysis pinpointed that GCs from oocytes unable to develop into embryos (B,C) were better characterized than those from oocytes able to give viable embryos (A,D).

Limitations, reasons for caution: This study was conducted on a cohort of patients selected based on tight inclusion/exclusion criteria. Further analyses should also include elder women and/or presenting with ovarian infertility diagnosis.

Wider implications of the findings: The 17 identified and validated biomarkers could be the basis for the development of a data standardization system based on machine learning techniques, with the final scope to establish a reliable, non-invasive and objective tool to predict oocyte fate by analysing the biochemical composition of the surrounding GCs.

Trial registration number: Not requested as Basic Study.

P-222 Sperm derived from testicular sperm extraction is associated with differences in time-lapse morphokinetics of resulting human embryos

E. Van Marion, G. Van der Heijden, J. Speksnijder, W. Boellaard, J. Hoek, J. Laven, R. Steegers-Theunissen, E. Baart

Academisch Ziekenhuis Rotterdam, Wytemaweg 80, Rotterdam, The Netherlands

Study question: Is there a difference in developmental kinetics between embryos resulting from intracytoplasmic sperm injection (ICSI) with testicular derived sperm compared to ejaculated sperm?

Summary answer: The first cell cycle, from pronuclear appearance to disappearance, is significantly longer in embryos fertilized by testicular sperm, whereas the second cell cycle is faster.

What is known already: Embryo selection based on time-lapse morphokinetics is a promising method to improve implantation rates and time-to-pregnancy. However, morphokinetics can be influenced by culture conditions and patient characteristics. So far, little is known about the impact of the origin of the sperm cell used for fertilization on embryo morphokinetics. One earlier study showed that embryos from testicular sperm reached the 3- and 8 cell stage significantly later than embryos from epididymal sperm. Another study showed a delayed morula formation and blastocyst hatching in embryos derived from surgically retrieved sperm compared to ejaculated sperm. The clinical relevance of these observations is unclear.

Study design, size, duration: This is a retrospective study of couples (n = 299) undergoing their first intracytoplasmic sperm injection (ICSI) cycle with frozen-thawed testicular sperm (TESE-ICSI; n = 112) or fresh ejaculated sperm (normal ICSI; n = 187) between 31 January 2012 till 4 August 2017 at the Erasmus MC. A total of 798 oocytes were injected with testicular sperm and 978 oocytes with ejaculated sperm. Only transferred and cryopreserved embryos were annotated in the TESE-ICSI group (n = 310) and ICSI group (n = 496).

Participants/materials, setting, methods: All patients underwent ovarian stimulation, ICSI, TESE-ICSI and embryo transfer according to standard protocols. After injection, fertilized oocytes were cultured in the EmbryoScopeTM time lapse incubator in either Vitrolife G-series culture media (from January 2012 to 15 November 2014) or Sage 1-step (after 17 November 2014). Transfer was performed on Day 3 and embryos were frozen on Day 4. Embryos were annotated for pronuclear appearance and –fading, and for timepoints in reaching the 2-8-cell stage.

Main results and the role of chance: Significant differences were observed between the group that underwent normal ICSI vs. TESE-ICSI in female age (median age of 33.0 vs 31.6 years; p-value 0.045) and culture medium used (55.1% vs 97.3% Sage1, 44.9% vs 2.7% Vitrolife G-series; p-value <0.001). TESE-ICSI resulted in significantly less fertilized oocytes than ejaculated sperm (respectively 57% vs 75%; p-value <0.001). Implantation and live birth rates were comparable between normal ICSI and TESE-ICSI (41.2% vs 41.1% and 24.6% vs 24.1%, respectively). A linear mixed model was used to correct for clustering of embryos from one patient and for differences in age. TESE-ICSI embryos needed more time from pronuclear appearance to disappearance compared to embryos from normal ICSI (beta 0.74 h, 95% CI [-0.07 to 1.55]; p-value 0.073). These results suggest that embryos from TESE-ICSI need more time before nuclear envelope breakdown, possibly due to repair of DNA damage or changes in epigenetic profiles. Remarkably, despite the initial delay, TESE-ICSI embryos reached the six cell stage significantly earlier (beta -2.68 h, 95% CI [-4.10 to -1.25]; p-value <0.001). Also, the interval between pronuclear fading and the 3-cell stage (t3-tPNf), was shorter (-1.25 h 95% CI [-1.97 to -0.53]; p-value 0.001), an important parameter in morphokinetic selection models.

Limitations, reasons for caution: When adding culture medium to our mixed model analysis results become less significant. More research is needed on the specific effect of culture medium on morphokinetics. The testicular sperm cells were frozen, whereas the ejaculated sperm cells were fresh. However, freezing was previously not observed to have an effect.

Wider implications of the findings: Prediction models based on time-lapse annotations become a more common tool for embryo selection. In our study TESE-ICSI embryos developed significantly faster without impacting on implantation potential. However, using the previously published KIDscore Day 3 selection model would lead to significantly more unjustly discarded embryos in the TESE-ICSI group.

Trial registration number: not applicable

P-223 Importance of multinucleation at the two-cell stage on embryo development

S. Arrones[1], C. Olmedo[2], I. Martinez-Rodero[3], S. Marín[3], M. Barea[3], I. Cuevas Saiz[4]

[1]*MasVida Reproducción, Reproduction, Sevilla, Spain*

[2]Hospital General Universitario de Valencia, Medicina Reproductiva, Valencia, Spain
[3]Hospital General Universitario de Valencia, Unidad de Medicina Reproductiva, Valencia, Spain
[4]Hospital General Universitario de Valencia, Unidad de Medicina Reproductiva, Chiva, Spain

Study question: To study the impact of multinucleation at the 2-cell stage in human embryos regarding development, implantation and abortion rate.

Summary answer: In our study no correlation was found between multinucleation at two-cell stage and embryo development, implantation status or abortion.

What is known already: According to literature, multinucleation is related to aneuploidies, detrimental effect on implantation and higher abortion risk. However, time-lapse technology has shown that an important number of the cultured embryos are multinucleated at the 2-cell stage. This has led to reconsider the impact of this event in normal embryo development.

Study design, size, duration: A retrospective morphokinetical analysis of 323 Known Implantation Data (KID) embryos was performed. Analysis consisted in comparing KID and abortion relative to 2-cell stage multinucleated versus non-multinucleated embryos. Here, both clinical and biochemical abortions were considered.

Participants/materials, setting, methods: We retrospectively analyzed the implantation data of 323 embryos which were cultured at MIRI-TL® incubator with Continuous Single Culture Media (Irvine®). This analysis consisted in comparing embryo implantation and abortion rates according to whether they had multinucleation in 2-cell state. Data were analyzed by Student´s t-test using SPSS 22.0 v. statistics software.

Main results and the role of chance: From the 323 KID embryos, 76 were multinucleated at the 2-cell stage (23,5%). Among them, 26 were KID+ and 50 KID- (34,2% vs. 65,8% respectively). The other 247 embryos (76,5%), showed no multinucleation, 61 were KID+ (24,7%) and 186 were KID- (75,3%). No significant differences were found between implantation status (KID+/KID-) of multinucleated and non-multinucleated embryos. Regarding abortion, no significant statistical differences were found between multinucleated (26,9%) and no multinucleated (27,9%) 2-cell embryos.

Limitations, reasons for caution: It would be necessary to increase the number of analyzed embryos to confirm this hypothesis.

Wider implications of the findings: According to these results it is reasonable to consider multinucleation at the two-cell stage as not informative or predictive for implantation potential or abortion risk.

Trial registration number: No

P-224 Lipid and antioxidant supplements improve cryotolerance and embryonic quality of Metaphase II mouse oocytes undergoing vitrification

I. Viana[1], A. Vireque[2], P. Navarro[3]

[1]Universidade de São Paulo - Faculdade de Medicina de Ribeirão Preto, Ginecologia e Obstetrícia, Ribeirão Preto-Brazil e Semear Fertilidade
[2]Invitra - Assisted Reproduction Technology LTDA, Pesquisa e Desenvolvimento, Ribeirão Preto, Brazil
[3]Universidade de São Paulo - Faculdade de Medicina de Ribeirão Preto, Ginecologia e Obstetrícia, Ribeirão Preto, Brazil

Study question: May lipid and antioxidant added to vitrification media improve cryotolerance and embryonic quality of blastocyst originating from metaphse II (MII) mouse oocytes that underwent vitrification?

Summary answer: Short-term exposure of MII mouse oocytes to lipid and antioxidant biomolecules during vitrification safeguards blastocyst inner cell mass (ICM), which improve safety of oocyte cryopreservation.

What is known already: Clinical application of oocyte vitrification was approved only in 2013. Preservation of oocytes by vitrification had significantly higher survival rate, clinical pregnancy, and implantation rates than slow freezing. Although recently there has been a consistent improvement in efficiency of vitrification with live birth rates similar to fresh oocytes, safety remains obscure. The scientific literature anticipates that lipids, serum derivatives and antioxidants added to sperm freeze medium have improved sperm viability and pregnancy rates. However, the state-of-the-art does not yet contemplate the development of new cryoprotective media for human oocytes containing lipids and antioxidants with greater biosafety and efficacy.

Study design, size, duration: The total number of vitrified MII oocytes was 484. Three cryoprotectant formulations were investigated: Tvitri-4 (control/standard vitrification media n = 127), Tvitri-4-AX (T4-Antioxidants n = 133), Tvitri-4-LIPID-AX (T4-LIPIDS-Antioxidants n = 111) and Tvitri-4-LIPID-AX-PL (T4-LIPIDS-Antioxidants-Phospholipids n = 113). IVF was performed with oocytes surviving the thawing process: CT (191), Tvitri-4 (127), Tvitri-4-AX (129), Tvitri-4-LIPID-AX (107) and Tvitri-4-LIPID-AX-PL (109) and blastocysts rates were analyzed. ICM cells, TE (trophectoderm) and total cells were compared from a total of 20 blastocysts per group.

Participants/materials, setting, methods: Females from 8-12-week-old C57Bl/6 were submitted to superovulation with pregnant mare's serum gonadotropin and human chorionic gonadotropin (hCG) for obtaining of *in vivo* matured oocytes. The oocytes were distributed in following groups: Fresh control; Tvitri-4; Tvitri-4-AX; Tvitri-4-LIPID-AX and Tvitri-4-LIPID-AX-PL. After devitrification, oocyte survival rates were observed and in vitro fertilization was performed. Blastocyst rates and embryonic quality evaluated by ICM, TE and total cell number were compared among groups using ANOVA and Tukey's multiple comparisons.

Main results and the role of chance: The blastocyst formation rate from CT oocytes was 58%. The survival rates ($p = 0.2275$) and blastocyst rates (0.4274) of the vitrified eggs in Tvitri-4, Tvitri-4-AX, Tvitri-4-LIPID-AX, Tvitri-4-AX-LIPID-PL were 100% and 48%, 96.7 and 47.4%, 96 and 57% and 96.9 and 51.3%, respectively. The number of ICM cells, TE and total cells of the blastocysts were: CT (19.5 ± 3.48, 51.45 ± 6.56, 70.95 ± 9.63), Tvitri-4 (14.85 ± 2.28, 33.0 ± 5.78, 47.85 ± 6.76), Tvitri-4-AX (16.05 ± 4.11, 34.7 ± 8.01, 50.75 ± 11.4), Tvitri-4-LIPID-AX (17.85 ± 3.95, 34.95 ± 7.48, 52.80 ± 9.78), Tvitri-4-LIPID-AX-PL (17.80 ± 3.69, 35.6 ± 7.11, 53.4 ± 9.75). The mean number of ICM cells was similar among CT and lipid plus antioxidant-supplemented media (Tvitri-4-LIPID-AX, and Tvitri-4-LIPID-AX-PL groups) ($p>0.05$). Inversely, ICM cells of CT were higher than Tvitri-4 and Tvitri-4-AX ($p = 0.0009$). Regarding the number of TE and total cells, blastocyst from CT have better parameters than others experimental groups ($p<0.0001$).

Limitations, reasons for caution: The clinical applicability of these findings is challenged by the small sample size but positively affected by highly consistent and reproducible in vitro outcomes, with excellent survival of vitrified-thawed oocytes and blastocyst rates in a mouse model widely used in pre-clinical studies and quality control in ART laboratory.

Wider implications of the findings: Adequate lipid supplementation during vitrification seems to be crucial to embryo development of cryopreserved oocytes. The primary endpoints were concluded and reinforced the potential for efficacy and safety of the new cryoprotectant formulation containing lipid and antioxidant biomolecules, which would have clinical applicability by improving the safety of this technique.

Trial registration number: Ethics committee on the use of animals - Medical School of Ribeirão Preto - University of São Paulo - 233/2014

P-225 The proportion of immature/compromised oocytes impairs ooplasmic maturity of the mature cohort retrieved

S. Chow, A. Parrella, M. Irani, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can the performance of the retrieved mature oocytes be influenced by the fraction of immature and/or compromised cohort retrieved?

Summary answer: An increasing share of immature/compromised oocytes among the retrieved cohort may foretell embryo developmental competence and subsequent live birth rate.

What is known already: The achievement of complete oocyte maturation is a prerequisite to accomplish fertilization ability and yield conceptuses capable of implanting. The meiotic progression and ooplasmic maturity are integral events allowing the attainment of oocyte competence. While oocyte nuclear maturity is assessed by the extrusion of the first polar body, indeed ooplasmic readiness is a subtle phenomenon that has been known for some time but has still been poorly detected.

Study design, size, duration: Couples treated by ICSI between 1993 and 2017 involving young female partners (≤ 35 years old) and men with adequate semen parameters were included. Cycles were divided into four groups according to the proportion of MII oocytes at time of retrieval: *Optimal* (76-100%), *adequate* (51-75%), *partial* (26-50%), and *minimal* (0-25%). Ovarian stimulation and ICSI were performed in a standard fashion. Fertilization and pregnancy characteristics was compared between the four groups.

Participants/materials, setting, methods: The average maternal age was 31.9 ± 3 years while paternal age was 35.1 ± 5 years. A total of 8,861 ICSI cycles in which 87,029 MII oocytes were injected using ejaculated spermatozoa were included. T-test was used to compare the mean values of the number of injected oocytes. Chi-squared test was used to compare the percentages of categorical variables.

Main results and the role of chance: Cycles were allocated into the following four oocyte maturity ratio groups: *optimal (*n = 5516), *adequate* (n = 2599), *partial (*n = 635), and *minimal* maturation (n = 111). Maternal age was comparable among the four groups (31.9 ± 2, 31.9 ± 2, 32.0 ± 2, and 31.8 ± 2 years, respectively). The mean numbers of injected oocytes were 11, 8.9, 4.8, and 1.4, respectively ($P<0.0001$). The decreasing proportion of MII oocytes was associated with a significant increase of germinal vesicle (GV) from 5.5% to 48% ($P<0.0001$). The number of degenerated oocytes at time of retrieval increased from 1% to 10.3% ($P<0.0001$). Consequently, the minimal group presented the lowest rates of normal fertilization (2-pronuclei) (78.6% to 63.2%, $P<0.0001$) and corresponding highest rates of abnormal fertilization (digynic 3-pronuclei) (2.7% in the *optimal* group versus 4.3% in the *minimal* group, $P = 0.03$). The clinical pregnancy rates (52.2 to 32.0%, $P<0.0001$), and live birth rates (49.1% to 30.0%, $P<0.0001$) were also affected by the decreasing proportion of MII oocytes among the total cohort retrieved.

Limitations, reasons for caution: To control for the confounding effect of oocyte aneuploidy, this study only included young female partners. In this study, while we prove the obvious synergy between nuclear and ooplasmic maturity required for optimal outcomes, we did not provide a direct marker of the latter but only an indirect evidence.

Wider implications of the findings: This study indicates that cytoplasmic component needs to complement nuclear maturity to achieve successful ART outcomes. It provides guidance toward superovulation protocols aimed at achieving lower proportion of MI, GV, and degenerated oocytes in order to yield a higher fraction of more competent MII sibling oocytes.

Trial registration number: N/A.

P-226 Era of frozen blastocyst embryo transfer might replace that of fresh blastocyst embryo transfer—A large retrospective cohort study

W. Saab[1], V. Seshadri[1], A. Alchami[1], S. Cawood[2], C. Heath[2], R. Odia[2], B. Sowry[2], X. Vinals Gonzalez[2], P. Serhal[1]

[1]Centre for Reproductive and Genetic Health, Clinicians, London, United Kingdom
[2]Centre for Reproductive and Genetic Health, Embryologists, London, United Kingdom

Study question: Does frozen blastocyst transfer have a better clinical outcome compared to fresh blastocyst transfer in all patients undergoing IVF/ICSI treatment across all age groups?

Summary answer: This study demonstrates that frozen blastocyst on (day 5/6) compared to a fresh blastocysts transfer resulted in significantly better pregnancy outcome irrespective of age.

What is known already: Elective frozen-embryo transfer has been shown to result in a higher live-birth rate than fresh-embryo transfer among anovulatory women with the polycystic ovary syndrome. The hormonal effect of ovarian stimulation on the endometrial lining has been attributed as one of the possible causes for the lower pregnancy rates during fresh transfer in this subcategory of patients. Pregnancy and perinatal outcomes of frozen embryos have shown to have similar outcome to that of fresh in women. In addition, Day 5 blastocyst transfer result in a better pregnancy rates compared to day 6 blastocyst transfers.

Study design, size, duration: Retrospective single centre cohort study evaluating the pregnancy outcome of total of 4049 blastocyst embryo transfers (fresh and frozen D5/6) between January 2014 to December 2017, was performed. During that period 2272 frozen embryo transfers and 1777 fresh embryo transfers were done.

Participants/materials, setting, methods: Patients undergoing fresh and frozen blastocyst transfers were included. Study was conducted at a single UK centre, CRGH London. Clinical pregnancy rates were calculated for fresh day 5, fresh day 6, frozen day 5 and frozen day 6 blastocyst transfers from January 2014 to December 2017. Live birth rates for the above categories were also calculated from January 2014 to December 2016. Results were compared. SPSS version 23 was used for analysis.

Main results and the role of chance: Age was normally distributed and comparable between fresh day 5 and frozen day 5 transfer (p = 0.095). It was also comparable between fresh day 6 and frozen day 6 transfers (p = 0.622). The number of embryos transferred per cycle was significantly more in the fresh compared to the frozen embryo transfers irrespective if the blastocyst was day 5 (1.6 ± 0.5 vs 1.3 ± 0.4, p = 0.000) or day 6 (1.8 ± 0.5 vs 1.3 ± 0.48, p = 0.000) respectively. Pregnancy rates were significantly higher for frozen embryo transfers compared to fresh transfers irrespective if the blastocyst was day 5 (65.8% vs 62.9%, p = 0.048) or day 6 (48.5% vs 35.2%, p = 0.011). Similarly, better outcome was seen in the clinical pregnancy rates for frozen compared to fresh transfers. Clinical pregnancy rates for day 5 frozen vs fresh (61.8% vs 58.1 %, p = 0.027) and those for day 6 transfers (45.1% vs 34.1%, p = 0.039) irrespectively. Live birth rate was significantly higher with frozen embryos compared to fresh embryos irrespective if the blastocyst was day 5 or 6. Live birth rate for day 5 frozen vs fresh blastocyst (51.1% vs 49.2%). Live birth rates for day 6 transfer frozen vs fresh (33.8% vs 31.1%).

Limitations, reasons for caution: Embryo quality was not analysed to check if there is any difference between the grade of the frozen vs the fresh embryos which could have attributed to the better pregnancy outcome in the frozen group.

Wider implications of the findings: This is the first large prospective study to compare outcome of frozen blastocyst with fresh blastocyst transfer relating to the day of blastocyst development. The results are very reassuring suggesting a possible benefit of freeze all policy at the blastocyst stage and transfer embryos on a frozen cycle.

Trial registration number: Not applicable.

P-227 Is Day 3 (D3) Laser Assisted Hatching Better than Day 1 (D1) Laser Assisted Hatching in PGS/PGD Cycles?

V. Reddy[1], J. Dasig[1], O. Badamjav[1], Q. Zhao[1], J.H. Moon[1], Y. Qin[1], A. Masoudi[1], B. Behr[2]

[1]Lucile Packard Childrens Hospital- Stanford Fertility and Reproductive Health, Obstetrics and Gynecology, Sunnyvale, U.S.A.
[2]Stanford University, Obstetrics and Gynecology, Palo Alto, U.S.A.

Study question: The goal of this study was to evaluate whether there is a difference in the blastocyst development rate between embryos that were hatched using a laser on D1 versus D3.

Summary answer: There was no statistically significant difference in the blastocyst rate between the 2PN hatched on D1 versus cleavage stage embryos hatched on D3.

What is known already: D3 assisted hatching of some patients' embryos in non-PGS/PGD cycles is standard in embryology practice. However, due to an increase in blastocyst biopsy cycles, our lab adopted the policy to hatch on D3 to enhance the trophectoderm hatching potential on day 5 for easier biopsy.

Study design, size, duration: This study was carried out between May and October 2017 at Stanford Fertility and Reproductive Health, USA. Total of 261 2PN from 24 patients were prospectively randomized to be hatched on D1 or D3.

Participants/materials, setting, methods: Total of 130 2PN on D1 and 131 embryos on D3 were hatched using a 1460 nm, 300 mW diode laser. The hatching was performed on the outer edge of the zona pellucida using only a single 470-µs pulse. The embryos were cultured in the same single step medium from day 1 to day 6.

Main results and the role of chance: There was no significant difference in the blastocyst rates between the two groups (p > 0.05). There were a total of

123 and 122 embryos ≥5 cell grade 2 on D3 in the cohorts that were hatched on D1 and D3, respectively. Blastocyst rate was 66.9% (87 total blastocysts, with 37 on day 5) and 61% (80 total blastocysts, with 41 on day 5) with a grade ≥3BB in the D1 and D3 cohorts, respectively. Fisher's exact test with two tails was used.

Limitations, reasons for caution: This was a pilot study. IVF and ICSI were not equal as 20% 2PN that were hatched on D1 and 22% embryos that were hatched on D3 came from IVF. The study is limited to laser assisted hatching only.

Wider implications of the findings: By hatching on D1, embryos for PGS/PGD cases can be cultured uninterrupted in the incubator until the blastocyst stage to harness the full potential of single step culture media. This is especially useful for clinics that do not use time-lapse technologies.

Trial registration number: NA.

P-228 Oocytes cryoconservation and reproductive outcome: evaluation of embryo metabolomiic profiles

M. Santonastaso, F. Caprio, R. Ianniello, M.D. D' Eufemia, A. Natella, N. Colacurci

Seconda Università degli Studi di Napoli, Dpt. of Woman-Child and General and Special Surgery, Naples, Italy

Study question: Does oocyte cryopreservation change the metabolism of the embryo obtained?

Summary answer: Oocyte cryopreservation determines a greater activation of embryo metabolism.

What is known already: The oocytes vitrification is successfully applied to maximize the safety and efficacy of ovarian stimulation cycles in an IVF treatment, proving to be an effective approach also for the preserving female fertility.Oocyte vitrification showed a fertilization and implantation rates comparable to those of fresh oocytes, even if it is lack the possible effects of vitrification on metabolic status of the developed embryos. Recent data prove that the culture media of embryos that were positive or negative for successful implantation showed specific metabolomic signatures. However,there is some weak evidence that metabolomics technologies studying culture media of embryo developed from vitrified oocytes.

Study design, size, duration: Spent embryo culture media (ECM) were collected on day 3 before transfer from April 2017 to November 2017

Participants/materials, setting, methods: The control group was the ECM obtained from fresh oocyte (n = 9).The study group was composed of culture media of embryos developed from vitrified oocytes (n = 7). The oocyte vitrification-thawing was conducted in accord to the manufacturer's instructions. After the embryos were removed from the culture, the spent culture media were collected and we analyzed metabolomic profile by ^{1}H-NMR. Embryo quality was assessed by Gardner morphological classification. The data were analyzed using the unpaired Student's t-test (p-value≤0.05)

Main results and the role of chance: The IVF outcomes (fertilization, embryo quality and implantation rate) were statistically significant less in study group compared to control group. Our ^{1}H-NMR analysis evidenced that in culture media of embryos developed from vitrified oocytes the levels of formate, albumin, H-Cα lactate, H-Cβ lactate, glucose and endotoxin were lower in comparison to embryo obtained from fresh oocyte. The reduced embryo quality observed in study group can be certainly correlated to the different levels of these molecules.

Limitations, reasons for caution: Study limitation is the low number of samples analyzed.

Wider implications of the findings: Our study showed that quantitative and qualitative modifications of metabolites were linked to embryo development. We can suggest to integrate embryo analysis through the study of metabolomic parameters on culture medium. Detecting embryo with greater capacity for development and implantation will increase the oocyte cryopreservation success.

Trial registration number: None.

P-229 Can the distribution of morphokinetic parameters help predict pregnancy viability in women undergoing In-Vitro Fertilization/Single Embryo Transfer (IVF/SET)? A time lapse (TL) study

I. Souter[1], G. Christou[2], I. Dimitriadis[3], C. Sacha[4], N. Piekarski[2], J. Diemick[2], C.L. Bormann[3]

[1]Massachusetts General Hospital-Harvard Medical School, Obstetrics/Gynecology-Reproductive Endocrinology and Infertility, Dover- MA, U.S.A.
[2]Massachusetts General Hospital Fertility Center, Obstetrics/Gynecology-Reproductive Endocrinology and Infertility, Boston, U.S.A.
[3]Massachusetts General Hospital-Harvard Medical School, Obstetrics/Gynecology-Reproductive Endocrinology and Infertility, Boston, U.S.A.
[4]Massachusetts General Hospital and Brigham and Women's Hospital-Harvard Medical School, Obstetrics/Gynecology-Reproductive Endocrinology and Infertility, Boston, U.S.A.

Study question: Is there an association between the distribution of early- and/or late-morphokinetic parameters (as assessed by TL-microscopy) and pregnancy viability following IVF/SET?

Summary answer: Neither early- nor late-morphokinetic parameters predicted pregnancy viability in IVF/SET cycles. However, most embryos successfully implanting reached early blastulation within a defined time range.

What is known already: TL-monitoring is a novel tool widely used to predict an embryo's developmental and implantation potential. Several morphokinetic parameters, either static and/or interval, in early and/or late stages of embryonic development have been assessed as predictors of reproductive outcomes and appear promising. However, it remains unclear whether blastocysts resulting in successful pregnancies differ in all or some of these morphokinetic parameters from those of morphologically normal embryos that fail to implant or establish a viable pregnancy.

Study design, size, duration: Retrospective cohort of 191 women undergoing IVF/SET at a major academic center between 9/2013 and 4/2016. Women with embryos cultured to the blastocyst stage in a TL-monitored incubator and selected for fresh SET were eligible. Embryos resulting in viable pregnancies (progressing to ≥20 weeks gestation) were compared to those from unsuccessful transfers in regards to the distribution of certain early- and late-morphokinetic parameters.

Participants/materials, setting, methods: The primary outcome was time-period from pronuclei fading (tPNf) to early-blastulation (P_{SB}). Secondary outcomes were time-periods from i) tPNf to 1st-cytokinesis (P_1), ii) 2- to 3-cells (P_2), iii) 3- to 4-cells (P_3), iv) 4- to 5-cells (P_4), and v) 5- to 8-cells (P_8).

Statistics: Mann-Whitney U-, χ^2-tests, multiple logistic-regression to calculate odds ratio (OR), 95% confidence interval (95%CI) controlling for potential confounders (maternal age, body mass index (BMI), basal-FSH, fertilization method).

Main results and the role of chance: Groups did not differ in baseline characteristics (basal FSH, AMH, antral follicle counts). In 58.1% of cycles ICSI was utilized.

Following IVF/SET, 58.1% (111/191) of the patients conceived a viable pregnancy. When all embryos were included in the analysis and morphokinetic parameters from viable-pregnancies were compared to those from unsuccessful transfers in regard to P_{SB} distribution, no difference was noted [median (95% range): 68.78(59.78-77.81) vs. 69.26(59.28-79.81), p = 0.43; for viable pregnancy vs. unsuccessful SETs, respectively). Similarly, none of the remaining morphokinetic parameters' distributions differed between groups [median (95% range): 2.53(1.93-3.24) vs. 2.50(1.83-3.34), p = 0.42; 10.97 (2.94-12.67) vs. 10.97(2.11-13.40), p = 0.81; 0.69(0.00-8.51) vs. 0.58(0.00-8.32) hours, p = 0.18; 11.62(0.68-14.81) vs. 11.58(2.20-14.71), p = 0.72; and 4.34(0.83-18.55) vs. 4.67(1.28-15.93) hours, p = 0.71] for P_1, P_2, P_3, P_4 and P_8, respectively].

However, for the vast majority (80%) of embryos resulting in viable pregnancies, the time to reach early blastulation ranged between 61.96-75.72 hours. When P_{SB} remained in that range, the odds of a viable pregnancy were increased by 166% overP_{SB} durations slower or faster than that [adjusted OR (95%CI): 2.66 (1.17, 6.04); p = 0.02]. No other time period affected the odds of achieving a viable pregnancy.

Limitations, reasons for caution: The study was limited by its retrospective design. Moreover, only morphokinetic parameters thought to predict blastocyst formation were studied and algorithms taking into consideration standard morphologic criteria and/or genetic composition of embryo were not included.

Wider implications of the findings: Among women undergoing IVF/SET, no single morphokinetic parameter predicted pregnancy. However, the odds for a viable pregnancy were significantly higher among embryos that reached early blastulation within a defined time range. Additional studies taking into consideration morphologic criteria and ploidy status are needed to develop algorithms helpful in embryo selection.

Trial registration number: Not applicable.

P-230 Simple embryo selection for vitrified-warmed blastocyst transfer cycles: blastocyst derived from 4-cell embryo at 40-42 hours after insemination has the potential to improve clinical outcomes

J.H. Cha, J.W. Lee, S.H. Shin, Y.J. Kim, S.K. Lee, H.J. Cha, J.H. Kim, D.H. Kim, E.H. Kang, J.H. Ahn, H.Y. Kim, K.A. Pak, J.S. Yoon, S.Y. Park

Agaon Fertility Clinic, IVF center, Seoul, Korea- South

Study question: Does blastocyst derived from 4-cell embryo at 40-42 hours after insemination (Bla-4c) has the potential to improve clinical outcomes in vitrified-warmed blastocyst transfer cycles?

Summary answer: Bla-4c has significantly higher clinical outcomes compared to the blastocyst derived from non-4-cell embryo at 40-42 hours after insemination (Bla-n4c).

What is known already: The number of cells is the morphological marker strongly associated with implantation potential. Optimal results are achieved when 4-cell embryos are transferred on day 2. Implantation potential decreases when the number of cells is other than four. Developments of extended embryo culture and cryopreservation techniques have allowed IVF programs to offer patients the chances of embryo transfer without ovum-pick-up.

Study design, size, duration: A total of 880 vitrified-warmed blastocyst transfer cycles were retrospectively analyzed from June 2014 to September 2017. The cycles with frozen sperm, surgical retrieved sperm, genetic diagnosis, oocyte donation, poor responder, and advanced maternal age (≥38 years) were excluded.

Participants/materials, setting, methods: Cycles were divided into 2 groups based on the origin of blastocyst (Bla-4c, n = 336 vs. Bla-n4c, n = 544). 4-cell stage embryos were separated from non-4-cell stage embryos at 40-42 hours after insemination and culture them to blastocyst stage. Vitrification was performed for cryopreservation of blastocyst. The quality of warmed blastocyst was evaluated by Gardner and Schoolcraft's classification. The number of embryos transferred was less than or equal to two.

Main results and the role of chance: There were no differences between Bla-4c and Bla-n4c regarding female age (33.1 ± 2.3 vs. 33.4 ± 2.5, p = 0.136), the number of embryos transferred (1.5 ± 0.5 vs. 1.5 ± 0.5, p = 0.499), and abortion rate (14.4% vs. 18.5%, p = 0.354). However, Bla-4c achieved significantly higher rates of survival (99.2% vs. 97.5%, p = 0.022), good quality (≥BB) embryos (66.1% vs. 47.1%, p = 0.000), biochemical pregnancy (47.9% vs. 41.0%, p = 0.044), clinical pregnancy (39.3% vs. 28.9%, p = 0.001), ongoing pregnancy (33.6% vs. 23.5%, p = 0.001), and implantation (31.5% vs. 24.1%, p = 0.004) than those of Bla-n4c.

Limitations, reasons for caution: This study was based on static observation. The assessment of 4-cell embryo development was done at given time point (40-42 hours after insemination). Further studies are required prospectively to confirm our findings with respect to the rates of live birth outcomes.

Wider implications of the findings: Pre-selection of 4-cell embryo at 40-42 hours after insemination can eliminate inappropriately developed embryo and increase the chance to transfer appropriately developed embryos to the patients. Bla-4c has the potential to improve clinical outcomes in vitrified-warmed blastocyst transfer cycles.

Trial registration number: not applicable.

P-231 Non-invasive biomarkers for embryo quality in sterile patients

I. Martínez Rodero[1], J. Marí-Alexandre[2], J.M. Moreno-Moya[3], S. Marín-Real[1], M. Barea[1], C. Olmedo-Illueca[1], I. Cuevas-Sáiz[1]

[1]Hospital General de València, Reproductive Medicine Unit, Valencia, Spain
[2]Health Research Institute La Fe, Unit of Hemostasia- Thrombosis- Atherosclerosis and Vascular Biology-, Valencia, Spain
[3]Oslo University Hospital, Reproductive Department, Oslo, Norway

Study question: To improve reproductive prognosis in sterile patients subjected to IVF, especially in endometriosis, by means of measuring miRNAs in CCs (Cumulus Cells) through quantitative RT-PCR.

Summary answer: For the first time, miRNAs expression has been measured in CCs endometriosis patients, where snU6 has been found downregulated compared to control group.

What is known already: Considering the need of selecting embryos with the highest implantation potential, morphological selection could be improved with the use of new methodologies. Among them, cumulus cells transcriptomics is a less invasive technique, since the analysis is not performed to the embryo but to cells removed prior to ICSI procedure. To our knowledge, there is no previous study of miRNAs expression in CCs of endometriosis patients. However, there are previous results of CCs miRNA profile sequencing. To notice is report by Tong et al., who using RNA-seq and validation by RT-qPCR identified hsa-miR-16-5p, hsa-miR-26a-5p and hsa-miR-101-3p in CCs.

Study design, size, duration: This preliminary work retrospectively analyzed miRNA expression of single-oocyte CCs from 34 patients undergoing ICSI and single embryo transfer, from 2015 until 2016. Exclusion criteria were Polycystic Ovary Syndrome, severe male factor and patients without Known Implantation Data (KID). Only CCs corresponding to the transferred embryo were included. Four clinical groups were defined according to endometriosis and KID. Control group was KID+ without endometriosis.

Participants/materials, setting, methods: From 34 total patients, 6 suffered from endometriosis and 28 did not. From endometriosis, 2 were KID+ and 4 KID-. From non-endometriosis group, 15 were KID+ (control group) and 13 KID-. The expression of 6 miRNA plus presumptive normalizer (snU6) was measured in CCs by rt-qPCR: hsa-miR-101-5p, hsa-miR-223-5p, hsa-miR-16-5p, hsa-miR-26b-5p, hsa-miR-124-3p, hsa-miR-335-5p. They were measured from microdrops where CCs were contained when total RNA was isolated. RefFinder software was used to select normalizer.

Main results and the role of chance: miRNAs of study were quantified below detection limit in blank culture media where CCs had been collected and stored, so they did not interfere in our results. 4 miRNAs and snU6 were successfully detected, while 2 did not (miRNA-101-5p and miRNA-124-3p). RefFinder output pointed at miR-26b-5p as better normalizer than snU6. The robustness of miR-26b-5p expression in our samples could be liked to its target, which is a cell cycle gene. When comparing miRNAs fold-change values between KID+ and KID- groups, no statistical differences were found. However, when we compared miRNAs expression data in endometriosis vs. non-endometriosis patients, snU6 was statistically significant ($p<0,05$). Allegra and colleagues are the unique reference of CCs transcriptome in endometriosis context, where they found genes related to inflammation, such as TNF-α, down-regulated in endometriosis. Interestingly, snU6 serum levels have been significantly correlated with established serum markers of inflammation, such as TNF-α, suggesting snU6 is specifically downregulated in inflammatory diseases (Benz et al., 2013). Surprisingly, in our study snU6 levels were lower in CCs of endometriosis patients, pointing that snU6 is also downregulated here. In line with that, exacerbated inflammation has been postulated to play an important role in endometriosis (Stilley et al., 2012).

Limitations, reasons for caution: Among limitations is reduced sample size. This is a frequent situation in IVF units performing less than 500 cycles per year, since samples are considerable reduced when non-KID cases are discarded. Another limitation is the methodology for selecting miRNAs of study.

Wider implications of the findings: For future insights, we consider using single-cell technology in CCs with a larger number of patients, including endometriosis. It is important to continue trying to improve reproductive chances of

these type of patients. Also, it would be interesting to validate miR-26-5p as normalizer gene for RT-qPCR in CCs.

Trial registration number: not-applicable

P-232 Single embryo transfers in frozen-thawed cycles may help to lower twin pregnancies and complications when compared to double embryo transfers without compromising outcomes

H.K. Yelke, Y. Kumtepe Colakoglu, C. Pirkevi Cetinkaya, S. Kahraman

Istanbul Memorial Hospital, Assisted Reproductive Technologies and Reproductive Genetics Center, Istanbul, Turkey

Study question: Is the cumulative live birth rate of subsequent frozen-thawed cycles similar to that of double embryo transfers?

Summary answer: The cumulative pregnancy rate of patients with a potential OHSS risk is not compromised when good or top-quality blastocysts are transferred in FET cycles.

What is known already: IVF success has generally been measured based on live birth rates after a single episode of treatment resulting in the transfer of a first fresh or frozen thawed embryo. This fails to capture the real chance of having a baby after a number of complete cycles-each involving the replacement of remaining frozen-thawed embryos. Therefore, cumulative rate of live birth is more important since it better summarizes the chance of a live birth over an entire treatment period.

Study design, size, duration: This retrospective cohort study includes patients whose blastocysts were "all-frozen" between January 2015 and January 2016. The cumulative pregnancy rate was calculated for all patients whose live birth data was available until October 2017. For comparison, a patient group under 35 who have received a double blastocyst in a FET cycle in the same period were included in the analysis.

Participants/materials, setting, methods: The cumulative pregnancy rate was calculated by dividing the total number of births by the number of fresh cycles. The mean female age in the elective single embryo transfer (eSET; n = 486) group and in the double embryo transfer (DET; n = 457) group was 29.7 and 30.3, respectively.

Main results and the role of chance: The live birth data was available for 427 out of 486 patients who came to our clinic for a FET cycle and whose blastocysts were frozen because of a potential OHSS risk. 45.2% of first FET cycles (n = 193) resulted in a live birth. From the patients who did not get pregnant in their first FET and came for a second FET (n = 225) 39 resulted in a live birth (17.3%). When outcomes were calculated cumulatively, with a relative increase of 20.1%, the cumulative live birth rate of the eSET group has been calculated as 54.3%. The live birth rate of the DET group which has been transferred in the same period, was 55.1%. The statistical comparison of the live births of both groups gives a non-significant p value. Moreover, the multiple pregnancy rate was 1.2% and 38.5% in the cumulative eSET and DET groups, respectively ($p<0.0001$). When term pregnancies were analyzed, 84% of singleton pregnancies were found to be delivered after the 37th week of pregnancy whereas only 29.4% of twin pregnancies achieved term ($p<0.0001$).

Limitations, reasons for caution: Cumulative pregnancy outcomes are calculated as the number of pregnancies per initiated cycle, therefore the rate vary depending on patients who come forward to use their remaining frozen embryos over time.

Wider implications of the findings: In recent years, improvements in laboratory conditions and embryo-endometrium synchronization have resulted in higher pregnancy rates with the transfer of blastocyst-stage embryos in FET cycles. Therefore, a cumulative eSET strategy is advisable with the additional benefit of reducing multiple pregnancy risks and consequently neonatal complications.

Trial registration number: Not applicable.

P-234 Can assisted reproduction technologies decide unintentionally the sex of the babies?

C. Olmedo Illueca, I. Cuevas Saiz, I. Martíinez Rodero, S. Marín Real

Hospital General Universitario de Valencia, Reproductive Medicine Unit, Valencia, Spain

Study question: The main objective is evaluating the possible effect of assisted reproductive technologies (ARTs) on the sex ratio of the offspring.

Summary answer: We found statistical significance in sex ratio when transferring embryos at blastocyst stage, while there is no correlation when embryos are transferred at cleavage stage.

What is known already: Sex ratio calculated as male proportion is 1.7 times higher than female under natural conception. However, at birth, this sex ratio diminishes to 1.05 caused by abortion and other reasons. Under in vitro conditions this proportion could be modified. Studies using preimplantation genetic diagnosis (PGD) shown sex ratio at cleavage stage embryos is lower than those at blastocyst stage. In addition, sex ratio at birth was significantly higher in IVF compared to ICSI embryos. Recently, a group of researchers found correlation between male's BMI during treatment and higher probability of giving male singletons.

Study design, size, duration: This retrospective study included all live birth from IVF cycles between 2005 and 2017. During this period 399 babies were born from IVF or ICSI fresh and frozen cycles.

Participants/materials, setting, methods: A total of 333 patients were included in our study. All the analysis was carried out with Statistical Package for the Social Science software (SPSS version 21.0). Pearson χ^2 test was used to compare the distribution of categorical variables in different groups. We compare sex ratio at birth with the day of embryo transfer (Cleavage-stage or blastocyst-stage) in singletons and twins, the ART employed (conventional IVF or ICSI) and embryos from fresh or frozen cycle.

Main results and the role of chance: When we compare the sex ratio with the day of embryo transfer we found statistically significant differences towards the males when we transfer the embryos at blastocyst stage (2.57). At cleavage-stage the ratio at birth is maintained at 1.08 towards males, very similar to natural conditions (1.05). However, we did not find any association between sex ratio and ART employed nor the fresh/ frozen groups.

Our results suggested that the day of embryo transfer is directly related with the sex ratio at birth towards males. Blastocyst embryos are selected because male embryos grow faster than female embryos. Furthermore, there is a higher mortality in female embryos that may be caused by inactivation of one of the X chromosomes. Our findings agree to other investigators results. The transfer of Blastocyst-stage embryos seems to be directly related with sex ratio at birth both singletons and twins.

Limitations, reasons for caution: This study had also limitations. The number of cases included in IVF group is lower than ICSI group. Furthermore, we do not know if our twins are monozygotic or dizygotic twins.

Wider implications of the findings: Since ARTs landscape is increasingly moving to day 5 transfer, this result should be considered, so we could be unintentionally selecting embryos towards male children. In that line, blastocyst selection criteria may be revised.

Trial registration number: Not applicable.

P-235 Exploring the use of mid-infrared spectroscopy to detect development and implantation biomarkers in spent culture media of human embryos

J. Sousa Emídio dos Santos[1], C. Calado[2], L. Ramalhete[2], M. Gallardo[1], L. Montero[1], A. Braula[1]

[1]*Malo Clinic - Ginemed, IVF unit, Lisbon, Portugal*
[2]*ISEL, Instituto Superior de Engenharia de Lisboa-, Lisbon, Portugal*

Study question: Can the mid-infrared spectra of spent embryo culture media predict the ability of an embryo to develop into blastocyst and implant?

Summary answer: Distinct spectra features have been observed in the metabolomic profile of media of embryos that developed into good quality blastocyst compared to those that arrested.

What is known already: There is great interest in detecting a biomarker with enough sensitivity and specificity to predict embryo development and implantation potential in order to select the best embryo from a cohort, for a single embryo transfer, reducing time to pregnancy and the economic and psychological burden of unsuccessful attempts. Approaches like single metabolite quantification by mean of high performance liquid chromatography and less

informative near-infrared spectroscopy haven't provided a reliable predictor. Mid-infrared spectroscopy is a powerful tool that provides richer spectra.

Study design, size, duration: Spent embryo culture media from embryos undergoing extended culture to the blastocyst stage was collected, frozen and subsequently used for the mid-infrared spectroscopy (MIR) analysis. A cohort of 101 embryos were analyzed in this pilot study. Data regarding embryo quality and development was collected retrospectively.

Participants/materials, setting, methods: Embryos were cultured from day 1-3 in 30 microliters drops of sequential media (G1Plus, Vitrolife, Sweden), with an oil overlay, at 37 °C, 6% CO_2, 5% O_2, and 90% humidity. Embryos were transferred to another culture dish by careful and individual pipetting and the media was collected within an hour and frozen at -20 °C. Sample processing and optimization of MIR spectral acquisition conditions, quality control indicators (ICQ) as the signal to noise ratio.

Main results and the role of chance: The processed MIR spectrum (e.g. the 2nd derivative) was analyzed and retrospectively evaluated for its association with embryo quality and development to blastocyst and embryo implantation. The high specificity and sensitivity of the technique is evidenced by statistically significant differences of diverse ratios of spectral bands between spent culture of embryos that developed poorly with those that produced good quality blastocysts.

Limitations, reasons for caution: The potential confounding factor of variables that can influence the analysis outcome, such as media type, volume of the culture drops, culture conditions, among others, has to be identified.

Wider implications of the findings: The informative MIR spectra shows potential to be used as a predictor of embryo development to blastocyst stage, and eventually, for the selection of the fittest embryo with highest implantation potential within a cohort.

Trial registration number: not applicable.

P-236 Increased anti-oxidative capacity of follicular fluid HDL is a positive predictor of embryo quality in modified natural cycle IVF

R. Nagy[1], A. Van Moontfoort[2], H. Groen[3], I. Homminga[2], D. Andrei[4], R. Mistry[4], J. Anderson[4], A. Hoek[2], U. Tietge[4]

[1]*University Medical Center Groningen, Pediatrics and Obstetrics & Gynecology, Groningen, The Netherlands*
[2]*University Medical Center Groningen, Obstetrics & Gynecology, Groningen, The Netherlands*
[3]*University Medical Center Groningen, Epidemiology, Groningen, The Netherlands*
[4]*University Medical Center Groningen, Pediatrics, Groningen, The Netherlands*

Study question: Is anti-oxidative function of follicular fluid (FF) high density lipoproteins (HDL) associated with embryo quality in modified natural cycle in vitro fertilization (MNC-IVF)?

Summary answer: A higher FF-HDL anti-oxidative function is associated with increased development of a top quality embryo on day two after fertilization.

What is known already: HDL are the main cholesterol carriers in FF. Thus far, FF-HDL have been mainly studied in the context of steroid hormone synthesis.

Study design, size, duration: For the present cross sectional study, between August 2013 and April 2017 FF and plasma samples were collected during 561 consecutive MNC-IVF cycles of 249 consenting patients in a single academic infertility treatment center.

Participants/materials, setting, methods: The anti-oxidative function of HDL, measured as the capacity to prevent native LDL oxidation in vitro, was determined in (i) 19 matched plasma and FF samples from randomly selected patients and (ii) FF from 375 MNC-IVF cycles, where one oocyte was retrieved and minimum FF blood contamination was present. The association between HDL anti-oxidative function and oocyte and embryo quality as well as occurrence of a viable pregnancy were assessed statistically by general estimating equations.

Main results and the role of chance: The anti-oxidative function of FF-HDL was significantly higher than that of matching plasma-HDL (84 [79.2-87.1] versus 67.2 [63.8-70.1]; p <0.001); more than 80% of the total FF anti-oxidative capacity was attributable to the presence of HDL. A higher FF-HDL anti-oxidative function was associated with higher odds of development of top quality embryos, association that persisted after adjustment for BMI and smoking (OR 2.04, 95%CI 1.18-3.53, p = 0.011). However, the anti-oxidative function of FF-HDL was not associated with the occurrence of an ongoing pregnancy.

Limitations, reasons for caution: The present study did not find an association between the anti-oxidative function of FF-HDL and ongoing pregnancy, possibly as a consequence of low power. Only patients from a single center participated.

Wider implications of the findings: More research on the oxidative stress/anti-oxidant balance of FF in relation to oocyte development and fertility outcomes is warranted. Further, definition of lifestyle interventions to increase the anti-oxidative capacity of FF-HDL holds potential to increase the success rates of IVF procedures and of natural conceptions.

Trial registration number: Nederlands Trial Register number NTR4409.

P-237 Cleavage stage versus blastocyst stage embryo transfer in oocyte donation cycles

G. Kontopoulos[1], P. Psathas[2], C. Dimitropoulos[2], I. Vasilopoulos[2], S. Grigorakis[2], T. Mantzavinos[2], E. Dedoulis[2], K. Agapitou[2], N. Vlahos[1]

[1]*Institute of Life- National Kapodestrian University of Athens, Institute for Life ART unit -Iaso Maternity Hospital, Athens, Greece*
[2]*Institute of Life, Institute for Life ART unit -Iaso Maternity Hospital, Athens, Greece*

Study question: Is there a difference in implantation and clinical pregnancy rates between day 3 cleavage stage and day 5 or blastocyst stage embryo transfer in frozen-thaw oocyte donation cycles.

Summary answer: Embryo transfers on day 5 are associated with significant improvement on implantation and clinical pregnancy rates in oocyte donation cycles.

What is known already: During the last few years a shift has occurred for transfer of embryos at the blastocyst stage. It has been shown that embryo transfer at the blastocyst stage following COH /ET has been associated with improved implantation rates and clinical pregnancy rates as compared to cleavage stage transfers. So far, there is no study evaluating this notion in oocyte donation cycles.

Study design, size, duration: This is a retrospective evaluation of all transfers performed after oocyte donation in our center during the period between January 2017 to December 2017. Oocyte donors is a unique populations in terms that they represent a good prognosis group, more homogeneous as compared to infertile patients. The study was approved by the ethics committee of the IASO maternity hospital and the scientific board of the IOLIFE fertility center.

Participants/materials, setting, methods: 303 oocyte donation cycles performed. From January 2017 to December 2017.

Donor ovarian stimulation was performed using a short GnRHantagonist protocol with rFSH. ICSI was performed in all donors. All embryos were cryopreserved either on cleavage or blastocyst stage.

Recipient endometrial preparation was standardized. Progesterone was initiated 3days prior to cleavage stage embryo transfers and 5-6 days prior to blastocyst stage transfers.Statistical analysis was done using SPSS, v25. A p value < 0.05 was considered significant.

Main results and the role of chance: Three hundred and one (301) frozen-thaw transfers from oocyte donation cycles where finally included in the study. There were 171 day 3 transfers out of which there were 92 clinical pregnancies (53.8%). In 123 day 5 transfers there were 75 clinical pregnancies (60.9%) In 7 day 6 transfers ,4 clinical pregnancies were reported (57%).

Overall there was no difference between the two groups in terms of the age of the donors, day 2 FSH, antral follicle count, number of MII oocytes and number of good quality embryos. There was no difference between the groups in terms of type of catheter use and documented difficulty during the transfer. Embryo transfers performed on day 3 were compared to transfers performed on blastocyst stage in terms of clinical and ongoing pregnancy rates. Day 5 and day 6 transfers were evaluated in the same group. Overall embryo transfers at the blastocyst stage were associated with significantly improved pregnancy rates

(60.7%) as compared to cleavage stage transfers (53,8%) p = 0.012. The risk of multiple pregnancies (mainly twins) was similar in the two groups (data not shown)

Limitations, reasons for caution: There is no complete information on the obstetrical outcome on a significant proportion of those pregnancies.

Wider implications of the findings: These findings suggest that in oocyte donation cycles embryo transfer at the blastocyst stage is associated with a significant improvement in pregnancy rates and should be adopted as a standard practice.

Trial registration number: Not applicable.

P-238 Can metabolomics provide information about blastocyst development?

I. Cuevas-Sáiz[1], C. Olmedo-Illueca[1], S. Marín-Real[1], I. Martínez-Rodero[1], S. Arrones[2], M. Barea[1]

[1]*Hospital General Universitario de Valencia, Reproductive Medicine Unit, Valencia, Spain*
[2]*MASVIDA Reproduccion- Sevilla, IVF laboratory, Sevilla, Spain*

Study question: Is blastocyst´s culture media metabolic profile correlated with other embryo selection criteria?

Summary answer: Metabolic profile is not correlated to implantation, nor to women's age or morfokinetic parameters but may be linked with expansion degree and cryoresistance of blastocyst.

What is known already: With the aim of improving Assisted Reproductive Techniques (ARTs) outcome, new methods for embryo selection have appeared in the last few years. One of them is metabolomics of embryo culture media. Up to now, metabolic profile is not able to predict clinical outcome, so there is controversy about its applicability to clinical context. Nevertheless, it is true that metabolomics provide valuable information about embryo metabolism. It has been demonstrated that embryo at blastocyst stage changes its metabolism to glycolysis, which generates lactate. Furthermore, lipids metabolism has been studied in other animal species, and it has been related to cryoresistance.

Study design, size, duration: This study included 48 blastocysts from 38 patients, whose transfer ended in Know Implantation Data (KID). All patients performed an IVF treatment with fresh transfer at the blastocyst stage between September of 2016 until March of 2017.

Participants/materials, setting, methods: Embryos culture media (Continuous Single Complete, Irvine) were stored after transfer in day 5 was performed. All embryos were cultured in MIRI-TL (ESCO- Medical Ò) incubator, so that morphokinetical data was available for study. Culture media was analysed by Magnetic Nuclear Resonance (MNR). Spectrum obtained were processed and analysed by Principal Component Analysis (PCA) and Partial Least Squares Regression (PLS-DA) using MATLAB. T-student test was performed using SPSS 15.0 v and significance was set as 0,05.

Main results and the role of chance: The 48 spectrum of culture media were significative separated in two groups based on its composition. More specifically, three regions of spectrum: lactate region (0.075 ± 0.003 in group 1 vs 0.05 ± 0.01 in group 2), lipids HDL+LDL+VLDL region (0.15 ± 0.03 in group 1 vs 0.72 ± 0.30 in group 2) and mobile lipids (0.09 ± 0.03 in group 1 vs. 0.82 ± 0.40 in group 2). Although the difference was not significant, blastocyst from group 1 tended to be more expanded than blastocyst from group 2 (p-value>0,05). No correlation was found between the two groups and KID, nor with patient's age and morphokinetic parameters (p-values>0,05).

With these results, metabolic profile of embryos cultured until blastocyst stage may not be related with implantation status. Nevertheless, two groups of blastocysts were differentiated in terms of its metabolism, particularly in lactate and lipids content of their culture media. This differentiation is independent from patient's age and morphokinetic parameters measured until day 5.

Limitations, reasons for caution: To confirm these preliminary results, it would be necessary to increase the number of culture media samples.

Wider implications of the findings: Metabolic differences found could be linked with grade of blastocyst expansion. Lactate differences between two groups refer to glucose intake in glycolysis, since results indicate there is more lactate production in more expanded blastocyst. Furthermore, we found less lipid content in more expanded blastocyst, which could be related to cryoresistance.

Trial registration number: Not applicable

POSTER VIEWING

Endometriosis, endometrium and fallopian tube, and benign disorders of the endometrium and fallopian tube

P-239 Preimplantation genetic screening in endometriosis and non-endometriosis patients in a single institution

S.J. Chon[1], B.H. Yun[2], Y.S. Jung[3], Y.J. Cho[1], S.Y. Jung[1]

[1]*Gil Hospital, Obstetrics and Gynecology, Incheon-si, Korea- South*
[2]*Severance Hospital, Obstetrics and Gynecology, Seoul, Korea- South*
[3]*Wonju Severance Hospital, Obstetrics and Gynecology, Wonju, Korea- South*

Study question: Is there any difference in between prevalence of aneuploidy embryos in endometriosis and non-endometriosis patients using preimplantation genetic screening?

Summary answer: No.

What is known already: Endometriosis is defined as the presence of endometrial tissue outside the uterine cavity and it leads to chronic inflammation with oxidative stress, and genetic variations which eventually decrease pregnancy rates and live birth rates. Among these various factors, meiotic spindle alterations have been reported disturbing on chromosomal segregation and organization in endometriosis patients which could cause aneuploidy. As ART increases striving for higher pregnancy rate, it is believed that majority of aneuploidy embryos might cause lower live birth rates. Therefore people were recommended for PGS patients who are considered to be at high risk of having aneuploidy embryos.

Study design, size, duration: Cross sectional study.

Retrospective chart reviews.

Patients who have undergone IVF and PGS from August, 2014 to July, 2017.

PGS was recommended to couples who have at least one of these criteria; woman's age ≥37 years old, ≥ one parent has chromosomal mosaicism, spontaneous abortion ≥ 2 times, implantation failure ≥ 2 times.

Patients who were diagnosed with endometriosis were 19 people and who were not diagnosed with endometriosis were 93 people.

Participants/materials, setting, methods: Eighty two embryos from 19 patients with endometriosis and 371 embryos from 93 non-endometriosis women were enrolled. All of them were indicated for IVF with PGS. A cleavage-stage embryo biopsy was performed on Day 3 of embryo development by extruding one blastomere from embryos reaching at least the six-cell stage, and samples were taken for analysis on the same day.

Main results and the role of chance: Aneuploidy rates in between the two groups according to age groups in both endometriosis and non-endometriosis groups consistently tended to increase when they were calculated according to embryos. Among patients less than 35 years old, the aneuploidy rates were 52.6 %, 72.9 %, and among patients equal to greater than 41 years old, the aneuploidy rates were 89.6 %, 87.7 % in both endometriosis and non-endometriosis groups.

We saw whether age, abnormal karyotype, history of recurrent pregnancy loss, history of recurrent implantation failure, serum AMH, number of retrieved oocytes have significant impact on abnormal PGS. Among these factors, other than history of recurrent pregnancy loss and number of retrieved oocytes, they were significantly related to aneuploidy embryos that they were set for confounding factors and associations in between presence of endometriosis and aneuploidy embryos were re-analyzed. Presence of endometriosis was not significantly associated with abnormal PGS result (Exp(B) = 0.766, 95% CI = 0.401-1.465, *P*-value = 0.420).

Limitations, reasons for caution: The number of cases of endometriosis was small and endometriosis stages are missing. Also, we cannot say non-endometriosis patients do not have endometriosis. Lastly, PGS was done in

blastocyst staged embryos that we cannot say that abnormal chromosomal segregation and organization of embryos were thoroughly analyzed.

Wider implications of the findings: Although the sample size is small, we certainly are sure that the results of this study would be meaningful in recognizing that the aneuploidy rates in between the endometriosis and non-endometriosis groups are not much different in certain groups of Korean population.

Trial registration number: not applicable.

P-240 Factors affect the outcome of IVF and the recurrence of the endometrial disease of patients with atypical endometrial hyperplasia (AEH) and early well-differentiated endometrial adenocarcinoma (EC)

H. Li, X. Song, R. Li, J. Qiao

Peking University Third Hospital, Department of Obstetrics and Gynecology-Reproductive Medical Center, Beijing, China

Study question: When to initiate IVF is safe and effective for patients with atypical endometrium hyperplasia(AEH) and early well-differentiated endometrial adenocarcinoma (EC) after fertility-sparing treatment?

Summary answer: It is safe and effective to start IVF immediately after achieving first complete response (CR) for patients with AEH and early EC.

What is known already: The available data support the relative safety and efficacy of progestin therapy and allow fertility-sparing patients to achieve their fertility goals in a short window of disease resolution.More and more women with AEH and EC after fertility-sparing treatment have to receive IVF treatment. Although some literatures report that IVF is safe to these patients, the number of the cases is small. The factors that affect the outcome of IVF and the recurrence of the disease are still not clear.

Study design, size, duration: A total of 60 patients with AEH and early well-differentiated EC after fertility-sparing treatment were included. All these patients received IVF treatment in Reproductive medical center of Third hospital,Peking university between May 2011 and May 2017. Data of the results was retrospectively analysis.

Participants/materials, setting, methods: According to the time to start IVF after the first time to CR, 60 patients were divided into within 3 months (group A) and after 3 months (group B).The implantation rate, clinical pregnancy rate,spontaneous abortion rate and recurrence rate were compared between the two groups.

Main results and the role of chance: A total of 60 patients were included, 45 with AEH and 15 with EC. The follow-up time from the first CR was 39.6 ± 26.9 months. Ninety-five ovum pickup cycles were performed. There were 67 fresh embryo transfer cycles and 54 FET cycles. A total of 36 patients achieved 47 pregnancies, and 25 patients gave 32 babies. The pregnancy rate per cycle in fresh cycle was 38.8%(26/67),and the pregnancy rate per cycle in FET cycle was 25.93%(14/54). The pregnancy rate of fresh cycles in Group A and B was 39.1% and 38.6%, respectively(P = 0.969).In FET cycles,the pregnancy rate was 50% and 24% in Group A and B,respectively (P = 0.583). The total recurrence rate was 30% (18/60) during the follow-up period. It was significantly higher in the group B than the group A (17.1% vs 48%, P = 0.022).

Limitations, reasons for caution: This study is nonrandomized,as the proportion of such patients in IVF is low, and the number of cases was relatively small, so some statistical results may be limited by the smal sample size.

Wider implications of the findings: From the results of the paper, the recurrence of the endometrial disease is associated with the initiation of IVF after the first CR, and the outcome of IVF is not related to the starting time of IVF. It is recommended that IVF should be started as soon as possible.

Trial registration number: none.

P-240 Factors affect the outcome of IVF and the recurrence of the endometrial disease of patients with atypical endometrial hyperplasia (AEH) and early well-differentiated endometrial adenocarcinoma(EC)

H. Li, X. Song, R. Li, J. Qiao

Peking University Third Hospital, Department of Obstetrics and Gynecology-Reproductive Medical Center, Beijing, China

P-241 Chronic endometritis: Prevalence using hysteroscopy and CD138 immunohistochemistry and impact on reproductive outcome in patients with previous IVF/ICSI failure

S. Anis Hebisha[1], N. Mashaly[2], N. Elbadawy[3]

[1]*Faculty of Medicine-Alexandria University, OBGYN, Alexandria, Egypt*
[2]*Faculty of Medicine-Alexandria University, Pathology, Alexandria, Egypt*
[3]*Research Institute- Alexandria University, Pathology, Alexandria, Egypt*

Study question: To evaluate the prevalence of CE in women with previous IVF/ICSI failure using hysteroscopy and CD138 immunohistochemistry and whether subsequent antibiotic treatment positively impacts implantation.

Summary answer: In women with previous IVF/ICSI failure the diagnosis and treatment of chronic endometritis CE, significantly improves implantation and pregnancy rates in subsequent attempts.

What is known already: A healthy receptive endometrium is essential for embryo implantation.Recently, the relationship between chronic endometritis (CE) and infertility-related conditions such as previous implantation failure has emerged as an area of inquiry. CE is diagnosed by endometrial biopsy, and the presence of plasma cells in the endometrial stroma is the generally accepted histological diagnostic criterion for CE.Recently, an immunohistochemical (IHC) stain capable of detecting CD38 and CD138 plasma cellspecific surface antigens was introduced for the confirmation of the presence of plasma cells inside the endometrium.The hysteroscopic evaluation of endometrial inflammatory disease showed a good sensitivity for detecting CE.

Study design, size, duration: Design: prospective cohort study.

145 women aged between 25 and 38 years with history of previous IVF/ICSI failure included in the study during three years.

Participants/materials, setting, methods: women underwent hysteroscopy and endometrial sampling for CD138 immunohistochemistry. Women diagnosed with CE were treated with antibiotics until follicular phase biopsy showed no CE. Patients were placed in two groups based on presence or absence of CE (group A and B, respectively). Primary outcome was sensitivity, specificity and accuracy of hysteroscopy in relation to immunohistochemistry (as a gold standard) in diagnosis of CE. Secondary outcomes were implantation and pregnancy rates in the post-treatment IVF/ICSI attempt.

Main results and the role of chance: Primary outcome was sensitivity, specificity and accuracy of hysteroscopy in relation to immunohistochemistry (as a gold standard) in diagnosis of CE. Secondary outcomes were implantation and pregnancy rates in the post-treatment IVF/ICSI attempt.

Prevalence of CE was 23.4% (34/145) using hysteroscopy and 19.3% (28/145) using immunohistochemistry (golden standard) showing 78.6%, 89.7%, and 87.5% sensitivity, specificity and accuracy respectively.

Implantation rate in subsequent cycles was significantly higher in group A vs. B (35.16% vs 16.43%, $p = 0.001$*). Group A also showed higher pregnancy rate compared to group B (57.14% vs 34.18%, $p = 0.076$*).

Limitations, reasons for caution: larger number of study cases is needed.

Wider implications of the findings: In women with previous IVF/ICSI failure the diagnosis and treatment of CE significantly improves implantation and pregnancy rates in subsequent attempts therefor hysteroscopy and endometrial sampling should be considered in evaluation of the endometrium in infertile women and specially before starting assisted reproductive technique ART.

Study question: Can pain and brain activation be observed in cynomolgus macaques with endometriosis?

Summary answer: Macaques with endometriosis demonstrate marked abdominopelvic pressure hypersensitivity and thalamic and insula activation, which were reduced with morphine and dienogest treatment.

What is known already: The mechanism of abdominopelvic pain associated with endometriosis is poorly understood, as reflected by the lack of effective treatments that offer significant pain relief for endometriosis patients. While more preclinical studies are needed, one potential barrier to translating preclinical findings to clinical application is that rodents, a species with a reproductive system that is distinct from that of humans, are most frequently used as the species to model clinical endometriosis. By contrast, the cynomolgus macaque is anatomically and phylogenetically closer to humans than rodents.

Study design, size, duration: This was an observational, preclinical study utilizing cynomolgus macaques (Macaca fascicularis) diagnosed with naturally occurring endometriosis. During abdominal pressure pain assessment, macaques were restrained and awake and during brain imaging, macaques were anesthetized with propofol. Following acute dosing with morphine, meloxicam and acetaminophen, macaques were treated for eight weeks with dienogest.

Participants/materials, setting, methods: Five macaques with endometriosis (10-18 yo) and three healthy controls (10 yo) were used. Responsiveness to pressure in the abdominopelvic area was measured using a pressure algometer and the effects of morphine, meloxicam, acetaminophen and dienogest on pressure sensitivity were determined. Non-noxious abdominopelvic pressure-induced brain activation was visualized with functional magnetic resonance imaging (fMRI; 3.0 T MRI Signa HDxt (GE)) and the effects of drug treatment on brain activation were observed with fMRI.

Main results and the role of chance: Macaques with endometriosis displayed significantly decreased abdominopelvic pressure thresholds compared to healthy macaques ($P < 0.05$), suggestive of pressure hypersensitivity. Morphine ($P < 0.05$) but not meloxicam or acetaminophen acutely ameliorated pressure hypersensitivity. Dienogest treatment ameliorated pressure hypersensitivity beginning on the second week of treatment ($P < 0.05$) which persisted for at least four weeks following termination of dienogest treatment ($P < 0.01$). Abdominal pressure also induced bilateral activation of the insular cortex and thalamus, which was reduced with an acute dose of morphine and eight weeks of dienogest treatment. Interestingly, while the mean endometrioma volume tended to decrease over time in dienogest-treated macaques, this was not statistically significant compared to the pre-treatment volume ($P = 0.09$).

Limitations, reasons for caution: The current study utilized a small sample size with possibly differing stages of endometriosis for each macaque. Whether it is possible to measure 'spontaneous pain" in the macaques with endometriosis, whether through behavior or brain activity, has yet to be determined.

Wider implications of the findings: The current macaque findings suggest that endometriosis patients could have significant pain-related brain activation. If so, then brain activation in the macaque could be utilized as a preclinical biomarker against which to develop treatments that not only reduce symptoms but modify the underlying disease.

Trial registration number: N/A.

P-243 Antifertility effectiveness of a novel copper-containing intrauterine device material and its influence on the endometrial environment in rats

S. Hu[1], W. Xia[1], C. Zhu[1], Q. Yu[2]

[1]Family Planning Research Institute- Tongji Medical College, Huazhong University of Science and Technology, Wuhan- Hubei, China
[2]Reproductive Medicine Center- Tongji Medical College-Tongji Hospital, Huazhong University of Science and Technology, Wuhan- Hubei, China

Study question: This study was designed to investigate the antifertility effectiveness of a novel copper-containing intrauterine device (Cu-IUDs) material and its effect on the endometrial environment in rats.

Summary answer: This study demonstrates that micro-Cu/LDPE/MVQ exhibits satisfactory contraceptive efficacy and causes fewer side effects than Cu.

What is known already: Cu-IUDs have excellent contraceptive efficacy, the existing Cu-IUDs are associated with undesirable side effects, such as menorrhagia, intermenstrual bleeding, pelvic pain, and spotting.

Study design, size, duration: One hundred sixty healthy female rats were randomly divided into four groups of 40 each: (a) a sham-operated control group (SO group); (b) the Cu/LDPE/MVQ group; (c) the LDPE/MVQ group; and (d) the Cu group.

Participants/materials, setting, methods: Twenty rats in each group were mated with male rats of proven fertility, from 30 days after insertion, and the antifertility rates (ATs) were observed at Day 12 of pregnancy. The pathological changes and factors associated with bleeding, pain, and inflammation in the endometrium of the remaining rats in each group were then investigated 90 days after insertion, and the surface condition of the implants was analyzed 90 days after insertion.

Main results and the role of chance: The contraceptive effectiveness was 100% in both the bulk Cu group and the micro-Cu/LDPE/MVQ group, and that in the LDPE/MVQ group was 30%. On day 90 after insertion, histopathological observation and the ultrastructural changes of the endometrium showed that the damage caused by bulk Cu was much more severe than that caused by the Cu/LDPE/MVQ microcomposite and that the surface of the Cu/LDPE/MVQ microcomposite was much smoother than that of the bulk Cu. Furthermore, compared with the sham-operated control group, the

concentrations of tissue plasminogen activator and prostaglandin E2 were significantly increased 90 days after insertion in all experimental groups except for the LDPE/MVQ group ($P < 0.05$), and the parameters in the Cu/LDPE/MVQ group were significantly lower than those in the Cu group ($P < 0.05$). In addition, the expression levels of matrix metalloproteinase 9, tissue inhibitor of metalloproteinase 1, plasminogen inhibitor 1, CD34, vascular endothelial growth factor, substance P, and substance P receptor in the endometrium in all experimental groups were significantly lower than those in the Cu group 90 days after insertion ($P < 0.05$).

Limitations, reasons for caution: We chose rats for the antifertility effectiveness and safety. We did not use other animals to show that the novel copper-containing composite are the most promising materials.

Wider implications of the findings: The micro-Cu/LDPE/MVQ may be useful in intrauterine contraceptive devices.

Trial registration number: not applicable.

P-244 Impact of long term pretreatment with GnRH agonist before standard GnRH agonist protocol for IVF/ICSI on cumulative live birth rates of infertile women with adenomyosis

M.H. Chen, W. Qiong, G. Jun, L. Lu, Z. YIngying, Z. Canquan

The First Affiliated Hospital of Sun Yat-sen University, Reproductive medicine center, Guangzhou-Guangdong, China

Study question: Can long term pretreatment with GnRH agonist before standard GnRH agonist protocol improve cumulative live birth rates (CLBRs) for infertile women diagnosed as adenomyosis compared with standard agonist protocol alone?

Summary answer: CLBRs per IVF/ICSI ovarian stimulation cycle were lower in long term GnRH agonist pretreatment group than without pretreatment group for infertile women with adenomyosis.

What is known already: GnRH agonist can cause hypoestrogenism therefore reduce uterine size in adenomyosis. Long term use of GnRH agonist is shown to improve pregnancy outcomes in women with adenomyosis in frozen embryo transfer cycle. However, it is unknown whether long term pretreatment with GnRH agonist before standard GnRH agonist protocol for IVF/ICSI can improve CLBRs of infertile women with adenomyosis.

Study design, size, duration: This is a retrospective cohort study; A total of 232 ovarian stimulation cycles and 201 women diagnosed as adenomyosis who underwent ovarian stimulation for IVF/ICSI with standard GnRH agonist protocol with or without long term GnRH agonist pretreatment at our hospital from January 2010 to March 2017 were identified and reviewed.

Participants/materials, setting, methods: Infertile women with adenomyosis who attempted ovarian stimulation for IVF or ICSI were categorized into two groups (standard GnRH agonist protocol with or without long term pretreatment with GnRH agonist). CLBR was defined as the first live birth per ovarian stimulation cycle including fresh and frozen cycles and evaluated by group. Binary logistic regression was used to assess the association between controlled ovarian hyperstimulation (COH) protocol and cumulative live birth after adjusting for confounding factors.

Main results and the role of chance: Oocyte retrieval was cancelled in 14 cycles. Baseline characteristics including female and male age, female BMI, gravidity and times of previous miscarriage, basal FSH, proportion of patients complicated with endometriosis as well as insemination method were similar in the two groups. Stimulation outcome including number of retrieved oocytes and mature oocytes, number of transferred embryos, high quality embryos and frozen embryos were similar in the two groups. Cumulative live birth rates were lower in standard GnRH agonist protocol with long term GnRH agonist pretreatment than without pretreatment (32.4% vs 46.6%, $P = 0.044$). The CLBRs is associated with female age (OR 0.923, 95% CI 0.852-0.994, $P = 0.035$), standard GnRH agonist protocol without long term pretreatment (OR 2.299, 95% CI 1.124-4.705, $P = 0.023$) and number of high quality embryos (OR 1.833, 95% CI 1.508-2.227, $P<0.001$) after adjusted for basal FSH, proportion of patients complicated with endometriosis.

Limitations, reasons for caution: As a retrospective study, our analysis depended on previously recorded data; therefore, certain variables such as serum CA125 level could not be collected.

Wider implications of the findings: Long term pretreatment of GnRH agonist may be not necessary for infertile women with adenomyosis who undergo IVF/ICSI with standard GnRH agonist protocol.

Trial registration number: not applicable.

P-245 Adenomyosis down regulates endometrial L-selectin ligands at the mid-secretory phase during menstrual cycle

F.W. Chang[1], T.H. Lai[2,3,4], J.J. Lin[3,5], Q.D. Ling[4,5]

[1]Department of Obstetrics and Gynecology, Tri-Service General Hospital, National Defense Medical Center
[2]Department of Obstetrics and Gynecology, Cathay General Hospital, Taipei, Taiwan
[3]Fu Jen Catholic University School of Medicine, New Taipei City, Taiwan
[4]Institute of Systems Biology and Bioinformatics, National Central University, Taoyuan City, Taiwan
[5]Cathay Medical Research Institute, Cathay General Hospital, New Taipei City, Taiwan

Study question: Does adenomyosis impair L-selectin ligand (LSL) expression in human endometrium?

Summary answer: Adenomyosis decreases LSL expression in the luminal epithelium of the endometria at the mid-secretory phase during the menstrual cycle.

What is known already: The relationship between adenomyosis and infertility is still unclear, but severe adenomyosis has a negative impact on pregnancy rate in clinical observation. One of the possible pathophysiology is impaired endometrial receptivity. LSL is a biomarker for endometrial receptivity. Defects in LSL expression leading to implantation failure were reported in women with endometriosis, PCOS and unexplained infertility. However, LSL expression in adenomyosis is still unknown.

Study design, size, duration: This is a retrospective, experimental study. Forty-two endometrial samples from reproductive-aged women with adenomyosis underwent hysterectomy were obtained at Cathay General Hospital, Taipei, Taiwan from Aug 2008 to July 2009. Twelve samples were collected from the proliferative phase, 10 from the early-secretory phase, 9 from the mid-secretory phase, and 11 from the late-secretory phase. Another 11 endometrial samples were collected from menopausal women as controls.

Participants/materials, setting, methods: The inclusion criteria of the participants were: (1) $35 < age < 50$ years; (2) regular menstrual cycle; (3) $BMI < 28$; (4) no hormone therapy at least 2 months before surgery; (5) no known endometrial pathologies. Immunohistochemistry with MECA-79 Ab, western blotting and RT-PCR were performed to evaluate LSL expression. The intensity of immunostaining was analyzed by HSCORE. Non-parametric Kruskal-Wallis one-way analysis of variance with multiple comparisons was performed to examine differences among phases.

Main results and the role of chance: In luminal epithelium, MECA-79 reactivity increased from the proliferative to late-secretory phase but decreased at the mid-secretory phase. The mean HSCOREs among the proliferative, early-secretory and late-secretory phase were significant differences ($P<0.05$). Five LSL genes were detected in adenomyotic endometria: PODXL, EMCN, CD300LG, GLYCAM1, and CD34. The mRNA expression of LSL genes occurred differentially among phases. Especially, PODXL differed significantly among phases ($P<0.05$). Comparison with the mRNA expression in the proliferative and mid-secretory phase, all the LSL genes totally increased in the mid-secretory phase then that in the proliferative phase. The mRNA expressions of CHST2 and CHST4 genes, which involved in the generation of LSL epitopes and LSL activity, were expressed without significant differences among phases.

Limitations, reasons for caution: The small number of samples could limit the power of the study. The heterogeneity of the samples could impact the results. Finally, because of ethical considerations, normal endometrial samples cannot be obtained from healthy women as controls.

Wider implications of the findings: Adenomyosis may cause abnormalities in the production of LSL, which may contribute to impaired endometrial receptivity and implantation failure. Further studies via in vitro and in vivo are required to determine the mechanisms related to the decrease of LSL expression in adenomyosis.

Trial registration number: None.

P-246 Defecation associated (dys)functions after surgical resection of (recto)sigmoid infiltration by deep infiltrating endometriosis

A. Al-Saidi[1], E.R. Klinkert[2], H.S. Hofker[1], M. Trzpis[1], P.M.A. Broens[1]

[1]University Medical Center Groningen, Surgery, Groningen, The Netherlands
[2]University Medical Center Groningen, Obstetrics & Gynaecology, Groningen, The Netherlands

Study question: Do the defecation associated outcomes in patients after surgical resection of (recto)sigmoid infiltration due to Deep Infiltrating Endometriosis (DIE) resemble the outcomes of healthy women?

Summary answer: Constipation, fecal incontinence (FI), Irritable Bowel Syndrome (IBS) and their symptoms have a significantly higher prevalence in patients after (recto)sigmoid resection of DIE than healthy women.

What is known already: Patients with DIE are known to experience fecal problems, such as constipation and FI. It is also known that patients with DIE tend to have more IBS related problems and hypertonia of the pelvic floor muscles. Further, vaginal delivery is known to influence fecal problems. (Recto)sigmoid resection performed for DIE has been reported to improve the defecation associated outcomes.

Study design, size, duration: For this cross-sectional study we included 181 adult women who had been treated with a (recto)sigmoid resection for DIE between January 2005 and December 2015. Of these women 132 filled in the questionnaire. The data of the control group, i.e. 680 women from the general Dutch population, were collected in 2015, and we used them retrospectively. Patients and controls with comorbidities which are known to influence defecation and fecal continence were excluded (n = 2 and n = 119 respectively). Afterwards, 130 patients were age-matched with female controls from the Dutch population in a 1:2 ratio. The afore described steps resulted in a data base which consisted of 130 patients and 260 controls.

Participants/materials, setting, methods: All patients and controls completed the validated Groningen Defecation and Fecal Continence questionnaire (DeFeC). Constipation, FI and IBS were defined according to the Rome IV criteria.

Main results and the role of chance: The prevalence of constipation, FI and IBS in the patients was significantly higher than in the control group (50.8% versus 26.2%, p<0.001, 15.4% versus 5.0%, p = 0.001, and 14.6% versus 5.4%, p = 0.002, respectively). Patients also used laxatives and other forms of conservative treatment more often (OR = 2.780, p<0.001). In addition, constipated patients experienced the co-existence of FI more often than their healthy counterparts (9.2% versus 1.5%, p<0.001). Surprisingly, women who have had less vaginal deliveries did suffer more from FI (p = 0.011). Furthermore, multivariate analysis showed that women who underwent (recto)sigmoid resection for DIE were more likely to be constipated or fecally incontinent (respectively p<0.001 and p = 0.002), independently of history of vaginal birth.

Limitations, reasons for caution: In this cross-sectional study we included only patients who had already undergone surgery; the occurrence of these symptoms before surgery is therefore unknown. Moreover, functional tests could indicate the pathophysiological factors behind the increased fecal problems.

Wider implications of the findings: The prevalence of fecal problems is significantly higher in patients who underwent (recto)sigmoid resection for DIE than in healthy controls. Further research is important to improve the complaints of patients.

Trial registration number: METc 2014/516

P-247 The human fallopian tube vs endometrium: can differences in function and steroid hormone receptor expression be explained by differential hormone responsiveness?

A. Maclean, E. Bunni, S. Makrydima, A. Withington, J. Drury, D. Hapangama

University of Liverpool- Liverpool Women's Hospital- Crown Street- Liverpool- L8 7SS, Centre for Women's Health Research, Liverpool, United Kingdom

Study question: Are there spatial and temporal differences in cellular proliferation and steroid hormone receptor expression in the human fallopian tube (FT), as there are in the endometrium?

Summary answer: The premenopausal FT does not show cyclical changes in cellular proliferation, with a similar steroid hormone receptor expression pattern to the quiescent postmenopausal endometrium.

What is known already: The human FT epithelium exists as a continuum of the endometrium. Both tissues share the same embryological origin. The endometrium is widely accepted as the main target organ for the ovarian steroid hormones, and undergoes a well-described monthly cycle of proliferation, differentiation, shedding, and regeneration throughout a woman's reproductive life. Hormonal regulation is exerted through the cognate ovarian steroid hormone receptors (ERa, ERb, PR, and AR), which are expressed in endometrial cells. Although the steroid hormone dependent cyclical changes are well described in the endometrium, the effect of the same hormones on the FT epithelium has not been comprehensively studied.

Study design, size, duration: A prospective observational study, analysing matched full thickness human endometrial and FT samples, from 38 healthy women undergoing hysterectomy for benign conditions, including 28 samples from premenopausal women, and 10 from postmenopausal women. Full thickness samples were obtained to allow investigation of the three compartments of the endometrium: the luminal epithelium, the functionalis, and the basalis. The FT samples were taken from both the isthmic and the fimbrial areas.

Participants/materials, setting, methods: Matched endometrium and FT samples were analysed by immunohistochemistry, for proliferative marker Ki-67, and steroid hormone receptors AR and PR (n = 38). Gene expression of AR and PR was examined by qPCR in matched endometrial and FT samples (n = 5). Primary human endometrial and FT epithelial cells were treated with E2 and DHT in short term cultures, and the expression of Ki-67, AR, and PR analysed by IHC and qPCR (n = 7).

Main results and the role of chance: The FT displayed low levels of proliferation throughout the menstrual cycle in all compartments, whereas the premenopausal endometrium was highly proliferative, particularly the functionalis (p = 0.03).

Interestingly, AR expression was high in the FT, and was weak in the matched premenopausal endometrium (p = 0.004). There was no significant difference in AR expression between the FT and the postmenopausal endometrium. PR expression in the FT and endometrium was not significantly different. AR and PR expression showed no correlation in the FT.

As both AR and PR are thought to be regulated by oestrogen in the endometrium, the matched FT and endometrial cell cultures with E2 and DHT in vitro, to explore the steroid hormone receptor response to ovarian hormones. In the FT, E2 treatment increased AR protein expression in the glands, and increased AR mRNA expression. There was no effect of E2 treatment on PR expression in the FT. DHT treatment increased protein AR expression in the FT glandular epithelium, and increased AR mRNA expression in the FT. There was no effect of DHT treatment on PR protein expression in the FT or endometrium, but there was an increase in PR mRNA expression in the FT.

Limitations, reasons for caution: This is a descriptive study with short-term culture of primary human endometrial and tubal epithelial cells in vitro, with a small sample size of matched endometrium and FT samples.

Wider implications of the findings: The FT does not undergo cyclical proliferation, and shares similarities in steroid hormone receptor expression with the postmenopausal endometrium. These findings contribute towards understanding the physiology of the FT. Further research in this area will enable research into disorders of the FT, such as ectopic pregnancy, infertility, and FT cancer.

Trial registration number: This work was funded by the ITM/Department of Women's Health at the University of Liverpool. All authors have to declare.

P-248 Comparison of IVF results in cases of severe endometriosis: after or without previous surgery

M. Camus[1], A.S. Gremeau[2], C. Valdeyron[2], L. Dejou-Bouillet[2], N. Bourdel[2], F. Brugnon[3], M. Canis[2], J.L. Pouly[2]

[1]CHU Estaing, ob gyn, Clermont-Ferrand - France, France
[2]CHU Estaing, ob gyn, Clermont-Ferrand, France
[3]CHU Estaing, Clinical Biology, Clermont-Ferrand, France

Study question: Does surgery before in-vitro fertilization (IVF) improve the results of assisted reproductive technologies (ART) in patients with severe endometriosis?

Summary answer: There is evidence that IVF without previous surgical treatment results in a decreased delivery rate per cycle and per patient.

What is known already: Whether to operate severe endometriosis or not to improve ART results remains a debate. There is still no international consensus about the management of infertile patients with severe endometriosis. A recent french study demonstrated among a 110 patients cohort that IVF results were lower without previous surgery. But some others studies provided opposite conclusions.

Study design, size, duration: A 190 patients cohort was analysed (retrospective analysis on prospective recorded datas). All patients presented severe endometriosis with rectovaginal nodule and/or multiple endometriomas and/or major adhesions. The decision to operate or to move directly to IVF was taken by trained laparoscopic surgeons according to the expected chance of pregnancy after surgery and the potential risk of surgery.

Participants/materials, setting, methods: We could include 41 patients in the no surgery group (group NS) and 149 patients in the surgery group (group SU). All data were prospectively recorded. Main outcomes were clinical delivery rates per cycle (fresh+frozen transfers) and crude and actuarial cumulative rates to obtain the first delivery. A complementary analysis was done for attempts to obtain a second delivery. All outcomes are provided in terms of delivery.

Main results and the role of chance: The delivery rate per attempt to obtain the first child was 18.6 % in group NS versus 28.6 % in the group SU ($p = 0.051$).

The crude delivery rates after 5 attempts were respectively 43.9 % versus 54.4 % ($p = 0.23$).

The actuarial delivery rates after 5 attempts were respectively 52.2 % and 71.3 % ($p = 0.021$).

The delivery rate per attempt to obtain a second child was 75 % in the NS group versus 32.3 % in the SU group ($p = 0.09$).

A step by step analysis of IVF results among the attempts to obtain the first delivery shows a difference in defavour of the non operated group for the risk to collect no oocyte (10.3 % versus 4.6 %- $p = 0.003$), the mean number of oocytes (5.8 versus 7.4 – $p<0.008$) and the risk for miscarriage (35 % versus 17% -$p = 0.04$).

Limitations, reasons for caution: Retrospective study, subjective decision to operate or not and unicentric study.

Wider implications of the findings: This study suggests that operating severe endometriosis improves IFV results. On the other hand, if surgery is considered to be too risky, first-line IVF results seem to be acceptable. Surgery should thus be the first step because it is the only way to judge on operability.

Trial registration number: No object.

P-249 Aberrant ER stress induction in response to progesterone enhances endometriotic stromal cell invasiveness

D. Choi[1], J. Choi[1], M. Jo[2], E. Lee[1], D.Y. Lee[1]

[1]*Sungkyun Kwan University Samsung Medical Center, Dept. of Ob/Gyn, Seoul, Korea- South*

[2]*Samsung Biochemical Research Institute, Center for Clinical Research, Seoul, Korea-South*

Study question: Whether endoplasmic reticulum (ER) stress is involved in the regulation of human endometrial cell invasiveness through AKT/mTOR pathway, and is this associated with the altered invasiveness in endometriotic cells?

Summary answer: Abnormal ER stress induction in response to progesterone was observed in endometriotic stromal cells, which led to the alteration of invasiveness via AKT/mTOR pathway.

What is known already: ER stress is a common cellular stress response, which is known to reduce invasiveness in some cell types including ovarian and breast cancer cells through inhibiting AKT/mTOR pathway. Recent studies have shown that ER stress is suppressed by estrogen in human endometrial cells, which suggests that estrogen may promote **endometrial cell invasiveness** by down-regulating ER stress. Therefore, aberrant ER stress in response to progesterone may contribute to the altered invasiveness found in endometriotic tissues.

Study design, size, duration: Normal endometrial stromal cells (NESCs) and endometriotic cyst stromal cells (ECSCs) were cultured with tunicamycin to induce ER stress. To evaluate the effects of estrogen and progesterone on ER stress, AKT/mTOR pathway and invasion, NESCs and ECSCs were cultured with estrogen and/or progesterone. In addition, to evaluate the cycle-dependent induction of ER stress and invasion, normal endometrial and endometriotic tissues were collected according to menstrual cycle.

Participants/materials, setting, methods: The expression level of glucose-regulated protein 78 (GRP78) was measured by Western blot to evaluate ER stress induction. As ER stress-mediated C/EBP homologous protein (CHOP)/tribbles homologue 3 (TRIB3) pathway is a negative regulator of AKT, CHOP and TRIB3 expression was measured to evaluate the effects of ER stress on AKT/mTOR pathway. In addition, cell invasiveness was evaluated by measuring the expression of invasion associated proteins (MMP2 and MMP9) and by performing invasion assay.

Main results and the role of chance: The expression levels of GRP78, CHOP and TRIB3 protein were markedly increased in NESCs treated with tunicamycin compared with control cells, which was accompanied by decreased AKT, mTOR activity and cellular invasiveness. Similarly, progesterone treatment significantly increased CRP78, CHOP, TRIB3 expression in NESCs. Subsequently, cellular invasiveness decreased through the inhibition of AKT and mTOR activity. This progesterone-induced decrease in cellular invasiveness was reversed by the inhibition of ER stress using either mifepristone (progesterone receptor modulator) or salubrinal (ER stress inhibitor). These results suggest that progesterone increases ER stress, which then is directly involved in regulation of NESC invasion. In contrast, progesterone had no significant effects on CRP78, CHOP, TRIB3 expression, AKT, mTOR activity and cellular invasiveness in ECSCs. Furthermore, in contrast to normal eutopic endometrium, endometriotic tissues showed constant CHOP, TRIB3, MMP2 and MMP9 expression throughout the menstrual cycle.

Limitations, reasons for caution: Only primary human endometrial and endometriotic stromal cell cultures were used in this study.

Wider implications of the findings: Our results reveal new insights into the pathogenesis of ovarian endometriotic cyst, and it may also allow the development of new therapeutic strategies based on the modulation of endometriotic cell invasiveness.

Trial registration number: not applicable.

P-250 The new strategy of dydrogesterone protocol as progestin primed ovarian stimulation is effective for patients with ovarian endometriosis undergoing in vitro fertilization

N. Iwami, H. Kamiya, N. HIrayama, Y. Kobayashi, M. Kawamata, N. Ozawa, T. Yamamoto, E. Watanabe, O. Moriwaka

Kamiya Ladies Clinic, Center of reproduction, Sapporo, Japan

Study question: Is dydrogesterone (DYG) regimen as progestin primed ovarian stimulation (PPOS) effective for patients with endometriosis during controlled ovarian stimulation(COS), compared to GnRH antagonist protocol?

Summary answer: Higher number of oocytes could be retrieved in DYG protocol than in GnRH antagonist protocol. The pregnancy rates were comparable between the two groups.

What is known already: A Large number of women with endometriosis eventually seek IVF/ ICSI to achieve pregnancy, but endometriosis is an estrogen-dependent chronic inflammatory condition that affects the pregnancy rate compared to women with other causes of infertility.Some progestin have been used for endometriosis therapy for more than 40 years, the use of progesterone may improve the embryo quality of women with endometriosis. Recently, PPOS using DYG was reported as very convenient regimen for patients during COS.

Study design, size, duration: This was prospective controlled study of 133 women with endometriosis (aged <41) undergoing COS for IVF/ICSI and frozen embryo transfer (FET) at our private infertility clinic from June 2016 through

October 2017. The patients were allocated alternately into two groups, one with DYG protocol (n = 68) and the other with GnRH antagonist protocol (n = 65).

Participants/materials, setting, methods: In DYG protocol, dydrogesterone (20 mg/day) was administered simultaneously with HMG (150-225IU) beginning on day 2 or 3. Ovulation was triggered with GnRH agonist and HCG (1000IU) when the leading follicle matured. All high quality embryos were cryopreserved for later transfer. The primary outcome measure was the number of retrieved oocytes. The secondary measure was the clinical pregnancy rate. Statistical analysis was performed using unpaired t-test and chi-square contingency.

Main results and the role of chance: Patient characteristics: the age, body mass index, basal hormone profile, duration of infertility, and AMH level were similar in the two groups. None of the patients experienced a premature LH surge in both groups. No significant difference was found between the two groups for the HMG dose and the stimulation duration of HMG. In DYG group, the number (mean±SD) of retrieved oocytes (10.71 ± 6.97 vs. 7.45 ± 4.71, P<0.01), and the number of mature oocytes (8.68 ± 5.74 vs. 6.18 ± 4.12, P<0.01) were significantly higher than in GnRH antagonist group. Other parameters such as fertilization rate, viable embryo rate, and the cycle cancellation rate due to no viable embryos were similar (P> 0.05). During the follow-up period of FET, a total of 120 patients completed 182 FET cycles, and single embryo transfer was performed in 93.6% of the patients. No significant difference was found in the clinical pregnancy rate (DYG group; 43.3% vs. GnRH antagonist group; 38.8%, P = 0.541), respectively (difference 4.48%; 95% confidence interval (CI): -9.86 – 18.8%), and ongoing pregnancy rate (DYG group; 38.1% vs. GnRH antagonist group; 31.8%, P = 0.369), respectively (difference 6.38%; 95% CI: -7.52 – 20.3%).

Limitations, reasons for caution: Patients affected of all stage of endometriosis have been included and the number of patients was small, because of single-center setting. A large sample size is needed to draw a firm conclusion.

Wider implications of the findings: This study shows that DYG regimen is feasible to improve the number of oocyte collected, and DYG has the advantages of oral administration, user convenience and cost reduction, so possibly providing a new choice for women with endometriosis undergoing IVF/ICSI treatment in combination with FET.

Trial registration number: Not applicable.

P-251 The expression of microRNA in uterine leiomyoma cell: submucosal versus subserosal leiomyoma

Y.J. Kim[1], Y.Y. Kim[2], S.Y. Ku[2], S.M. Lee[1], J.H. Shin[1], T. Kim[3], J. Y. Hur[1]

[1]Korea University Guro Hospital, Obstetrics & Gynecology, Seoul, Korea- South
[2]College of Medicine- Seoul National University, Departments of Obstetrics and Gynecology, Seoul, Korea- South
[3]Korea University Anam Hospital, Obstetrics & Gynecology, Seoul, Korea- South

Study question: To compare the expression of microRNA (miR)s in leiomyoma cells according to their location in the uterus.

Summary answer: The expression profile of miR in leiomyoma cells was different according to their location in the uterus.

What is known already: The expression profile of miR in uterine leiomyoma cells is different from that of normal uterine myometrial cell. Although the impact of uterine leiomyoma on uterine receptivity to embryos has been known to vary according to their location in the uterus, the difference of miR expression in submucosal versus subserosal leiomyoma cells is still rare known.

Study design, size, duration: To analysis of expression of miR and target gene, 18 of matched sample of leiomyoma and myometrium tissue were obtained from 9 of women with subserosal leiomyoma and 9 of women with submucosal leiomyoma by pelviscopic myomectomy.

Participants/materials, setting, methods: The relative expressions of miRs related leiomyoma and the candidate target genes in leiomyoma cells were compared to the related myometrial cells by RT-PCR. The target gene expression was analyzed after in vitro culture of leiomyoma cells with transfection of miR analogues. All experiments were repeated more than 3 times with more than 3 different portion of samples.

Main results and the role of chance: The relative expressions of miR-29 (0.633-fold, P = 0.031) in leiomyoma cells were downregulated compared to the myometrial cells and the relative expressions of estrogen receptor β (2.121-fold, P<0.001) and matrix metalloproteinase-1 (1.923-fold, P<0.001) were upregulated in leiomyoma cells compared to myometrial cells. After transfection with mimic of miR-29 into leiomyoma cells in-vitro-cultured, the expression of estrogen receptor β and matrix metalloproteinase-1 were downregulated (0.215-fold and 0.105-fold, P<0.001 in all). After transfection with mimic and inhibitor of miR-29 into leiomyoma cells in-vitro-cultured, the expression of estrogen receptor β and matrix metalloproteinase-1 were down- (0.215-fold and 0.105-fold, P<0.001 in all) and up-regulated (8.354-fold and 4.721-fold, P<0.001 in all). The expressions of miR-29 in submucosal leiomyoma relative to myometrium was upregulated compared to the subserosal leiomyoma relative to myometrium (1.213 ± 0.562 vs. 0.412 ± 0.214, P<0.001). The expression of estrogen receptor β (1.515 ± 0.467 vs. 2.124 ± 0.870, P = 0.041) and matrix metalloproteinase-1 (1.484 ± 0.230 vs. 2.221 ± 1.021, P = 0.021) in submucosal leiomyoma cells were downregulated compared to subserosal leiomyoma cells.

Limitations, reasons for caution: To fully understanding the regulatory roles of miRs on leiomyoma growth, further extended study with the other miRs related to leiomyoma should be necessary.

Wider implications of the findings: The difference in profiles of miR expression between submucosal and subserosal leiomyoma may implicate that miRs relate the growth of leiomyoma to alter the biomechanics of the uterus.

Trial registration number: Not available/This study was supported by grants of Ministry of Education, Republic of Korea (2016R1D1A1A02937287).

P-252 Comparison of uterine natural killer (uNK) cells count in the peri-implantation endometrium between natural cycles and hormone replacement therapy cycles

W.J. Yang[1], X. Chen[2], Y. Zhao[2], T.C. Li[2]

[1]Taiwan IVF Group Center, Department of Infertility and Reproductive Medicine, Hsinchu City, Taiwan R.O.C.
[2]The Chinese University of Hong Kong, Department of Obstetrics and Gynecology, Shatin, Hong Kong

Study question: Is there any difference in uNK cells count between natural cycles and hormonal replacement therapy (HRT) cycles in women undergoing IVF-ET treatment around the time of implantation?

Summary answer: There is no significant difference in uNK cells count between natural cycles and HRT cycles in the peri-implantation period.

What is known already: Our previous study, using a standardized method for uNK cells counting, has established a reference range for uNK cells count in natural cycles. However, the number of uNK cells may be influenced by the hormone level and the findings may not apply to HRT cycles in women undergoing IVF-ET treatment.

Study design, size, duration: A total of 163 women from two IVF centres participated in the study, including 55 women in natural cycles and 108 women in HRT cycles. All endometrial biopsies were collected precisely on the putative day of blastocyst transfer, that is seven days after LH surge (LH+7) of the natural cycles or five days after initiation of progesterone (P+5) of the HRT cycles.

Participants/materials, setting, methods: Endometrial sections were immunostained for CD56 to identify uNK cells. Image capture and cell counting were performed by a standardised protocol agreed and published by the participating centres. Results were expressed as percentage of positive uNK cells/total stromal cells.

Main results and the role of chance: There is no significant difference (p>0.05) in uNK cells count between natural cycles (median 2.28%, range 0.99-4.78%) and HRT cycles (median 2.55%, range 0.69-5.02%) in women undergoing IVF-ET treatment on the putative day of blastocyst transfer. Using our established reference range from 1.2% to 4.5% for uNK cell percentage, there is no significant difference in high uNK cell rate between natural cycles (9.1%, 5/55) and HRT cycles (10.2%, 11/108).

Limitations, reasons for caution: The prognostic value of uNK cells measurement has yet to be confirmed.

Wider implications of the findings: Observations on uNK cells in natural cycles may be applicable to those in HRT cycles. Further studies may be considered whether the same conclusion applies to other receptivity markers.

Trial registration number: non.

P-253 The effect and mechanisms of GM-CSF on endometrial regeneration

J. Liu[1], Y. Ying[1], J. Li[1], S. Wang[1], R. Zhang[1], J. Xu[1], P. Lv[1], C. Zhou[2], J. Chen[2], Y. Liu[1], Y. Wu[1], Y. Huang[1], Y. Chen[1], L. Chen[1], D. Zhang[1]

[1]Women's Hospital- School of Medicine-Zhejiang University, Key Laboratory of Reproductive Genetics Ministry of Education and Department of Reproductive Endocrinology, Hangzhou, China
[2]Women's Hospital- School of Medicine-Zhejiang University, Department of Pathology, Hangzhou, China

Study question: Does granulocyte macrophage colony-stimulating factor (GM-CSF) play a role in endometrium and can it be used as a new application for treating thin endometrium?

Summary answer: GM-CSF might play a key role in endometrium and could provide new ideas for improving endometrial condition.

What is known already: GM-CSF is a cytokine normally expressed in the female reproductive tract and has key roles in embryo implantation and subsequent development. GM-CSF receptor in human endometrium suggests that epithelial-derived GM-CSF may influence various endometrial biological activities and local inflammatory response. However, the role and mechanism of GM-CSF on the endometrium have not been investigated.

Study design, size, duration: A total of 57 female ICR mice (aged 8 weeks) were used to generate thin endometrium model and assess the effect of GM-CSF. Human endometrial tissues were obtained from patients who underwent hysterectomy for uterine myomas, and patients who underwent hysteroscopy and endometrial biopsy for infertility examination.

Participants/materials, setting, methods: We established thin endometrium mice model by uterine perfusion with 20 μL 90% ethanol. GM-CSF were intraperitoneal injected and then the endometrial thickness by HE staining, Ki67 expression by immunohistochemistry and the number of embryo implantation after mating were evaluated, comparing to the control group. The effects of GM-CSF on primary cultured human endometrial glandular and stromal cells were examined by BrdU assay, transwell assay, followed by exploring protein signaling pathway by Western Blot.

Main results and the role of chance: 90% ethanol caused distinct endometrial injury in mice, with observably thinner endometrial thickness, decreased expression of Ki67 in endometrial glandular cells, and reduced number of embryo implantation. Compared with the saline group, GM-CSF injection was significantly beneficial for rescuing the thickness of impaired mice endometrium, improving the expression of Ki67 in endometrial glandular cells, and increasing the number of embryo implantation. GM-CSF significantly promoted the proliferation of primary cultured human endometrial glandular cells and the migration of stromal cells. GM-CSF significantly activated p-Akt and increased the expression of p70S6K and c-Jun protein, which could be blocked by LY294002, the PI3K/Akt pathway inhibitor.Our study found that GM-CSF is beneficial for regeneration of injured endometrium in mice, and can promote the proliferation of primary human endometrial glandular cells and the migration of endometrial stromal cells. The effect of GM-CSF on endometrial glandular cell proliferation is via activating the PI3K/Akt signaling pathway.

Limitations, reasons for caution: I.p. injection of GM-CSF in mice can not totally simulate human uterine perfusion.

Wider implications of the findings: We found that GM-CSF can improve endometrial regeneration and it has potential application in clinical therapies to improve reproduction. It provides new ideas for the treatment of infertile patients, who have difficulty in endometrial proliferation, with thin endometrium or severe intrauterine adhesion.

Trial registration number: Not applicable.

P-254 Treatment outcomes in women with endometrioma at time of IVF/ICSI treatment. An analysis of 4416 fresh and frozen treatment cycles using mainly SET

M. Feichtinger[1,2,3,4], J.I. Olofsson[5], E. Nordenhök[1], N. Hadziosmanovic[6], K.A. Rodriguez-Wallberg[1,3]

[1]Karolinska University Hospital, Obstetrics and Gynecology- Division of Reproductive Medicine, Stockholm, Sweden
[2]Medical University of Vienna, Obstetrics and Gynecology, Vienna, Austria
[3]Karolinska Institutet, Oncology/Pathology, Stockholm, Sweden
[4]Wunschbaby Institut Feichtinger, Wunschbaby Institut Feichtinger, Vienna, Austria
[5]Karolinska Institutet, Division of Obstetrics and Gynecology- Department of Women's and Children's Health, Stockholm, Sweden
[6]Uppsala University, Uppsala Clinical Research Center, Uppsala, Sweden

Study question: Do IVF/ICSI outcomes differ between patients with presence of ovarian endometrioma versus patients with infertility from other causes?

Summary answer: Women with endometrioma had a significantly reduced ovarian response compared to controls and required higher gonadotropin stimulation doses; however, treatments resulted in similar cumulative live-birth.

What is known already: Single-embryo transfer (SET) with subsequent frozen-embryo transfer was shown to result in similar cumulative live-birth rates compared to double-embryo transfer in patients <36 years. Some studies suggested a negative effect of endometrioma on oocyte yield and number of embryos cryopreserved, which maintain live-birth rate in the fresh cycles although cumulative live-birth rate might be reduced.

Study design, size, duration: Single-center, retrospective cohort study of patients treated between January 2009 - December 2013. A total of 2651 patients underwent 4416 treatment cycles (2426 fresh and 1990 frozen). In 66 cases, the women presented with endometrioma at time of IVF/ICSI treatment (cases) and they were compared to infertile women without endometriosis (controls N = 2585).

Participants/materials, setting, methods: Seventy percent of patients underwent IVF/ICSI followed by SET and single FET in consecutive frozen-thawed cycles. Primary outcome measures: Oocyte and embryo yield, ovarian sensitivity index and live birth rate in fresh and frozen cycles as well as cumulative. Multivariable GEE models were applied including all subsequent treatment cycles, controlling for age, stimulation protocol and IVF/ICSI.

Main results and the role of chance: Women with endometrioma were similar to controls as regards to age (33.56 vs. 34.05 years, p = 0.31) or BMI (p = 0.97), however, they required higher gonadotropin doses for stimulation (3081 vs. 2370 IU FSH; p = 0.03) and their treatments resulted in reduced oocyte yields (7.64 vs. 9.54 retrieved oocytes, p = 0.0055) and number of frozen embryos (1.86 vs. 2.51; p = 0.0042). In fresh or frozen cycles, live-birth rates were similar between women with endometrioma vs. controls (25.0% vs. 25.5% per OPU, respectively, p = 0.94, and 27.5% vs. 28.4% per ET, respectively, p = 0.78, and FET per ET 25.0% vs. 26.2%, respectively, p = 0.86). The cumulative live-birth per OPU did not differ between the groups (38.4% vs. 34.7%, respectively, p = 0.39).

Limitations, reasons for caution: Retrospective character of the study. Endometrioma might be un- or misdiagnosed.

Wider implications of the findings: Elective SET and consecutive frozen-thawed cycles can be encouraged also in patients with endometrioma. Women with endometrioma had a reduced ovarian sensitivity to gonadotropins resulting in lower oocyte yields and less frozen embryos but similar live-birth rates per ET when compared to controls.

Trial registration number: Not applicable.

P-255 Impact of endometrial thickness on IVF/ICSI outcome

S. Suhail, H. Latif Khan, Y. Latif Khan

Lahore Institute of Fertility & Endocrinology, LIFE, Lahore, Pakistan

Study question: To determine any existing correlation among endometrial lining thickness (ELT) and pregnancy out come in patient's undergone IVF/ICSI cycle.

Summary answer: ELT was found to be an independent positive prognostic factor for clinical pregnancy outcome.

What is known already: Receptivity of endometrium is a pre-requisite for initiation of a thriving pregnancy during IVF/ICSI treatment. Endometrium proliferates under hormonal influence especially estrogen and progesterone, involved in the control of endometrial thickness measured through trans-vaginal ultrasonic scanning (TVS).

Study design, size, duration: A retrospective cohort study was conducted on the available clinical data of 1500 patients, since from January 2015 to December 2017 at the Lahore institute of fertility and endocrinology, Hameed Latif Hospital Lahore, Pakistan.

Participants/materials, setting, methods: Fifteen hundreds cycles were divided into three groups based on ELT on the hCG day; First Group with ELT < 7-8 mm, Second group 2 ELT 8-14 mm and third group ELT > 14 mm.

A logistic regression analysis was conducted using a stepwise procedure to identify the variables which were significantly associated with the outcome of clinical pregnancy. Furthermore, ROC (Receiver-operating Curve analysis) and Chi-square test were used to validate the whole model.

Main results and the role of chance: Our primary outcome is that thicker endometrial lining associated with positive beta-hCG and clinical pregnancy. First group had significantly decreased pregnancy rate, embryo implantation and live birth rates than 2nd and 3rd group ($p < 0.001$). However, no significant difference was found among spontaneous abortion and miscarriage rate in between the three groups. A higher clinical pregnancy rate was observed when ELT > 15 mm.

Limitations, reasons for caution: not applicable.

Wider implications of the findings: the ranges of endometrium defines in the abstract. the endometrium range divided into three categories.

Trial registration number: not applicable.

P-256 Influence of the microRNA let-7d on epithelial-to-mesenchmal transition in endometriosis

C. Brandhorst[1], L. Kiesel[1], B. Greve[2], M. Götte[1]

[1]*Münster University Hospital, Gynecology and Obstetrics, Münster/Westf., Germany*
[2]*Münster University Hospital, Radiotherapy-Radiooncology, Münster/Westf., Germany*

Study question: Does the microRNA let-7d have an impact on epithelial-to-mesenchymal transition in endometriosis?

Summary answer: Let-7d differentially affects the expression of mesenchymal markers in epithelial endometriotic and endometrial stroma cells.

What is known already: MicroRNAs are small noncoding RNAs that regulate gene expression at the posttranscriptional level. A dysregulation of miRNAs is observed in endometriosis, and may be functionally linked to the pathogenetic process. Let-7d is implicated in regulating EMT in malignancies. Let-7d is downregulated in the serum of endometriosis patients during the proliferative phase.

Study design, size, duration: In vitro study on the endometriotic epithelial cell line 12Z and the endometrial stroma cell line ST-T1b.

Participants/materials, setting, methods: Cells were transiently transfected with let-7d precursors to study the effects of miRNA upregulation in vitro. The impact of let-7d on cell viability and cell cycle progression was studied by MTT assay and flow cytometry, respectively, whereas invasiveness was assayed in matrigel invasion chambers. Predicted targets of let-7d were identified by microRNA.org database analysis, and target regulation was confirmed by quantitative real-time PCR and Western Blotting.

Main results and the role of chance: Let-7d upregulation had no significant effect on cell viability, whereas cell cycle analysis revealed a shift to the gap phases (G1/G2/M) in let-7d-transfected St-T1b cells. Data in the invasion assay were highly variable. A differential effect of let-7d upregulation was observed in endometrial stroma cells and endometriotic epithelial cells: In St-T1b cells, let-7d induced downregulation of the mesenchymal markers fibronectin and N-cadherin ($n>3$, $p<0.05$), whereas a panel of mesenchymal markers (Fibronectin, Snail1, Snail2, Vimentin, Twist and ZEB2) was upregulated upon let-7d transfection in 12Z cells ($n>3$, $p<0.05$).

Limitations, reasons for caution: This is an in vitro study based on a transient transfection approach in immortalized cell line models. Additional targets may be involved in the phenotypic changes.

Wider implications of the findings: Let-7d differentially affects the expression of mesenchymal markers in endometrial stroma and epithelial endometriotic cells, and may be implicated in regulating EMT as a contributing factor to locally invasive growth of endometriotic cells. Further exploration of this hypothesis in primary cells and animal models is worthwhile.

Trial registration number: Not applicable.

P-257 Caesalpinia sappan induces apoptosis of ectopic endometrial cells through inhibition of pyruvate dehydrogenase kinase

J.K. Joo[1], K. Ha[2], B. Kim[2], K. Lee[3], S. Han[3], K. Yun[3], E. Jeun[3], J. Park[3], E. Ryu[3], H. Yoon[3]

[1]*Pusan National University Hospital, OB/GY, Busan, Korea- South*
[2]*Pusan National University, Korean Medicine, Busan, Korea- South*
[3]*Pusan National University Hospital, obstetrics and gynecology, Busan, Korea- South*

Study question: We thought that if we returned the Warburg-like metabolic reprogrammed metabolism of endometriosis to normal metabolism, we could induce apoptosis of endometriosis.

Summary answer: The expression of TGF-β, PDK-1, PDK-2, PDK-4 and lactate production were increased in 12Z cells. Activated oxidative phosphorylation decreased mitochondrial membrane potential and increased ROS.

What is known already: Endometriosis has similar characteristics to cancer. It has been reported lactate production was elevated in endometriosis patients, and previous studies have also suggested that Warburg-like metabolic reprogramming may be associated with endometriosis. Heartwood of *Caesalpinia sappan(CS)* have been a medicinal herb used for improving blood circulation, accelerating hemostasis, removing of extravasated blood and reducing swelling. Especially, heartwood of CS was used for treating gynecological symptoms including algomenorrhea and amenorrhea. Recently, it has been reported that treatment of cisplatin with CS components arrests cell cycle and increases apoptosis in colon cancer. However, the effect of CS on endometriosis was not studied.

Study design, size, duration: Heartwood of CS was crushed and extracted with distilled water. The extract was filtered and concentrated using a rotary evaporator and lypophilized using a freeze dryer to yield of powder. The powder was dissolved in DMSO to prepare a stock solution and was diluted with culture medium prior to use in the in vitro experiments. Immortalized normal human endometrial (HES cells) and endometriotic epithelial cells (12Z) were used.

Participants/materials, setting, methods: The cytotoxicity of CS was examined using a MTT assay and lactate production of 12Z cells were measured with fluorometric assay kit. LDH activity was determed by measuring the decrease of absorbance at 340 nm. Also, in vitro pyruvate dehydrogenase kinase assay was done. Total RNA and protein was isolated from HES and 12Z cells and measured by RT-PCR and western blot analysis. Apoptotic cells treated with CS in12Z cells were examined.

Main results and the role of chance: The lactate production of 12Z cells was further increased higher than that of HES cells. There was no change in LDHA expression in between HES and 12Z cells. However, the phosphorylation of PDH was increased in 12Z cells. TGF-β expression was higher in 12Z cells than in HES cells. 12Z cells were more sensitive to CS-induced cytotoxicity compared with HES cells. CS reduced lactate production but not inhibited activity nor expression of LDHA. CS inhibited the phosphorylation of PDH through suppressing PDKs expression. CS produced ROS production in endometriotic cells.). In addition, cell viability reduced by CS is reversed by NAC treatment. CS induced apoptosis in endometriotic cells. In previous studies, endometriosis was resistant to apoptosis. These anti-apoptotic cells develop into endometriosis of endometrial cells refluxed into the abdominal cavity. Experiments were conducted to determine whether apoptosis of endometriotic cells was induced by CS treatment. 12Z cells were identified by FACS in that apoptotic cells were increased by CS treatment. The apoptosis signals were also increased in cleaved caspase 3 and cleaved PARP, confirming the occurrence of apoptosis.

Limitations, reasons for caution: In this study, CS treatment did not inhibit the downstream of TGF-β signaling pathway, but decreased PDK expression. Therefore, it is necessary to elucidate the mechanism responsible for suppressing PDK expression by CS treatment. The dose of CS should be determined by further *in vivo* studies.

Wider implications of the findings: We suggest that CS can be a candidate for development of novel drug treating endometriosis through inhibiting aerobic glycolysis and inducing ROS-mitochondria mediated apoptotic cell death.

Trial registration number: not applicable.

P-258 Extended doxycycline treatment versus salpingectomy in the management of patients of hydrosalpinx undergoing IVF-ET

H. El-Shaer, U. Fouda, M. Taymour, A. Wali, F. Darweesh

Cairo university, Obstetrics and Gynecology department, Giza, Egypt

Study question: Is treatment with doxycycline before and after oocyte retrieval as effective as salpingectomy in minimizing the detrimental effect of hydrosalpinx on the outcomes of IVF-ET?

Summary answer: Salpingectomy is more effective than extended doxycycline treatment before and after oocyte retrieval in improving the outcomes of IVF-ET in patients with hydrosalpinx undergoing IVF-ET.

What is known already: Several prospective and retrospective studies revealed that hydrosalpinx has a detrimental effect on the outcomes of IVF-ET. A Cochrane review revealed that laparoscopic salpingectomy improves the outcomes of IVF-ET. A small retrospective study revealed that extended doxycycline treatment before and after oocyte retrieval was as effective as salpingectomy in improving the outcomes of IVF-ET.

Study design, size, duration: A retrospective analysis of the outcomes of the fresh IVF-ET cycles for patients with hydrosalpinx who were treated with salpingectomy prior to IVF cycle (n = 260) or extended doxycycline treatment (n = 45) in Riyadh fertility and reproductive health center during the period between 2012 and 2017. Laparoscopic salpingectomy or ultrasound guided aspiration of hydrosalpingeal fluid were offered to patients. Patients who declined surgery and aspiration of hydrosalpingeal fluid received doxycycline treatment.

Participants/materials, setting, methods: In doxycycline group, doxycycline (100 mg/ 12 h) was started one week before anticipated oocyte retrieval and continued for one week after oocyte retrieval. In salpingectomy group, laparoscopic salpingectomy was performed two months before IVF-ET cycle. The first attempt IVF-ET cycles after treatment were included in the analysis. Patients with age ≥ 37 years, anti-Müllerian hormone (AMH) ≤ 0.66 ng/ml, antral follicle count (AFC) < 6 and previous IVF cycles were excluded from the study.

Main results and the role of chance: The implantation, clinical pregnancy, ongoing pregnancy and live birth rates were significantly higher in the salpingectomy group (20.91% Vs. 9.91%, P value = 0.007, 44.62% Vs. 20% P value = 0.002, 39.62% Vs. 17.78%,P value = 0.005 and 37.31%Vs. 15.56% P value = 0.005 respectively) The abortion rate was comparable between both groups (11.21% Vs. 11.11 %, P value = 0.993). No significant differences were detected between both groups in age, basal FSH, AFC, AMH level, retrieved oocytes, fertilization rate, quality of embryos transferred and number of embryos transferred. None of the patients in salpingectomy group had peri-operative complications.

Limitations, reasons for caution: The retrospective design and the small sample size are the main limitations of the study.

Wider implications of the findings: The data presented in the current study suggest that extended doxycycline treatment before and after oocyte retrieval is not effective in minimizing the detrimental effect of hydrosalpinx on the outcomes of IVF-ET. Further, larger well designed randomized controlled trials should be conducted to confirm the findings of this study.

Trial registration number: Not applicable.

P-259 Exploring the RNA landscape of uterine fluid extracellular vesicles

P. Vigano[1], E. Giacomini[1], G.M. Scotti[2], S. Makieva[1], F. Simeoni[2], E. Papaleo[3], J. Ottolina[3], P. Giardina[3], I. Molineris[2], G. Tonon[2], D. Lazarevic[2]

[1]*IRCCS San Raffaele Scientific Institute, Reproductive Sciences Laboratory- Division of Genetics and Cell Biology, Milan, Italy*

[2]*IRCCS San Raffaele Scientific Institute, Center for Translational Genomics and BioInformatics, Milan, Italy*

[3]*IRCCS San Raffaele Scientific Institute, Obsterics and Gynecology Unit, Milan, Italy*

Study question: Can RNA species present in uterine fluid (UF)-derived extracellular vesicles (EVs) represent a potential noninvasive proxy of respective endometrial tissue transcripts?

Summary answer: RNA species in UF-derived EVs mirror the transcriptome of endometrial tissue, can discriminate between the menstrual phases and are enriched in molecules involved in migration.

What is known already: The human endometrium is a highly dynamic tissue that is cyclically shed, repaired, regenerated and remodelled, primarily under the orchestration of ovarian-derived hormones. Studies addressing the dynamics of phase transition and tissue abnormal remodelling have been based so far on endometrial sampling analysis that is unfortunately associated with several problems. EVs of uterine origin has been recently identified. Selective packaging of RNA/miRNA profile into uterine EVs has been demonstrated using cell lines. Data on the comparative RNA profile between the endometrial tissues and the corresponding UF-derived EVs are very limited.

Study design, size, duration: Endometrial tissues and UF samples were simultaneously obtained from proven fertility women (n = 10). Endometrial tissues were obtained with the use of a pipelle while UFs were obtained with a balloon hysterosonosonography catheter to avoid vaginal contamination. Based on the histological dating, 5 samples were in proliferative and 5 in secretory phase of the cycle. EVs have been isolated by differential ultracentrifugations.

Participants/materials, setting, methods: For RNAseq analysis, libraries were synthesized using Lexogen 3'UTR mRNA kit, starting from total RNA. In average, 10 M reads of 75 nt length were produced by Illumina NextSeq 500 via SBS technology. Two parallel differential expression (DGE) analyses were performed comparing RNA presence in proliferative and secretory phase on correspondent tissues and EVs. RNAs in EVs were ranked according to the normalized cpm counts. The Webgestalt platform was used for enrichment analysis.

Main results and the role of chance: Biotype composition of RNA species for each sample recognized most of them as derived from protein coding genes (86% in tissues and 77% in EVs), but fractions of Mt_rRNA (6% in tissues and 15% in EVs) and lincRNA (5% in tissues and 6% in EVs) were also present. Considering as 'expressed' those genes that showed at least 1 cpm on at least 5 samples, 15268 genes defined tissue samples transcriptional profile, while only 4132 were found in UF-derived EVs. Even if 'expression' in EVs was generally more unstable, it correlated well with that observed in tissues, especially considering mean values (Spearman coefficient 0.81). DGE analysis could identify 139 genes up-regulated in UF-derived EVs in the secretory phase ($p<0.01$) and none up-regulated in the proliferative phase. Nine genes (TMEM37, TNS2, RIMKLB, PABPN1, ITGB8, ALDH1A3, SNHG25, DCDC2, MECOM) varied simultaneously in tissues and UF-derived EVs according to phases. Among the biological processes enriched in the 20% RNAs with the greatest difference in ranking of secretory versus proliferative phase, those involved in cell migration regulation were identified. Of 57 meta-signature genes recently identified as human receptivity transcriptomic biomarkers (Scie Rep 2017), 18 (31%) were found to be present in UF-derived EVs.

Limitations, reasons for caution: UF-EVs samples showed an overall greater variability in cpm means among samples compared to those found in corresponding endometrial tissues. Therefore, the definitive RNA profile should be evaluated in a greater number of samples.

Wider implications of the findings: UF-derived EVs might be used as non-invasive endometrial biopsy to predict endometrial normal functions and dysfunctions becoming an advancement in the molecular medicine era.

Trial registration number: not applicable.

P-260 Extended doxycycline treatment versus aspiration of hydrosalpingeal fluid at the time of oocyte retrieval in the management of patients with ultrasound visible hydrosalpinx undergoing IVF-ET

U. Fouda, H. Elshaer, M. Taymour, F. Darweesh, A. Wali

Cairo university, Obstetrics and Gynecology department, Cairo, Egypt

Study question: Is treatment with doxycycline before and after oocyte retrieval as effective as ultrasound guided aspiration of hydrosalpingeal fluid in minimizing the detrimental effect of hydrosalpinx on the outcomes of IVF-ET?

Summary answer: Ultrasound guided aspiration of hydrosalpingeal fluid is more effective than extended doxycycline treatment in improving the outcomes of IVF-ET in patients with ultrasound visible hydrosalpinx.

What is known already: The negative impact of the hydrosalpinx on the outcomes of IVF-ET has been confirmed by several retrospective and prospective studies. Several randomized controlled trials revealed that ultrasound guided aspiration of hydrosalpingeal fluid is effective in improving the outcomes of IVF-ET. A small retrospective study revealed that extended doxycycline treatment before and after oocyte retrieval was effective in minimizing the detrimental effect of hydrosalpinx on the outcomes of IVF-ET. Till now, no studies have yet compared the effectiveness of ultrasound guided aspiration of hydrosalpingeal fluid with extended doxycycline treatment in the management of patients with ultrasound visible hydrosalpinx undergoing IVF-ET.

Study design, size, duration: A retrospective analysis of the outcomes of the IVF-ET cycles for patients with ultrasound visible hydrosalpinx who were treated with ultrasound guided aspiration of hydrosalpingeal fluid (n = 61) or extended doxycycline treatment (n = 36) in Riyadh fertility and reproductive health center during the period between 2012 and 2017. Laparoscopic salpingectomy or aspiration of hydrosalpingeal fluid were offered to patients. Patients who declined surgery and aspiration of hydrosalpingeal fluid received doxycycline treatment.

Participants/materials, setting, methods: In doxycycline group, doxycycline (100 mg/12 hours) was administered one week before the expected time of oocyte retrieval and continued for one week after oocyte retrieval. In aspiration group, aspiration of hydrosalpingeal fluid was performed under ultrasound guidance at the time of oocyte retrieval. The analysis included the first attempt IVF-ET cycles after treatment. Exclusion criteria were age $\geq$ 37 years, anti-Müllerian hormone (AMH) $\leq$ 0.66 ng/ml, and antral follicle count (AFC) < 6.

Main results and the role of chance: The implantation, clinical pregnancy and live birth rates were significantly higher in the aspiration group (16.35% Vs. 6.52 %, P value = 0.024, 36.07% Vs. 16.67% P value = 0.042, and 32.79% Vs. 13.89 %,P value = 0.039 respectively). The abortion rate was comparable between both groups (9.09% Vs. 16.67%, P value = 0.595). The age, basal FSH, AFC, AMH level, duration of infertility, percentage of patients with bilateral hydrosalpinx, retrieved oocytes, fertilization rate, quality of embryos transferred and number of embryos transferred were comparable between both groups. None of the patients in the aspiration group had flaring of infection or peritonitis.

Limitations, reasons for caution: The main limitations of the current study are the retrospective design and the small sample size. The results of this study should be confirmed by larger well designed randomized controlled trials.

Wider implications of the findings: Extended doxycycline treatment before and after oocyte retrieval should not be used in the management of patients with ultrasound visible hydrosalpinx who declined salpingectomy prior to IVF-ET. Ultrasound guided aspiration of hydrosalpingeal fluid is a simple, safe and effective option for those patients.

Trial registration number: Not applicable.

P-261 Fertility preservation outcomes in endometriosis patients: A Pilot Study

S. Mokhtar[1], S. Ansaripour[1], A. Mohazab[2], N. Madadi[1], A. Mohammadzade[1]

[1]*Avicenna infertility treatment center, Infertility, Tehran, Iran*
[2]*Avicenna infertility treatment center, Endometriosis, Tehran, Iran*

Study question: Does endometriosis affect ART outcomes for fertility preservation?

Summary answer: The size of endometrioma inversely affects the number and quality of oocytes and embryos, the clinical pregnancy rate is not related to the endometriosis characteristics.

What is known already: Fertility preservation may be of interest for women with endometriosis, particularly whom with bilateral un-operated endometriomas and those who previously had excision of unilateral endometriomas and require surgery for a contralateral recurrence. However, we should consider the probability of low successful outcomes and complication of the ovarian stimulation and ovum pick up in endometriosis patients. the feasibility and potential benefits of fertility preservation procedures in women with endometriosis are warranted prior to implementing its use in routine clinical practice.

Study design, size, duration: This cross-sectional study has conducted since March 2017 to January 2018, 52 patients with endometriosis who were referred for fertility preservation via ART, have been studied. They underwent controlled ovarian stimulation and ART results including number and quality of oocytes and embryos and also clinical pregnancy rate were obtained. Endometriosis characteristics such as presence, size, laterality, the number of endometriomas, the coexistence of DIE and previous history of endometriosis surgery were registered.

Participants/materials, setting, methods: 57 controlled ovarian stimulation cycles with GnRH antagonist protocol have been studied, and ovarian puncture were performed, then ART results were followed. The number and quality of oocytes and embryos were assessed and the clinical pregnancy rate was calculated in patients who underwent embryo-transfer (18 patients). Multivariate regression analysis, bi variate correlations and Chi-square test were applied for evaluation of impressive factors on ART results. The level of significance was considered 0.05.

Main results and the role of chance: Controlled ovarian stimulation and ovum pick up were performed for 52 patients, 10 patients had repeated COH cycles and embryo cryopreservation has performed, except 5 patients who had Oocytes cryopreservation. COH cycles were canceled for 5 cases due to poor ovarian responses. 18 patients had 23 embryo transferred cycle. Age and BMI mean and SD of cases were 33.11 $\pm$ 4.72 and 23.87 $\pm$ 3.9 respectively. From 46 patients who have previously suffered from infertility, there was mild to moderate male factor in16 cases. There was an inverse relation between the size of endometrioma and number of oocytes(P-value = 0.011), the quality of oocytes (P-value = 0.002), the number of embryos (Pvalue = 0.004), the quality of embryos(Pvalue = 0.007). The number and quality of oocytes and embryos have related to age and AMH levels significantly. Although these effects were not significant for clinical pregnancy rate (26% per embryo transfer) and there is no statistical relationship between those ART outcomes and endometriosis characteristic such as DIE, laterality and number of endometrioma and previous surgery history.

Limitations, reasons for caution: The cases of the study are more severe than total endometriosis population due to referral nature of Avicenna infertility clinic and endometriosis clinic. Because of rare cases of fertility preservation in normal population, selection of a standard control group seems unavailable.

Wider implications of the findings: Age, AMH level and the size of endometrioma significantly affect the number and quality of oocytes and embryos in endometriosis patients who were referred for fertility preservation.Our intresting findings offer further study to find which endometriosis patients benefit from fertility preservation via ART.

Trial registration number: This study is not clinical trial.

P-262 The gametotoxic effects of the endometrioma content: insights from a parthenogenetic human model

A. Paffoni[1], V. Bolis[2], S. Ferrari[2], L. Benaglia[2], L. Restelli[2], E. Somgiliana[3]

[1]Azienda Ospedaliera Sant'Anna - Presidio di Cantù, Procreazione medicalmente assistita, Cantù, Italy
[2]Fondazione IRCCS Ca' Granda, Infertility Unit, Milan, Italy
[3]University of Milan, Department of Clinical Sciences and Community Health, Milan, Italy

Study question: To evaluate the effect of exposure of human cryopreserved oocytes to endometriotic fluid using a validated experimental model of human parthenogenesis.

Summary answer: Exposure of human oocytes to endometriotic fluid has a negative effect on the morphology of deriving embryos/parthenotes mainly due to an excess of cellular fragmentation.

What is known already: Exposure to the content of endometriotic cysts may be harmful to the oocyte and may alter its subsequent developmental potential as an embryo due to the presence of several potentially toxic substances such as growth factors and interleukins, matrix metalloproteinases, catalytic iron and lipid peroxide. The great amount of free iron in endometriotic cysts is a matter of concern because of the risk of local production of the highly toxic reactive oxygen species. However, experimental data supporting these concerns are scanty both in humans and in animal models.

Study design, size, duration: A randomized in vitro study conducted between January 2016 and July 2016. A three-folds decrease in the rate of day 3 good quality parthenotes for exposed oocytes compared to unexposed ones was considered important (from 37% to 12%, based on previuos data). Considering a survival rate of 80% after warming, the total number of oocytes to be used for the study were 140 (type I and II errors equal to 0.05 and 0.20, respectively)

Participants/materials, setting, methods: Oocytes used for the study protocol were donated by consenting women aged <42 years. After thawing, oocytes belonging to every single patient were randomly (1:1) allocated to fertilization medium containing endometriotic fluid (exposed oocytes) or to the fertilization medium (control). After 3 minutes of culture, oocytes were rinsed and activated using ionomycin followed by 3-hours incubation in 2 mM 6-DMAP. Parthenotes were cultured until day 5 and embryological parameters were registered daily.

Main results and the role of chance: Twenty-three women donated a total of 147 vitrified oocytes (range 2-17). After warming, 121 intact oocytes were randomized in 13 sets of experiments. A total of 60 oocytes were randomized to the exposure group while 61 oocytes were randomized to the non exposure group. The day after treatment and activation, 42 parthenotes (70%) among exposed oocytes and 46 parthenotes (75%) among unexposed oocytes were observed (p = 0.51). The developmental rates on day 3 and day 5 did not significantly differ between the two groups. The RRs (95%CI) of exposed oocytes for activation, cleavage on day 3 and blastulation on day 5 were 0.93 (0.75-1.16), 0.88 (0.65-1.19) and 0.47 (0.19-1.15), respectively. Conversely, data on morphology tend to support a detrimental effect of endometrioma fluid exposure. The rate of day 3 good quality parthenotes was 22% (13/60) and 41% (25/61) in exposed and unexposed oocytes, respectively (RR = 0.53; 95%CI: 0.30-0.93, p = 0.031). A trend was observed also in the development of good quality-expanded blastocysts on day 5, 5% (3/60) and 13% (8/61) of oocytes, respectively (RR = 0.39, 95%CI: 0.11-1.37). A significantly higher proportion of parthenotes failing to develop to the blastocyst stage showed cellular fragmentation in the exposed compared to unexposed parthenotes (RR = 0.64, 95%CI: 1.04-2.57; p = 0.024).

Limitations, reasons for caution: We used a fixed experimental model that cannot mimic all the variability of every possible clinical conditions. Endometriotic fluids from three different patients were used; even though we did not observed differences based on the donor of the endometriotic fluid, we cannot exclude possible different biological effects.

Wider implications of the findings: Even if robust inferences cannot be drawn, because our findings were obtained in an experimental context, we believe that our study has some potential clinical implications and can be interpreted as a scientific support of the common dogma that ovarian endometriomas should not be punctured or aspirated during oocytes retrieval.

Trial registration number: not applicable.

P-263 High mobility group box-1 increases cell proliferation, expression of adhesion molecules, and secretion of cytokines in human endometrial stromal cell in endometriosis

J. Yun, J.H. Lee, S.K. Seo, S. Cho, Y.S. Choi, B.S. Lee, B.H. Yun

Severance Hospital- Institute of Women's Life Medical Science- Yonsei University College of Medicine, Division of Reproductive Endocrinology- Department of Obstetrics and Gynecology-, Seoul, Korea- South

Study question: Does endogenous ligands such as High mobility group box-1 (HMGB-1) signaling may play a pathogenic role developing endometriosis?

Summary answer: HMGB-1 is important in establishment of endometriosis through inflammatory pathway, which leads increase of inflammatory cytokines and change adhesion molecules in ectopic endometrial stromal cell.

What is known already: Oxidative stress and chronic inflammation play important roles in the pathophysiology of endometriosis. A representative Damage-associated molecular pattern (DAMP), HMGB-1 has previously shown increased release from the endometrial stromal cell at oxidative stress. Moreover, recombinant HMGB-1(rHMGB-1) stimulated cell proliferation and increased expression of Toll like receptor 4(TLR4) in human endometrial stromal cell(HESC), suggesting altered pathologic endometrium according to oxidative stress and chronic, endogenous inflammation.

Study design, size, duration: In-vitro, experimental study using primary cell culture and molecular biologic methods.

Participants/materials, setting, methods: HESC culture was done using ectopic endometrium from the surgical specimen. HESCs were examined to see cell proliferation and HMGB-1 release according to H_2O_2 treatment. Then, HESCs were treated with rHMGB-1 by dose dependent fashion. The supernatants acquired during the rHMGB-1 treatment were examined to measure inflammatory cytokines such as TNF-a, IL-1b, IL-6 and IL-10. Adhesion molecule, angiogenic marker, DAMP receptors were measured by RT-PCR and western blotting from HESCs treated with rHMGB-1.

Main results and the role of chance: HESCs showed decreasing cell viability and increasing HMGB-1 release according to H_2O_2 treatment. Cell proliferation and invasion was significantly increased according to the treated dose of rHMGB-1. Expression of mRNA and the protein expression of TLR4, RAGE, VEGF, ICAM-1 increased significantly according to the treated rHMGB-1 concentration. E-Cadherin showed decrease in mRNA and protein by increase of rHMGB-1 treatment. Inflammatory cytokines from the supernatants of HESC during rHMGB-1 treatment showed significant increase.

Limitations, reasons for caution: Our study is limited in that we only performed in vitro analysis using HESCs. Therefore, in vivo studies are required.

Wider implications of the findings: Our results support that the progression of endometriosis may be guarded by oxidative stress and endogenous stimuli results in chronic inflammatory pathway.

Trial registration number: NRF-2012R1A1A1013167

P-264 Circulating Cf-DNA quantification according to the location of the endometriotic lesions

S. Hamamah[1], A. Torre[2], S. El Moghrabi[3], F. Entezami[4], P. Santulli[5], C. Chapron[5], D. Haouzi[3]

[1]Hôpital Arnaud de Villeneuve, Service de Biologie et de Médecine de la Reproduction B, Montpellier Cédex 5, France
[2]Division of Child Health- Obstetrics & Gynaecology, Department of Obstetrics and Gynecology- University of Nottingham, Nottingham, United Kingdom
[3]Inserm U1203, Hôpital St-Eloi- IRMB- CHU MOntpellier, Montpellier, France
[4]Laboratoire Eylau-UNILABS-La Muette- Clinique de La Muette-Ramsay-Générale de Santé, ART department, Paris, France
[5]Université Paris Descartes- Sorbonne Paris Cité- Faculté de Médecine- Assistance Publique - Hôpitaux de Paris AP-HP- Groupe Hospitalier Universitaire GHU Ouest-

Centre Hospitalier Universitaire CHU Cochin, Department of gynecology Obstétrics II and Rep,

Study question: Is there an association between the circulating Cf-DNA (CCf-DNA) and the location of the endometriotic lesions?

Summary answer: CCf-DNA concentrations was higher in the deep pelvic endometriosis compared with control and other types of endometriosis.

What is known already: Circulating Cf-DNA are present in the bloodstream and their quantification is already used as a biomarker for gynaecological disorders such as ovarian and endometrial cancer. To date, only one study reported the potential role of CCf-DNA as potential biomarker for minimal and mild endometriosis. However, no studies analyzed the CCf-DNA according to the location of the endometriotic lesions.

Study design, size, duration: This was an retrospective study using serum prospectively collected from non-pregnant patients from the Cochin Hospital who were between 18 and 41 years of age (mean ± sem: 31.5 ± 0.6 years), and who underwent surgery for symptomatic benign gynecological conditions between January 2011 and December 2013.

Participants/materials, setting, methods: Surgery was performed on 76 patients available preoperative MRIs. After a thorough surgical examination of the abdomino-pelvic cavity, 55 women with histologically proven endometriosis and/or adenomyosis were allocated to the endometriosis group and 21 symptomatic women without evidence of endometriosis with or without adenomyosis to the endometriosis free group. CCf-DNA was extracted from 200 µl of serum and quantified by qPCR using primers amplifying ALU115 sequences in both groups and according to surgical endometriosis phenotypes.

Main results and the role of chance: CCf-DNA concentrations were similar in the endometriosis free group with or without adenomyosis (245 ± 70 *vs* 200 ± 29 fg/µL respectively, p = 0.6). The concentration of CCf-DNA was significantly higher in the endometriosis group than in the control group (342 ± 66 *vs* 215 ± 38 fg/µL, p = 0.1). In addition, accordingly to the location of the endometriotic lesions, the CCf-DNA concentrations was higher in the deep pelvic endometriosis (359 ± 110 *vs* 215 ± 38 fg/µL) compared with control group, superficial peritoneal and ovarian endometriosis.

Limitations, reasons for caution: These findings must be validated in a large cohort of patients to judge of the relevance of the CCf-DNA quantification as potential biomarker of endometriosis.

Wider implications of the findings: These findings of significantly increased concentrations of CCf-DNA in serum of patients with endometriosis suggests that CCf-DNA might be a potential biomarker for developing non-invasive diagnostic test in endometriosis.

Trial registration number: Not applicable.

P-265 The use of home remedies and complementary health approaches in endometriosis

B. Leeners[1], E. Gross[1], K. Geraedts[1], M. Rauchfuss[2], M. Wölfler[3], F. Haeberlin[4], S. Von Orelli[5], M. Eberhard[6], P. Imesch[7], D. Fink[7], B. Imthurn[1], A. Kohl Schwartz[1]

[1]*Department of Reproductive Endocrinology, University Hospital Zürich, Zürich, Switzerland*
[2]*Charité Berlin- University Hospital, Department of Psychosomatics, Berlin, Germany*
[3]*University Hospital Graz, Gynecology and Obstetrics, Graz, Australia*
[4]*Canton hospital St. Gallen, Gynecology and Obstetrics, St. Gallen, Switzerland*
[5]*Triemli hospital Zürich, Gynecology and Obstetrics, Zurich, Switzerland*
[6]*Canton Hospital Schaffhausen, Gynecology and Obstetrics, Schaffhausen, Switzerland*
[7]*University Hospital Zurich, Gynecology, Zurich, Switzerland*

Study question: How do endometriosis-affected women use complementary health approaches (CHA) and home remedies (HR)?

Summary answer: Persisting disease symptoms and dissatisfaction with medical support are key factors for the use of CHA and HR in women with endometriosis.

What is known already: Endometriosis is characterized by pain symptoms such as dysmenorrhea, dyspareunia and chronic pelvic pain. The physiology of nociception and pain syndromes is not yet fully understood, but it is assumed that somatic mechanisms interact with psychological factors and are further modified by individual differences in pain perception. Surgical treatment of endometriosis lesions followed by hormonal and/or analgesic therapies are typical approaches to alleviate pain symptoms. However, these conventional treatments are often associated with adverse effects and endometriosis pain symptoms may reoccur despite treatment.

Study design, size, duration: Retrospective cross-sectional data analysis of 574 women with endometriosis, recruited in hospitals and associated private practices and self-help groups in Switzerland, Germany and Austria between 2010 and 2016. Primary outcome measures were frequency and perceived efficacy of the use of CHA and HR. The secondary outcome was the analysis of confounders such as duration of disease, stage of disease, disease symptoms, as well as satisfaction with conventional health care.

Participants/materials, setting, methods: Included were women aged 18 to 59 with surgically confirmed endometriosis. Data was acquired with a questionnaire focusing on endometriosis in general, including questions on surgical and hormonal therapies. The use of CHA and HR was assessed. The pain was investigated with a modified version of the validated standard questionnaires such as the Brief Pain Inventory and Pain Disability Index. Outcome measures were compared for the hospital recruited and the self-help recruited group.

Main results and the role of chance: A total of 359 (62.5%) from 574 included women with confirmed diagnosis of endometriosis, applied any form of CHA/HR. The approaches "topical heat" (by 48.6%) and "repose" (by 43.0%) were applied most often, followed by "movement/massage" (by 25.4%), "homeopathy/phytotherapy" (by 22.8%) and "acupuncture/traditional Chinese Medicine (TCM)" (by 22.6%) of the women. Therapeutic effect was assigned high (80.3% for "topical heat", 70% for "repose", 69.2% for "movement/massage", 44.3% for acupuncture/TCM ans 42% for "homeopathy/ phytotherapy". Women suffering from chronic fatiguing disease symptoms selected more often alternative therapies (odds ratio 3.14, 95% confidence interval 1.39–7.11, p = 0.006) compared to women without these characteristics. In total 18.9% (109/574) of women felt well supported by their physician in dealing with endometriosis-associated pain, while 13.8% (79/574) did not at all. Women in the self-help group were significantly more frequently dissatisfied with the treatment provided by their physicians (p<0.001). Furthermore, women dissatisfied with the treatment provided by their physicians used significantly more often complementary approaches. Our study shows that the majority of women with endometriosis seek additional treatment strategies such as CHA/HR to deal with and/or cure symptoms of the disease, as they seem to provide a good symptom alleviation than hormonal therapies.

Limitations, reasons for caution: Data analysis was based on questionnaire information of a non-standardized questionnaire. Apart from reports on endometriosis-related surgery, no other medical records were reviewed. As we asked for lifetime use of medication, we cannot give any information on time relations between conventional and complementary approaches.

Wider implications of the findings: Women dissatisfied with medical support and persisting disease symptoms frequently used CHA and HR. Gaining control and actively participating in the treatment motivates them to seek additional options. Women's' needs should be respected while counselling and a more active role should be offered in developing individual treatment strategies.

Trial registration number: ClinicalTrials.gov NCT 02511626.

P-266 Fatigue – an underestimated symptom in endometriosis

A. Ramin-Wright[1], A.S. Kohl Schwartz[2], K. Geraedts[1], M. Rauchfuss[3], M.M. Wölfler[4], F. Haeberlin[5], S. Von Orelli[6], M. Eberhard[7], B. Imthurn[1], P. Imesch[8], D. Fink[8], B. Leeners[1]

[1]*University Hospital Zurich, Reproductive Endocrinology, Zurich, Switzerland*
[2]*University Hospital Bern, Gynecology- Gynecological Endocrinology and Reproductive Medicine, Bern, Switzerland*
[3]*Charité Berlin, Psychosomatics, Berlin, Germany*
[4]*University Hospital Graz, Gynecology and Obstetrics, Graz, Austria*
[5]*Canton Hospital St. Gallen, Gynecology and Obstetrics, St. Gallen, Switzerland*
[6]*Triemli Hospital Zurich, Gynecology and Obstetrics, Zurich, Switzerland*
[7]*Canton Hospital Schaffhausen, Gynecology and Obstetrics, Schaffhausen, Switzerland*

[8]University Hospital Zurich, Gynecology, Zurich, Switzerland

Study question: Is fatigue a frequent symptom of endometriosis which should be given more consideration?

Summary answer: Fatigue is an underestimated symptom of endometriosis as it affects numerous women with endometriosis, but is not widely considered clinically or discussed in literature.

What is known already: Along with pain, fatigue can be a symptom of endometriosis which may cause major distress and further reduce the quality of life of women with endometriosis. However, few studies with large sample sizes have investigated prevalences and confounders of fatigue as a symptom of endometriosis.

Study design, size, duration: The study was designed as a multi-center matched case-control study. Recruitment took place at hospitals and private practices in Switzerland, Germany, and Austria between 2010-2016. Data was collected from 1120 women, 560 of them with endometriosis.

Participants/materials, setting, methods: Age +/- 3 years and ethnic background were chosen as matching criteria. Endometriosis diagnosis of 560 women was surgically and histologically confirmed while 560 controls were selected by surgical exclusion or absence of symptoms. More women showed an advanced disease stage (61.9% rASRM III or IV). Materials included surgical and histological reports as well as data retrieved from a self-administered questionnaire. Variable relationships were established by regression analysis and associations were quantified as odds ratios.

Main results and the role of chance: Severe fatigue is a very frequent symptom in women diagnosed with endometriosis (50.7% versus 22.5% in control women, p<0.001). Fatigue in endometriosis is associated with insomnia (OR: 10.37, CI: 6.83-15.75, p<0.001), chronic pain (OR: 2.56, CI: 1.81-3.62, p<0.001), and occupational stress (OR: 1.53, CI: 1.10-2.13, p = 0.012), but it is independent of age, time since first diagnosis, and stage of the disease.

Limitations, reasons for caution: Women with asymptomatic endometriosis cannot be excluded in the control group which would lead to underestimation of our results. The data was retrieved from a self-administered questionnaire, therefore, answers are at risk for recall biases. The study's design allows no evaluation of causal effects.

Wider implications of the findings: Our study is the first to systematically investigate fatigue in endometriosis in a large study population. High fatigue prevalences demonstrate the need of addressing it when managing the disease. In addition to treating endometriosis, it would be beneficial to reduce insomnia, pain, and occupational stress to better manage fatigue.

Trial registration number: ClinicalTrials.gov, NCT 02511626

P-267 A specific serum cytokines profile determines disease phenotype in adenomyosis-affected women

M. Bourdon[1,2], P. Santulli[1,2], S. Chouzenoux[2], K. Bailly[2], C. Maignien[1], L. Marcellin[1,2], L. Doridot[2], F. Batteux[2], C. Chapron[1,2]

[1]Cochin - Port Royal, Service de Gynécologie Obstétrique II and Reproductive Médicine Professor Chapron, Paris Cedex 14, France
[2]Institut Cochin- INSERM U1016- Université Paris Descartes- Sorbonne Paris Cité, Laboratoire d'immunologie, Paris, France

Study question: Is there a specific serum cytokines profile in adenomyosis women according to the adenomyosis phenotype, as compared to disease-free counterpart?

Summary answer: A decrease in serum interleukin (IL)23, IL31, IL25, IL33 levels was identified adenomyosis women with associated diffuse and focal form as compared to disease-free counterpart.

What is known already: Adenomyosis is a benign uterine disorder characterized by the presence of heterotopic endometrial stroma and glands deeply into the myometrium associated with hypertrophy of adjacent uterine smooth muscle cells. Different forms of adenomyosis can be distinguished: Diffuse adenomyosis (DIF-ADE), Focal adenomyosis (FOC-ADE) and the association of diffuse and focal lesions (DI/FOC-ADE). The origin of ectopic endometrial implants within the myometrium is still debated and could be multiple. Abnormal immune phenomena have been described trying to understand adenomyosis physiopathology. However, the immune imbalance in adenomyosis is still poorly understood.

Study design, size, duration: This cohort study, conducted in a tertiary care university hospital, included 80 women who have received a pelvic magnetic resonance imaging (MRI) performed by one senior radiologist during the preoperative work-up.

Participants/materials, setting, methods: According to MRI findings women were allocated to two groups: Adenomyosis (ADE) group (n = 60) and the control group of women without any criteria for ADE at MRI (n = 20). Women in the ADE group were further sub-divided according to adenomyosis phenotypes: DIF-ADE, FOC-ADE and FOC/DIF-ADE. For all women, blood samples were obtained prior to a surgical procedure and serum cytokine levels were assayed by multiplex immunoassay.

Main results and the role of chance: Serum levels of interleukin (IL)23 (237.77 pg/ml ± 70.97 in ADE-group versus 1855.04 ± 1411.33 in control-group, p = 0.019), IL25 (31.98 ± 8.54 vs. 222.08 ± 170.90 respectively, p = 0.006), IL31 (10.13 ± 3.83 vs. 91.51 ± 71.21 respectively, p = 0.034), IL33 (3.77 ± 1.23 vs. 17.86 ± 11.49 respectively, p = 0.016) and IL17F (16.29 ± 2.35 vs. 30.12 ± 8.29 respectively, p = 0.042) were significantly decreased in adenomyosis-affected women as compared to controls. In DIF/FOC –ADE group, a significant decrease of serum IL23, IL31, IL25, IL33 levels were identified as compared to controls.

Limitations, reasons for caution: Diagnostic of adenomyosis was based only on strict imaging criteria and no correlation with local adenomyotic lesions has been performed.

Wider implications of the findings: Our results may provide new clues for understanding the pathogenesis of adenomyosis, potentially associated with an immunotolerant process more pronounced in associated diffuse and focal forms of adenomyosis.

Trial registration number: None.

P-268 Comparison of effect of Silymarin and Cabergoline on experimental model of endometriosis

S. Jouhari[1], M.M. Naderi[2], A. Mohamadzade[1], S. Khazali[3], S. Zafardoust[1], F. Fatemi[1], Z. Mohamadi[4], H. Soltanghoraee[2]

[1]Avicenna Research Institute- ACECR, infertility, Tehran, Iran
[2]Avicenna Research Institute- ACECR, Reproductive Biotechnology Research Center, Tehran, Iran
[3]Ashford and St. Peter's Hospital NHS Foundation Trust-, Centre for Endometriosis and Minimally Invasive Gynaecology CEMIG, Chertsey, United Kingdom
[4]Avicenna Research Institute- ACECR, Nanobiotechnology Research Center, Tehran, Iran

Study question: What is the effects of Silymarin and Cabergoline on induced endometrial lesion in experimental model of endometriosis?

Summary answer: Silymarin and Cabergoline administration resulted in decreased size and hystopathological grade of the induced endometrial lesions in experimental endometriosis model of rat.

What is known already: Previous lines of evidence suggest that cabergoline (dopamine agonist) is effective in treatment of patients with endometriosis (reducing size and symptoms). But less is known regarding the effects of silymarin (a natural compound with antioxidant effects).

Study design, size, duration: Twenty four female Sprague-Dawley mature rats.

were used for an experimental study in the Avicenna Research Institute.

Participants/materials, setting, methods: Endometriosis was surgically induced in 24 rats.animals were randomized into three groups. Group I was administered 100 mg/kg Silymarin S.C, group II was given 0.5 mg/kg Cabergoline S.C and group III had no medication.The rats medicated 3 weeks. Then rats were sacrificed and size and histopathological grade of the endometriotic implants and biochemical parameters were evaluated.Serum and peritoneal levels of vascular endothelial growth factor (VEGF), total antioxidant capacity(TAC) and tumor necrosis (TNF)-α were compared between groups.

Main results and the role of chance: All the animals had comparable baseline characteristics. We found that the size of endometrial lesions decreased significantly in cabergoline ($p<0.001$) and silymarin ($p<0.001$) groups. The

histopathology grade was significantly lower in cabergoline ($p<0.001$) and silymarin ($p<0.001$) groups compared to controls. There was no significant difference between study groups regarding serum levels of VEGF, TNF-α and peritoneal levels of TAC. Those receiving silymarin had significantly higher TAC compared to control after 21 days of therapy ($p<0.001$).

Limitations, reasons for caution: The study was performed on animal subjects.Endometriosis studies in humans are challenging to perform as the measured effect of the treatment on the actual peritoneal lesion will necessitate surgical interventions. The second weakness of the current data is the knowledge regarding the administration route of the treatment for human patients.

Wider implications of the findings: cabergoline and silymarin administration resulted in decreased size and histopathologic grade of the induced endometrial lesions in animal model of rat. Silymarin appear to be a virtual novel therapeutic agent for treatment of endometriosis probably due to its potent anti-oxidative properties.

Trial registration number: Not applicable.

P-269 The effect of endometriosis on the antimüllerian hormone level in patients with infertility

P. Romanski[1], P. Brady[1], A. Thomas[1], L. Farland[1,2], M. Hornstein[1]

[1]*Brigham & Women's Hospital/Harvard Medical School, Department of Obstetrics-Gynecology and Reproductive Biology, Boston, U.S.A.*
[2]*Harvard T.H. Chan School of Public Health, Department of Epidemiology, Boston, U.S.A.*

Study question: Among patients with infertility, is endometriosis associated with differences in baseline antimüllerian hormone (AMH) levels?

Summary answer: Patients with endometriosis, regardless of prior ovarian cystectomy, were observed to have lower AMH values and higher incidence of diminished ovarian reserve at infertility evaluation.

What is known already: Patients with moderate to severe endometriosis experience an accelerated decline in AMH levels following ovarian cystectomy which may lead to a decreased reproductive life span. It is unclear whether women with endometriosis have lower AMH levels at baseline. Conversely, polycystic ovarian syndrome is associated with higher AMH levels and a longer time to menopause compared to normo-ovulatory controls.

Study design, size, duration: This retrospective cohort study included three groups of women who presented for infertility evaluation at our tertiary care center from 04/27/2015 to 05/31/2017: 29 women with endometriosis and a history of ovarian cystectomy (EndoOC), 29 women with endometriosis without a history of ovarian cystectomy (Endo), and 240 women with male factor infertility (MFI; control group).

Participants/materials, setting, methods: AMH levels (ng/mL; using Ansh Labs Ultra-Sensitive assay) were measured as part of the routine infertility evaluation. Patients diagnosed with endometriosis were surgically staged per the revised American Society for Reproductive Medicine scoring system. Linear regression using robust standard errors and logistic regression models were adjusted *a priori* for age, body mass index, race, and smoking status to estimate adjusted beta coefficients (aβ) and adjusted odds ratios (aOR) with 95% confidence intervals (CI).

Main results and the role of chance: The mean ± standard deviation of age (years) and body mass index (BMI; kg/m^2) was similar across groups: EndoOC age = 33.4 ± 3.5, BMI = 25.2 ± 5.9; Endo: age = 33.9 ± 3.9, BMI = 25.8 ± 5.7; MFI: age = 34.0 ± 3.6, BMI = 25.4 ± 5.9. Compared to the MFI group (4.0 ± 3.1 ng/mL), a lower mean AMH level was observed in the EndoOC group (3.1 ± 2.9; aβ -1.12, 95% CI [-2.2, -0.05]) and in the Endo group (2.7 ± 2.3; aβ -1.30, 95% CI [-2.17, -0.43]). The mean AMH level was similar for the Endo group compared to the EndoOC group (aβ -0.09, 95% CI [-1.34, 1.16]). Women were more likely to have an AMH <1 in the EndoOC group (24.1%; aOR 3.53, 95% CI [1.22–9.25]) and in the Endo group (24.1%, aOR 2.71, 95% CI [1.00–7.40]), compared to women in the MFI group (10.8%). The proportion of women with an AMH <1 was similar for the Endo group compared to the EndoOC group (aOR 1.00, 95% CI [0.27 – 3.65]).

Limitations, reasons for caution: The generalizability of these results to women with endometriosis and normal fertility may be limited. Given our small sample, we have limited power to detect differences in AMH levels between different stages of endometriosis which may represent important disease heterogeneity.

Wider implications of the findings: Lower baseline AMH levels in infertility patients with endometriosis could suggest an increased rate of decline in ovarian reserve over time in this population. Early referral for fertility assessment and treatment in patients with known endometriosis may be prudent.

Trial registration number: not applicable.

P-270 Oral contraceptive use in women with pelvic pain and endometriosis: history of ineffectiveness or discontinuation due to side-effects

N. Alsowayan, M. Bedaiwy, P. Yong, C. Allaire, C. Williams, S. Lisonkova

University of British Columbia, Faculty of Medicine- Department of Obstetrics and Gynaecology, Vancouver, Canada

Study question: To investigate the relationship between failure of combined oral contraceptive pill (COC) regimens due to ineffectiveness or side effects, and pelvic pain severity and quality-of-life in women with endometriosis.

Summary answer: Discontinuation of COC due to ineffectiveness for pain or due to side-effects, was associated with more severe pelvic pain and poorer quality-of-life in endometriosis.

What is known already: COCs are regarded as the first line of therapy in treating endometriosis associated chronic pelvic pain. Although several studies were performed to evaluate their effectiveness, many has reported patient discontinuation of treatment because of side effects intolerability or lack of symptomatic control without expanding this trend.

Study design, size, duration: Analysis of a prospective patient registry from a tertiary care referral center for patients with endometriosis and pelvic pain between December 2013 to and April 2015.

Participants/materials, setting, methods: 656 patients in reproductive age who were prospectively consented for the registry. Patients had to fill the online questionnaire which included eleven point numeric rating scale (0-10) for pain symptoms, Endometriosis Health Profile 30 "EHP-30", Patient Health Questionnaire "PHQ-9" for depression assessment, and Generalized Anxiety Disorder "GAD-7" questionnaire for anxiety assessment.

Main results and the role of chance: Prior cyclical COC use was reported by 362 (55.2%) women, of which 167 (25.5%) stated it was ineffective for their pain and 139 (21.2%) stated they discontinued due to side effects. Previous continuous COC was reported by 267 (40.7%) women, of which 110 (16.8%) stated it was ineffective and 80 (12.2%) stated they discontinued due to side effects. Worse chronic pelvic pain severity in the last 3 months was associated with a history of ineffectiveness of COC use whether cyclical ($p<0.008$) or continuous ($p<0.001$). Worse dysmenorrhea and poorer quality-of-life was present in women who reported a history of COC discontinuation due to side effects.

Limitations, reasons for caution: Retrospective analysis potentiates for selection and information bias. However, our data was collected prospectively through online patient questionnaire, thus it was dependent on the accuracy of subject's input.

Wider implications of the findings: Further research is needed to identify novel treatment approaches for women with endometriosis who are non-responders to COC.

Trial registration number: not applicable.

P-271 Reciprocal changes of H3K27ac and H3K27me3 at the promoter regions of the critical genes for endometrial decidulaization

N. Katoh[1], K. Kuroda[2], J. Tomikawa[1], H. Ogata-Kawata[1], R. Ozaki[2], A. Ochiai[2], M. Kitade[2], S. Takeda[2], K. Nakabayashi[1], K. Hata[1]

[1]*National Center for Child Health and Development, Department of Maternal=Fetal Biology, Tokyo- Setagaya-ku, Japan*
[2]*Juntendo University, Obstetrics and Gynecology, Bunkyo-ku, Japan*

Study question: To capture the epigenetic dynamics and to understand its roles during decidualization, we conducted transcriptome and epigenome profiling for endometrial stromal cells and decidualized cells.

Summary answer: We discovered that the promoter regions of the genes critical for decidualization are often associated with the reciprocal changes of H3K27ac and H3K27me3 marks.

What is known already: Decidualization, the transformation of endometrial stromal cells (ESCs) into secretory decidual cells, is essential for embryo implantation and placental development, and is dependent on the postovulatory increases in progesterone and local cyclic AMP production levels in humans. The responsiveness of ESCs to the hormonal cues is thought to be potentiated by genome-wide chromatin remodeling followed by the coordinated action of decidua-specific transcriptional networks. However, information for such epigenetic alterations has been limited.

Study design, size, duration: Endometrial biopsies were obtained from the uterine fundus from two women of reproductive age without endometriosis who underwent laparoscopic cystectomy. The tissues were processed for primary endometrial stromal cell culture. The primary cells remained untreated (D0), or decidualized for 4 days (D4) and 8 days (D8) in the presence of 8-bromo-cAMP and progesterone. Genomic DNA, total RNA, and formaldehyde-fixed chromatin were prepared from cells.

Participants/materials, setting, methods: The resultant endometrial stromal (D0) and decidualized cells (D4, D8) from two donors were subjected to transcriptome and methylome profiling as well as chromatin immunoprecipitation followed by next-generation sequencing (ChIPseq) for H3K27ac (an active chromatin mark), and for H3K9me3 and H3K27me3 (repressive chromatin marks). DNA methylation, gene expression, and histone enrichment profiles were compared between untreated (D0) and decidualized (D4 and D8) cells to search for differential gene expression and epigenetic modifications upon decidualization.

Main results and the role of chance: Although the H3K27ac and H3K27me3 profiles have already been reported previously, our data for these histone modifications enabled us to have detected larger numbers of peaks and differentially enriched regions upon decidualization. Among the epigenetic modifications examined (DNA methylation, H3K27ac, H3K9me3, and H3K27me3), the H3K27ac patterns changed most dramatically, with a moderate correlation with gene expression changes, upon decidualization. We revealed that subsets of up- and down-regulated genes upon decidualization were associated with reciprocal changes of H3K27ac and H3K27me3 modifications at their promoter region and were enriched with genes essential for decidualization. The top 23 genes most extremely up-regulated were found to contain four genes (namely, WNT4, ZBTB16, PROK1, and GREB1) that have been shown to be essential for decidualization. The top 8 genes most extremely down-regulated also contained two genes, CRABP2 and PTHLH, whose down-regulation has been shown to be critical for decidualization. These results demonstrate a central role of epigenetic regulation in the coordinated gene expression changes required for decidualization. We minimized the role of chance in our results by obtaining and assessing datasets from two independent donors. Our dataset is useful to elucidate further the molecular mechanisms underlying decidualization.

Limitations, reasons for caution: It should be noted that all results were obtained through the analysis of in vitro decidualized cells from donors without abnormality in endometrium. It is important to obtain epigenome profiles of ESCs and decidualized cells from donors with endometriosis and compare such datasets with those obtained in this study.

Wider implications of the findings: siRNA knockdown screening for the genes with the reciprocal changes of H3K27ac and H3K27me3 at their promoter region will help identifying additional critical genes for decidualization. Such genes represent novel targets for the development of therapeutic drugs to recover the implantation and the pregnancy rates of recurrent miscarriages.

Trial registration number: not applicable.

P-272 A comparison of Toll-like receptors and cytokine profiles in the endometrium around the time of implantation between women with and without chronic endometritis

Y. Liu[1], G.C.W. Man[1,2], X. Chen[1], F. Wu[1], W.C. Cheung[1], Y. Zhao[1], J. Huang[1], C.C. Wang[1], T.C. Li[1]

[1]*The Chinese University of Hong Kong, Obstetrics and Gynaecology, Shatin- New Territories, Hong Kong*

[2]*The Chinese University of Hong Kong, Orthopaedics and Traumatology, Shatin- New Territories, Hong Kong*

Study question: Does the presence of chronic endometritis (CE) affect the expression of Toll-like receptors (TLR) and inflammatory cytokine profiles in endometrial tissues around the time of implantation?

Summary answer: The expression of TLR1, 2, 3, and 4 and Interferon gamma (IFN-γ) in the endometrial tissues of women with CE was higher than without CE.

What is known already: The prevalence of CE has been found to be higher in women with recurrent miscarriage and recurrent implantation failure. However, the exact mechanism whereby implantation is affected in women with CE is largely unknown. One earlier study showed the expression of TLR4 was increased in women with CE. Another study showed the alteration of cytokine profiles in CE patients. However, in these earlier studies, the validity of the observations has been questioned because the specimens were not precisely timed, and because it is well recognized that TLRs and cytokine profiles change throughout the cycle.

Study design, size, duration: This is a non-interventional observational study on the expression of 10 TLRs and 17 different inflammatory cytokines in precisely timed endometrial tissue collected from 83 women with reproductive failure.

Participants/materials, setting, methods: Endometrial tissue was collected from participants seeking treatment for infertility. All specimens were collected on day LH+7. Chronic endometritis was defined as plasma cell density above normal range established from a fertile control population (> 5.15 CD138+ plasma cells/0.1 mm^2, Liu Y *et al.*, in press). TLRs 1-10 were stained by conventional immunohistochemistry for each specific antibody. In addition, 17 different inflammatory cytokines were analysed with the Luminex technique (Millipore, Billerica, MA) following protein extraction.

Main results and the role of chance: Among 83 patients studied, 19 were found to have CE, and the other 64 did not have CE. There was no difference in age, duration of infertility, and the number of miscarriage between these two groups.

In women with CE, the endometrial expression of some TLRs was significantly altered. In particular, stronger expression of TLR 1, 2, 3, and 4 were observed in endometrial epithelial and glandular cells when compared with women without CE.

Among the 17 cytokines examined, the expression of IFN-γ in women with CE was 3.69 pg/mL, which was significantly higher ($p = 0.034$) than that of in women without CE, 3.47 pg/mL. However, there was no statistically significant difference found among the other 16 cytokines and chemokines (EGF, G-CSF, GM-CSF, IL-10, IL-12P40, IL-12P70, IL-13, IL-1α, IL-1β, IL-2, Il-4, IL-5, IL-6, MCP-1, MIP-1β and TNF-α) studied. The data indicate that altered amount of IFN-γ in human endometrium with CE may be a result of higher expression of TLR 1, 2 3, and 4.

Limitations, reasons for caution: The relative small sample size of this study precludes the analysis of the relationship between conception and pregnancy outcome.

Wider implications of the findings: It appears that adverse effect of CE on reproduction is mediated via the IFN-γ pathway. Further study should be conducted to explore how alteration of IFN-γ leads to implantation failure with the regulation of TLRs.

[7]Hôpitaux Universitaires de Strasbourg, Laboratoire de Diagnostic Génétique, Strasbourg, France

Study question: Endometriosis has long been suspected of familial tendencies. Our goal is to identify genes involved in the pathogenesis of ovarian endometriosis by using genomic approach.

Summary answer: Whole exome sequencing (WES) on a large consanguineous Turkish family revealed a possible causative gene mutation segregating with ovarian endometriosis phenotype in the family.

What is known already: Endometriosis is a common gynecologic disease defined as the growth of endometrial tissue outside the uterine cavity. Laparoscopic visualization of endometriotic lesions remains the 'gold standard' in diagnostic tests. Though, only 70–75% of visually diagnosed lesions are confirmed histologically. Despite its high prevalence and incapacitating symptoms, the etiology of endometriosis remains unclear. A number of chromosomal loci have been found to be associated with endometriosis in selective populations; however genes that play a role in endometriosis remain to be identified.

Study design, size, duration: This study has been performed at the Strasbourg University, France in collaboration with the Bahceci Health Group, Istanbul, Turkey. A large, consanguineous Turkish family having six affected women in two generations as well as more than two unaffected women was available for the study. 19 well-defined individual ovarian endometriosis cases and 20 endometriosis free women were also included for further validation.

Participants/materials, setting, methods: Saliva samples, not pathological samples, have been used for the WES in order to avoid possible accumulation of mutations in the pathological samples. Genomic DNA was extracted from saliva according to the manufacturer's instructions (DNAGenotech, Ottowa, Canada). WES was performed on four affected and two non-affected samples by the Institute of Genetics and Molecular and Cellular Biology microarray and sequencing platform, member of the 'France Génomique programme'. Suspected mutations were confirmed via Sanger sequencing.

Main results and the role of chance: We identified a heterozygous 3'-UTR variation in an autosomal gene which is co-segregating with the ovarian endometriosis phenotype in the family. The gene in question is located on chromosome 19, belongs to protein family that regulates endometrial epithelial cell adhesion, trophoblast motility and invasion during implantation. The variation is predicted to be deleterious via different prediction tools. In order to validate the identified mutation and check for other possible mutations in the gene, all exons and exon/intron boundaries of the identified gene were amplified and sequenced in 19 ovarian endometriosis patients and 20 controls. The analysis is still on going.

Limitations, reasons for caution: Our study contains only a limited number of Turkish patients. Mutation screening should be continued on larger groups of ovarian endometriosis patients, including women of other ethnicities. Also for obvious ethical reasons, no in-vivo works were possible.

Wider implications of the findings: In long term, results will help us to define potential non-invasive test for ovarian endometriosis. Understanding the fundamental molecular mechanisms in ovarian endometriosis pathogenesis is the first step to develop novel therapeutic approaches, to eliminate endometriosis lesions and to prevent recurrence.

Trial registration number: Not applicable.

P-274 Assisted Reproductive Techniques (ART) and their possible effect on the progression of endometriosis symptoms

M. Mathiasen[1], A.G. Egekvist[2], U.S. Kesmodel[3], U. Breth Knudsen[4,5], M. Seyer-Hansen[2]

[1]Aarhus University and Aarhus University Hospital- Denmark, Department of Obstetrics and Gynecology, Aarhus, Denmark
[2]Aarhus University Hospital AUH, Department of Obstetrics and Gynecology, Aarhus, Denmark
[3]Herlev and Gentofte University Hospital, Department of Obstetrics and Gynecology, Herlev, Denmark
[4]The Regional Hospital in Horsens, The Fertility Clinic, Aarhus, Denmark
[5]Aarhus University, Institute of Clinical Medicine, Aarhus, Denmark

Study question: Do women with endometriosis experience worsening in endometriosis symptoms (quality of life, pain, bowel symptoms) when undergoing controlled ovarian stimulation (COS) during assisted reproductive techniques (ART)?

Summary answer: This study did not find worsening in the abovementioned parameters during ART, which supports ART as a suitable therapeutic option for infertile women with endometriosis.

What is known already: 10-25% of women with endometriosis require ART to conceive. During COS levels of estrogen increases, hence in theory increasing the risk of progression of symptoms related to endometriosis. Anaf et al. identified four cases of rapidly growing sigmoid endometriosis during ovarian stimulation resulting in cessation of ART and bowel surgery. Ten similar cases have occurred in our department since 2007. Moreover, isolated cases with severe worsening of endometriosis during COS have been reported.

Study design, size, duration: Prospective cohort study carried out from February 2016 to October 2017 with a total of 177 women recruited. Participants were excluded during the study if they were lost to follow-up, or if egg retrieval was cancelled. This study is based on questionnaires containing the Endometriosis Health Profile (EHP-30), and pain and bowel habits were evaluated on the numerical rating scale (NRS). Questionnaires were administered before and after COS in one cycle of ART.

Participants/materials, setting, methods: Patients < 40 years old were recruited from three fertility clinics and the endometriosis unit, Aarhus University Hospital (AUH). Depending on endometriosis diagnosis (confirmed by previous laparoscopy, transvaginal ultrasound or magnetic resonance imaging) and ART, patients were assigned one of three groups (endometriosis with or without ART, or no endometriosis undergoing ART). According to power calculations each group should include 48 women. Median and mean changes in pain and quality of life scores are reported.

Main results and the role of chance: 52 women with endometriosis undergoing ART (+Endo/+ART), 50 not undergoing ART (+Endo/-ART), and 52 without endometriosis undergoing ART (-Endo/+ART), answered two questionnaires.

The three groups differed significantly on all pain parameters (general and worst non-menstrual pelvic pain, dyschezia, dyspareunia, and dysuria) at baseline, women without endometriosis had a significantly better score in all EHP-30® modules (pain, control and powerlessness, social support and emotional well-being) except self-image where the groups did not differ. Bowel parameters (constipation, diarrhea, nausea, vomiting and bloating) were comparable between the groups, except that +Endo/-ART indicated worse bloating.

Changes from 1st to 2nd questionnaire indicated that -Endo/+ART experienced a one NRS point greater worsening in the parameters 'tired" and 'general non-menstrual pelvic pain" compared to women with endometriosis ($p = 0.003$, and $p<0.001$). Regarding worst non-menstrual pelvic pain, the median changes were 1, 2.5, and 0 for +Endo/+ART, -Endo/+ART, and +Endo/-ART, respectively ($p<0.001$). Women with endometriosis, undergoing ART or not, experienced a slight improvement in EHP-30® modules during ART compared to -Endo/+ART who worsened in all modules except 'self-image". None of the three groups changed in bowel parameters except bloating where both ART groups experienced an increase of one NRS point compared to +Endo/-ART ($p = 0.020$).

Limitations, reasons for caution: Women with endometriosis were included regardless of stage, which caused disease heterogeneity. +Endo/-ART was recruited from a tertiary referral center. Hence, this group may have particularly severe endometriosis stages. In the group of women without endometriosis subclinical disease might have been present without the clinicians' knowledge.

Wider implications of the findings: Our results are in line with previous studies (Benaglia et al. and Coccia et al.) which further supports ART as a suitable therapeutic option for infertile women with endometriosis. Our two reference groups added new information by allowing differentiation between changes in parameters caused by ART and endometriosis individually.

Trial registration number: The Danish Data Protection Agency: Registration number 2012-58-006). ClinicalTrials.gov: NCT02762461.

P-275 Molecular characterization of PRM associated endometrial changes (PAEC) following mifepristone treatment

N.R. Boggavarapu[1], C. Berger[1], S. Queckbörner[1], E. Norlin[1], K. Hornaeus[2], A. Falk[2], M. Engman[1], L. Pgl[1], K. Gemzell-Danielsson[1]

[1]*Karolinska University Hospital, Women and children health, Stockholm, Sweden*
[2]*Uppsala University, Analytical chemistry, Uppsala, Sweden*

Study question: Does endometrium displaying PAEC after mifepristone treatment have a characteristic gene and protein expression?

Summary answer: Molecules significantly altered in PAEC after mifepristone exposure are mainly involved in the structural architecture of tissue, which may explain the morphological features of PAEC.

What is known already: The non-physiological endometrial changes caused by the progesterone receptor modulator mifepristone, PAEC, have previously been morphologically described but not explored at molecular level in regards to both gene and protein expression.

Study design, size, duration: A comparative analysis of gene and protein expression between endometrium displaying PAEC (n = 7) and endometrium that did not develop PAEC (n = 6) after three months of mifepristone treatment was performed. The current observational cross-sectional study is part of a previous randomized, placebo-controlled clinical trial at Karolinska University Hospital in Stockholm, Sweden.

Participants/materials, setting, methods: Endometrial biopsies, obtained from pre-menopausal women treated with mifepristone prior to surgery due to uterine leiomyoma, were evaluated regarding occurrence of PAEC and a comparative analysis of molecular expression between endometrial samples displaying PAEC and non-PAEC endometrial samples was performed. Methods used include microarray analysis, real time PCR, Ingenuity Pathway Analysis and Proteomics Analysis with Mass Spectrometry and Immunohistochemistry.

Main results and the role of chance: Combinations of characteristic non-physiological features were observed in 53.8% of collected endometrial samples. We observed non-decidualized stroma and both inactive and secretory active glands as well as extensively apoptotic glands, mitotic glands and apoptotic degeneration and atrophy.

Microarray analysis showed 181 differentially regulated genes by a minimum of two-fold in PAEC samples compared to non-PAEC samples. 142 genes were upregulated and 39 were downregulated. Microarray findings were validated by real time PCR for nine genes, three of them, THY1 (p = 0.02, fold change (FC) = 3.18), ADAM12 (p = 0.04, FC = 3.28) and TN-C (p = 0.04, FC = 3.21) reported in endometrial function were differentially regulated with PAEC. The proliferation marker MKi67 was not statistically significantly altered between the groups.

Mass spectroscopic analysis showed 25 proteins upregulated and 5 downregulated in endometrium with PAEC compared with non-PAEC and most of the proteins including TUBA4A (p = 0.002), MYOF (p = 0.006), TPM4 (0.013), RRBP1 (p = 0.021) and CSRP1 (p = 0.001), DPYSL3 (p = 0.012), FMOD (p = 0.045) are involved in tissue morphology. Mass spectrometry findings were validated with immunohistochemistry and were found to be in accordance with mass spectrometry results, but none of the tested antibodies were statistically significant by immunohistochemistry.

Limitations, reasons for caution: Although most of the endometrial samples from the clinical trial were used for analysis in this study, the main limitation is the small sample size. 14 women were randomized to receive mifepristone in the pilot study.

Wider implications of the findings: Our study has generated new knowledge on the molecular profile of endometrium displaying PAEC after 3 months of mifepristone treatment due to symptomatic leiomyoma. This knowledge is of great importance as the application of progesterone receptor modulators (PRMs) for the medical management of benign gynecological conditions is increasing.

Trial registration number: www.clinicaltrials.gov:NCT00579475

P-276 Endometriosis pathogenesis: role played by the oxidative stress due to MTHFR mutations

A. Clement[1], D. Cornet[2], P. Neveux[1], P. Clement[1], Y. Menezo[1]

[1]*Laboratoire Clement, Laboratoire Clement, PARIS, France*
[2]*Clinique de la Muette, Paris, Paris, France*

Study question: Can endometriosis in infertile patients be linked to the oxidative stress due to methylenetetrahydrofolate reductase (MTHFR) mutations?

Summary answer: A clear relationship has been established between MTHFR mutations and the pathogenesis of endometriosis. Treating patients to by-pass MTHFR mutations consequences improves ART outcomes.

What is known already: Endometriosis pathogenesis is unclear and its etiology is complex. Recent studies mention the role of oxidative stress implicated in the pathophysiology of endometriosis by causing a general inflammatory response in the peritoneal cavity (Augoulea, 2009).

MTHFR is a key enzyme involved in folate metabolism and in the genesis of major antioxidant molecules (gluthatione, hypotaurine). Oxidative stress can be induced by polymorphisms of MTHFR through the increased homocysteine level (Guo, 2016).

To our knowledge, no study in the literature analyzed the role played by MTHFR in the endometriosis genesis of infertile patients.

Study design, size, duration: From January 2016 to january 2018, we followed 30 infertile patients suffering from endometriosis and having had at least 1 ART (Assisted Reproductive Technologies) cycle failure.

At first, we compared the MTHFR mutations distribution in our population.

The patients carrying a MTHFR mutation were afterwards treated and we compared the pregnancy rates obtained before and after treatment.

Participants/materials, setting, methods: All the infertile patients involved in this study were diagnosed with endometriosis according to the ESHRE 2013 guidelines.

The presence of MTHFR C677T was determined from a venous blood sample, using real time PCR with the RealFast™ assay (ViennaLab Diagnostic GMBH, Vienna, Austria).

The infertile patients with recurrent ART failures (2 to 7) and carrying MTHFR mutations were treated with 5MTHF (5 Methylene Tetrahydrofolate), a treatment by-passing the problems linked to MTHFR impaired activity.

Main results and the role of chance: Among the endometriosis population of our study, 60% of the patients are carrying the MTHFR mutation (46.7% in a heterozygous state, 13.3% in a homozygous state). This proportion is significantly more important ($p<0.05$) than the proportion of patients carrying MTHFR mutations in the general population: 50.5% (Zappacosta, 2009).

Furthermore, after we treated infertile couples with endometriosis and recurrent ART failures (2-7) carrying MTHFR mutations, we significantly improved their ART outcomes (average ongoing pregnancy rate per cycle: 23.4% before treatment; 29.6% after treatment, $p<0.05$).

Limitations, reasons for caution: Our results needs to be confirmed on a larger population. The genetic analysis of the MTHFR gene needs to be enlarged to other mutations related to the one carbon cycle in order to screen all the patients in which fertility could be affected by oxidative stress due to MTHFR mutations.

Wider implications of the findings: Endometriosis can be explained by MTHFR mutations. The resulting oxidative stress impairs the fertility of the female patients.

Therefore, by improving the methylation and decreasing the oxidative stress, treating MTHFR mutation carriers improves the quality of the gametes and their ART outcomes.

Trial registration number: None.

P-277 Functional genomic meta-analysis identifies similarities between endometrial-related subfertilities

A. Devesa-Peiro[1], P. Sebastian-Leon[2], F. Garcia-Garcia[3], V. Arnau[4], A. Pellicer[5], P. Diaz-Gimeno[2]

[1]*University of Valencia / IVI-RMA Fundación IVI. Genomic & Systems Reproductive Medicine, Valencia, Spain*
[2]*IVI-RMA Fundación IVI. Instituto de investigación sanitaria INCLIVA- University of Valencia, Research. Genomic & Systems Reproductive Medicine, Valencia, Spain*

[4]University of Valencia-CSIC, ETSE. Institute for Integrative Systems Biology I2SysBio, Valencia, Spain
[5]IVI-RMA Fundación IVI. Instituto investigación sanitaria La FE- University of Valencia., Reproductive Medicine. Pediatrics- Obstetrics and Gynecology, Valencia, Spain

Study question: Are there relevant enriched functions shared both within and between endometrial-related subfertilities as endometrial adenocarcinoma, endometriosis, Recurrent Implantation Failure (RIF) and Recurrent Pregnancy Loss (RPL)?

Summary answer: Specific enriched functions were common between all considered endometrial-related subfertilities. RIF and endometriosis were the most similar, and RPL differed from all others.

What is known already: Endometrial-related pathologies are complex, multifactorial conditions affecting female fertility. Prior studies described endometrial adenocarcinoma, endometriosis, RIF, and RPL through transcriptomics analysis using case vs control approaches to identify altered genes and functions. However, the underlying mechanisms linking these conditions to endometrial subfertility remain controversial due to small sample sizes and differing experimental designs. Functional meta-analysis techniques provide a more robust method to highlight the most important functions associated with a set of individual studies. The objective of this research was to identify enriched shared functions within and between endometrial-related subfertilities studies for robustly underlaying the common molecular basis.

Study design, size, duration: An in-silico study involving systematic review, transcriptomic analysis, and functionally integrative meta-analysis was applied to selected case vs control experiments associated with endometrial-related pathologies. From 613 datasets, we included 3 from endometrial adenocarcinoma, 2 from RIF, 2 from RPL, and 2 from eutopic endometrium of endometriosis. Functional meta-analysis techniques were employed to a) separately identify shared functions and pathways related to each single condition; and b) to determine altered functions common between endometrial-related conditions.

Participants/materials, setting, methods: Raw data were downloaded from Gene Expression Omnibus (GEO). Selected datasets were preprocessed, normalized using quantile method (Limma R-package), and explored through principal component and clustering analysis. Gene Set Enrichment (mdgsa R-package) was performed on differential expression analysis results (Limma R-package). Functional meta-analysis was performed using DerSimonian & Laird random-effects model to identify significant shared functions (False Discovery Rate (FDR) < 0.05). Functional databases consulted were Gene Ontology and Kyoto Encyclopedia of Genes and Genomes.

Main results and the role of chance: Functional meta-analysis allowed us to identify functional connections within studies related to each endometrial-related pathology. Functions such as cell junctions, p53 signaling pathway, endoplasmic reticulum, and cell adhesions (3.9412e-07<=FDR< = 0.00016) were associated with adenocarcinoma; proteasome complex, amine transport, apical part of cell, and chromosome-related functions (7.2107e-06<=FDR< = 0.04849) with RIF; DNA replication and ribonucleoprotein complex (0.00035<=FDR< = 0.04281) with RPL; and proteasome, mitochondria, and microtubule-related processes (0.00434<=FDR< = 0.04823) with endometriosis. Results from integrating all endometrial subfertilities (adenocarcinoma, RIF, RPL, endometriosis) identified 8 shared functions related to cell projections (0.00282<=FDR< = 0.03690), chromatin DNA binding (FDR = 0.0440), and organelle assembly (0.00053<=FDR< = 0.0336). Furthermore, when RPL, RIF, and endometriosis were integrated by pairs, RPL was the least similar, having only one common function with RIF (FDR = 0.0484) and 8 with endometriosis (1.0609e-05<=FDR< = 0.04390). RIF and endometriosis were the most similar, sharing 21 functions (1.1262e-08<=FDR< = 0.04823). Finally, those pathologies involving tissue growth (endometrial adenocarcinoma and endometriosis) were found to have a higher number of altered genes and functions than RIF or RPL.

Limitations, reasons for caution: Despite including good-quality GEO datasets, this study is limited by available endometrial-related subfertilities and the heterogeneity between studies. However, all datasets were transcriptomically analyzed using the same methodology and the applied meta-analysis incorporates the variability of each study, robustly integrating them at a functional rather than at a gene level.

Wider implications of the findings: Due to functional alteration similarities between endometriosis and RIF, there is evidence that eutopic endometrium is affected, supporting the controversial idea that endometriosis affects endometrial function. Shared detected functions between all considered endometrial subfertilities could enable development of a common method to diagnose all of them.

Trial registration number: not applicable.

P-278 Interventions for endometriosis related infertility: a systematic review and network meta-analysis

R. Hodgson[1], H.L. Lee[2], R. Wang[3], B.W.J. Mol[3], N. Johnson[3]

[1]Cairns Hospital, Women's Health, Cairns, Australia
[2]Adelaide University, School of Medicine, Adelaide, Australia
[3]Robinson Research Institute, University of Adelaide, Adelaide, Australia

Study question: What is the comparative effectiveness of different treatments for women with endometriosis associated subfertility?

Summary answer: More research is required to clarify the relative effectiveness of treatments for endometriosis-related infertility.

What is known already: Most recognised therapies have not been directly compared in randomised controlled trials, therefore there is no direct evidence to inform clinical decision-making, hence selection of the most effective treatment is difficult. NMA compares multiple treatments in one statistical model. It is possible to guide treatment decision-making through the provision of a hierarchy of effectiveness of the treatment options. In the setting of subfertility related to endometriosis, the ability to apply this model is invaluable, as it is an area where there are numerous intervention options, and it has the potential to promote selection of the optimal therapy.

Study design, size, duration: A systematic review and network meta-analysis of relevant randomised control trials (RCTs) was performed. We searched electronic databases including, MEDLINE, Embase and the Cochrane Central Register of Controlled Trials (CENTRAL), as well as reference lists to identify eligible studies.

Participants/materials, setting, methods: We included RCTs comparing any medical or surgical interventions to each other or placebo/ no treatment in couples with endometriosis associated subfertility. The primary effectiveness outcome is a composite of clinical pregnancy.

Main results and the role of chance: 4,252 titles/abstracts were identified through the literature search, of which we included 27 trials reporting on 2,195 women with endometriosis associated subfertility. We included 14 different interventions in NMA. The most frequent direct comparisons were surgical laparoscopy versus surgical laparoscopy plus gonadotrophin releasing hormone analogues (GnRHa) (7 studies, 686 women), surgical laparoscopy versus placebo (3 studies, 483 women), GnRHa versus danazol (4 studies, 127 women) and danazol versus placebo (2 studies, 99 women). All 27 studies reported on clinical pregnancy. In vitro fertilisation (IVF) and intrauterine insemination (IUI) could not be included in the NMA, as RCTs compared only different stimulation protocols for IVF and for IUI and none of the RCTs compared IUI or IVF versus no treatment, placebo or other interventions.

Network meta-analysis showed that compared to placebo, Lipiodol (OR 7.56, 95% CI 1.95-29.37) and surgical laparoscopy plus pentoxifylline (OR 3.44, 95 CI 1.08-10.93) resulted in more clinical pregnancies; GnRH-a (OR 1.54, 95% CI 0.93-2.56) and surgical laparoscopy OR 1.43, 95% CI 0.93-2.56) were likely to result in more clinical pregnancies. Dydrogesterone (OR 3.00, 95%CI 0.69-13.30), pentoxifylline (OR 1.98, 95%CI 0.55-7.17) and laparoscopy plus danazol (OR 1.72, 95%CI 0.34, 8.78) showed imprecise effect sizes.

Limitations, reasons for caution: The CIs in most interventions with large ORs were imprecise and therefore should be exercised with caution. The value of the NMA was limited as IVF and IUI could not be included. Live birth was reported in only 5 studies in the network meta-analysis.

Wider implications of the findings: The most important conclusion is that more RCTs are needed to clarify the relative effectiveness of treatments for endometriosis-related infertility, in particular RCTs comparing IVF or IUI to other treatments including surgical laparoscopy and lipiodol to other treatments.

Trial registration number: N/A.

P-279 The role of reproductive tract microbiome in infertility

V. Gota, M.R. Mitropoulou, S. Arkouli, G. Basios, T. Arkoulis

IVF Mitosi, Embryology Lab, Pireaus, Greece

Study question: How the microbiome of the endometrium of asymptomatic women with a history of infertility influences IVF techniques?

Summary answer: The molecular investigation of endometrium tissue from infertile women for common microbes unravels "silent" infections that may affect on Assisted Reproductive Technologies (ART).

What is known already: The human microbiome has gained much attention recently for its role in health and disease. Sexually transmitted infections are a major concern to clinicians and researchers in the field of reproductive medicine especially if the inflammation concerns the endometrium. An untreated inflammation caused by those agents, can lead to serious consequences, including miscarriages, tubal obstruction, preterm birth, chronic pelvic pains and unexplained infertility. The most common used method for microbe detection is based on culture results of cervicovaginal secretions. However, this diagnostic method is insufficient since it is difficult to detect any kind of infection in the upper genital tract.

Study design, size, duration: The aim of our study is to use the endometrium as a study material for the molecular detection -using real time PCR- of *Chlamydia trachomatis*, *Ureoplasma sp*, *Mycoplasma hominis*, *Mycoplasma genitallium* and Herpes I/II. In order to subtract cervicovaginal secretions and to detect microbes directly from the endometrium, we used a pipelle suction to retrieve the material. In the present study, endometrium tissue samples of Greek women were collected from January 2013 till December 2017.

Participants/materials, setting, methods: The study group was a total of 358 Greek women of age 36.4 ± 4,8 (Mean ± St.Dev) with fertility problems. Endometrium samples were collected with endometrial biopsy under hysteroscopy with mild sedation of the women and were screened for the presence of *Chlamydia trachomatis*, *Ureoplasma sp*, *Mycoplasma hominis*, *Mycoplasma genitallium* and Herpes I/II by real time PCR. The procedure of sample collection trying to mimic the embryo transfer technique.

Main results and the role of chance: In the overall study group, the prevalence of *Chlamydia trachomatis* was 1.1%, *Ureoplasma sp* was 7.26%, *Mycoplasma hominis* was 0.83%, *Mycoplasma genitalium* was 0.27% and Herpes I/II was 0.27%. There is a prevalence of Ureoplasma sp infection in the upper genital tract of infertile women. These findings suggest that microbiome present in the upper genital tract and could be detected efficiently by molecular techniques (real time PCR).

Limitations, reasons for caution: The sample collection occurs under mild sedation of the women.

Wider implications of the findings: Our study suggests that there is a possible correlation with uterus microbiome and infertility. In addition, our results demonstrate that the investigation of endometrium tissue for infectious microbes by using real time PCR, could be used as an alternative technique, unraveling a "silent infection".

Trial registration number: Not applicable.

P-280 Effect of endometriosis on sperm motility and organization of the tail microtubules

P. Lorca[1], I. Velasco[2], P. Sáez[3], M.I. Acien[2], M.J. Gomez[3]

[1]*Universidad Miguel Hernández de Elche, Medicina Clinica, San juan de alicante, Spain*
[2]*Universidad Miguel Hernández de Elche, Salud Pública- Historia de la Ciencia y Ginecología, San Juan de Alicante, Spain*
[3]*Universidad de Alicante, Biotecnología, Alicante, Spain*

Study question: To evaluate in vitro the effect of peritoneal fluid (PF) from women with endometriosis on sperm motility and organization of the sperm flagellar structure.

Summary answer: In vitro exposure of sperm to endometriosis PF is associated with an early decrease of progressive motility and an alteration of the tail microtubules.

What is known already: Endometriosis is a hormone-dependent disease associated with infertility in 30% of patients. The peritoneal fluid (PF) of women with endometriosis decreases sperm function and interfere with the correct oocyte-sperm interaction. The clinical relevance of sperm motility is evident, but the molecular mechanisms involved in this process have not yet been fully understood.

Study design, size, duration: Experimental study. 36 patients were recruited for the study obtaining the sample of PF during surgery (18 patients with endometriosis and 18 with other benign ovarian cysts).

Participants/materials, setting, methods: Human donor sperm was incubated during 24 and 48 hours in absence (control group) or presence of PF diluted at 20% from women with (n = 18) and without endometriosis (n = 18). Sperm motility was assessed by optical microscopy and the organization of the sperm tail microtubules was evaluated by fluorescence microscopy (alpha-tubulin immunostaining) in all experimental conditions, evaluating three types of patron after staining: 1) continuous tail; 2) discontinuos tail; and 3) not stained tail.

Main results and the role of chance: Sperm motility decreased significantly along the time of culture in all conditions. The greatest difference was observed at 24 hours, being a higher decrease in endometriosis group compared to non-endometriosis group ($p = 0.004$) and control ($p = 0.001$). Regarding to the alpha-tubulin distribution, the greatest difference was observed at 48 hours of culture in all patrons: 1) continuous tail, $p = 0.008$; 2) discontinuos tail, $p = 0.002$; and 3) not stained tail, $p = 0.046$, comparing endometriosis versus non-endometriosis group.

Limitations, reasons for caution: The main limitation of our study is the introduction of a possible variability in the basal cell properties because of the selection of four different human sperm donors. Moreover the sample size must be increased in order to establish definitive conclusions.

Wider implications of the findings: Previous studies have described altered sperm motility comparing PF from endometriosis patients to healthy women. In our study, we compared the condition of endometriosis to other ovarian pathologies, showing that quality sperm is more affected by factors present in the endometriosis PF.

Trial registration number: NA.

P-281 Comparing the clinical efficacy of intrauterine cook balloon and contraceptive device in preventing adhesion reformation and improving pregnancy outcomes after hysteroscopic adhesiolysis in IVF/ICSI

H. Chen[1], Y. Li[2], H. Guo[3], G.X. Lu[2], G. Lin[2], F. Gong[2]

[1]*Reproductive and Genetic Hospital of CITIC-XIANGYA, Reproductive center, Changsha, China*
[2]*Institute of Reproductive and Stem Cell Engineering- Basic Medicine College- Central South University-Reproductive and Genetic Hospital of CITIC-XIANGYA, China,*
[3]*Reproductive and Genetic Hospital of CITIC-XIANGYA, China,*

Study question: Are the intrauterine cook balloon effective for preventing adhesion reformation and improving pregnancy outcomes?

Summary answer: The long term intrauterine cook balloon placement for 2 months with hormone replacement therapy are efficacy in preventing adhesion reformation and improving clinical outcomes.

What is known already: There are many strategies now available to prevent adhesion recurrence and restoring endometrium. Previous studies have described that intrauterine cook balloon and IUD are of similar efficacy in the prevention of adhesion reformation. But both devices were removed only after 1 week. The recurrence of adhesion rate is 10-30%, and the study did not report the pregnancy outcomes following the treatment. Limited dates are available whether to increase days of cook balloon stents can decrease the recurrence of adhesion rate and remove the balloon in the FET cycle can promote endometrial proliferation and improve the clinical pregnancy rate.

Study design, size, duration: This retrospective analysis involved 566 infertile women with moderate to severe intrauterine adhesion and received the frozen thawed embryo transfer (FET) cycle at the Reproductive and Genetic Hospital of CITIC-Xiangya between October 2016 and July 2017.

Participants/materials, setting, methods: The patients in the cook balloon group were matched by 1:2 with IUD controls. At the end of the hysteroscopy procedure the patients were fitted with cook balloon or IUD for 2

months. In all cases hormone replacement therapy was commenced since the third day of menstrual cycle that the first hysteroscopy were carried out, until FET cycle which second-look hysteroscopy was carried out in the proliferative phase 2 months after the first surgery.

Main results and the role of chance: According to the inclusion criteria and exclusion criteria, there were 76 cook balloon patients and 152 IUD control patients.

The hysteroscopy outcomes suggested that there was no statistical different in adhesion grade(P = 0.647), American Fertility Society (AFS) score before operation(6.8 ± 1.31vs 6.58 ± 1.28, P = 0.233) in two groups. But compared to IUD group, the AFS score after operation(P = 0.00) and recurrence of adhesion(1.32%vs 20.4%, P = 0.00) were significantly decreased in cook balloon group. It is comparable to the endometrial thickness on embryo transfer (ET) day(9.65 ± 1.12vs 9,66 ± 1.66,P = 0.963), number of embryo transferred (1.30 ± 0.61vs 1.36 ± 0.58, P = 0.527), high quality embryo rate(55,71%vs 51.38%, P = 0.552) and cancellation rate(7.89% vs 5.26%, P = 0.435) between cook balloon group and IUD group. The clinical outcomes suggested that the implantation rate(32.32% vs 19.43%;P = 0.013), clinical pregnancy rate(44.28% vs 25%;P = 0.004), ongoing pregnancy rate(40% vs 20.83%;P = 0.003) in cook balloon group are higher than IUD group.

Limitations, reasons for caution: Lack the evaluating of the bacterial colonization or infection in the uterus after 2 months with cook balloon stent. Well-designed, adequately powered random controlled trials are needed.

Wider implications of the findings: Long term intrauterine cook balloon placement can improve the pregnancy outcomes of infertile women with moderate to severe intrauterine adhesion.

Trial registration number: none.

P-282 A long-term pretreatment with GnRH agonists prior to IVF/ICSI does not improve the clinical pregnancy rate in patients with endometriosis: a systematic review

A.A. Marino[1], S. Gullo[2], A. Volpes[1], F. Sammartano[1], A. Maiorana[3], A. Allegra[1]

[1]ANDROS Day Surgery Clinic, Reproductive Medicine Unit, Palermo, Italy
[2]ANDROS Day Surgery Clinic, Medical Statistics Unit, Palermo, Italy
[3]A.R.N.A.S. Civico Hospital, Department of Obstetrics and Gynecology, Palermo, Italy

Study question: Does a long-term pituitary suppression with GnRH agonists prior to IVF/ICSI improve the clinical pregnancy rate (CPR) in patients with endometriosis?

Summary answer: In endometriosis, a long-term pituitary suppression does not improve the CPR, increases the stimulation duration and total gonadotropins dose, reducing the number of retrieved oocytes.

What is known already: The mechanisms of endometriosis-associated infertility have been debated for years and they are still unclear. Excluding altered pelvic anatomy, these mechanisms include: abnormal folliculogenesis, elevated oxidative stress, altered immune function. In IVF, these factors lead to poor oocyte quality, impaired fertilization and implantation. In order to increase pregnancy rates in patients with endometriosis, various approaches have been proposed. A meta-analysis (Sallam et al., 2006) demonstrated that a down-regulation for 3-6 months with GnRH agonists prior to IVF/ICSI increases the odds of clinical pregnancy by >4-fold. This meta-analysis was included in the ESHRE guidelines published in 2014 (grade of recommendation B).

Study design, size, duration: A systematic review, based on PubMed, ISI-Web, Cochrane CENTRAL, EMBASE, was conducted to verify the effectiveness of the long-term pretreatment with GnRH agonists in patients with endometriosis. According to *PICO* format, inclusion criteria were: *Population*, endometriosis patients; *Intervention*, long-term pretreatment with GnRH agonists; *Control*, no long-term pretreatment; *Outcome*, clinical pregnancy in patients undergoing IVF/ICSI. Secondary outcomes were: duration of stimulation, total dose of gonadotropins, oocytes retrieved, fertilization rate (FR), embryos transferred, ongoing pregnancy rate (OPR).

Participants/materials, setting, methods: A bibliographic search was undertaken from 2006 to 2017, yielding 54 studies. Three researches (A.M., S. G., A.V.) reviewed independently the studies, excluding 36 studies after the first screening (title and abstract) and 10 studies after the second screening. The Mantel-Haenszel method was used to calculate odds ratios (OR) and heterogeneity among studies (I^2). The results were expressed as OR with 95% confidence intervals (CI). Standardized mean differences (SMD) between groups were used for continuous outcomes.

Main results and the role of chance: Eight studies were included. Three were RCTs; the remaining studies were cohort/case-control.

In two studies (Söritsa et al., 2015, Decleer et al., 2016), stage I-II endometriosis was considered; in three studies (Ma et al., 2008; Tamura et al., 2014; van der Houwen et al., 2014), stage III-IV endometriosis; in two studies (Surrey et al., 2010; Rodriguez-tarrega et al., 2016) all stages. In one case (Gong et al., 2009), the endometriosis was not classified.

The female age was comparable among the studies.

CPR was not significantly different in women receiving the long-term pretreatment compared with the control group (OR 1.25, 95% CI 0.82 to 1.91, I^2 = 0%). No differences in FR (OR 0.83, 95% CI 0.51 to 1.35, I^2 = 0%), number of embryos transferred (t=-1.26, p = 0.21, SMD -0.19, 95%CI -0.49 to 0.11, I^2 = 64%) and OPR (OR 1.36, 95% CI 0.80 to 2.31, I^2 = 0%) were observed. The patients pretreated had a lower number of oocytes retrieved in comparison with control group (t = -2.53, p = 0.01, SMD -0.20, 95%CI -0.35 to -0.04, I^2 = 36%), such as a longer duration of stimulation (t = 2.49, p = 0.01, SMD 0.41, 95%CI 0.09 to 0.73, I^2 = 76%), and a higher total dose of gonadotropins (t = 2.40, p = 0.07, SMD 0.48, 95%CI 0.09 to 0.88, I^2 = 84%).

Limitations, reasons for caution: In selected studies, patients with different stages of endometriosis were included. The couples' basal characteristics (AFC, AMH, FSH, BMI, seminal parameters, previous surgery) were not indicated in all the studies. Although the duration of the pretreatment with GnRH agonists was comparable among the studies, the formulations and dosages were different.

Wider implications of the findings: This review indicates no improvement in terms of IVF/ICSI success when the endometriosis patients are pretreated with GnRH agonists. We believe that diagnosis of endometriosis is not a critical parameter in the choice of treatment protocol.

Further well-designed studies are needed to corroborate our results.

Trial registration number: Not applicable.

P-283 Impact of endometriosis on assisted reproduction cumulative outcome

A. Bazzocchi, C. Zacà, M. Cattoli, M.A. Bonu, A. Borini

9.baby Family and Fertility Center, Assisted Reproduction, Bologna, Italy

Study question: Is cumulative live birth rate (CLBR) impaired in endometriosis patients?

Summary answer: Cumulative birth rate is overall significantly lower in endometriosis patients, compared to idiopathic infertility, but the significance disappears when adjusted for number of oocyte retrieved.

What is known already: Endometriosis can cause adhesive disease that alters pelvic anatomy and may yield an inflammatory altered immune environment that has the potential to impact oocyte quality, embryogenesis and implantation.

Several studies, including systematic reviews and meta-analyses, have yielded conflicting results regarding the impact of endometriosis on ovarian reserve and IVF outcomes; some suggest comparable ART outcomes between women with and without endometriosis, whereas others suggest that the presence of endometriosis negatively affects ART success, but cumulative success rates have not yet been analyzed.

Study design, size, duration: This is a retrospective cohort study. 1672 patients diagnosed with idiopathic infertility and 387 endometriosis patients who underwent IVF between 2009 and 2012, were included.

Participants/materials, setting, methods: CLBR has been calculated by adding up births resulting from fresh embryotransfer and births from thawing embryo cycles, per number of oocyte retrievals.

CLBR was evaluated in idiopathic group and endometriosis group. A further analisys included stratification per age and per number of oocytes retrieved.

Patiens aged < 37 years and 38-45 years, with more than 8 oocytes retrieved were analyzed in the two groups.

Main results and the role of chance: Number of oocytes retrieved was overall statistically lower in endometriosis group (6.3 vs 8.1; p< 0.001), as well as CLBR (16.5 % vs 21.8; P< 0.001).

In patients younger than 37 years old, with more than 8 oocytes retrieved (respectively 13.2 and 11.9 on average, in idiopathic and endometriosis; p = ns), CLBR was comparable between the two groups, with a tendency towards worse results in endometriosis group (41.5 % and 32.9%, p = ns)

In patients aged 38-45 years old, with more than 8 oocytes retrieved (respectively 12.5 and 13.8 on average, in idiopathic and endometriosis; p = ns), CLBR was comparable between the two groups, with even a tendency towards better results in endometriosis group (23.6 % and 29.2%, p = ns).

Therefore, the cumulative outcomes of assisted reproduction seem to be impaired by endometriosis, mainly by reducing the number of oocytes retrieved. When the number of oocyted retrieved is the same, cumulative birth rate is not statistically reduced in endometriosis patients, not even in older patients.

Limitations, reasons for caution: The study groups are quite small. The endometriosis group includes all endometriosis stages.

Wider implications of the findings: Given the importance of the number of oocytes retrieved in endometriosis, ovarian reserve should be preserved from radical surgery and ovarian stimulation should be personalized and improved, in order to obtain a good number of oocytes.

Trial registration number: Not applicable.

P-284 The sensitivity of DNA damage response target ovarian gap junction proteins in granulosa cells in women with advanced endometriosis

R. Chattopadhyay[1], S. Ghosh[2], S.K. Goswami[2], G. Bose[2], K. Jana[3], G. Ganguly Mukherjee[4], P. Chakraborty[4], B. Chakravarty[2]

[1]Institute of Reproductive Medicine, ART, Calcutta, India
[2]Institute of Reproductive Medicine, Assisted Reproductive Technology, Calcutta, India
[3]Bose Institute, Molecular Medicine, Kolkata, India
[4]Institute of Reproductive Medicine, Infertility, Calcutta, India

Study question: What is the impact of DNA damage response (DDR) on granulosa cells (GC) in women with advanced endometriosis?

Summary answer: Double strand breaks (DSBs) trigger ATM/ATR/Chk1 axis to activate DDR suppressing ovarian gap junction protein (GJP) expression in GCs in advanced endometriosis.

What is known already: Endometriosis is a disease associated with elevated reactive oxygen species (ROS), both in follicular environment and systemically. DSBs are the most critical type of DNA damage which activate signal transduction by ataxia telangiectasia mutated (ATM), ataxia telangiectasia (ATR) and Rad3-related proteins to promote DNA repair and arrest cell cycle. However, recent data document other factors besides DDR proteins responsible for detection of DSBs in mouse granulosa cell DNA. Attenuation of ovarian GJP (connexins (Cx)) involves decreased follicular development and growth retardation in oocytes. There is little information whether DDR target Cx proteins to alter follicular growth in advanced endometriosis.

Study design, size, duration: Experimental study; Samples of follicular fluid (FF) and GC were obtained from February 2016 to October 2017 from 48 infertile women, 14 with early endometriosis, 23 with advanced endometriosis and 11 with tubal or male factors of infertility as control group, who underwent ovarian stimulation for IVF at our Assisted Reproduction unit. FF was obtained during oocyte retrieval and MGC were isolated from the follicular fluids of each woman through a Histopaque gradient.

Participants/materials, setting, methods: GCs were exposed to FF to estimate ROS production by flow-cytometry. DNA damage was assessed by immunofluorescence to quantify histone-H2AX phosphorylation (γH2AX) foci. DDR (pATM, ATR, Chk1, GADD45G) and ovarian GJP expression (Cx 37, 43) were evaluated by immunoblot in MGCs. Effect of DDR on Cxs in endometrial epithelial cell line (RL95-2) was evaluated with addition of 10 mm ATM,ATR, Chk1,and GADD45 inhibitors by immunoblot. P <0.05 was considered to be significant as evaluated by Student's t-test.

Main results and the role of chance: GCs exposed to 50 µl/ml FF for up to 24 hours led to a significant increase in ROS production in both early and advanced endometriosis. No significant difference was observed between GCs in early endometriosis and controls in γH2AX foci assay; however, induction of DSBs was noted in advanced endometriosis showing more γH2AX foci (P<0.01). Increased levels of ROS and cell death induced by γH2AX accumulation result in the activation of DDR components in early and advanced endometriosis; pATM (NS, P<0.01), ATR (NS, P<0.01), Chk1 (NS, P<0.025), and GADD45G (P< 0.05, P<0.03). Moreover, a significant diminution was observed in Cx 37 (NS, P<0.01) and 43 (NS, P<0.03) protein expressions of GCs in early and advanced endometriosis. To evaluate the effect of DDR on Cxs *in vitro*, we observed addition of ATM inhibitor, ATR inhibitor and Chk1 inhibitor ameliorated the protein expression/s in the culture system considerably (P<0.001). However, a combination of all four inhibitors demonstrated no extra advantage. Taken together, the findings suggest that a reduction in both Cx protein expressions in advanced endometriosis after DSBs requires ATM/ATR/Chk1 activity, suggesting possible arrest in early pre-antral and antral follicles impeding folliculogenesis leading to production of incompetent oocytes.

Limitations, reasons for caution: Small sample size; Signals emitted from GCs is solely due to an increase in ROS was not evaluated by a ROS inhibitor either in early or advanced endometriosis. In addition, no positive control has been used for the experimental set-up/s.

Wider implications of the findings: DDR induced by increased ROS alter oocyte-granulosa cross talk to influence follicular growth and maturation in women with advanced endometriosis in GCs. Identification of other gap junctional proteins and elucidation of their physiological functions within the follicle must be research priorities of the future.

Trial registration number: Not applicable.

P-285 Systemic inflammation and coagulation status in stage 3-4 endometriosis

A. Vural[1], M. Dizdar[2], S. Sahin[2], B. Ergin[2], R. Arısoy[3], B. Mohammadi[4], G. Kıran[2]

[1]Ümraniye EAH, Obstetrics and gynecology, İstanbul, Turkey
[2]Health Sciences University- Umraniye Research and Education Hospital, Obstetrics and Gynaecology, Istanbul, Turkey
[3]Memorial Atasehir Hospital, Department of Obstetrics and Gynecology, İstanbul, Turkey
[4]University College of London - EGA Institute for Women's Health, Prenatal Genetics and Fetal Medicine, London, United Kingdom

Study question: Do the coagulation and inflammation status differ in women with surgically confirmed Stage III- IV endometriosis?

Summary answer: Neutrophil count and mean platelet volume are higher in women with stage-III/IV endometriosis and activated partial thromboplastin time is shortened compared to benign gynecologic pathologies.

What is known already: Local inflammatory process has a pivotal role in the pathogenesis of endometriosis. However, the role of systemic inflammation in the pathogenesis of endometriosis is unclear.

Study design, size, duration: This retrospective cohort study used data from a single medical center from 2012 to 2017.

Participants/materials, setting, methods: A total of 321 women who underwent surgery were evaluated. The case group (n: 220) included patients with a surgical diagnosis of stage III-IV endometriosis. The control group (n: 101) consisted of women with a surgical diagnosis of benign gynecologic pathology. The routine preoperative tests including complete blood count parameters, activated partial thromboplastin time, prothrombin time and International Normalized Ratio (INR) were obtained at a maximum of 1 month before surgery.

Main results and the role of chance: Mean platelet volume (MPV) and neutrophil count were higher in patients with endometriosis when compared to controls (8,63 ± 5,32 vs. 7,95 ± 1,45; p = 0,012) and (4,96 ± 2,58 vs 4,33 ± 1,34; p = 0,004) respectively. Although in the normal range, women with endometriosis had significantly shortened activated partial thromboplastin time (aPTT) (29,86 ± 3,19 vs 28,72 ± 2,69; p = 0,002) than controls. Conversely,

no difference was found for protrombin time, INR, platelet count, lymphocyte count between women with endometriosis and controls.

Limitations, reasons for caution: This study has some limitations: (1) the retrospective design of the study that could have influenced the interpretation of our findings and (2) the presence of only one type of controls, the surgical population. Therefore the results should be taken with caution.

Wider implications of the findings: Elevated neutrophil count and MPV and shortened aPTT in patients with Stage III-IV endometriosis may reflect an inflammatory and/or procoagulant systemic status in these patients. Further studies are warranted to confirm our findings and to assess the role of systemic inflammatory and coagulation markers in the pathophysiology of endometriosis.

Trial registration number: Not applicable.

P-286 Influence of peritoneal fluid from patients with endometriosis on sperm glycocalyx

P. Saez Espinosa[1], P. Lorca[2], I. Velasco[1,3], M.I. Acién[3,4], M.J. Gómez-Torres[1,5]

[1]Universidad de Alicante, Departamento de Biotecnología, Alicante, Spain
[2]Universidad Miguel Hernández de Elche, Medicina clínica, San Juan de Alicante, Spain
[3]Hospital Universitario San Juan De Alicante, Ginecología y Obstetricia, San Juan de Alicante, Spain
[4]Universidad Miguel Hernández de Elche, Salud Pública- Historia de la Ciencia y Ginecología, San Juan de Alicante, Spain
[5]Cátedra Human Fertility, Universidad de Alicante, Alicante, Spain

Study question: Can peritoneal fluid (PF) from women with endometriosis affect the redistribution of glycoconjugates in human sperm membrane?

Summary answer: Sperm cultured with PF from women with and without endometriosis presented different distribution of sugar residues in the glycocalyx.

What is known already: Endometriosis is a chronic gynaecological condition that affects around 10% of women of reproductive age and it is associated with infertility in 40% of the cases. Studies report that endometriosis significantly reduces oocyte quality, embryonic development and percentage of implantation. Also, it has been shown that PF from patients with endometriosis decreases sperm motility, acrosome reaction and the ability to penetrate the oocyte, hindering the correct interaction between oocyte and sperm. However, additional studies are necessary to know how the presence of endometriosis affects the disposition of glycocalyx sugars involved in sperm-oocyte recognition.

Study design, size, duration: We conducted a double-blind prospective study. A total of 30 PF were collected from patients with endometriosis (EP) (n = 15) and non-endometriosis (NEP) (n = 15) from November 2015 to September 2017. Semen samples were obtained from normozoospermic men (n = 5) as assessed according to World Health Organization criteria 2010.

Participants/materials, setting, methods: PF was collected by laparoscopy from EP and NEP. Sperm were capacitated by density gradients and cultured with 20% of PF during 0 h, 24 h, 48 h and 72 h (37°C and 5% CO_2). Controls were performed with commercial culture medium. Sperm cells were fixed in paraformaldehyde and carbohydrates were evaluated by fluorescent lectins: *Aleuria aurantia agglutinin* (AAA), *Concanavalin A* (ConA), *Peanut agglutinin* (PNA) and *Wheat germ agglutinin* (WGA). Results were observed by fluorescence microscopy and statistically evaluated.

Main results and the role of chance: Results showed significant differences in the location of certain sperm membrane carbohydrates depending on the PF. When we compared the results obtained in controls with cultures performed with PF from EP, significant differences ($p<0.05$) in the disposition of all sugars recognized by the AAA, ConA, WGA and PNA lectins at 24 h, 48 h and 72 h were found. On the other hand, these differences were reduced when comparing controls against FP cultures from NEP, since only significant differences were found in the distribution of carbohydrates identified by lectins ConA and AAA at 24 h and 48 h. In the same way, when contrasting the results obtained from the cultures using PF from patients with and without endometriosis, we found significant differences just in the location of the carbohydrates bound to the ConA and WGA lectins at 24 h. Therefore, these results allow mentioning that both the PF from EP and that of NEP influenced the distribution of sperm membrane sugars. However, as indicated by the results these glycocalyx differences are more marked when the sperm were cultured with PF of EP.

Limitations, reasons for caution: A relative small number of peritoneal fluids would be the main limitation of our study.

Wider implications of the findings: The high rate of significant differences found between the sugars glycocalyx location of sperm cultured with PF from EP and controls could negatively affect sperm-oocyte recognition and therefore be associated with infertility in endometriosis.

Trial registration number: Not applicable.

P-287 Role of TGF-b on endometriotic stem cells and its differentiation into cells with cancer phenotype

L.L.K. Parameswaran Grace, S. Vignesh-Srinivasan, M. Saare, J. Retkowski, A. Iyengar, C. Garcia Pascual, K. Gemzell-Danielsson

Karolinska Institute, Women's and Children's Health, Stockholm, Sweden

Study question: Does high levels of TGF-b reduce the invasiveness of endometriotic stem cells (EndoSC) and their differentiation into cells with cancer phenotype?

Summary answer: Treatment with TGF-b reduced invasion of EndoSC at doses and positively alters the expression of genes that are highly expressed in pre-cancerous cells.

What is known already: In a previous study, high mRNA levels of TGF-b1 was observed in stem cells derived from endometriotic tissue. High levels of TGF-b is seen in peritoneal fluid (PF) of endometriosis patients and is positively correlated to the severity of endometriosis.

Study design, size, duration: Tissues from endometrioma were collected after the planned surgical excision of endometrioma from women (n = 16) underwent surgery for endometriosis.

Participants/materials, setting, methods: EndoSC were isolated from endometriotic tissue using stem cell markers CD73, CD90, and EpCAM. Spheroids (50 m) were generated from EndoSC and the effect of TGF-b (2 ng/ml; 250 ng/ml; with/without TGF-b inhibitor Ly2109761) on cell invasion was studied by invasion assay. Molecules involved in epithelial-mesenchymal transition (SNAI1) and 20 genes over expressed in pre-cancer cells (SDC1, SDC4, ESR1, CTNNB1, BMI1, ARIDA1 ect.) were studied by real time PCR.

Main results and the role of chance: Treatment with TGF-b reduced the invasion of EndoSC spheroids. Addition of TGF-b inhibitor Ly2109761 reversed this effect in a dose dependent manner with the up regulation of SDC -1 and -4 indicating a direct link with Syndecan family and cell invasion process. Analysis of gene expression data by heat-maps with supervised hierarchical cluster and principle component analysis showed few samples clustered together with similar expression of molecules (TGF-b, ESR1, CTNNB1, BMI1, ARIDA1 and SDC4) known to be involved in pre-malignant conditions.

Limitations, reasons for caution: This study is limited by a small sample size and results will need to be confirmed in a larger study.

Wider implications of the findings: Results from this study if confirmed in a larger sample may help in developing treatment strategies to reduce the risk of endometriosis-associated cancer by using TGF- b inhibitor.

Trial registration number: NA.

P-288 Wnt signaling as a target for the treatment of endometriosis

R. Assaf[1], O. Farah[2], T. Tulandi[3], D. Dufort[3]

[1]McGill University, Medicine- Division of Experimental Medicine, montreal, Canada
[2]University of California San Diego, Pathology, San Diego, Canada
[3]McGill University Health Centre, Obstetrics and Gynecology, Montreal, Canada

Study question: We ultimately aim to assess Wnt signaling as a target for treatment of endometriotic lesions *in vivo* and *in vitro*.

Summary answer: We have shown that Wnt signaling is auto-activated in endometriotic lesions and appears to play a role in the development of endometriosis lesions.

What is known already: Endometriosis is a chronic condition defined by the presence of endometrial tissue outside the uterine cavity. It affects about 15% of women of reproductive age and can cause severe pain and infertility. The painful symptoms are only treated with hormonal treatments that achieve amenorrhea. Our lab has shown that Wnt signaling plays a role in the development of endometrial glands and in stromal cell proliferation and this pathway appears to be aberrantly activated in lesions of endometriosis patients.

Study design, size, duration: For *in vivo* experiments, we used 5 control and 5 mutant mice for each of the 3 time-points of disease development, and 10 mice for the *in vitro* mouse experiments.

For the *in vitro* patient study, we are in the process of obtaining endometriosis samples from 30 patients and treating them with different Wnt signaling inhibitors. We are measuring proliferation rates and investigating gene expression changes and expect to observe a reduction in proliferation following treatment.

Participants/materials, setting, methods: We are using the established auto-transplantation mouse model with a Wnt reporter strain to look at Wnt signaling activation *in vivo*, as well as a uterine-specific Porcupine conditional knock-out strain to study the role of Wnt signaling in endometriosis. We are comparing the *in vitro* proliferation of endometriotic cells in controls and mutants.

Peritoneal endometriosis lesions are obtained by physicians from the MUHC-RVH Department of OBGYN from women of reproductive age presenting with the condition.

Main results and the role of chance: We observed canonical WNT signaling activation in the lesions of reporter mice, but not in Porcupine knock-out mice, during the intermediate stages of the disease. Since these mutant mice do not express Wnt ligands in their reproductive tract, the activation of Wnt signaling must be due to uterine Wnt ligands, and not WNTs produced by other tissues. Additionally, mutant mice developed smaller lesions 3 and 6 weeks after the induction of endometriosis. This suggests that Wnt signaling is involved in endometriosis this mouse model. We are now looking to verify this *in vitro* in mouse endometriotic cells and patient samples.

Limitations, reasons for caution: Other mouse models exist, and some model the initiation of the disease more accurately, but the auto-transplantation model allows us to evaluate the development of endometriosis.

Wider implications of the findings: Understanding the function of Wnt signaling in the development and maintenance of endometriosis could lead to the identification of a new treatment to induce regression of the disease. The upstream signaling component Porcupine could be targeted to treat endometriosis, which our lab is currently testing *in vitro* and *in vivo*.

Trial registration number: not applicable.

P-289 Outcomes of conventional IVF versus ICSI in infertile women with endometriosis: a retrospective cohort study

A. Chargui[1], M. Bourdon[2], L. Ferreux[1], C. Maignien[2], A. Sallem[1], A.S. Gille[1], C. Patrat[1], J.P. Wolf[1], P. Santulli[2], K. Pocate-Cheriet[2]

[1]Hôpital Cochin - Assistance Publique des Hôpitaux de Paris, Service d'Histologie Embryologie Biologie de la Reproduction, PARIS, France
[2]Hôpital Cochin - Assistance Publique des Hôpitaux de Paris, Service de Gynécologie-Obstétrique II et de Médecine de la Reproduction, Paris, France

Study question: Are biological and clinical outcomes in infertile women with endometriosis better after ICSI than after conventional IVF?

Summary answer: Fertilization rate is significantly higher in ICSI cycles versus conventional IVF. Secondary outcomes are similar in the two groups.

What is known already: Endometriosis is a benign chronic gynaecological disease, defined as the presence of endometrial tissue outside the uterus. Prevalence is estimated to reach 15% of reproductive-aged women and 25-50% of infertile women. ART are commonly offered for managing endometriosis-related infertility. However it has been showed that peritoneal fluid from women with endometriosis inhibits the binding of spermatozoa to the zona-pellucida. One previous study concluded that ICSI is a better option than IVF in endometriosis because of a higher rate of fertilization leading to more embryos. There nonetheless remains a lack of knowledge concerning the optimal treatment between IVF and ICSI.

Study design, size, duration: Retrospective cohort study including 538 cycles (341 IVF and 197 ICSI) in infertile women with endometriosis performed between October 2012 and October 2017 at a tertiary care center (Cochin Hospital, APHP-Paris). Among the 538 cycles, fresh embryo transfer (FET) at Day 2/3 was performed for a total of 238 women (157 IVF and 81 ICSI).

Participants/materials, setting, methods: IVF and ICSI cycles were performed in women under 42 years having at least five cumulus-oocyte complexes (COC) after oocyte retrieval with ejaculated sperm. Primary outcome (fertilization rate) was compared between IVF and ICSI for the studied population and in FET subgroup. Secondary outcomes (number of embryo D2/D3, blastocyst formation) and clinical outcomes (implantation, miscarriage and ongoing pregnancy rates) were compared for FET subgroup. Statistical analysis was conducted using univariate and multivariate logistic regression models.

Main results and the role of chance: For the baseline characteristics between women undergoing IVF or ICSI, only AMH and AFC were significantly lower in ICSI group (p-values were respectively: 0.01 and 0.006). A significantly higher fertilization rate was reported in the studied population and FET subgroup (62.97 ± 22.12 % for IVF *versus* 69.11 ± 22.99% for ICSI $p = 0.001$ and 62.98 ± 22.16 for IVF *versus* 69.27 ± 19.30 for ICSI $p = 0.03$, respectively). No significant difference in the number of retrieved oocytes was found.

In the FET subgroup, no significant difference was shown when comparing the mean number of embryos at Day2/3 for IVF *versus* ICSI (7.2 ± 3.16 and 5.79 ± 2.77; $p = 0.074$), the mean number of embryos per transfer ($p = 0.825$) and blastocyst formation rate (42.0 ± 51.5% *versus* 36.0 ± 32 95%; $p = 0.85$). Clinical outcomes (implantation, miscarriage and ongoing pregnancy rates) were similar between the two groups.

Limitations, reasons for caution: Histological proof of endometriosis was not available for all the patients. Cumulative pregnancy rate was not evaluated because couples are still having frozen blastocysts not yet transferred.

Wider implications of the findings: These findings need to be confirmed by further prospective studies taking into account the stage of endometriosis. Yet, it brings a new insight in the complex task of dealing with infertile deep infiltrating endometriosis patients and might help physicians to choose between IVF and ICSI to optimize ART outcomes.

Trial registration number: No funding was sought for this study. Authors declare no competing interests.

P-290 Endometrial receptivity: Expression profile of candidate genes in endometriosis

C. Marrocco, A. Luddi, L. Governini, A. Capaldo, B. Semplici, V. Pavone, L. Boschi, V. De Leo, P. Piomboni

Siena University, Molecular and Developmental Medicine, siena, Italy

Study question: Are the genes involved in endometrial receptivity differentially expressed ineutopic compared to healthy endometrium? Does the hormonal hyperstimulation modulates thisprofile?

Summary answer: There is a different gene expression profile in tissues from healthy and eutopicendometrium. The in vitro hormonal hyperstimulation may affect this specific fingerprinting.

What is known already: Many pathologies affecting endometrial functionality should alterimplantation process and, as a consequence, cause infertility. Among others, endometriosis has anegative impact on embryo implantation and pregnancy rate and, for these reasons, it is consideredas one of the major causes of women infertility. Really, despite the great progress achieved byassisted reproductive techniques, implantation represents one of the most crucial stage. Moreover,several evidences suggest that controlled ovarian hyperstimulation may alters endometrialphysiology thus impairing receptivity, with possible negative effects on the embryo implantation.

Study design, size, duration: For this study, we have collected 6 endometrial tissue biopsies from healthy subjects and fromwomen with endometriosis, who underwent surgical interventions starting from January to October2017. Gene expression analysis of 24 genes involved in endometrial receptivity was carried out intissue biopsies and in primary HESC untreated or treated with FSH in combination with LH orhCG.

Participants/materials, setting, methods: The primary HESCs prepared from endometrium ofhealthy or endometriotic women, collected during

implantation window, were treated for 24 h withFSH in combination with LH or hCG, in order to reproduce hormonal hyperstimulation conditions.mRNA, extracted from both endometrial tissue and HESC was subjected to qRT-PCR in order toevaluate the expression levels of 24 selected genes involved in endometrial receptivity.

Main results and the role of chance: The investigated genes resulted differentially expressed inhealthy compared to eutopic endometrium, both in tissue and in stromal endometrial cells. Inaddition, we observed that in vitro hormonal stimulations significantly affect the gene expressionprofile of stromal endometrial cells. In particular, the expression of LIF and LIF receptor (LIFR)resulted differently modulated in healthy and eutopic endometrial tissue, whereas in HESC both LIFand its receptor have the same trend of expression. Noteworthy, the hormonal treatmentsignificantly reduced the expression of LIF in stromal cells, whereas significantly increased theexpression of its receptors. Among other genes, PAEP mRNA levels are significantly increased ineutopic compared to healthy tissue HESC, whereas its expression was extremely low in botheutopic and healthy HESCs, becoming undetectable upon hormonal treatment.

Limitations, reasons for caution: Different parameters may influence the response tohyperstimulation protocols, therefore larger study needs to be carried out in order to definitivelyvalidate these findings.

Wider implications of the findings: This approach allowed us to identify key genes whose expression is significantly modulated ineutopic compared to healthy HESC, also in response to hormonal hyperstimulation. This study, ifreplicated in a larger population, might contribute in understanding impact of the ovarianhyperstimulation protocols used in ART cycles.

Trial registration number: NONE.

P-291 Endometriosis is associated with a lower number of oocytes during IVF independently of serum AMH level

D. Albu[1], A. Albu[2]

[1]Carol Davila University of Medicine and Pharmacy, Gynecology, Voluntari, Romania
[2]Carol Davila University of Medicine and Pharmacy, Endocrinology, Voluntari, Romania

Study question: Does the serum anti-mullerian hormone level (AMH) overestimate the oocytes yield in infertile patients with endometriosis undergoing in vitro fertilization (IVF)?

Summary answer: In infertile patients, endometriosis is an independent predictor of a lower number of oocytes retrieved during IVF after adjustment for serum AMH and other confounders.

What is known already: AMH is a member of TGF-ß superfamily recognized as a biomarker of ovarian response and as a reliable tool for controlled ovarian stimulation (COS) for IVF. Endometriosis is a hormonally-mediated inflammatory condition, being hypothesized that the members of TGF-ß family, including AMH, are increased, affecting its ability to reflect the ovarian reserve. However, data showing the predictive value of AMH for IVF outcome in endometriosis are limited.

Study design, size, duration: We performed a retrospective study which included 376 infertile female patients undergoing controlled ovarian stimulation for IVF between June 2016 –June 2017

Participants/materials, setting, methods: The study group included 94 patients with endometriosis and 282 patients with other causes of infertility. All the patients were evaluated and treated for infertility with IVF in a private outpatient clinic. Only patients with endometriosis, tubal causes, idiopathic infertility and male factor were included. Patients with polycystic ovary syndrome were excluded from the study. The following data were recorded: age, body mass index (BMI), AMH, gonadotrophins dose, number of oocytes retrieved during IVF protocol.

Main results and the role of chance: The mean age of the study group was 34.23 ± 3.5 years, mean BMI 22.1 ± 3.81 kg/m^2, mean AMH value 2.57 ± 0.78 ng/mL. The two groups of patients were similar in terms of age, BMI and gonadotrophins dose used during COS. Patients with endometriosis had significantly lower AMH serum level (2.13 ± 0.99 versus 2.95 ± 1.1 ng/mL, p<0.05) and obtained a lower number of oocytes during IVF (6.24 ± 4.6 versus 7.84 ± 4.9, p<0.005) in comparison with control group. After adjustment for confounders (including AMH level) in a model of multivariate linear regression, both endometriosis (beta=-0.117, p = 0.019) and AMH (beta = 0.519, p<0.001) independently predicted the number of oocytes retrieved during IVF.

Limitations, reasons for caution: The limitations of the study are its retrospective design and the lack of data about the subtypes of endometriosis. Moreover, our study did not include patients with an increased level of AMH (possibly as a consequence of inflammation) and our results can not be applied to these patients.

Wider implications of the findings: The results of our study suggest that patients with endometriosis could have decreased response to COS in comparison with patients with other causes of infertility with similar AMH level. Therefore, AMH serum level might not have the same predictive value in patients with endometriosis.

Trial registration number: NA.

P-292 Telomerase component, Dyskerin (DKC1), is expressed and hormonally regulated in healthy endometrium: implications for endometrial pathologies

R. Al-Nafakh[1], M. Adishesh[1], J. Drury[1], G. Saretzki[2], D. Hapangama[1]

[1]Institute of Translational Medicine- University of Liverpool- Liverpool Women's Hospital, Department of Women's and Children's Health, Liverpool, United Kingdom
[2]Institute for Cell and Molecular Biosciences and the Ageing Biology Centre, Campus for Ageing and Vitality- Newcastle University, Newcastle, United Kingdom

Study question: Is dyskerin expressed in the healthy endometrium, altered in proliferative endometrial conditions and is it regulated by ovarian steroid hormones?

Summary answer: Healthy human endometrium expresses dyskerin, significantly lower dyskerin protein levels are observed in endometrial cancer and the expression is regulated by oestrogen, progesterone and dihydrotestosterone (DHT).

What is known already: Telomeres are maintained and elongated by the specialized enzyme telomerase. Telomerase activity is important for endometrial epithelial proliferation, dynamically regulated by ovarian steroid hormones and is implicated in endometrial proliferative conditions such as endometriosis and endometrial cancer. Although two of the core subunits of telomerase holoenzyme, the RNA Component, hTERC and the catalytic component, hTERT have been extensively studied in human tissues including the human endometrium, the 3rd component, dyskerin protein is not well described. The effect of ovarian steroid hormones on dyskerin in human cells is not yet known.

Study design, size, duration: A prospective observational study, included endometrial samples collected from 240 women in total. They were 52 healthy premenopausal (29 proliferative phase; 23 secretory phase); 32 postmenopausal women; 29 women with endometriosis (18 eutopic secretory phase; 11 ectopic endometriotic samples). 109 women with endometrial cancer. A further 18 women using a Mirena IUCD were also recruited.

Participants/materials, setting, methods: Endometrial samples were analysed with immunohistochemistry and western blotting for dyskerin protein, qPCR for *DKC1* gene expression. Telomerase activity was measured by TRAP assay, hTERC mRNA levels with qPCR. The hormone receptor expression in the endometrial samples were measured using immunohistochemistry and a four-tiered Liverpool endometrial steroid quick score. Ki67 proliferative index was evaluated as the percentage of immunopositive cells. Endometrial cancer cell line, Ishikawa was used to examine in-vitro hormonal regulation.

Main results and the role of chance: Healthy human endometrium showed a dynamic spatio-temporal expression pattern of dyskerin. The expression of dyskerin protein and mRNA was significantly increased in healthy postmenopausal endometrium, compared with the premenopausal endometrium (P = 0.0022 and P = 0.0021 respectively). Secretory endometrium had the lowest *DKC1* mRNA expression levels compared with the postmenopausal endometrium (P = 0.01).

We did not see a significant difference in dyskerin protein or DKC1 mRNA levels in the eutopic secretory endometrium of women with endometriosis compared with secretory phase from healthy women.

This was in contrast to *hTERC* which was significantly upregulated in secretory endometrium of women with endometriosis compared with healthy secretory endometrium (p = 0.0199).

Dyskerin immunoscores were significantly low in endometrial cancer samples compared with the healthy postmenopausal endometrium (P = 0.0002).

DKC1 mRNA levels were up regulated by oestradiol (E2) and DHT and down regulated by progesterone *in vitro* in Ishikawa cells. Progesterone induced downregulation of *DKC1* was counteracted by E2. However, in our in vitro study, ovarian steroid hormones did not have an obvious effect on telomerase activity measured by TRAP assay.

Limitations, reasons for caution: This is an observational study. The sample size that we have used to evaluate *DKC1* mRNA and telomerase activity was relatively small.

Wider implications of the findings: The observed in vivo and in vitro data showed that dyskerin is hormonally regulated and its immunoexpression was significantly lower in endometrial cancer compared with healthy postmenopausal endometrial tissue. That suggests that dyskerin might be a new target in developing treatments for endometrial proliferative disorders such as endometrial cancer.

Trial registration number: not applicable

P-293 Interactions between GSTs genes polymorphisms and trace metals are associated with endometriosis

G.L. Lai[1], C.R. Tzeng[2], C.Y. Yeh[1]

[1]*Taipei Medical University, School of Public Health, Taipei, Taiwan R.O.C.*
[2]*Taipei Medical University and Hospital, Center for Reproductive Medicine and Sciences, Taipei, Taiwan R.O.C.*

Study question: Are there interactions between GSTs genes polymorphisms and trace metals for endometriosis.

Summary answer: Yes, null genotype of GSTs genes may modify the effect of blood zinc and lead for endometriosis.

What is known already: The women with null types GSTs genotypes may associate with risk of endometriosis. Besides blood metal levels such as lead and cadmium are also associated with risk of endometriosis.

Study design, size, duration: This is a cross-sectional study design. From 2008 through 2010, this study included 181 women who visited the infertility clinic at Taipei Medical University Hospital. 64 endometriosis women and 117 non-endometriosis women were included.

Participants/materials, setting, methods: Blood samples were taken from each woman. Trace metal levels in blood were measured by inductively coupled plasma mass spectrometry (ICP-MS). The genotypes for GSTM1 and GSTT1 genes were identified by PCR.Odds ratios (ORs) and 95% confidence intervals (CIs) were calculated using multiple logistic regression models adjusted for probable confounders.

Main results and the role of chance: In stratification analysis, the null type GSTM1 group is with an OR = 0.34 (3rd tertile vs. 1st tertile, 95% CI, 0.13–0.86) for a reversed association between zinc levels and endometriosis and OR = 2.22 (3rd tertile vs. 1st tertile, 95% CI, 1.05-4.73) for an association between lead levels and endometriosis. The null type GSTT1 group is with an OR = 0.26 (3rd tertile vs. 1st tertile, 95% CI, 0.09–0.75) for a reversed association between zinc levels and endometriosis. In present type GSTM1 and GSTT1 group are with non-significant OR for associations between both these metal levels and endometriosis.

Limitations, reasons for caution: Because of the hospital-based design, generalization of these results to the general Taiwanese population and to other ethnic groups needs caution.

Wider implications of the findings: The GST family genes are known to be involved in the metabolism of environmental chemical agents. Women with null type GSTM1 and GSTT1 genotypes may be sensitive to zinc and lead exposure for having endometriosis.

Trial registration number: not applicable

P-294 No treatment versus surgical management of endometrioma on the IVF outcomes

V. Trindade[1], M.R. Hentschke[2], M. Badalotti[2], A. Petracco[2], J.D.R. Michelon[2]

[1]*Medical Resident in Human Reproduction, Fertilitat - Center for Reproductive Medicine, Porto Alegre, Brazil*
[2]*Doctor in Medicine, Fertilitat, Porto Alegre, Brazil*

Study question: Does surgery have a positive impact on the IVF outcome of patients with endometrioma?

Summary answer: Surgery for endometrioma showed to favor pregnancy rate and live birth rate per cycle, but this was not statiscally significant.

What is known already: Two meta-analyses have assessed the impact of endometrioma resection on IVF outcomes. One demonstrated no significant differences in clinical pregnancy rates, comparing surgical resection to no treatment. Other suggested that surgical management of endometrioma resulted in no benefits for a subsequent IVF cycle. Also, some studies suggested a decrease in ovarian reserve in women with endometrioma, and some studies suggested a further decrease in ovarian reserve after surgery.

Study design, size, duration: Retrospective case-control study, performed at Fertilitat - Reproductive Medicine Center, from 2001-2017, including 252 IVF cycles. Patients included were referred to IVF due to endometriosis. Group 1 was composed by patients who had laparoscopic excision of endometriomas by cystectomy or cauterization of the cyst. Group 2 was composed by patients who had an image of endometrioma confirmed by an ultrasound exam, and did not receive surgical treatment.

Participants/materials, setting, methods: We found 76 IVF cycles on group 1 and 176 IVF cycles on group 2. Number of oocytes retrieved, pregnancy rate and live birth rate was compared between groups. Summary data were presented as mean and standard deviation. Student's *t*-test or chi-square test were used. The null hypothesis was rejected when p <0.05

Main results and the role of chance: Group 1 was composed by 76 IVF cycles. Group 2, by 176 IVF cycles. The maternal age between group 1 and 2 was: 35.1 ± 3,5 *vs* 35.8 ± 3.7 year-old, p = 0,15. The number of oocytes retrieved between group 1 and 2 was: 5,5 ± 3,7 *vs*. 6,0 ± 5,1, p = 0,25. From 76 IVF cycles in Group 1, there were 47 embryo transfer cycles. From 176 IVF cycles in Group 2, there were 107 embryo transfer cycles. The number of embryo transferred per cycle was 2.0 ± 0.7 *vs* 2.1 ± 0.8 p = 0,66, between Group 1 and 2 respectively. The pregnancy rate between Group 1 and 2 was 21 (44,68%) *vs*. 41 (38,31%), p = 0,45. The live birth rate between Group 1 and 2 was 15 (31,91%) *vs* 29 (27,10%), p = 0,54.

Limitations, reasons for caution: Group 1 had fewer patients. On Group 1, there were different surgical techniques.

Wider implications of the findings: In patients with endometrioma, surgery seems to improve pregnancy and live birth rate, but this was not statiscally significant. It is important to assess the surgery risks of ovarian intervention, when current evidence suggests that women treated with surgery have similar cycle outcomes compared to those not treated.

Trial registration number: Not applicable.

P-295 Results from a case-control study comparing mean aneuploidy rates and pregnancy outcomes in women with and without endometriosis undergoing In Vitro Fertilization (IVF) cycles

R. Venturella[1], A. Vaiarelli[2], D. Lico[1], D. Cimadomo[2], L. Rienzi[2], B. Laura[3], C. Gentile[3], E. Alviggi[4], S. Alfano[4], P. D'Alessandro[4], F. Zullo[1], A. Conforti[5], F. Ubaldi[2]

[1]*University Magna Graecia, Chair of Obstetrics and Gynecology, Catanzaro, Italy*
[2]*Valle Giulia Clinic, GENERA center for Reproductive Medicine, Roma, Italy*
[3]*Poliambulatorio SALUS, GENERA Marostica, Marostica, Italy*
[4]*Clinica Ruesch, GENERA Napoli, Napoli, Italy*
[5]*University Federico II, Obstretics and Gynecology, Napoli, Italy*

Study question: Do women with and without endometriosis undergoing IVF with Pre-implantation genetic test for aneuploidies (PGT-A) before blastocysts transfer differ for aneuploidy rates and reproductive outcomes?

Summary answer: Endometriosis patients do not differ from their age and MII obtained oocytes-matched healthy peers for mean aneuploidy rates and for pregnancy outcomes in IVF cycles.

What is known already: It has been estimated that 30-50% of women with endometriosis can't conceive naturally and affected IVF patients have worse outcomes than women without endometriosis, such as lower number of oocytes retreived, reduced fertilization, implantation and pregnancy rates.

Several pathways have been exploited to explain the endometriosis-related subfertility, both at ovarian than at the endometrial side. The evidence that peritoneal higher levels of reactive oxygen species and inflammatory cytokines can cause oocyte microtubule and chromosome instability has suggested that even the rate of embryo aneuploidy could be increased in these patients, contributing to the poorer IVF outcomes of endometriosis patients.

Study design, size, duration: This study retrospectively evaluated data of women producing at least one blastocyst subjected to PGT-A after Intracytoplasmic Sperm Injection from November 2008 to March 2017. To limit the potential bias of the analysis, a case-control study design was adopted. Age at pick-up, number of previous IVF failures and number of MII oocytes were chosen as matching criteria, since they are reported among the strongest success predictors in IVF. Every case was matched with two controls.

Participants/materials, setting, methods: Data available from the entire PGT-A population were reviewed and the study population was divided into two groups, according to the presence or the absence of endometriosis. Demographic (age, previous miscarriage, previous failed IVF) and IVF-related information (number of MII, injected and fertilized oocytes, of blastocysts, of euploid blastocysts, of single embryo transfers, of positive beta-Human chorionic gonadotropin, biochemical pregnancy, clinical pregnancy loss, miscarriage and live birth rates) were collected and compared between groups.

Main results and the role of chance: In this study, 249 women affected by endometriosis were matched with 498 women without the disease, according to maternal age at pick-up (38.1 ± 2.9 years), previous IVF failure (0.6 ± 0.8 cycles) and number of MII oocyte retrieved (7.1 ± 3.8 per pick-up). In our population, the percentage of fertilized oocytes per number of MII oocyte was significantly lower in women with endometriosis than in control groups (77 vs 74%).

Percentage of blastocysts obtained per fertilized oocytes (51.0 vs 53.3%), mean blastocyst rate per fertilized oocyte per cycle (56.5 ± 25.2% vs 58.3 ± 26.8%), percentage of euploid blastocysts per biopsied embryo (49.4 vs 50.1%) and mean euploidy rate per blastocyst per cycle (46.8 ± 38.7% vs 43.7 ± 37.3%) did not differ between control patients and women with endometriosis.

Moreover, no significantly differences in terms of percentage of positive pregnancy tests per Single Euploid Embryo Transfer (eSET) (52.4 vs 57.7%), percentage of Biochemical Pregnancy Loss per positive pregnancy test (11 vs 10.6%), percentage of miscarriages per clinical pregnancy (12.3 vs 12.9%) and percentage of ongoing implanted blastocysts or babies born per SET (41.0 vs 44.9%) were detected between group. According to Post-hoc power calculation, we had 80% power to detect a 10% difference in the mean euploidy rate per cycle between groups.

Limitations, reasons for caution: This is a first retrospective analysis performed in 3 IVF Italian centers undergoing PGT-a cycles and eSET. Prospective studies could allow better stratification of endometriosis type and stage. Moreover, only patients which obtained at least one blastocysts have been included in the final analysis.

Wider implications of the findings: Our preliminary data demonstrate that the rate of aneuploidy and the pregnancy outcomes are not statistically significantly different between women with endometriosis as compared with age-matched controls in the IVF population. Aneuploidy therefore could not be related to the poorer IVF outcomes of endometriosis patients.

Trial registration number: not applicable.

P-296 RCT of intra-uterine administration or subcutanious injection of GCSF (granulocyte colony-stimulating factor) before embryo-transfer on resistant thin endometrium in IVF

R. Singh[1], M. Singh[2]

[1]*Bhopal Test Tube Baby Centre, Infertility, Bhopal, India*
[2]*Bhopal Test-Tube-Baby Centre, Infertility, Bhopal, India*

Study question: Does intrauterine administration Or Subcutanious injection of G-CSF (granulocyte colony-stimulating factor) prior to Embryo Transfer in patients with resistant thin endometrium improve endometrial thickness and pregnancy rate in IVF?

Summary answer: Subcutanious injection OR Uterine perfusion with G-CSF represents a promising new tool for the currently mostly intractable problem of inadequate, thin endometrium.

What is known already: In 2009, GCSF was successfully used in patients with recurrent abortions (Scarpellini & Sbracia 2009),and later another study reported promising results by using GCSF in four women undergoing IVF who had demonstrated highly inadequate endometrium(Gleicher et al. 2011). Since then, several studies with controversial results have evaluated the effect of GCSF on endometrial thickness and IVF success (Kunicki et al. 2014, Li et al. 2014,Xu et al. 2015). The implantation and pregnancy rates were significantly higher (Scarpellini & Sbracia 2012,et al.2015), whereas did not affect endometrial thickness, implantation, or pregnancy rates (Barad et al. 2014, Li et al. 2014).

Study design, size, duration: The study group (n = 56) received either intrauterine infusion of 300 microgramme /1 ml of G-CSF, or subcutanious injection of GCSF and control group (n = 56) underwent either placebo-saline infusion or placebo subcutanious multivitamin injection before Embryo Transfer.

Participants/materials, setting, methods: The study group (n = 56) received either intrauterine infusion of 300 microgramme G-CSF, or SC injection of GCSF and control group (n = 56) underwent either placebo-saline infusion OR placebo subcutanious injection before ET.

G-CSF was administered per intrauterine catheter on the day of hCG administration. If the endometrium had not reached at least a 7-mm within 48 h, a second infusion was given following oocyte retrieval and same was for Subcutanious route.

Main results and the role of chance: The endometrial growth was significantly different within the two groups. An improvement was shown between the control and G-CSF groups. Endometrial expansion to minimal thickness occurred within approximately 48–72 hour from G-CSF infusion./ SC injection. In all the subjects at the time of infusion of G-CSF, endometrial thickness was 6.23 ± 1.45 mm, and,after infusion /SC injection it increased significantly to 8.46 ± 1.27 mm. The IR and PR were statistically significantly higher in the group that received intrauterine infusion of G-CSF/ SC injection (24% and 34%, respectively) as compared with the control group (11% and 16%, respectively).

Optimal endometrial thickness reflects an adequate maturation, which is a key factor for embryo implantation.

Limitations, reasons for caution: The main strengths of our study were its randomized,controlled design and to evaluate for the first time the efficacy of both systemic subcutaneous and local intrauterine GCSF administration on IVF success.

Further more RCT are required to establish the best route and dose of GCSF administration in IVF patients.

Wider implications of the findings: Uterine perfusion or SC injection with G-CSF represents a promising new tool for intractable problem of thin endometrium. Proliferative and secretory changes in the endometrial lining are the result of a complex intrauterine environment where sex steroid hormones and different local factors play an important role for endometrial thickening.

Trial registration number: NOT APPLICABLE.

P-297 Optimising for patients with endometriosis and reducing the time of the gynaecological examination with a new concept of a pelvic examination chair

G. Edelstam[1], M. Hagmar[2], L. Makdessi[3]

[1]*Obstetrics & Gynecology, Obstetrics & Gynecology, Stockholm, Sweden*
[2]*Clinical Sciences- Danderyd Hospital, Department of Obstetrics & Gynaecology-Danderyd Hospital, SE 182 88- Stockholm-, Sweden*
[3]*Obstetrics & Gynecology, Obstetrics & Gynecology- Vrinnevi Hospital, 603 79 Norrköping, Sweden*

Study question: Is it possible to improve the pelvic examination and particularly for patients with pain due to endometriosis?

Summary answer: The intrusive examination process was compensated by improved comfort and respect for the patients' integrity which also significantly reduced the examination time.

What is known already: Most women with endometriosis have an unpleasant expectancy on gynaecological examinations. If an examination has been unpleasant, the patient will be hesitant to future pelvic examinations and vaginal ultrasounds. Awkward examination positions may cause psychological stress

for the patients with a subsequent risk of generating or magnifying a negative experience. The gynaecological chair with stirrups has had the same design for many years. One reason for the lack of development could be that the examination products are designed from the medical perspective. Human-oriented innovations for comfort irrespective of age and gender should be developed in collaboration with the patients.

Study design, size, duration: A prototype of a gender neutral pelvic examination chair was constructed without stirrups and with built-in heating in the soft upholster. The new technical solution provided improved integrity for the patient with the perineum only exposed during the examination procedure. The patients and the gynaecologists who performed the examination, answered 131 questionnaires concerning experiences after the examinations in the traditional examination chair and in the new prototype, respectively. The examination time was registered.

Participants/materials, setting, methods: The protypes of pelvic examination chairs were evaluated at outpatient gynaecological wards of two different university hospitals. The investigation was carried out by 13 gynaecologists who examined 131 patients in two subgroups with and without endometriosis. The questionnaires were filled out after the examinations were coded and collected feedback on an easy 5 graded scale on 9 questions.

Main results and the role of chance: The questionnaires demonstrated significance ($p<0.01$) in favour of the new concept on a majority of the aspects evaluated. The new pelvic examination chair with heating and without stirrups was rated significantly more comfortable and respectful for the patient's integrity. There were no differences between the groups in their attitude towards going through a pelvic examination, neither in any experience of pain during the examination. A question concerning the experience of examination without stirrups was rated 3.8 on the five graded scale. The gynaecologists were significantly more positive on all questions comparing the pelvic examination chairs with and without stirrups. Measuring the examination time demonstrated a significantly shorter procedure without stirrups. The time saved (average 1.6 minutes per patient) during a day on an outpatient gynecological clinic can permit that one patient more can be examined per day. The patients were not randomised to examination in the different pelvic examinations chair but the number of patiens and gynaecologists participating reduces the role of chance.

Limitations, reasons for caution: The questionnaires were coded but the investigation was for practical reasons not randomised. The patients were randomly invited to participate before the examination. There were no differences between the groups in the patients´ attitude towards going through a gynaecological examination, neither in any experience of pain during the examination.

Wider implications of the findings: The results in the present study demonstrated that minor adjustments of a gynaecological chair can generate a significantly more positive examination experience for the patients in a majority of the aspects investigated. This might have a positive impact on the drop-out rate from fertility treatments.

Trial registration number: not applicable.

P-298 IVF or ICSI: Which is better in women with endometriosis associated infertility requiring ART?

L.Y. Tan[1], K. Brown[2], H. Dhanani[2], L. Hughes[1], F. Tekpetey[1], B. Abu Rafea[1]

[1]*The Fertility Clinic- Victoria Hospital- Western University, Department of Obstetrics and Gynaecology, London, Canada*
[2]*Schulich School of Medicine and Dentistry, Western University, London, Canada*

Study question: Does IVF or ICSI improve reproductive outcomes in women with endometriosis associated infertility compared to infertile women with no endometriosis?

Summary answer: The findings of this study seem to suggest that there is no added benefit and it is potentially detrimental to recommend ICSI in women diagnosed with endometriosis associated infertility especially in moderate to severe (Stage III & IV) endometriosis.

What is known already: Endometriosis is associated with infertility. Between 25–50% of infertile women have endometriosis and 30 – 50% of women with endometriosis are infertile. Many of these women will have to undergo IVF. Abnormal folliculogenesis, impaired oocyte and embryo quality due to radical oxidative stress and imbalances in the levels of cytokines and interleukins have been described as potential contributors to infertility in women with endometriosis. We wondered if utilising ICSI may overcome these stressors and improve fertilisation rate and pregnancy rate in women with endometriosis associated infertility.

Study design, size, duration: A retrospective cohort study was performed and included 262 conventional IVF cycles and 260 ICSI cycles from 2006 – 2016 at the Fertility Clinic in London, Ontario, Canada.

Participants/materials, setting, methods: The study group included women with endometriosis associated infertility who were surgically staged according to the ASRM revised classification of endometriosis: 1996. They were classified as no endometriosis (control group), minimal to mild (Stage I & II) endometriosis or moderate to severe (Stage III & IV) endometriosis. Women aged > 40 years old, male factor infertility, donor gametes and gestational surrogates were excluded.

Linear and logistic regression analyses were performed to examine the association between stages of endometriosis and method of fertilisation on various reproductive outcomes. The primary outcome was live birth rate. The secondary outcomes included number of oocytes retrieved, percent of oocytes fertilised, number of embryos transferred, number of embryos that developed to blastocyst, biochemical pregnancy rate and clinical pregnancy rate. Outcomes were adjusted for age, BMI, FSH, and number of embryos transferred.

Main results and the role of chance: No statistically significant differences in reproductive outcomes were noted between women with no endometriosis and those with minimal to mild (stage I & II) endometriosis whether conventional IVF or ICSI was utilised. However, ICSI was associated with a 71% decrease in clinical pregnancy rate (OR = 0.29, $p = 0.046$) and approached statistical significance for a 69% decrease in live birth rate (OR = 0.31, $p = 0.0796$) for women with moderate to severe (stage III & IV) endometriosis.

Limitations, reasons for caution: The small sample size of this study may result in the possibility of observations occurring by chance alone.

Wider implications of the findings: Further study with a larger sample size will need to be done to further delineate the relationship between ICSI and endometriosis associated infertility. However, at this time caution should be practiced against recommending ICSI when there is no clear indication of failed fertilisation with conventional IVF or male factor infertility, especially in women diagnosed with endometriosis associated infertility.

Trial registration number: Not applicable.

ETHICS AND LAW

P-299 A comparative analysis of marketing materials used to recruit egg donors in Belgium, Spain and the United Kingdom

V. Provoost[1], C. Coveney[2], L. Culley[2], C. Herbrand[2], S. Lafuente[3], V. Pavone[3], G. Pennings[4], N. Hudson[2]

[1]*Bioethics Institute Ghent BIG Ghent University, Vakgroep Wijsbegeerte en Moraalwetenschap, Gent, Belgium*
[2]*De Montfort University, Centre for Reproduction Research, Leicester, United Kingdom*
[3]*Spanish National Research Council, Institute of Public Goods and Policies, Madrid, Spain*
[4]*Ghent University, Bioethics Institute Ghent BIG- Department of Philosophy and Moral Sciences, Ghent, Belgium*

Study question: How is egg donation framed in clinic marketing material used to recruit and/or inform potential egg donors in (Dutch speaking) Belgium, Spain and the UK?

Summary answer: In Belgium, egg donation (ED) was constructed as an engagement that required considerable investment and entailed clear risks in contrast to Spain and the UK.

What is known already: Across Europe, ED recruitment is performed in different ways. Some countries permit a range of advertising methods while others limit or completely prohibit any form of advertising relating to human bodily material (e.g. Belgium). Much of the existing research on recruitment of gamete donors comes from the US where market forces shape practice more directly. This paper focusses on Belgium, Spain and the UK - three countries that hold a stake in the growing global reproductive bio-economy and share features of technological innovation and expertise, but have adopted different regulatory positions in relation to the governance and marketing of ED.

Study design, size, duration: An interdisciplinary team of researchers (bioethics, political economy, sociology) conducted a content analysis (including high frequency words analysis) as well as a comparative thematic analysis to consider 'framing' of egg donation in the data. Interdisciplinary auditing was used to challenge constructed categories and the conceptual framework at several points in the analysis. The findings were compared with country laws and informed consent rules and the implications for informed consent were studied.

Participants/materials, setting, methods: In Belgium, all Dutch language websites of centres were included compared to around 20 clinic websites in both Spain and the UK. For the latter countries, maximum variation sampling was used taking into account geographical location, number of cycles, and sector (public/private). In Belgium, ED is almost entirely situated in the publicly funded system whereas in Spain and the UK it is mainly performed in the private sector.

Main results and the role of chance: In all three countries, ED recipients were presented as women whose fertility problems were no fault of their own, constructing a clear need for the donor to fulfil. Descriptions of medical profiles included 'early menopause' while natural menopause was absent. With regard to the act of donating, in Spain and the UK, words such as 'sharing', and 'helping' were considerably more frequently used compared to the Belgian data. Especially in Spain, ED was constructed as a form of solidarity between women nonetheless with a clear emphasis on the compensation. In Belgium, where clinic advertising is strictly regulated, ED was presented as requiring a considerable investment of time and energy from the donor. Potential egg donors in Belgium were repeatedly warned that the act was 'not straightforward' and 'something to reflect about very carefully'. The Belgian material also appeared to be more focussed on risks and side effects than the Spain and UK material. The data were analysed within the policy context of the countries. We will discuss the possible impact of the public/private sector setting and of the Belgian ban on advertising for the way ED is framed and the implications of the differences in marketing material for informed consent.

Limitations, reasons for caution: The results are limited to three countries, and to a (well considered) selection of clinics, therefore precluding generalisation to whole countries. Further research will be needed on the effects of recruitment discourses on potential donors in order to generate more general conclusions and recommendations.

Wider implications of the findings: These results can contribute to a more complete understanding of the recruitment of egg donors as a practice that depends on specific discourses and is embedded in particular policy contexts. The identification of problematic framing of marketing material is crucial in terms of safeguarding true informed consent of donors.

Trial registration number: Not applicable.

P-300 Attitudes and opinions towards gestational surrogacy among physicians working within reproductive medicine and obstetrics in Sweden

K. Wånggren[1], C. Stenfelt[2], G. Armuand[3], A. Skoog Svanberg[4], G. Sydsjö[5]

[1]Karolinska University Hospital and Karolinska Institutet- Huddinge, Reproductive medicine and CLINTEC, Stockholm, Sweden
[2]Karolinska Institutet, Department of Clinical Science Intervention and Technology, Stockholm, Sweden
[3]Linköping University, Department of Clinical and Experimental Medicine- Faculty of Health Sciences, Linköping, Sweden
[4]Uppsala University, Department of Women's and Children's Health, Uppsala, Sweden
[5]Linköping University, Linköping & Department of Clinical and Experimental Medicine- Faculty of Health Sciences, Linköping, Sweden

Study question: What attitudes and opinions do physicians working within obstetrics and reproductive medicine in Sweden display towards gestational surrogacy?

Summary answer: The physicians were relative positive towards surrogacy being introduced in Sweden, however they had concerns about the risk of coercion or emotional pressure and exploitation.

What is known already: Gestational surrogacy is not allowed in Sweden, however about 50 children are born annually to Swedish citizens through cross-border surrogacy. Very sparse investigations suggest that there is no evidence of harm for the surrogate, her family or the child, but there is an ongoing debate about the ethical aspects and medical and psychological risk for the surrogate and for the child in the future.

Study design, size, duration: A cross sectional survey study was conducted in 2016. Questionnaires was sent to 141 physicians working within obstetrics and reproductive medicine.

Participants/materials, setting, methods: This was a Swedish nationwide study including all physicians working with assisted reproduction technology (ART) at both public and private IVF units as well as obstetricians heading maternity clinics and all delivery departments in the hospitals. The study-specific questionnaire measured attitudes and experiences in three domains: Attitudes towards surrogacy, Assessment of prospective surrogate mothers, and Obstetric and delivery care for surrogate mothers.

Main results and the role of chance: A total of 103 of the physicians returned the questionnaire yielding a response rate of 74%. While 63% of the physicians were positive or neutral towards altruistic surrogacy being introduced in Sweden, only 28% thought that it should be publically financed. The majority of the physicians agreed that surrogacy involves risk of exploitation of women's bodies (60%). They also expressed concerns about potential surrogate mothers not being able to fully understand the risks of entering pregnancy on behalf of someone else, and agreed that there was a need that a clear legal contract to be written stating the responsibilities of all involved. They also expressed concern that there is a risk that the commissioning couple might pay 'under the table' to the surrogate mother (82%). As concerns the attitudes of specific professional groups, ART-physicians were more positive towards legalization as well as public financing compared to those working within maternity and delivery care. Severe gestational problems, depression, and preeclampsia in potential surrogate mothers were all regarded as criteria for rejection.

Limitations, reasons for caution: The attitudes and opinions reported here are based on hypothetical situations. It is possible that physicians would think differently if surrogacy were to be allowed in Sweden. Due to the anonymous design we were not able to identify non-responders in order to assess the representativeness.

Wider implications of the findings: The study findings provide important knowledge about attitudes towards surrogacy among the ART-physician and obstetricians who would be the ones to implement surrogacy if it were to be allowed in Sweden. Further discussions about legalization of surrogacy should include views from a wide field of different medical professions and laymen.

Trial registration number: Not applicable.

P-301 Ethical evaluation of informing relatives of premature menopause (PM) patients

M. Rasekh[1], S.R. Ghaffari[2], M. Rafati[3], F. Ameri[1]

[1]Avicenna Research Institute Shahid Beheshti University- Evine, Bio. Law and Ethics Department- Nano-Biotechnology Research Center, Tehran, Iran
[2]1-Avicenna Research Institute Shahid Beheshti University- Evine- 2- Fetal Health Research Center- Hope Generation Foundation, Reproductive Biotechnology Research Center, Tehran, Iran
[3]1- Avicenna Research Institute Shahid Beheshti University- Evine- 2- Fetal Health Research Center- Hope Generation Foundation, Reproductive Biotechnology Research Center, Tehran, Iran

Study question: As PM has genetic origins, is it morally right to require the PM patient to inform her relatives so as to receive ATRs?

Summary answer: In general, it is morally right and justifiable to require a PM patient to inform her relatives who are in reproductive age.

What is known already: Genetic science has enabled us to identify genetic causes of PM. Chromosome disorders and cases of advanced mutation of FMR1 (fragile X Syndrome) are known as the most prominent genetic causes of PM. Genetic techniques of Next-Generation Sequencing help growing identification of single-gene causes of PM in recent years.

There is an up to 50% PM risk for patient's relatives. Also, 6% of cases of sporadic PM and 13% of familial PM disease is a result of FMR1 Pre-mutation and Fragile-X Syndrome carriage. Therefore, informing relatives at risk of PM saves their natural reproduction and helps preventing unhealthy reproduction.

Study design, size, duration: Firstly, the cases available in the Avicenna ARTs Clinic over the last five years are studied. Secondly, based on the empirical data, ethical arguments for and against informing the PM patients' relatives are considered. Thirdly, we conclude with the moral stance of our research to the defence of a general rule of necessity of informing, as this would be conducive to a natural healthy reproduction and prevention of giving birth to children with severe illnesses.

Participants/materials, setting, methods: Experts in the area genetics, law and philosophy are involved in this study. Materials are taken from the data existing in the Clinic relating to the issue at hand, and also analytical substance derived from the related areas. All ethical requirements for research are met. The research is conducted on the basis of a combined method. That is, it is based both on empirical and analytical (moral) methods.

Main results and the role of chance: Notwithstanding the advantages PM patients gain from ARTs services, confidentiality of certain information may be violated. In this regard, there exist two obligations which may fly in the face of each other: 1. patients' or geneticists' obligation to let the patients' relatives know the possibility of PM and exigency of genetic screening; and 2. an obligation to keep information of child conceived through ARTs confidential.

The are two radical approach on this issue: 1. taking confidentiality as an absolute value and plan all other actions on this basis; and 2. profound significance of obligation to inform people on the basis of the principle of no harm and taking all measure on this basis.

Given the above, if PM patients do not inform their relative they may inflict harm on them, especially where the relatives could have taken measures to utilize the awareness of their genetic situation.

On the other hand, informing the relatives has to be morally set in tune with the confidentiality of information of children resulted from ARTs, as this may amount to disclosure of the conception methods of such children and in the end damage their quality of lives. How can we make a balance here?

Limitations, reasons for caution: As the study is taking place in a traditional and heavily religious context, cautions have to be taken on the airing and publishing of the results of the study.

Wider implications of the findings: Given the context of the study, implementation of the results of the study has to be well thought and cautiously initiated.

Trial registration number: n/a.

P-302 Reproductive Endocrinology Infertility (REI) specialists' utilization and attitudes towards expanded carrier screening for oocyte donors

S.R. Lindheim[1], T. Glenn[1,2], O. Obiako[1], J. Madeira[3], N. Pereira[4], H. Mertes[5], G. Pennings[5]

[1]Wright State University Boonshoft School of Medicine, Dayton, OH
[2]Department of OB/GYN Wright Patterson AFB/ Dayton, OH,
[3]Maurer School of Law, Indiana University, Bloomington, IN
[4]Weill Cornell Medicine, New York, NY
[5]Bioethics Institute Ghent, Ghent University, Department of Philosophy and Moral Science

Study question: To report REIs' current utilization and attitudes towards ECS for OD in clinical practice.

Summary answer: Data suggests disagreement concerning the utilization and dissemination of ECS. Standardized guidelines are needed to clarify ECS application and provide guidance regarding ethical quandaries.

What is known already: ECS has become an increasingly important component of preconception and prenatal care, however its use for OD remain unclear globally. Currently, American Society for Reproductive Medicine (ASRM) advises that genetic screening should be performed based on the donor's ethnic background and family history, while European Society of Human Reproduction and Embryology (ESHRE) recommends it based on effectiveness and proportionality.1,2

Study design, size, duration: An IRB approved qualitative survey study from February to December 2017. A total of 83 responses were obtained.

Participants/materials, setting, methods: A 33-question qualitative survey was distributed through SurveyMonkey® to all Society for Reproductive Endocrine Infertility (SREI) members.

Main results and the role of chance: Of 83 surveys, 81 (97.6%) were completed. Based on current ASRM recommendations, 86.7% of REIs request donors to update their medical history, particularly after identifying a heritable condition. While 60.2% of respondents discuss ECS with recipients, only 26.5% of recipients request it. ECS for ODs is utilized by 51.5% prior to acceptance, while 54.7%. responded that ODs could also decline ECS or request information not be disclosed. However, 75% felt that OD agencies and sperm banks have a responsibility to obtain ECS on all their donors. From a practice standpoint, REI physicians (46.7%), nurses (12.0%), and geneticists (34.8%) counsel those with positive carrier status. Overall, 57.8% agreed that ECS should not be offered until the clinical significance is understood for rare diseases. Moreover, 30.6% believed that ECS could lead to a genetically selected population. In contrast, 58.1% felt screening should be performed regardless of clinical significance. Interestingly, only 20.5% excluded carriers with heritable conditions from their OD pool.

Limitations, reasons for caution: Limitations of this survey-based study include varying interpretation of the questions, ability to skip questions, and low response rate. The sensitive nature of the questions may have deterred individuals from replying honestly or at all, even considering the anonymous nature of the survey.

Wider implications of the findings: ECS is becoming customary practice for third party reproduction. However, varying responses have been reported concerning who/what to test, counseling patients, and notifying individuals of positive carrier status. Our data suggests the necessity of standardizing guidelines including the inclusion and exclusion of third party gamete donors with a positive carrier status especially as genetic testing advances and a wider array of genetic aberrations are discovered.

P-303 The ethics of commercialization: a temporal analysis of newspaper coverage of IVF add-ons in the UK

A. Geampana, M. Perrotta, A.S. Giraud, J. Hamper

Queen Mary University of London, School of Business and Management, London, United Kingdom

Study question: What changes have occurred in recent reporting on IVF add-on treatments in the UK?

Summary answer: During the past year, the public conversation has shifted from concerns about perceived low-rates of success to issues surrounding add-on costs and patient financial strain.

What is known already: Most media analyses of assisted reproductive technologies have focused on the North American context (Campbell 2011; Markens 2012; Orr et al. 2017). Although the UK provides a unique case where public debates about the cost of IVF treatments have been prominent, there have been few systematic media reviews to clearly identify temporal changes in how public concerns have been framed in recent years.

Study design, size, duration: We performed a search of all newspaper articles published in the last four years (2013-2017) using the Factiva database. The key words used were "IVF" and "Add on." We included all articles that were: 1) focused on IVF and add-ons and 2) published in the UK media. In total, we retrieved 93 articles. After further screening, we selected 67 records, as some were duplicates, while others were on topics outside of our inclusion criteria.

Participants/materials, setting, methods: Data were analyzed using content analysis based on similar work in health-related areas (Graneheim and Lundman 2004; Forman and Damschroder 2007). Codes were developed both deductively and inductively according to standard qualitative methods used in the social sciences (Strauss and Corbin 1997). Articles were then coded in order to analyze emerging themes.

Main results and the role of chance: This study aimed to explore recent changes in public debates on IVF add-ons. The term "add-ons" is usually referred to additional treatments offered – often at an additional cost – to IVF patients on top their main treatment. However, as fertility professionals have pointed out, even the term "add-on" itself can be misleading as it can sometimes include routine treatments. We found that the UK public debate significantly changed in the wake of a BBC Panorama special on IVF add-ons. Although findings suggest that the UK media's focus has always been on commercialization issues, newspaper articles published before the BBC special mainly talked about the costs paid by older women undergoing IVF given their low chances of conceiving. However, starting with the end of 2016, the public debate has focused particularly on add-ons and the lack of evidence for their effectiveness. Such treatments are now represented mostly and indiscriminately as a scientifically unjustifiable cost for patients, focusing on the lack of evidence of their efficiency, safety and cost-effectiveness, and assuming a tacit and uncritical understanding of what "sufficient" and "robust" evidence is. Additionally, we found that the most commonly critiqued add-ons are PGS and intralipid infusion.

Limitations, reasons for caution: This study is limited to media coverage and does not include surveys or interviews with members of the public.

Wider implications of the findings: Previous authors have shown that media coverage can influence behaviours and health service utilization (Howe et al., 2002; Leask et al. 2010). The ways in which news reports are framed can affect policy initiatives in public health as well as the general public's understanding of IVF add-ons.

Trial registration number: not applicable

POSTER VIEWING
FEMALE FERTILITY

P-304 The anogenital distance can be a response biomarker in patients undergoing controlled ovarian stimulation for IVF

F. Fabregues Gasol[1], I. Gonzalez-Foruria[2], P. Joana[1], G. Sandra[3], C. Francisco[1]

[1]Hospital Clinic, Institut Clinic of Gynecology- Obstetrics and Neonatology, Barcelona, Spain
[2]Hospital Clinic /I. Dexeus, Institut Clinic of Gynecology- Obstetrics and Neonatology, Barcelona, Spain
[3]I. Dexeus, Unitat de Reproduccio Asistida, Barcelona, Spain

Study question: Is the length of the anogenital distance (AGD) a biomarker of ovarian reserve and response to controlled ovarian stimulation (COS)?

Summary answer: Shorter AGD is associated with presence of poor ovarian response.

What is known already: Organ development during prenatal life is influenced by the prevailing intrauterine environment, and it has been suggested that nutritional, environmental and toxic factors could affect ovarian reserve set prenatally. AGD is a biomarker of prenatal-hormonal environment and observational studies have shown an association between its length and reproductive parameters in both sexes.

Study design, size, duration: This was a prospective cohort study of 437 women treated with IVF/ICSI conducted in a tertiary-care university hospital between January and December 2016.

Participants/materials, setting, methods: Patients were divided into three groups: poor responders (<3 oocytes) (n = 50), normoresponders (4-15 oocytes) (n = 332) and high responders (>15 oocytes) (n = 55).Clinical characteristics, ovarian reserve markers, total doses of gonadotropins used and ovarian sensitivity index (OSI) were recorded. Patients with previous pregnancies, polycystic ovary syndrome (PCOS), endometriosis and previous ovarian or genital surgery were excluded. AGD_{AC} (anus-clitoris) and AGD_{AF} (anus-fourchette) were measured before proceeding to oocyte pick-up. Multiple linear regression and logistic regression analyses were used.

Main results and the role of chance: Baseline FSH, AMH, AFC and age were significantly different among the three groups of ovarian response, as were the units of gonadotropin used, and the ovarian sensitivity index (OSI) ($P< 0.001$). Both AGD_{AC} and AGD_{AF} measurements were positively correlated with AMH levels ($r = 0.38$ and $r = 0.21$; $P< 0.05$), AFC ($r = 0.41$ and $r = 0.20$; $P< 0.05$), the OSI ($r = 0.24$ and $r = 0.19$; $P< 0.05$) and the number of oocytes retrieved ($r = 0.29$ and $r = 0.28$, respectively; $P< 0.05$). Conversely, there was a negative correlation between both AGD measurements and the doses of gonadotropins used ($r = -0.19$ and $r = -0.15$; $P< 0.05$). The area under the curve (AUC) for prediction of poor response of AGD_{AC} was 0.70 (95%CI 0.66-0.75), which was comparable to the classic ovarian reserve markers, such as AFC and AMH. AGD_{AF} showed a significantly worse predictive capacity for poor ovarian response (AUC 0.60 [95% CI 0.55-0.60]) than AMH and AFC.

Limitations, reasons for caution: As this was an observational study, causal inference cannot be ruled out.

Wider implications of the findings: The findings of this study suggest that *in utero* exposure to certain hormonal environments could affect the ovarian reserve set prenatally.

Trial registration number: No.

P-305 Non steroidal anti-inflammatory drugs (NSAID) such as ibuprofen have only a limited effect on on the intrafollicular milieu of pre-ovulatory follicles

I. Bienz, N. Bersinger, M. Eisenhut, A. Kohl, M. Von Wolff

University Women's Hospital, Division of Gynaecological Endocrinology and Reproductive Medicine- Inselspital, Bern, Switzerland

Study question: What is the impact of NSAID, specifically ibuprofen, on the intrafollicular milieu of naturally matured pre-ovulatory follicles?

Summary answer: Ibuprofen slightly decreases cytokine and estradiol but not matrix metalloprotease concentrations in the fluid of naturally matured pre-ovulatory follicles.

What is known already: NSAID are not recommended around ovulation in women trying to conceive spontaneously. In contrast, in Natural Cycle IVF (NC-IVF) NSAIDs are used in daily routine to reduce the risk of premature ovulation. NSAID inhibit cyclooxygenases (COX2) that catalyse the synthesis of PGE2, a key prostaglandin in the inflammatory cascade of ovulation. Ibuprofen, at a dosage of 3×400 mg/day, is a frequently used analgesic in women.

Study design, size, duration: Prospective, within-subjects study, performed at a University based infertility centre between 2014 and 2017 and including 19 women undergoing NC-IVF. Patient age was 26-44 years; menstrual cycles were regular. If an early onset of an LH-surge (10-20 IU/L) was diagnosed the women were administered ibuprofen (3×400 mg/day), and follicle aspiration was performed 36 hours after HCG injection. If no LH-surge was detected no ibuprofen was taken.

Participants/materials, setting, methods: Follicular fluid was collected from the 19 women, undergoing one cycle with and one cycle without ibuprofen. The concentrations of follicular cytokines (IL-1β, IL-6, IL-8, IL-12, GM-CSF, TNFα, VEGF), prostaglandin E2, matrix metalloproteases-2 and -9 and hormones (LH, FSH, estradiol, total testosterone, AMH) were determined by

single or multiplexed immunoassays and compared in matched cycles with and without ibuprofen administration.

Main results and the role of chance: In the follicular fluid of ibuprofen treated women, IL-8 was significantly ($P<0.05$) decreased and IL-6 and PGE2 showed a trend towards reduced concentrations compared to controls (IL-8, 170 pg/mL vs. 218 pg/mL, $P<0.05$; IL-6, 2.2 pg/mL vs. 3.3 pg/mL; PGE2, 5.4 ng/mL vs. 6.3 ng/mL). Estradiol concentration was also lower in patients with Ibuprofen (2293nmol/L vs. 3047nmol/L, $P<0.05$). However, other cytokines, matrix metalloproteases and hormones, including IL-1β, TNFα, VEGF, MMP-2, MMP-9, LH, FSH, total testosterone and AMH, were unchanged between cycles with or without ibuprofen. Our study revealed that NSAIDs, specifically ibuprofen, had some but limited impact on the follicular physiology. It also showed that ibuprofen can postpone ovulation in most women for several hours.

Limitations, reasons for caution: The number of included women was limited due to the strict, within-patient inclusion criteria.

Wider implications of the findings: As the effect of ibuprofen on prostaglandin and cytokine concentrations in follicular fluid is small, the treatment with this medication around ovulation should be safe in the analysed dosage in women trying to conceive spontaneously as well as under IVF treatment.

Trial registration number: Not applicable.

P-306 Dynamic culture of human ovarian tissue in a perfusion flow-through bioreactor enhances follicle progression as compared to static culture in gas-permeable dishes

R. Talevi[1], G. Catapano[2], M. Di Nardo[1], V. Costanzo[1], V. Barbato[1], S. Braun[1], A. Merolla[1], R. Ferraro[3], R. Gualtieri[1]

[1]Università degli studi di Napoli Federico II, Dipartimento di Biologia, Napoli, Italy
[2]University of Calabria, Dept. of Environmental & Chemical Engineering, Cosenza, Italy
[3]Iatropolis, Centro Genesis, Caserta, Italy

Study question: Can in vitro continuous perfusion of human ovarian tissue strips improve follicle progression and viability of follicles over culture in gas-permeable dishes (PD)?

Summary answer: Culture in dynamic perfusion flow-through bioreactors (PB) vs static gas-permeable dishes significantly increased follicle progression to the secondary stage.

What is known already: In vitro culture of strips of human ovarian tissue in static PD enhances follicle viability and progression over conventional gas-impermeable dishes by improving oxygen availability in situ. However, progression to the secondary stage is not yet optimal for subsequent follicle isolation and culture until complete oocyte maturation. This is possibly due to suboptimal control of culture conditions and the absence of physiological biomechanical cues in static culture dishes. Dynamic continuous perfusion bioreactors may enable the physiological availaibility of solutes as well as the application of physiological fluid mechanic stresses to tissue.

Study design, size, duration: This paper reports on a comparative study of static versus dynamic bioreactors for the culture of human ovarian biopsies. Tissue strips 1×1×0.5 mm from each patient (n = 4) were cultured in static oxygen permeable dishes (PD) and in dynamic perfusion flow-through bioreactors (PB) for 6 days. Follicle quality, progression and viability were respectively assessed through histology and live/dead assay under confocal microscopy.

Participants/materials, setting, methods: Ovarian biopsies, collected from consenting patients (age <35) during laparoscopic surgery for benign gynecologic conditions, were cut with a tissue chopper and cultured in PB and PD for 6 days in alpha-MEM medium plus supplements at 37°C, 5% CO2 and 95% humidity in air. Fresh (D0) and cultured strips (D6) were fixed and stained for histological analysis or labelled with live-dead far red and Hoechst 33342 for viability assessment at the confocal microscope.

Main results and the role of chance: Overall 1349 follicles were analysed. Data showed that ovarian strips at day 0 mainly contain follicles at the primordial stage (primordial, 72.5%; primary, 24.3%; secondary, 3.2%) characterized by a good quality (grade1, 42.5%; grade2, 27.3%; grade3, 30.2%). Culture for 6 days in PB generally yielded significantly higher follicle progression (primordial, 24.4%; primary, 46.2%; secondary, 29.4%), viability (64.4%), and quality (grade1, 28.4%; grade2, 38.6%; grade3, 33%) than in PD (primordial, 34.5% ($p<0.05$); primary, 47.9% (NS); secondary, 17.6% ($p<0.01$) - viability, 64.3% (NS) - grade1, 22.5% (NS); grade2, 31.7% (NS); grade3, 45.8% ($p<0.01$)). The results suggest that dynamic culture of human ovarian tissue strips in the perfusion flow-through bioreactor for 6 days enhances follicle progression as compared to static culture in gas-permeable dishes in the patients under investigation.

Limitations, reasons for caution: Due to the high heterogeneity of ovarian tissue structure and follicle density and the limited number of patients, this preliminary study needs to be validated on a higher number of tissue strips and in a larger cohort of patients.

Wider implications of the findings: In perfusion flow-through bioreactors, oxygen perfusion, nutrients availability and biomechanical cues have a key role in the health and progression of cultured follicles. This approach may increase the yield of secondary follicles and enhance the efficiency of two-step protocols for human *in vitro* folliculogenesis.

Trial registration number: not applicable.

P-307 Thyroid autoimmunity is associated with higher risk of premature ovarian failure - A nationwide Health Insurance Research Database study

J.Y.P. Ho[1], Y.T. Hsieh[2]

[1]China Medical University Hospital, Center for Reproductive Medicine, Taichung City, Taiwan R.O.C.
[2]China Medical University Hospital, Department of Chinese Medicine, Taichung City, Taiwan R.O.C.

Study question: Is thyroid autoimmunity associated with higher risk of low ovarian reserve and premature ovarian failure?

Summary answer: Thyroid autoimmunity have a significantly higher risk of premature ovarian failure.

What is known already: Premature ovarian failure is closely related with autoimmune disease and thyroid autoimmunity may account for diminished ovarian reserve in some studies. However, there is no large scale cohort study to demonstrate the association between thyroid autoimmunity and premature ovarian failure.

Study design, size, duration: A population-based retrospective cohort study on the foundation of the National Health Insurance Research Database was designed in a longitudianl-time-course fashion. National Health Insurance (NHI) program in Taiwan since March1, 1995 and included 99.9% of the 23 million population of Taiwan. Patients between January 1, 2000 to December 31, 2013 were eligible for recruitment.

Participants/materials, setting, methods: An autoimmune thyroid disease cohort was composed of patients with autoimmune thyroid disease older than 25 years of age and younger than 40 years of age. The comparison cohort consisted of patient in the National Health Insurance Research Database without autoimmune thyroid disease matched by age at a ratio of 1:3.95.

Main results and the role of chance: Overall, 2736 autoimmune thyroid disease patients and 10821 comparison patients were followed-up until a diagnosis of ovarian failure, amenorrhea or menopausal syndrome had been made. Compared with the comparison cohort, patients with autoimmune thyroid disease presented a 78% higher risk for ovarian failure (95% CI = 1.44-1.97) and a 49% higher risk of ovarian failure after adjustment (95% CI = 1.08-2.07). The cumulative incidence of amenorrhea or ovarian failure in thyroid autoimmunity group were significantly higher than in comparison group.

Limitations, reasons for caution: This is a retrospective study with ICD-9 disease code analysis for the statistical association between two diseases.

Wider implications of the findings: Given that the autoimmune thyroid disease is highly associated with early diminished ovarian reserve or even premature ovarian failure, the option for infertility treatment may be re-directed to more efficient methods in infertile patients diagnosed with autoimmune disease.

Trial registration number: non-clinical trials.

P-308 Possibilities of preimplantation genetic screening (PGS) in overcoming the impact of age on assisted reproductive technologies (ART) results

V. Lokshin, R. Valiev, S. Karibaeva, A. Rybina, A. Malik, Y. Tyugay, I. Khoroshilova

The international clinical reproductive center "PERSONA"., Reproductology, Almaty, Kazakhstan

Study question: Does PGS increase pregnancy rate in advanced age women? Is there a relationship between AMH level and the frequency of aneuploidy?

Summary answer: A strong correlation between AMH and aneuploidy was found. The frequency of clinical pregnancy is significantly higher in women of older reproductive age after CGH.

What is known already: The inefficiency of assisted reproductive technologies can be as a result of many factors. Aneuploidy is directly depends on the maternal age and rarely associated with the morphological characteristics of the embryos. PGS are used for diagnosis chromosomal rearrangements and selection balanced or healthy embryos. Consequently PGS can increase pregnancy rate and prevent transmission of unbalanced rearrangements to offspring.

Study design, size, duration: Since November 2016 to December 2017 the retrospective open comparative study of 282 embryos from 99 couples was conducted in the international clinical reproductive center "PERSONA".

Participants/materials, setting, methods: All couples were undergone IVF and FET programs. Embryos were undergone biopsy of trophoectoderm on day 5 or 6 with examination by a-CGH to diagnose chromosomal abnormalities. All 99 women were divided into two groups at different ages. The first group included 32 women under 35 years old, the average age was 29.7 years. The second group included 67 women over 36 years and older (average age 41.6 years).

Main results and the role of chance: In the first group 460 oocytes and 85 embryos were obtained. In the second group 559 oocytes and 197 embryos were obtained. Chromosomal abnormalities of embryos in both groups were identified: 45.8% and 56.3% respectivly. There was a strong correlation between the level of AMH and the probability of obtaining an euploid embryo, r = 0.99. An average AMH in group 1 was 4.79+ 2.2, the level of euploidy was 54.2%. An average AMH level in group 2 was 2.98 + 2.9, the level of embryo euploidy was 43.7%, $p<0.05$. Pregnancy occurred in 57.1% in group 1, in the 2nd group pregnancy occurred in 64.5%, $p<0.05$.

Limitations, reasons for caution: Non.

Wider implications of the findings: Applying of PGS allows to increase the pregnancy rate up to 65% for embryo transfer to reduce the risk of a chromosomal pathology with a probability of up to 95%. There is a direct relationship between AMH level and the probability of receiving an euploid embryo.

Trial registration number: 1 PK.

P-309 The most accurate approach for reproductive tract microbiome analysis

M. Díaz[1], A. Bernabeu[2], B. Lledo[3], J. Ortiz[3], A. Masbou[4], D. Keefe[4], J. Llacer[2], R. Bernabeu[2]

[1]*Instituto Bernabeu, IVF laboratory, Alicante, Spain*
[2]*Instituto Bernabeu, Reproductive Medicine, Alicante, Spain*
[3]*Biotech, Molecular Biology Department, Alicante, Spain*
[4]*New York University, Langone Fertility Centre, New York, U.S.A.*

Study question: Does primer selection have any effect on vaginal and endometrial microbiome analysis?

Summary answer: V3V5 primers sets are better suited to identify microorganisms at genus and species abundance. Thus, experimental design is essential when examining the vaginal/endometrium microbiome.

What is known already: The human microbiome is tightly related to health in disease states as well as the reproductive system. Its analysis using a marker gene and NGS became in a powerful tool. The 16S-rRNA contains nine hypervariable regions (V1V9) flanked by conserved regions, which makes an ideal target of bacterial classification. However, most NGS-platforms are not capable of covering the full-length gene. Thus, short regions have been prioritized. Currently, there is no consensus of which region best reflects the vagina/endometrium microbiome. The aim was to investigate if the reproductive-tract microbiome profile will have subtle variations by virtue of the primer set used.

Study design, size, duration: A prospective study was performed. Patients attenting to our clinic were recruited from May to December 2017. In order to detect different diversity in the microbiome, samples were taken at different stages from the same patient (n = 22): luteal phase in the previous cycle, the day of the embryo transfer, the day of the BHCG sample and the day of the ultrasound in the case of getting pregnant.

Participants/materials, setting, methods: In order to avoid confusion factors that can affect the variability and diversity in the microbiome profile we included patients that performed a frozen embryo transfer. DNA was extracted using the PureLink Microbiome DNA Purification kit. To evaluate biases introduced by primer selection V3V4 and V3V5 were used. Sequencing and bioinformatics analysis were performed according to Illumina Metagenomics protocol using the NexteraXT library on the Miseq instrument.

Main results and the role of chance: Overall, the average classification rate at genus level was 90.2% and at species level 74.32% for all samples. Regarding the sample collection, differences were shown when we compared the endometrium and the vaginal samples, for genus and species classification results (60.0 + 25.6 vs 98.7 + 0.6, $p<0.05$; 44.0+ 21.0 vs 81.1+4.1, $p<0.05$). For primer set used, no differences were reported in the classification rates for V3V4 and V4V5 at genus and species level when we consider all the samples. However, when we consider the subset of vaginal samples, higher numbers of classified microorganisms at genus level were obtained when we used V3V5 (99.0+0.1 vs 98.3+ 0.7, $p<0.05$). Regarding the diversity studies 35 different genus and 13 species at top frequencies were detected among samples, suggesting that genus studies give us more information about the microbiome diversity, revealing more than unique Lactobacillus OTU. Species identification of Lactobacillus is more difficult using a V3V4 primer set. Thus, V3V5 provides both breadth and depth of communities dominated by these genera, V3V5 amplicons will reveal either lactobacilli-dominant or lactobacilli-diminished groups. Because the reproductive tract microbiome is a Lactobacilli dominant, experimental design is essential for a broad species detection when examining the vaginal/endometrium microbiome.

Limitations, reasons for caution: The study is limited due to the sample size. A higher sample size should be used in future studies to corroborate the current findings. The lack of a standardized workflow has led to uncertainties regarding the transparency and reproducibility of microbiome studies.

Wider implications of the findings: In conclusion, the microbiome profile will have subtle variations by virtue of the primer set used. V3V5 will distinguish more accurate species in Lactobacillus predominant communities.The unification of analysis procedures and the implementation of standardized workflows may be done in order to minimize variation introduced in the results.

Trial registration number: Not applicable.

P-310 Melatonin attenuates aging of post-ovulatory mouse oocytes via a SIRT1-MnSOD dependent pathway

Q. Yang, S. Dai, X. Luo, S. Yingpu

The First Affiliated Hospital of Zhengzhou University, Reproductive medcine centor, Zhengzhou, China

Study question: The underlying mechanisms of how melatonin improves the quality of post-ovulatory aged oocytes remain largely unclear.

Summary answer: melatonin delays post-ovulatory mouse oocyte aging via a SIRT1-MnSOD-dependent pathway.

What is known already: The quality of post-ovulatory metaphase II oocytes undergoes a time-dependent deterioration as a result of the aging process. Melatonin is considered an anti-aging agent.

Study design, size, duration: *In vitro* aged MII oocytes were used in experiments at 0, 6, 12 and 24 h. For the melatonin treatment, the treated oocytes were incubated in the IVF medium with a final concentration of 10^{-7}, 10^{-5}, or 10^{-3} M melatonin.

Participants/materials, setting, methods: To collect the metaphase-II (MII) oocytes, mice were stimulated by an intraperitoneal injection of 7.5 IU of Pregnant Mares Serum Gonadotropin (PMSG), and 7.5 IU human Chorionic Gonadotropin (hCG) was injected to induce superovulation. The mice were

sacrificed 12-14 h after the hCG was used. The cumulus-oocyte complexes (COCs) were obtained by breaking the oviductal ampullae.

Main results and the role of chance: In this study, we found that there were elevated ROS levels and impaired mitochondrial function demonstrated by reduced mitochondrial membrane potential ($\Delta\Psi m$) and increased mitochondrial aggregation in oocytes aged 24 h, accompanied by an increased number of meiotic errors, unregulated autophagy-related proteins and early apoptosis, which led to decreased oocyte quality and disrupted developmental competence. However, all of these events can be largely prevented by supplementing the oocyte culture medium with 10^{-3} M melatonin. Additionally, we found that the expression of sirtuin family members (SIRT1, 2, 3) was dramatically reduced in aged oocytes. In addition, *in vitro* supplementation with melatonin significantly upregulated the expression of SIRT1 and antioxidant enzyme MnSOD, but this action was not observed for SIRT2 and SIRT3. Furthermore, the protective effect of melatonin on the delay of oocyte aging vanished when the SIRT1 inhibitor EX527 was used to simultaneously treat the oocytes with melatonin. Consistent with this finding, we found that the post-ovulatory oocyte aging process was markedly attenuated when the oocytes were treated with the SIRT1 activator SRT1720.

Limitations, reasons for caution: This study was done only in vitro.

Wider implications of the findings: Melatonin can be used in IVF for prevents oocyte aging.

Trial registration number: none.

P-311 Peripheral blood mononuclear cells in IVF practice: 2 years experience

E. Zhylkova[1], O. Feskov[2], V. Feskov[3], O. Blazhko[4]

[1]*Centre of Human Reproduction Sana-Med, Genetic laboratory, Kharkiv, Ukraine*
[2]*Clinic of Professor Feskov A.M. Sana-Med Ltd., Administration, Kharkov, Ukraine*
[3]*Sana-Med Ltd., IVF department, Kharkov, Ukraine*
[4]*Clinic of Professor Feskov A. M. Sana-Med Ltd., IVF Department, Kharkov, Ukraine*

Study question: Do the application of intrauterine transfer of peripheral blood mononuclear cells (PMBC) improve embryo implantation rates in IVF?

Summary answer: The IVF success rates were higher in the PBMC-treated group (P <0.01) comparing with the non-treated group in "cryo" IVF cycles.

What is known already: A human endometrium is able to accept embryos only during some limited period. Endometrium should be prepared to embryo transfer to achieve embryo implantation. There is a suggestion that maternal immune cells are able to support the process of embryo implantation.

Study design, size, duration: The aim of the work was to examine the influence of intrauterine peripheral blood mononuclear cells application on embryo implantation rates for infertile patients in "fresh" and "cryo" IVF cycles. The study's protocol was approved by the Center's IRB.During January 2016 - December 2017, a total of 890 infertile couples were subjected to IVF treatment. All the infertile patients were divided into two groups: with application of PBMC and without one.

Participants/materials, setting, methods: PBMC were applied for 401 patient – 216 "fresh" IVF cycles and 165 ET after blastocysts cryopreservation. Non-PBMC group consisted of 489 patients – 240 "fresh" IVF cycles and 249 "cryo" IVF protocols. Two high quality blastocysts were transferred in each case. PBMC were applied after previous culture before the ET. Verifications of associations of PBMC application with implantation rates were accomplished by the Chi-square test ($\chi 2$ test).

Main results and the role of chance: The implantation rate was significantly higher in PBMC-treated group in "cryo" IVF protocol comparing with ETs of vitrified blastocysts without PBMC ($df = 1$, $\chi 2 = 9.852$, $\chi 2_{critical} = 6.635$, $P < 0.01$). There was no significant difference in implantation rates in both groups after "fresh" IVF attempts. We haven't considered the age of the patients in the present study. But out previous investigations showed the PBMCs affects in "fresh" IVF cycles in patients after 38 years old.

Limitations, reasons for caution: ET and vitrification of the blastocyst can be carried out for the embryos with the high quality of morphology.

Wider implications of the findings: More detailed investigations in this field could explain the role of immune system in the implantation process and early pregnancy control. PBMC therapy could improve implantation rates in patients with recurrent IVF failures with the high quality embryos.

Trial registration number: -

P-312 Use of granulocyte colony-stimulating factor during an assisted reproductive treatment does not increase the risk of birth defects

M. Cruz[1], D. Alecsandru[2], J.A. García-Velasco[3], A. Requena[3]

[1]*IVI Madrid, IVF Lab, Madrid, Spain*
[2]*IVI Madrid, Immunology, Madrid, Spain*
[3]*IVI Madrid, Reproductive Medicine, Madrid, Spain*

Study question: To assess the effect of administration of granulocyte colony-stimulating factor (G-CSF) in newborns resulting from an assisted reproductive treatment.

Summary answer: Administration of G-CSF during the first steps of pregnancy does not imply a higher risk of perinatal complications or malformations in offspring.

What is known already: G-CSF illustrates the scope of reproductive immunology, as they act on reproductive function at different levels such ovulation, embryo implantation and embryo development. Despite their growing interest in the reproductive field, actions of G-CSF have still not been explained concerning its effects on the early stages of embryo development. Information available up to date indicates that administration of G-CSF is safe in terms of risk of perinatal complications on offspring, although further studies are needed to show the harmlessness of this drug in newborns.

Study design, size, duration: Retrospective study performed in 11 private clinics belonging to IVI-RMA group from January 2014 to December 2016. Our study group included 33 live-born children from a pregnancy in which G-CSF was administered compared to the control group, which contained 3798 children from couples also undergoing an assisted reproductive treatment in the same clinics and in whose pregnancy this drug was not ordered. Couples were called a month after delivery date to obtain perinatal information.

Participants/materials, setting, methods: G-CSF is essential in the uteroplacental cytokine network needed to establish and maintain pregnancy. Patients with KIR-HLA-C mismatch and recurrent miscarriage as the study group were treated as off label and after a signed informed consent, with a daily subcutaneous administration of 13 mUI of filgrastim (Neupogen, Amgen, USA) from the embryo transfer until the end of the ninth week of pregnancy. Statistical analysis was performed by ANOVA and Chi-squared where applicable.

Main results and the role of chance: There were no statistical differences in mother's age (40.9 ± 0.1 vs. 38.9 ± 1.8, $p = 0.055$), body mass index (23.2 ± 0.2 vs. 22.6 ± 1.5, $p = 0.503$), children's weight (2952 ± 200 g vs. 3145 ± 270 g, $p = 0.184$), gestational age (38 ± 1 w vs. 37 ± 1 w, $p = 0.926$) and length (50.7 ± 2.1 cm vs. 50.0 ± 1.3 cm, $p = 0.969$) between control group and women treated with G-CSF respectively. According prematurity rate, we did not also observe relevant variances in the percentage of births before week 36 (10.0% vs. 9.5%, $p = 0.783$) and week 32 (2.2% vs. 0.0%, $p = 0.585$) for the control and the study group respectively. Finally, we also analyzed the percentage of children under 2500 g (19.6% vs. 11.8%, $p = 0.570$) and under 1500 g (2.5% vs. 0.0%, $p = 0.454$) and as the previous data, we did not find significant differences for non-treated and filgrastim treated women.

According adverse perinatal outcomes, we did not find any birth defect in children included in the study group compared to a 2.1% of children affected by some congenital anomaly.

Limitations, reasons for caution: A limitation of our study is the small sample size, which makes difficult to draw conclusive results. Moreover, a consequence of a retrospective study is that not all pertinent risk factors are likely to have been identified and subsequently recorded. Therefore, only association can be inferred from the results.

Wider implications of the findings: The above analysis of the effect of G-CSF of *in vitro* fertilization perinatal outcomes in infertile women suggest the safety of G-CSF use in pregnancy, as no neonates complications have been observed. Even though, this treatment should be used carefully.

Trial registration number: Not applicable.

P-313 Control of actin nucleators by maturation regulating factors in mouse oocytes

F. Tepekoy Ozcelik[1], G. Akkoyunlu[2]

[1]*Istinye University Faculty of Medicine, Histology and Embryology, Istanbul, Turkey*
[2]*Akdeniz University Faculty of Medicine, Histology and Embryology, Antalya, Turkey*

Study question: Does MAPK/ERK kinase (MEK) inhibition and maturation promoting factor (MPF) activation affect actin nucleators Spire-1 and Spire-2 in mouse oocytes?

Summary answer: MEK inhibition and MPF activation results in elevated levels of Spire-1 and Spire-2 at different stages of oocyte meiotic maturation.

What is known already: Meiotic resumption of the oocyte is mainly driven by MPF. During meiotic arrest, MPF is inhibited by protein kinase A (PKA), thus inactivated PKA leads to meiotic resumption. Resumption of meiosis results in two inequivalent cells: the polar body and oocyte. Chromosome migration regulated mainly by actin nucleators, takes place to achieve this asymmetric division. Actin nucleators Spire-1 and Spire-2 are known to have roles in asymmetric division of oocytes. MAPK signaling, known to regulate MPF, is also associated with asymmetric division of oocytes, though it is unclear whether it directly affects actin nucleators, or through the activation of MPF.

Study design, size, duration: The oocytes retrieved from 10 mice were pooled and divided into 4 groups for in vitro culture: MEK inhibitor PD98059 (1), PKA inhibitor H89 for MPF activation (2) and combination of these inhibitors (3), DMSO only as vehicle (4). The oocytes were analyzed at germinal vesicle breakdown (GVBD) (2 hours), spindle formation (5 hours), spindle migration (7 hours) and polar body extrusion (PBE) stages as wells as at germinal vesicle (GV) stage without culturing process.

Participants/materials, setting, methods: MEK inhibitor PD98059 and PKA inhibitor H89 for MPF activation was applied during IVM to the GV oocytes retrieved from preovulatory ovarian follicles of 3-5 weeks old female BalbC mice after follicle activation. GVBD and PBE rates of the oocytes were determined. The localizations of Spire-1 and Spire-2 were detected through immunofluorescence. Spire-1, Spire-2, pERK1/2 and pCREB protein levels were determined via Western blot for oocytes at different stages. All experiments were repeated 3 times.

Main results and the role of chance: MEK inhibitor at a concentration of 50 μM significantly reduced pERK1/2 (MEK phosphorylation target) levels of the oocytes. pCREB, the downstream target of PKA was significantly reduced at 10 μM concentration of PKA inhibitor. The inhibitors were applied at these doses during IVM of the oocytes.

GVBD rates were similar in different groups, while PBE rates were lower in MEK inhibition group. Cortical localization of Spire-1 and Spire-2 was detected in oocytes by IF at all stages of meiotic maturation. In control group, both cortical and total Spire-1 level was significantly the lowest at spindle migration stage, though Spire-2 cortical localization was the lowest in GV oocytes. MEK inhibition resulted in a decrease both in cortical Spire-1 and Spire-2 levels in PBE oocytes. PKA inhibition (MPF activation) led to increase in cortical Spire-1 levels in spindle migration stage oocytes, while it resulted in increase of cortical and total Spire-2 levels in PBE oocytes. Application of MEK inhibition and MPF activation at the same time caused an increase in Spire-1 levels at PBE oocytes, pointing out a compensation of the decreasing effect of MEK inhibition. However, Spire-2 levels remained low with no compensation of MEK inhibition in PBE oocytes.

Limitations, reasons for caution: This study only includes the inhibition of a particular member of MAPK signaling and a certain regulator of MPF. However, the relation of actin nucleators with MAPK and MPF might also be through their upstream or downstream regulators.

Wider implications of the findings: The factors affecting actin nucleation contribute to correct positioning of the meiotic spindle during oocyte maturation. Proper manipulation of actin nucleators by chemical inhibitors or activators during IVM of oocytes might enhance the development potential of the embryo leading to an increased success rate in fertility treatments.

Trial registration number: This work was supported by The Scientific and Technological Research Council of Turkey (TUBITAK).

P-314 Anti-Müllerian hormone may have a rebound effect in long-term human ovarian tissue grafts co-transplanted with Endothelial Cells

L. Man[1], L. Park[1], G.L. Schattman[1], Z. Rosenwaks[1,2], D.J. James[1,2]

[1]*Weill Cornell Medical College, Center for Reproductive Medicine and Infertility, New York, U.S.A.*
[2]*Weill Cornell Medical College, Tri-Institutional stem cell Derivation Laboratory, New York, U.S.A.*

Study question: Will co-transplantation of human ovarian tissue with Anti-Müllerian hormone (AMH) producing endothelial cells (ECs) keep a larger cohort of quiescent follicles in long-term grafts?

Summary answer: Co-transplantation of human ovarian tissue with AMH producing ECs in long-term grafts may create a rebound effect and cause follicular requirement.

What is known already: AMH has been suggested to exert a repressive input on activation and/or growth during normal folliculogenesis. We have previously shown that direct paracrine delivery of AMH via lentivirally engineered exogenous endothelial cells (exECs) reduced premature follicular mobilization and growth upon co-transplantation at 2-weeks post grafts (Man, et al., 2017). Another group, using continuous administration of AMH via osmotic pump or intraperitoneal injection of lentivirally encoded AMH in a murine model showed similar results (Kano, et al., 2017).

Study design, size, duration: Cross-sectional study, xenograft of human ovarian tissue into NOD *scid* gamma (NSG) mice with co-transplantation of control exECs (n = 7) or exECs ectopically expressing human AMH (n = 8). Grafts were harvested at 14 weeks and the ratio of follicles in each treatment was assessed in histologic sections using light and confocal microscopy.

Participants/materials, setting, methods: Human ovarian tissue, originating from 2 patients, was co-transplanted with ECs or AMH-ECs; patient-matched ovarian tissue was used in control and experimental groups. Both control and AMH expressing ECs were transduced with lentiviral vectors encoding Red fluorescent protein (RFP). Grafts were harvested at 14 weeks and a ratio of follicles in each treatment was assessed in histologic sections.

Main results and the role of chance: AMH-ECs grafts revealed a shift in the follicular pool away from quiescence with a decreased percentage of primordial follicles. In contrast, grafts co-transplanted with ECs showed a significant retention of primordial follicles at 14 weeks. In these long-term grafts, we found a two-fold increase in primordial follicles median percentage with AMH-ECs; 10.84 ± 6.98 vs. ECs 22.51 ± 7.15, P = 0.05. We found a 2-fold decrease between a median ratio of primordial to growing follicles with AMH-ECs; 8.23 ± 3.62 vs. ECs 3.44 ± 1.07, P = 0.05.

Limitations, reasons for caution: Human ovarian tissue available for research is restricted, repeating the experiment at different time points may shed more light on the phenomenon we have described here.

Wider implications of the findings: As auto-transplantation of ovarian tissue becomes more widely practiced, resolution of mechanisms mediating follicular activation and growth are increasingly relevant. Our unexpected finding, given previous results indicating a suppressive input of AMH, suggests that transient AMH overexpression may initially suppress activation, but ultimately induces a rebound effect via negative feedback.

Trial registration number: not applicable.

P-315 Effect of Ulipristal Acetate (UPA) on the gene expression profiling of endometrial cells in culture

M.J. Munuce[1], M. Jiménez Guerrero[2], D. Cotán[2], A. García[2], A.M. Caille[1], P. Cuasnicú[3], L. Bahamondes[4], J. Horcajadas[2], D. Cohen[3]

[1]*Laboratory of Reproductive Medicine- School of Biochemical and Pharmaceutical Sciences- National University of Rosario, Biochemical Chemistry, Rosario, Argentina*
[2]*Andalusian Center for Developmental Biology- University Pablo de Olavide-SINAE, Genetics Department, Seville, Spain*

[3]Instituto de Biología y Medicina Experimental IBYME, CONICET-Buenos Aires, Buenos Aires, Argentina
[4]School of Medical Sciences- University of Campinas UNICAMP, Family Planning Clinic- Department of Obstetrics and Gynecology, Campinas, Brazil

Study question: To assess the effect of UPA, in concentrations compatible with emergency contraception (EC), on gene profile expression of an endometrium cell line in culture.

Summary answer: The presence of UPA modifies the transcriptomic signature of endometrial cells in culture.

What is known already: Emergency contraception consists in the use of drugs or devices to prevent pregnancy after unprotected sexual intercourse. Considering the fundamental role that progesterone has throughout the process ranging from ovulation to implantation and embryo development, UPA has been developed as a selective progesterone receptor modulator (SPRM) with agonist/antagonist activity and pharmacological applications in EC.

The principal mechanism of action of UPA is the inhibition or delay of follicular rupture when administered previous to LH peak. However, given its high effectiveness in the prevention of pregnancy (up to 5 days after intercourse), post-ovulatory effects related to endometrial receptivity, cannot be excluded.

Study design, size, duration: This basic research work was conducted in 2017 and designed as a prospective study. Epithelial cells of human endometrium carcinoma cell line (HEC-1A) were exposed 24 and 48 h to UPA (100, 250, 500 ng/ml) in triplicates. Total RNA was extracted and 192 genes associated with endometrial receptivity were evaluated by quantitative PCR.

Participants/materials, setting, methods: Fluidigm Microfluidic technology combines microarrays with real time PCR, where 192 genes are analyzed. This selected panel was analyzed after 24 and 48 h in culture. From normalized Cqs with respect to the constituent genes, Fold-Change (FC ≥ 0,5 in absolute value) was calculated to determine the differential gene expression between samples treated with UPA and controls. Gene Ontology was performed to identify the biological function of those representative genes.

Main results and the role of chance: Data showed that by 24 h of incubation, there are no significant changes of transcriptomic profile in those cells exposed to UPA (100, 250, 500 ng/mL) respect to controls cultured without the drug. However, by 48 h of incubation, there is a significant ($p<0,05$) increase in total transcriptomic profile in those cells exposed to UPA (at all concentration assayed) compared to controls. To determine which genes are differentially expressed after 48 h of culture, FC of the 192 genes related to endometrial receptivity were analyzed. Absolute value of FC increases with the concentration of UPA in culture, suggesting a dose-dependent trend of down-regulation of gene expression in the panel of genes analyzed. Considering those genes with FC ≥ 0,5 in absolute value, a Gene Ontology (DAVID) was performed to identify the biological function of those representative genes as well as the possible effects of UPA on those genes. Genes related to cellular adhesion and proliferation, signal transduction, growth factors, cytokine activity and estradiol response seem to be down regulated after UPA exposure.

Limitations, reasons for caution: Our study was carried out in vitro with a human endometrium carcinoma cellular model that expresses estrogen, progesterone, molecular adhesion receptors and proteases This could limit the extrapolation of results to the UPA effects on endometrial tissue.

Wider implications of the findings: The present study suggests that there are changes in gene expression of endometrial cells exposed to UPA at concentrations compatible with EC. Our data brings new evidence for the study of the molecular mechanisms of action of UPA, used for contraceptive proposal, on endometrium receptivity associated with embryo implantation.

Trial registration number: This study was supported by SINAE, University of Rosario (BIO 486 Res. 1480/2016), São Paulo Research Foundation (FAPESP) 2015/20504-9, CONICET and ANPCyT (PICT 2016-1057).

P-316 An increase of intracellular cyclic AMP improves mitochondrial function of bovine immature oocytes

S. Hashimoto[1], M. Yamanaka[2], T. Yamochi[1], H. Iwata[3], R. Kawahara-Miki[4], Y. Nakaoka[5], Y. Morimoto[6]

[1]Osaka City University Graduate School of Medicine, Reproductive Science Institute, Osaka, Japan
[2]IVF Namba Clinic, Research, Osaka, Japan
[3]Tokyo University of Agriculture, Department of Animal Science, Atsugi, Japan
[4]Tokyo University of Agriculture, Nodai Genome Research Center, Tokyo, Japan
[5]IVF Namba Clinic, Medical office, Osaka, Japan
[6]HORAC Grandfront Osaka Clinic, Medical office, Osaka, Japan

Study question: How does a transient increase of cAMP prior to in vitro maturation (IVM) improves oocyte competence?

Summary answer: An increase of intracellular cAMP improved oocyte quality by enhancement of its mitochondrial function. On the other hand, nuclear maturation did not proceed during treatment.

What is known already: IVM of oocytes is an important technology for assisted reproduction (ART) with a wide range of research and clinical applications. However, it is generally accepted that the development of embryos produced using IVM oocytes are lower than their in vivo counterparts probably due to inappropriate status of cytoplasm. It has been also shown that an artificial increase of intracellular cAMP before IVM significantly improves oocyte developmental competence in cattle and mice. However, the precise mechanism by which cAMP improves oocyte competence during an increase of cAMP remains to be elucidated.

Study design, size, duration: The changes of gene expression in bovine oocytes and surrounding somatic cells following FSK and IBMX treatment were investigated by transcriptome analyses. A total of 458 COCs were exposed to pre-IVM treatment. As references, 491 COCs without culturing to pre-IVM were also used. Time-dependent change of nuclear maturation of oocytes and mitochondrial function in oocytes following FSK and IBMX treatment were also assessed.

Participants/materials, setting, methods: Total RNA was extracted using the RNAqueous-Micro Kit (Thermo Fisher Scientific, CA, USA) from oocytes or cumulus cells separately after isolations of oocytes and cumulus cells. RNA of Clusters were generated on a cBot (Illumina), and two lanes for the four groups were sequenced as 50-bp reads (single end) on a HiSeq 2500 (Illumina). The oxygen consumption rates (OCRs), cytochrome c oxidase (CCO) activity in mitochondria and ATP contents of oocytes were also measured.

Main results and the role of chance: Although the expression of several genes related with the progress of meiotic maturation was up-regulated, the key gene for MPF activation, Cdc25 was down-regulated ($p < 0.01$). As a result, the duration required for meiotic maturation of oocytes treated with FSK and IBMX was the same as that of control oocytes. Meiotic resumption was arrested during FSK and IBMX treatment.

The expression of genes encoding proteins which compose beta-oxidation, glycolysis, mitochondrial electron transport system, lipase maturation, and transportation of fatty acids significantly increased in oocytes following FSK and IBMX treatment ($p<0.01$). The OCRs, the proportion of mitochondria with high CCO activity and ATP content in oocytes significantly increased ($p<0.01$).

Genes involved in glycolysis and ovarian steroidogenesis were significantly upregulated in cumulus cells following FSK and IBMX treatment ($p<0.01$).

Limitations, reasons for caution: Further studies should be required to assess whether the data obtained from bovine oocytes is applicable to human ART.

Wider implications of the findings: The data of the present study revealed that FSK and IBMX treatment at prophase stage induced the gene expression of glycolysis, fatty acid degradation and mitochondrial functions in oocytes, and accordingly improved mitochondrial functions and ATP levels in oocytes.

Trial registration number: Not applicable.

P-317 Vitamin B2 and B6 deficiency and overgrowth of intestinal candida adversely affect fertilized embryos

S. Idei[1], F. Yachiyo[2], W. Harimura[2], N. Shiozawa[3]

[1]Omiya Ladies Clinic, Gynecology, Saitama, Japan
[2]Omiya Ladies Clinic, Embryologist, Saitama, Japan
[3]Omiya Ladies Clinic, Nurse, Saitama, Japan

Study question: Could most favorable embryos be created by organic acid testing capable of realistic evaluation of nutrition deficiency and metabolism?

Summary answer: Vitamin B6 deficiency decreased the antral follicle count (AFC) and normal fertility rate. With intestinal candida overgrowth, significant decrease in good blastocyst count was observed.

What is known already: Apparently, metabolism of egg mitochondria determines the egg quality; however, most studies were based on dietary compositions with unclear nutrition details. In contrast, our study was based on organic acid testing, which can precisely assess both excess and deficiency of nutrition from metabolic products of nutrients after digestion and absorption.

Study design, size, duration: Of the patients who underwent an in vitro fertilization procedure (short or antagonist protocol) between November 2016 and December 2017, 82 patients (age: 26–45 years; mean: 38.2; 2 SD: ±8.62) who exhibited poor ovum count, fertilization rate, division rate, and/or blastocyst reach rate were subjected to organic acid testing. In this study, we retrospectively examined these patients. Of 82 patients examined, the number of patients suffering from candida overgrowth was abnormally high at 70 (80%).

Participants/materials, setting, methods: We categorized the subjects into the excessive deficiency group (<−2 SD) and normal group (>−2 SD) for vitamin B2, B6, B12, and folic acid, which are frequent and significant items among the test items, and the candida overgrowth group (>+2 SD) and normal group (<+2 SD) regarding intestinal bacteria. We assessed the AFC, ovum count, fertilization rate, and blastocyst reach rate of each group and compared by t-test.

Main results and the role of chance: Compared to the normal group, vitamin B2 deficiency group (<−2 SD) exhibited a significant decrease in the AFC ($P = 0.0056$; odds ratio, 0.73). The vitamin B6 deficiency group (<−2 SD) exhibited a significant decrease in the AFC ($P = 0.023$; odds ratio, 0.62) and normal fertility rate ($P = 0.0195$; odds ratio, 0.48) compared to the normal group. Although not statistically significant, we also observed a decline in two other items: the ovum count ($P = 0.0537$; odds ratio, 0.61) and day 3 good embryo count ($P = 0.063$; odds ratio, 0.49). Regarding intestinal bacteria, the candida overgrowth group demonstrated a significant decline in the blastocyst reach rate ($P = 0.0245$; odds ratio, 0.54) and good blastocyst reach rate ($P = 0.027$; odds ratio, 0.14) compared to the normal group. Although not statistically significant, a decrease was also observed in three other items: the day 3 good embryo count ($P = 0.087$; odds ratio, 0.70), good blastocyst reach rate ($P = 0.059$; odds ratio, 0.23), and used embryo count ($P = 0.0819$; odds ratio, 0.71).

Limitations, reasons for caution: The study cohort comprised only 82 patients; therefore, further investigation with larger sample size is warranted. In addition, the novelty of this study necessitates an additional examination by other institutes.

Wider implications of the findings: Improvement in the pregnancy rate can be anticipated by adequate supplementation of vitamin B2 and B6 and inhibition of candida overgrowth.

Trial registration number: none.

P-318 Granulosa cells provide elimination of apoptotic oocytes through unconventional autophagy-assisted phagocytosis

M. Yefimova[1], N. Bourmeyster[2], A. Bashamboo[3], C. Eozenouo[3], A. Burel[4], M.T. Lavault[4], C. Pimentel[5], S. Veau[5], S. Sun[5], S. Jaillard[5], B. Jégou[6], C. Ravel[7]

[2]*Univ-Poitiers- CHU Poitiers, STIM ERL 7003 CNRS Pole Biologie-Santé-, Poitiers, France*
[3]*Institut Pasteur, Unit of Human Developmental Genetics, Paris, France*
[4]*Univ-Rennes, Plateforme Biosit- MRIC, Rennes, France*
[5]*Univ-Rennes, CHU Rennes, Rennes, France*
[6]*Univ Rennes- Inserm- EHESP- Irset, Inserm, Rennes, France*
[7]*Univ Rennes- CHU Rennes- Inserm- EHESP- Irset-, CHU Rennes, Rennes, France*

Study question: Granulosa cells manifest a strong gonadotropin-dependent autophagy activity during folliculogenesis, which correlates with apoptosis. There was no data on the ability of granulosa cells to clean apoptotic oocytes.

Summary answer: Granulosa cells eliminate apoptotic oocytes and other apoptotic substrates through unconventional autophagy-assisted phagocytosis.

What is known already: The insufficiency to clean the tissues from apoptotic substrates strongly perturbs tissue homeostasis and causes autoimmunity. Premature ovarian failure (POF) is often associated with the presence of autoantibodies against ovarian proteins. The role in elimination of apoptotic oocytes during follicular atresia is commonly attributed to macrophages, which are found within the granulosa cell layer only in the most advanced stages of atresia. Living granulosa cells are known to clean their apoptotic counterparts in atretic follicles through autophagy-related mechanism. No data on the role of granulosa cells for disposal of apoptotic oocytes has been reported.

Study design, size, duration: Cultured human granulosa cells were used to study main phagocytosis (binging, ingestion, degradation) and autophagy (initiation, elongation, docking and fusion, degradation) steps after loading with apoptotic oocytes and other apoptotic substrates.

Participants/materials, setting, methods: Analysis of primary cultures of human granulosa cells and human granulosa cell line (KGN), for the presence of specific molecular markers and end-products characteristics for different steps of phagocytic and autophagic machineries by immunocytochemistry, confocal and electron microscopy and Western-blotting before and after loading with apoptotic substrates.

Main results and the role of chance: Granulosa cells manifest a strong ability to eliminate apoptotic substrates of different origin. As demonstrated kinetic studies, the rate of elimination of apoptotic substrates by granulosa cells is higher comparing with other phagocyte cells (Sertoli cells, retinal pigmented epithelium cells). The process of apoptotic cleaning by granulosa cells is strongly supported by autophagy in the process resembling LC3-associated phagocytosis (LAP). This indicates that granulosa cells should be considered as one of the most powerful non-professional phagocytes in the body, endowed with the ability to combine phagocytic and autophagy degradative pathways for ovarian homeostasis maintenance.

Limitations, reasons for caution: Thorough analysis of different steps (binding and ingestion, initiation, elongation, degradation) of both phagocytic and autophagic degradative processes depending on gonadotropin status merits to be performed.

Wider implications of the findings: Cleaning of apoptotic oocytes by surrounding granulosa cells seems likely to be a physiological mechanism involved in follicular atresia. Proper functioning of this mechanism may be a new strategy for the treatment of POF syndrome.

Trial registration number: GMR 2018-03

P-319 In vitro embryo development outcomes of DuoStim ovarian stimulation

K. Ozgur[1], M. Berkkanoglu[1], H. Bulut[2], E. Basol[1], K. Coetzee[3]

[1]*Antalya IVF, Clinic, Antalya, Turkey*
[2]*Antalya IVF, Clinic, Antalaya, Turkey*
[3]*Antalya IVF, laboratory, Antalya, Turkey*

Study question: To investigate in vitro embryo development outcomes following DuoStim in patients with poor follicular phase (FP) ovarian response.

Summary answer: Luteal phase (LP) ovarian stimulation not only contributes to oocyte number, but also to blastocyst number, blastocyst quality, and the chance of freeze-all.

What is known already: Studies have shown that it is possible to cumulatively increase the retrievable oocyte number in poor ovarian response patients by consecutively performing FP and LP ovarian stimulation in the same menstrual cycle.

Study design, size, duration: The study is a retrospective observational study being performed at a private IVF center. Poor ovarian response patients undergoing blastocyst freeze-all IVF cycles are prospectively being included in the study, as of May 2017. All ovarian stimulations are being performed using gonadotropin releasing-hormone (GnRH) antagonist co-treatment protocols, using combinations of recombinant follicle stimulating hormone (rFSH) and

human menopausal gonadotropin (hMG), with or without clomiphene citrate (CC) priming for follicular stimulation.

Participants/materials, setting, methods: Patients with poor response (≤5 oocytes) after FP ovarian stimulation who have at least two follicles of >5 mm at oocyte retrieval are eligible for inclusion. Indomethacin is being administered from the day of trigger to the day of oocyte retrieval. Follicles <10 mm at FP oocyte retrieval are not being aspirated, with LP ovarian stimulation commencing on or after the day of FP oocyte retrieval. The primary outcome measure is oocyte number.

Main results and the role of chance: Twenty-three eligible patients have thus far been included in the study. Two patients have had their LP ovarian stimulation discontinued, as the result of poor follicular development. Two patients did not undergo LP oocyte retrieval, because of premature ovulation. From a median day2-3 antral follicle count of 4.7, 1.8 oocytes have been retrieved at FP oocyte retrieval, increasing to 3.7 after LP oocyte retrieval. Similarly, the number of blastocysts increased from 0.52 to 1.1. Eight patients had blastocysts for cryopreservation after FP oocyte retrieval, increasing to 11 after LP oocyte retrieval. Four (4/12; 33.3%) good quality blastocysts (>2CC) were obtained from the FP and eight (8/13; 61.5%) from the LP.

Limitations, reasons for caution: The use of DuoStim prevents the use of fresh embryo transfer, necessitating effective cryopreservation and frozen embryo transfer protocols. While DuoStim may improve in vitro embryo development outcomes of patient with cycle dependent poor response, this may not include Bologna poor response patients.

Wider implications of the findings: LP ovarian stimulation increases the chances of patients having blastocyst freeze-all. Developing effective DuoStim protocols may benefit patients with reduced ovarian reserve, as well as, normal ovarian reserve patients wishing to cumulatively increase their reproductive chances or expedite effective treatment outcomes.

Trial registration number: N/A.

P-320 Neuropeptide phoenixin (PNX) and its novel receptor GPR173 induce COX-1/COX-2 expression and PGE2 production through the CREB signaling pathway

X.P. Nguyen, A. Iwase, T. Murase, U. Ganieva, Y. Qin, B. Bayasula, K. Shimizu, S. Osuka, T. Nakamura, M. Goto, F. Kikkawa

Nagoya University Graduate school of Medicine, Obstetrics and Gynecology, Nagoya, Japan

Study question: Can phoenixin in human granulosa cells has a direct effect on ovulation?

Summary answer: Phoenixin acts through its novel receptor GPR173 to induce COX-1, COX-2 expression, and PGE2 production by activating the CREB signaling pathway in human granulosa cells.

What is known already: Phoenixin is a recently discovered neuropeptide involved in regulating the reproductive system. Phoenixin activates the cAMP/PKA/CREB pathway through its receptor GPR173, a part of SREB (Super conserved Receptor Expressed in Brain) family. GPR173 also was detected at high level in the ovary. Studies have linked the CREB signaling pathway to induce COX-2 expression. Besides, cyclooxygenase (COX) enzyme is the key enzyme that controls the rate-limiting step of prostaglandin E_2 (PGE_2) synthesis, which has been recognized as a key mediator of ovulation. Whether the direct effect of phoenixin on PGE_2 biosynthesis and ovulation is still unknown.

Study design, size, duration: In vitro studies utilizing the human non luteinized granulosa cells line (HGrC1) was performed to investigate the effects of PNX on COX-1/COX-2 expression and PGE_2 production.

Participants/materials, setting, methods: HGrC1 was cultured with PNX-20 at 10 nM, 100 nM concentration with different time points, 1 hour, 3 hours, 6 hours, 12 hours and 24 hours. The levels of mRNA and protein were examined by RT-quantitative real-time PCR and western blotting. The PGE2 concentrations in the culture medium were measured by ELISA. siRNA targeting GPR173 was used to observe the influence of GPR173 receptor.

Main results and the role of chance: Our previous studies demonstrated that PNX and GPR173 present in human oocytes, granulosa cells and theca cells in various stages of development. Interestingly, GPR173 expression in granulosa cells from primary follicle and increases according to the stage of follicle development. We also confirmed the expression of PNX and GPR173 mRNA in HGrC1 cells. PNX-20 significantly induced the mRNA levels of COX-1 (2.25 ± 0.04-fold, $P < 0.001$) and COX-2 (2.76 ± 0.06-fold, $P < 0.001$) in a dose-dependent manner. The level of COX-1 and COX-2 were induced with the maximal effect observed after 3 hours treatment with PNX-20. PGE_2 production in culture medium was significantly enhanced by PNX-20 administration in a dose-dependent manner. We assessed CREB mRNA levels and found increased CREB mRNA upon PNX-20 100 nM treatment (1.44 ± 0.07, $P < 0.01$). In addition, our Western blotting results reveal that PNX-20 increased Phospho-CREB in 15 and 30 minutes of treatment (3.66-fold and 8.42-fold, respectively). Moreover, the silencing of GPR173 markedly reduced the PNX-induced increase in COX-1, COX-2 mRNA expression.

Limitations, reasons for caution: Although HGrC1 share common characteristics and are functionally similar to primary human granulosa cells, there are many differences between the primary granulosa cells and HGrC1 cells such as karyotype and the response to the stimulating factors.

Wider implications of the findings: Our results show that phoenixin act through GPR173 to induce COX-1, COX-2 expression and PGE2 production in human granulosa cells, by activating the CREB signaling pathway. Overall, these findings demonstrated that phoeinxin may participate in regulating human ovulation through the induction of cyclooxygenase-mediated PGE2 production.

Trial registration number: None.

P-321 CHK2 controls the oocyte pool in mammals

A. Martinez Marchal[1,2], A. Guixé[1,2], M.T. Guillot[1,2], M. García-Caldés[1,2], I. Roig[1,2]

[1]*Universitat Autònoma de Barcelona, Cell Biology- Phisiology and Immunology, Cerdanyola del Vallès, Spain*
[2]*Institut de Biotecnologia i de Biomedicina, Genome Integrity and Instability, Cerdanyola del Vallès, Spain*

Study question: Is the CHK2-dependent checkpoint responsible for the perinatal loss of oocytes? Does it control oocyte pool and mammalian female fertility?

Summary answer: CHK2 has a role in the pachytene checkpoint controlling the oocyte number in fetal ovaries. It also regulates the number of oocytes in adult females.

What is known already: During mammalian oogenesis, oogonia proliferate forming the so-called germinal cysts. They progress through meiotic prophase I and cysts break down due to massive perinatal oocyte death. During meiotic prophase I, double strand breaks (DSBs) are formed throughout the genome and repaired by homologous recombination. In response to errors in this process, the DNA damage response kinase CHK2 is activated promoting cell cycle arrest or even apoptosis. Contrary to what occurs in spermatocytes, oocytes present high numbers of unrepaired DSBs at pachynema, at the time of the massive oocyte death and cyst breakdown.

Study design, size, duration: We studied the number of oocytes and follicles present in control and *Chk2* mutant ovaries at different time points of animal development. We collected ovaries from $Chk2^{+/-}$ and $Chk2^{+/+}$ (control), and $Chk2^{-/-}$ (mutant) mice from 16 and 18 days *post coitum* (dpc), 0, 1, 2, 3, 40 and 400 days *post-partum* (dpp). For the fetal mice, the females were breed and timing was counted from the day when the vaginal plug was observed.

Participants/materials, setting, methods: For perinatal mice the ovaries were collected, fixed in 4% Paraformaldehyde, processed and sectioned at 7 µm. Every second section was stained by immunofluorescence against the germinal cell marker DDX4 with DAPI as counterstaining. The DDX4-positive cells were scored and classified. For adult females the ovaries were collected, fixed in Bouin solution, processed and sectioned at 7 µm. Every fifth section was stained with PAS-Hematoxylin and only the oocytes with visible nucleus were counted.

Main results and the role of chance: Control and mutant ovaries present the same number of oocytes at 16 dpc. However, at 18 dpc there is a significant two-fold increase in mutants compared to controls. This difference is still significant at 0 dpp, but is overturned during the following postnatal days. This data suggests that CHK2 regulates the number of oocytes in fetal ovaries, but there must be an alternative mechanism capable of levelling the number of oocytes

during the perinatal phase. Interestingly, while in young adult mice (40 dpp) we see no difference in the number of oocytes present in control and mutant ovaries, elder mutant mice (400 dpp) have three times more oocytes than control mice. In particular, this increase is due to an accumulation of primordial follicles, which represent the pool of oocytes available to use during the fertile period of a female. Therefore, our results show that CHK2 regulates the pool of oocytes present in adult mouse ovaries. We propose these data reflects how many oocytes may accumulate DNA damage and are naturally eliminated by a CHK2-dependent checkpoint. Thus, these findings suggest that CHK2 inhibition may extend the reproductive life of mammalian females.

Limitations, reasons for caution: The number of oocytes present in perinatal ovaries was highly variable between individuals and even between ovaries from the same mouse.

Wider implications of the findings: We found evidences that show that CHK2 controls the oocyte numbers both around birth and in adult females. Our results in elder mice suggest that inhibition of CHK2 could extend mammalian female fertility.

Trial registration number: not applicable.

P-322 Dual triggering in antagonist ICSI cycles

K. Yildiz, D. Deniz, R. Pabuccu, M.U. Ucar

Private Dogufertil IVF Center, Assisted Reproductive Technology Department, MALATYA, Turkey

Study question: Is it beneficial dual triggering with 0,1 mg/ml triptorelin asetat and 250 µcg recombinant hCG together in GnRH antagonist cycles.

Summary answer: It seems to be that dual triggering does'nt have superior effect over only rhCG triggering group in GnRH antagonist ICSI cycles.

What is known already: Final oocyte maturation is induced by human chorionic gonadotropin (hCG) after the controlled ovarian hyperstimulation (COH). According to some studies, dual triggering with a GnRH agonist and recombinant hCG does have improved oocyte maturation rates and pregnancy rates in IVF cycles compared to hCG alone groups.

Study design, size, duration: Single center, prospective, randomized clinical study.

Participants/materials, setting, methods: Two groups allocated as Group A (GnRH analog+ rhCG 56 patients) and Group B (only rhCG 66 patients) according to the triggering method. 0,1 mg/ml triptorelin asetat was used for GnRH analog and Ovitrelle for 250 µcg recombinant hCG (rhCG). Severe male infertility factor (<15 million sperm/ml) and poor ovarian reserve patients (<5 antral folicule count) were excluded from the study.When at least 3 follicules >17 mm the triggering was made randomly. P value set >0.05

Main results and the role of chance: Groups were comparable in terms of age, gonadotropin start dosage,total amount of gonadotropins, duration of stimulation (Table I)

Table I

Parameters	Group A (n = 56)	Group B (n = 66)	P value
Age	32.79 ± 5.71	34.09 ± 4.9	0,17 NS
Gonadotropin start dosage	212 ± 44	209 ± 46	0,71 NS
Total amount of gonadotropins	1948 ± 459	1991 ± 617	0,66 NS
Duration of stimulation (day)	9,39 ± 0,78	9,42 ± 0,90	0,83 NS

As main outcome of this study, collected total oocyte numbers, maturation and fertilization of oocytes and pregnancy rates were compared between the groups (Table II).

Table II

Parameters	Group A	Group B	P Value
Collected total oocyte numbers	11,13 ± 5,41	9,68 ± 4,17	0,09 NS
Mature Oocytes	8,5 ± 3,67	8,11 ± 3,46	0,54 NS
Fertilised Oocytes	6,23 ± 3,12	6,15 ± 2,52	0,87 NS
Pregnancy rates	28/56 (%50)	31/66 (%46,9)	0,73 NS

According to these results there isn't any significant difference between two groups in all parameters. We didn't see OHSS in any group.

Limitations, reasons for caution: None.

Wider implications of the findings: Dual triggering is alternative to classic only hCG trigger. Whether some studies mentioned as an significant increase in total collected oocyte number, mature oocyte number and pregnancy rates we didn't find any significant difference with these parameters. It seems that large-scale collaborative studies needed for future aspects.

Trial registration number: None.

P-323 Unravelling the molecular pathways responsible for sex determination in humans

J. Taelman[1], M. Popovic[1], L. Tilleman[2], M. Van der Jeught[1], D. Deforce[2], P. De Sutter[1], F. Van Nieuwerburgh[2], B. Heindryckx[1], S. Chuva De Sousa Lopes[3]

[1]Ghent University Hospital, Department of Reproductive Medicine, Ghent, Belgium
[2]Ghent University, Faculty of Pharmaceutical Sciences, Ghent, Belgium
[3]Leiden University Medical Center, Department of Anatomy and Embryology, Leiden, The Netherlands

Study question: What are the molecular signals governing sex determination in human fetal gonads?

Summary answer: While the antagonizing sex determination mechanisms of WNT and FGF signaling appear to be conserved between humans and mice, the key determining factors are different.

What is known already: Sex determination and germ cell maturation mechanisms vary widely between species. In female mice, upregulation of WNT4 initiates a signaling cascade, leading to the development of ovaries. Conversely in males, WNT4 signaling is repressed by SOX9 and its target FGF9, shortly after activation of the male fate determining SRY gene, resulting in the formation of testes. Human (partial) sex reversal case studies suggest that the antagonistic role of WNT and FGF signaling is conserved between mice and humans. Transcriptomic analysis of human fetal gonads may provide valuable insights into the underlying mechanisms of sex determination and maturation in humans.

Study design, size, duration: Single cell sequencing data, from human fetal gonads of both female and male samples, were analyzed in R (version 3.4.2). Developmental age ranged from week (W)5 to W26 of development for female, and W4 to W25 for male cells. Data were filtered to include only cells with cell types validated through marker gene expression, retaining a final dataset of 992 female and 852 male cells of various ages from 17 female and 12 male embryos.

Participants/materials, setting, methods: Genes from WNT and FGF signaling pathways, from Gene Ontology databases, were queried in the datasets to identify age- and cell type-specific genes of interest (GOI). Heatmaps were generated of those GOI to visualize differences between various developmental clusters of germ cells and somatic cells. Differentially expressed genes (DEGs) between germ cell and somatic clusters of specific ages were identified. Volcano plots were generated to visualize significant DEGs.

Main results and the role of chance: The analysis of DEGs between W4 and W9-W10 male fetal gonadal cells (FGCs) and Sertoli cells showed that,

similar to mouse, SOX9 was differentially upregulated in human Sertoli cells. Furthermore, comparison between W5 and W7-W8 FGCs and granulosa cells in female, revealed elevated expression of multiple WNT signaling genes. Markedly, unlike mouse, the female determining factor WNT4 was not differentially expressed in somatic cells compared to FGCs at the time of sex determination. However, we observed a significant increase in WNT6 expression at W7-W8. This suggests that although similar sex determining mechanisms exist between human and mouse, other WNT genes may fulfil differing key roles in humans. Furthermore, we have identified WNT-antagonizing factors, such as SOX10 and SOX11 in both W9-W10 male and W7-W8 female somatic cells. These genes may perform undescribed regulatory functions during sex specification, in humans. Surprisingly, we also identified FGF9, a male determining factor, to be elevated in female human somatic granulosa cells, thus further highlighting interspecies differences in the underlying mechanisms of sex determination.

Limitations, reasons for caution: DEGs were identified from existing in silico databases from human fetal gonadal cells. To further validate the expression of the GOI, immunofluorescence analysis in freshly isolated human gonadal material from 7-12 W is currently ongoing.

Wider implications of the findings: Defining the key regulatory players of WNT and FGF signaling during sex determination in humans will greatly contribute to elucidating the role of these pathways during germ cell development and maturation. Adaptation of culture conditions based on this knowledge may ultimately advance efforts to derive sex-specific germ cells *in vitro*.

Trial registration number: not applicable.

P-324 Oral Vitamin D supplementation impacts luteinized granulosa-cell transcriptomics

S. Makieva[1], F. Bonesi[1], E. Giacomini[1], A. Paffoni[2], V. Sarais[1], S. Ferrari[2], L. Pagliardini[1], E. Papaleo[1], E. Somigliana[2], P. Viganò[1]

[1]IRCCS San Raffaele Scientific Institute, Reproductive Sciences Laboratory- Division of Genetics and Cell Biology, Milan, Italy

[2]Ospedale Maggiore Policlinico, Infertility Center- Fondazione Ca'Granda, Milano, Italy

Study question: Can oral administration of Vitamin D (VD) to infertile women undergoing in vitro fertilization (IVF) influence luteinized granulosa-cell (GCs) gene expression?

Summary answer: Surprisingly, oral administration of VD manifests at the gene expression level in luteinized GCs, which were isolated during an oocyte retrieval procedure for IVF.

What is known already: There is evidence that circulating VD concentration in infertile women is associated with successful Assisted Reproductive Technology (ART) treatment. It is unclear whether this association is causal and no randomized clinical trial to date addressed this notion. We launched (2017) the first multi-centre controlled double-blinded randomized clinical trial to assess whether supplementation of VD will improve IVF clinical pregnancy rate. Herein we addressed one of the secondary objectives, whereby the indirect effect of VD supplementation on oocyte prognosis is explored. Specifically, we investigated the effect of the intervention on GCs transcriptomic machinery, critical regulator of oocyte maturation.

Study design, size, duration: The clinical trial aims to recruit 600 women with a baseline VD serum level <30 ng/ml, who are administered either 300,000 IU of 25-OH-vitamin D (VD group) or placebo (PL group) in a single oral shot. The duration of the study is set on three years.

Participants/materials, setting, methods: Follicular fluid (FF) samples were aspirated during the procedure of oocyte retrieval and GCs were isolated. Pilot transcriptomic analysis with RNAseq utilizing a subset of participant samples (n = 3 per group) and RT-PCR (n = 19 VD, n = 22 PL) was employed to scrutinize the differences between the two groups.

Main results and the role of chance: RNAseq analysis confirmed that GCs derived from the VD group owned a different transcriptomic signature compared to the PL group. The impact of VD on pathways involved in the GC-oocyte interaction was thoroughly explored and a number of genes were found differentially expressed between the VD and PL groups. The action of VD in GCs is plausibly mediated via the Vitamin D Receptor (VDR), the gene expression of which was 3.3 fold higher (±1.33, p = 0.046) in GCs of the VD group (n = 19) compared to PL group (n = 22). Notably, the expression of GC-specific genes traditionally associated with oocyte regulation, such as HAS2, VCAN, 3βHSD, AMHR-2, FSHR, PTGS2, GREM-1, CCND1, STAR, did not significantly change. Non-traditional GC-gene expression patterns reflecting GC-oocyte interaction following administration of Vitamin D warrant further investigation and promise to provide insight into the pathophysiology of oocyte maturation and inform future strategies for the improvement of IVF outcomes.

Limitations, reasons for caution: RNAseq validation on the protein level is pending for full interpretation of gene expression data.

Wider implications of the findings: Vitamin D supplementation may be influencing IVF outcomes via indirect control of GC-gene expression. The latter is critical for the GC-oocyte interaction and, hence, expected to impact oocyte quality.

Trial registration number: EUDRACT 2015-004233-27

P-325 Impact of the fresh cycle outcome on the subsequent frozen-thawed blastocyst transfer in medicated vs natural cycle

M. Bhaduri, N. Lee, Y. Khalaf, T. El Toukhy, J. Kopeika

Guy's and St Thomas' Hospital, Assisted Conception Unit, London, United Kingdom

Study question: Does the endometrial preparation regimen influence the outcome of frozen embryo transfer when preceding fresh transfer was unsuccessful?

Summary answer: Our study suggests that medicated frozen cycle is superior to natural cycle for patients where the preceding fresh cycle didn't result in a live birth.

What is known already: Currently, there is still no agreement whether different regimens of endometrial preparations in frozen embryo transfer cycles have equal effectiveness. It remains unclear whether hormonal preparation with estrogen and progesterone may enhance likelihood of pregnancy, when compared with a natural cycle environment.

Study design, size, duration: Between May 2015 and May 2017 the live birth rate of all naturals cycles was assessed in a case-controlled matched study with medicated frozen replacement cycles in a tertiary center.

Participants/materials, setting, methods: A total of 208 natural frozen cycles were case-matched by age, indication for ART, number of previous cycles and number of transferred thawed blastocysts with 528 medicated frozen cycles. Patients were offered natural frozen cycle if they had regular ovulatory menstrual cycle. Assuming $\alpha = 0.05$ and 80% power it was calculated that 722 frozen-thawed cycles were required to demonstrate a difference of 10% in live birth rate.

Main results and the role of chance: A total number of 981 embryos was transferred in 736 cycles were included. The mean age of patients who had natural and medicated cycles was 34.3 ± 3.8 and 33.7 ± 4.2 respectively (P = 0.07). The mean endometrial thickness was 8.7 ± 1.9 mm in natural and 9.5 ± 1.85 mm in medicated frozen cycles (P = 0.2). The mean number of transferred embryos was 1.3 ± 0.5 in the former and 1.4 ± 0.5 in the latter (P = 1.12). The live birth rate per frozen embryo transfer, was significantly lower in the natural (35/150, 23%) cycle in comparison with medicated frozen cycle (117/354 – 33%), RR 1.4, 95% CI 1.02-1.96, P = 0.036), if preceding fresh cycle did not result in a live birth. However, if fresh cycle resulted in live birth, there was no significant difference in subsequent frozen cycle whether it had natural (22/47 – 46%) or medicated (51/148–34%) preparation (RR 1.3, 95% CI 0.93 – 1.98, P = 0.11).

Limitations, reasons for caution: Although important variables such as age, indication for ART and previous attempts of transfer number of transferred embryos were comparable some bias could arise from the fact that allocation of frozen cycle was not random.

Wider implications of the findings: This study suggests that medicated cycle might be more preferential for patients in whom the fresh transfer did not result in live birth. This is a first study to report such observation and a randomised controlled study is needed to explore this hypothesis further.

Trial registration number: non-applicable.

P-326 Collagen, type I, alpha 1 (COL1A1) as potential molecular marker of ovarian aging and reproductive success in cumulus oophorus cells (CCs)

Study question: Could the expression of some Transforming Growth Factor (TGF)-beta family members in CCs be related to reproductive aging and/or Assisted Reproductive Technology (ART) outcomes?

Summary answer: Molecular analysis combined with a multiple endpoint evaluation in ART allows the identification of transcripts and proteins in CCs that seemingly reflect reproductive success/treatment outcome.

What is known already: Success rates in ART are still unsatisfactory, partly because of insufficient oocyte quality. As this property worsens with aging, it suggests that an age-related regulatory imbalance is likely to occur in the growing ovarian follicle of reproductively aged women. Due to their prominent role in follicular growth and oocyte maturation, abnormal CCs regulation appears as an important contributor to such imbalance. Apart from producing compounds that nurture the oocyte, CCs are important interveners in a set of reciprocal interactions with the oocyte that involve different members of the varied TGF-beta family of proteins.

Study design, size, duration: CCs pools were prepared for different molecular analysis performed in the Biomedicine Department of the Faculty of Medicine-Porto University, after women undergoing ART at CETI-Centro de Estudo e Tratamento da Infertilidade (Porto, Portugal) gave their informed consent. Collection was performed intermittently over 3 years, as the work progressed, following a strict methodology based on clinical and laboratory parameters, 118 samples were grouped using multiple criteria, including cell morphology assessment and data obtained during treatment.

Participants/materials, setting, methods: CCs were mechanically dissected from CCs-oocyte complexes after ovarian puncture of women aged between 27 to 43 years old. Upon proper morphological evaluation and sampling, they were washed and preserved in liquid nitrogen until RNA extraction, followed by its amplification and quantification by quantitative PCR (qPCR), transcription levels were measured and statically analyzed. Other samples were preserved at -20°C for protein assay, they were completely lysed and analyzed by Western Blotting followed by normalized quantification.

Main results and the role of chance: The work established a methodology for grouping CCs samples, based on multiple and specific criteria, aiming to increase groups homogeneity and biomarkers reliability. Gene expression analysis used qPCR arrays to allow simultaneous quantification of 84 transcripts linked to the TGF-beta family. Major changes in expression levels were subsequently confirmed by conventional qPCR. Comparing the medians of quantifications with Mann-Whitney's test ($p < 0,05$ was established for significance level), one of the transcripts - col1a1 – corresponding to alpha-1 type I collagen, was found to be significantly expressed in younger women ($p = 0,041$) compared to the older group and in CCs associated to better prognosis ($p = 0,036$), i.e. pools of cells retrieved from apparently mature complexes, which evolved to good quality embryos, resulting in a successful treatment outcome (clinical pregnancy). Interestingly, transposing this study to the protein level and using the same statistical methodology, a refractory tendency was observed, COL1A1 appeared more abundant in CCs corresponding to poorer prognosis samples, classified with less morphological quality and linked to unsuccessful treatment outcome ($p = 0,007$), being also more expressed in CCs from older women ($p = 0,003$). These results lead us to investigate the importance of COL1A1 and its regulatory effects on CCs.

Limitations, reasons for caution: The reduced amount of CCs collected in each sampling procedure limits the use for both analytical methods of gene expression profiling and western blotting. Moreover, women biological variability limits the homogeneity of the samples. The employment of multiple endpoints of analysis was meant to minimize this obstacle.

Wider implications of the findings: Both in physiological and in-vitro aging, CCs often exhibit modifications in the compaction grade of their extracellular matrix; interestingly COL1A1 is one of its major structural constituents. As this molecule is likely to become a biomarker, its assessment should become relevant during oocyte selection in the setting of ART.

Trial registration number: Not applicable.

P-327 The motility and localization of mitochondria related with the maturation of advanced age oocytes

K.H. Choi[1], H.R. Lee[2], D.W. Suh[2], H.H. Kang[2], M.K. Koong[2], Y.S. Kim[2], T.K. Yoon[2], K.A. Lee[3], J.J. Ko[3], H.T. Lee[4], J.H. Lee[2,3], S.J. Lee[5]

[1]CHA fertility center, Research, Seoul, Korea- South
[2]CHA fertility center Seoul- Station, Fertility laboratory, Seoul, Korea- South
[3]CHA University, Department of biomedical Science, Pochen, Korea- South
[4]Konkuk University, Department of Animal Biotechnology, Seoul, Korea- South
[5]Sahmyook University, Department of Animal Biotechnology, Seoul, Korea- South

Study question: What functional properties of mitochondria are induced to chromosomal error and poor quality in the maturation of advanced aged oocytes?

Summary answer: Poor motility and its movement of mitochondria could be related to chromosomal error and its poor quality in advanced aged oocytes.

What is known already: The major role of mitochondria is supported through bio-energy for oocytes' maturation and chromosomal meiosis. Advanced age oocytes have high aneuploidy ratios with poor quality, which is associated with low mitochondrial activity. However, there are still some questions about why advanced age oocytes have low functional activity in the mitochondria.

Study design, size, duration: This study is designed for motility and the localization of mitochondria with young ($n = 80$) and advanced age oocytes ($n = 60$). All experiments were repeated three times. The statistical differences were analyzed with SPSS.

Participants/materials, setting, methods: We performed confocal live imaging of young and advanced age oocytes stained with mitochondria specific staining dye from the GVBD to MII phase. Young oocytes were treated with Cytochalasin-B (CB), which is well known as a microtubule unstable agent. Next, we compared the localization and motility of mitochondria in young, old age and CB treated oocytes. In addition, we checked the speed and maturation ratio of oocytes in each group.

Main results and the role of chance: In this study, we found that young age oocytes showed dynamic mitochondrial motility gathering to the nuclear region during oocytes' maturation, whereas advanced age oocytes did not. Furthermore, the dynamic motility of mitochondria might be related with microtubule stability in oocytes. Unstable microtubules in young age oocytes showed a similar phenotype in advanced age oocytes, such as low dynamic motility of the mitochondria and slow maturation ratios from the GV to MII phase.

Limitations, reasons for caution: This is an animal study. Therefore, we needed more studies with human oocytes regarding mitochondrial activity, in order to see whether or not the motility and localization of mitochondria was related to oocyte aging in human samples.

Wider implications of the findings: Mitochondrial movement could be associated with oocyte maturation through microtubule stability, which depends on aging in mice. Therefore, these findings could contribute to rejuvenation of advanced age oocytes, such as young age oocytes. It can be a possible application to treat infertility for old women in the human reproductive medicine.

Trial registration number: not applicable.

P-328 Fertilization and embryonic development of eggs from naturally-aged mice

S.Y. Yoon[1], J.H. Eum[1], H.M. Jang[1], J. Kim[2], M. Lee[2], J.J. Ko[1], W.S. Lee[1], D.R. Lee[2]

[1]CHA University, Fertility Center of CHA Gangnam Medical Center, Seoul, Korea-South
[2]CHA University, Biomedical Science, Seoul, Korea- South

Study question: According to recent paper, the major mechanism of egg activation, Ca2+ oscillations at fertilization is largely unchanged by advancing maternal ages. How about fertilization and embryonic development is?

Summary answer: Fertilization and embryo development of eggs from naturally aged mouse are not affected by the age of maternal ages at least in well care condition.

What is known already: Female fecundity decreases with age, and the decline accelerates rapidly after 35 years. The main age-dependent decline is in the number and quality of eggs. The quality of eggs mostly due to an increase of chromosomal aneuploidy with advanced maternal age. The ooplasm could be affected by ageing. According to recent paper, the major mechanism of egg activation, Ca2+ oscillations at fertilization is largely unchanged by advancing maternal ages. Here we investigate the ability of fertilization and further embryonic development in eggs from naturally aged mouse from 7 weeks to 90 weeks old.

Study design, size, duration: MII eggs were collected from B6D2F1 mice 7weeks, 62~65 weeks, 65~68 weeks, 77~80 weeks, 89~92 weeks. Naturally aged mice were acquired at 30 weeks from commercial breeders and housed for a further periods.

Participants/materials, setting, methods: At 14 hr post hCG injection, both ovaries and oviducts were collected MII-cumulus mass. In older than 65 weeks, MII eggs were obtained from antral follicles by puncture with 29 G needles. Collected MII eggs were fertilized sperm from 12 weeks male mice. Fertilization rate was calculated by two pronucleus at 8 hr post insemination. Further embryo culture were performed for 5 days for blastocyst formation. ICM/TE counts were performed by immunostaining with anti-Oct 4 and DAPI staining.

Main results and the role of chance: Number of eggs in oviducts was decline in 62 weeks female mouse ($P<0.001$). No ovulated eggs were observed in more than 65 weeks. However, preovulatory healthy MII eggs were collected from antral follicles in those mouse ovary using needle puncture. The number of eggs were decreased from 62 weeks female mouse. Chromosomal abnormality was not seen in eggs from old eggs. Fertilization rate of these preovulatory eggs from 62 weeks to 90 weeks old was no difference compared to those from 7 weeks mouse. Also, most of the fertilized eggs developed blastocysts in vitro, and the total cell count of these blastocyst was no difference compare to those from 7 weeks mouse.

Limitations, reasons for caution: This study was designed to investigate the effects of natural aging on experimental animals raised in a well-maintained environment. However, it is difficult to interpret patients with pathological causes.

Wider implications of the findings: The aging of the ovaries as a result of natural aging does not affect the quality or fertilization of the eggs, and subsequent embryonic development. Nutritional and growing environments are important for the maturation and development of eggs. This research was supported by NRF-2017R1D1A1B03028155.

Trial registration number: non-clinical trials.

P-329 Downregulation of long non-coding RNA MALAT1 inhibits granulosa cell proliferation in endometriosis by activation of p21/p53 and ERK/MAPK signaling pathways

Y. Li, S.L. Chen

Nanfang Hospital- Southern Medical University, Center for Reproductive Medicine-Department of Gynecology and Obstetrics, GuangZhou, China

Study question: We want to explore the role of metastasis-associated lung adenocarcinoma transcript 1 (MALAT1), as an extensively expressed and evolutionarily conserved lncRNA, in endometriosis-associated infertility.

Summary answer: MALAT1 may play an important role in regulating the function of granulosa cells (GCs), proceeded to affect the growth and development of oocytes in endometriosis.

What is known already: Our findings first reported that MALAT1 was significantly down-regulated in endometriosis GCs and was associated with AFC. MALAT1 was primarily localized in the nuclei of GCs. Knockdown of MALAT1 in KGN cells obviously inhibited cell proliferation through restraining cell-cycle at G1/S phase, caused by p21/p53-mediated cell cycle arrest, and the activation of the ERK/MAPK pathway participates in this process.

Study design, size, duration: 80 GC samples were collected from endometriosis patients (38) and non-endometriosis women (42) undergoing in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI) treatment in the period of March 2014 to December 2015. All endometriosis patients were diagnosed by laparoscopy or laparotomy. The inclusion criteria for control women were as follows: regular menstrual cycles occurring every 25-35 days, antral follicle count (AFC) > 5, and were limited to male factor or tubal disease.

Participants/materials, setting, methods: We used human GCs and KGN cell line to investigated the potential role of MALAT1 in the endometriosis women undergoing assisted reproductive technology (ART). Quantitative reverse transcription PCR (qRT-PCR) was used to compare the expression of MALAT1 in GCs from 42 endometriosis patients and 38 controls. Then, we knocked down MALAT1 with locked nucleic acid (LNA) GapmeRs and performed CCK-8, EdU and Western blot to explore the role of MALAT1 in regulating cell proliferation.

Main results and the role of chance: MALAT1 was significantly downregulated in endometriosis GCs as compared with controls ($P<0.001$), statistical analyses indicated significant correlations between MALAT1 expression and AFC ($r = 0.343$, $P = 0.005$). The result of qRT-PCR to analyze RNA from nuclear and cytoplasmic fractions indicated that MALAT1 was predominately distributed in the nucleus. Knockdown of MALAT1, a significant increase in the protein levels of p21 and p53, and a decrease in cyclin D1 and CDK2 were observed, which are key regulators that is required for G1/S phase, however, no detectable changes were observed in apoptosis-related proteins. Moreover, MALAT1 knockdown significantly increased the levels of phosphorylated ERK1/2, while no detectable changes were observed in the total levels of ERK1/2, p38 MAPK, JNK, PI3K and AKT, as well as the levels of p-JNK, p-p38 MAPK, p-AKT and p-PI3K. With the presence of U0126 (a MAPK/ERK kinase inhibitor that inhibits MEK1/2 for downregulation of p-ERK), the upregulation of phospho-ERK1/2, p21 and p53 by the knockdown of MALAT1 was attenuated.

Limitations, reasons for caution: GCs were obtained from preovulatory follicles after Gn stimulation. The hormonal treatment used in IVF may alter the gene expression. These cells may not behave in the same way as GCs from small antral follicles. The isolation of primary cells inevitably causes contamination with other tissues, such as blood cells.

Wider implications of the findings: ERK/MAPK pathway is often aberrantly activated in human cancers and contributes to enhanced cell proliferation, however, in our study, the activation of ERK/MAPK pathway, conversely, contributes to suppress cell proliferation. Therefore, the direct link between the ERK/MAPK pathway and proliferation remains unclear and requires further study.

Trial registration number: not applicable.

P-330 Extracellular vesicles from human follicular fluid inhibit coagulation

R. Togawa[1], R. Nieuwland[2], C.M. Hau[2], N. Hajji[2], B. Toth[3]

[1]Heidelberg University Women's Hospital, Department of Gynecologic Endocrinology and Fertility Disorders, Heidelberg, Germany
[2]Academic Medical Centre of the University of Amsterdam, Department of Clinical Chemistry and Vesicle Observation Centre, Amsterdam, The Netherlands
[3]Medical University Innsbruck, Department of Gynecological Endocrinology and Reproductive Medicine, Innsbruck, Austria

Study question: Do extracellular vesicles from human follicular fluid promote coagulation?

Summary answer: For the very first time, extracellular vesicles from a human body fluid are shown to inhibit coagulation.

What is known already: Extracellular vesicles (EVs) are small, cell-derived particles which are abundantly present in body fluids. EVs in human body fluids promote and/or trigger coagulation by exposing phospholipids and/ tissue factor. Although it is known that follicular fluid (FF) contains EVs, it is unknown whether these EVs promote coagulation.

Study design, size, duration: FF was collected from patients undergoing hormonal stimulation for IVF/ICSI. The ability of FF and isolated EVs from FF to trigger clotting was measured in a plasma clotting test, the fibrin generation test (FGT). This study was approved by the ethical committee and informed consent was obtained from each volunteer.

Participants/materials, setting, methods: FF was fractionated by ultracentrifugation, and by size exclusion chromatography (SEC). The latter separates EVs from soluble components such as proteins. We measured the clotting activities of FF, FF fractionated by ultracentrifugation, and of EVs isolated by SEC.

Main results and the role of chance: Surprisingly, FF or ultracentrifugation fractions of FF did *not* trigger coagulation. In fact, when EVs were isolated by SEC, these EVs even *delayed* the clotting of plasma. For example, when clotting was triggered with thromborel (extrinsic coagulation), the clotting time (CT) increased from 654-813 seconds in the absence to 1214-1609 seconds in the presence of EVs. Similarly, clotting initiated by kaolin plus phospholipid (intrinsic coagulation) increased from 656-783 seconds without EVs to 913-1280 seconds in the presence of EVs. When EVs were pretreated with heparinase, the CTs increased 120 seconds and >500 seconds for extrinsic and intrinsic coagulation, respectively. Taken together, human FF contains EVs exposing or more heparinase-sensitive factors that inhibit the common pathway of coagulation.

Limitations, reasons for caution: Additional studies are needed to elucidate the role of anticoagulant EVs in the uptake of oocytes and fertilisation.

Wider implications of the findings: Follicular EVs may play a role in the uptake of oocytes by the fallopian tube.

Trial registration number: None

P-331 Cumulus cells GPX4 expression levels are higher in patients with successful embryo implantation

L. Von Mengden Meirelles[1], M.A. De Bastiani[1], L. Grun[1], L. Arruda[2], C.A. Link[3], M. Pozzer[2], F. Barbé-Tuana[1], F. Klamt[1]

[1]*Universidade Federal do Rio Grande do Sul, Biochemistry, Porto Alegre, Brazil*
[2]*Clínica ProSer, Embriology, Porto Alegre, Brazil*
[3]*Clínica ProSer, Clinic, Porto Alegre, Brazil*

Study question: Do the redox enzyme GPX4 mRNA expression levels in cumulus cells relate to embryo implantation rates?

Summary answer: Implantation rates shows to be higher in patients with higher cumulus cells *GPX4* expression levels, regardless of patient's clinical characteristics.

What is known already: *Cumulus oophorus* cells (CCs) represent the first interface of the gamete with the ovarian environment. Therefore, they can provide valuable information concerning the viability and genetic constitution of the oocyte and its environment. CCs are responsible for protecting oocytes from oxidative stress. *GPX4* encodes GPx protein GPX4 isoform, that acts preferably reducing lipid hydroperoxides and protects cells against membrane lipid peroxidation and cell death. It is possible that oocytes protected by CCs with better defense mechanisms against oxidative stress during oocyte maturation present greater chances of becoming a good quality oocyte.

Study design, size, duration: Pooled CCs samples were collected from 23 patients submitted to ICSI procedure and subsequent embryo transfer. Patients were analyzed for B-HCG detection at day 14 after transfer, and samples were divided between Positive (n = 8) and Negative (n = 15) groups accordingly to B-HCG result. Patients clinical characteristics, as Body Mass Index (BMI), age, stimulation protocol and infertility diagnosis were considered in the analysis.

Participants/materials, setting, methods: Total RNA was extracted from CCs samples and submitted to reverse transcriptase quantitative polymerase chain reaction (RT-qPCR). Oligonucleotides were selected to be RNA specific and complementary to the human sequence of Glutathione Peroxidase 4 (*GPX4*). The relative expression (real quantitative [RQ]) of the genes analyzed was calculated for each sample by the 2-ΔΔCT method. For the multiple regression analysis, clinical and experimental data were combined.

Main results and the role of chance: A baseline model were built using B-HCG result as the dependent variable and age, diagnosis, stimulation protocol and BMI as independent variables. We compared test models composed of the four clinical variables and RT-qPCR assay data against the baseline model. With the results being submitted to the regression model considering the clinical data, *GPX4* has shown to be a potential pregnancy biomarker. A significant model ($P = 0.\ 010541996$), containing four variables indicated that *GPX4* expression levels are overexpressed in Positive group, and this significance is independent of the clinical variables of each patient.

Limitations, reasons for caution: For validation, this result need to be tested in a larger cohort, with best interest in analyzing individually collected CCs samples from patients submitted to single embryo transfer.

Wider implications of the findings: Our study revealed that *GPX4* mRNA expression levels are related to embryo implantation potential, and therefore are promising candidates for identifying oocyte quality independently of patient clinical profile.

Trial registration number: This study was approved by ethics comittee of Universidade Federal do Rio Grande do Sul under the approval number 68081017.2.0000.5347.

P-332 The effect of recent contraceptive use on the probability to conceive: A comparison between hormonal contraceptives and a fertility awareness-based method

O. Lundberg[1], E. Berglund Scherwitzl[2], H. Kopp Kallner[3], J. Trussell[4], K. Gemzell Danielsson[5], R. Scherwitzl[2]

[1]*Natural Cycles, Science, Stockholm, Sweden*
[2]*Natural Cycles Nordic AB, Science, Stockholm, Sweden*
[3]*Karolinska Institutet, Department of Clinical Sciences at Danderyd Hospital, Stockholm, Sweden*
[4]*Princeton University, Office of Population Research, Princeton, U.S.A.*
[5]*Karolinska Institutet, Department of Women's and Children's Health, Stockholm, Sweden*

Study question: Are there differences in short- and long-term conception probabilities between women who recently used a fertility awareness-based contraceptive method and women who recently used hormonal contraceptives?

Summary answer: Results in this study suggest that FAB methods used for contraception increase short-term pregnancy rates with respect to hormonal contraceptives, but not ong-term pregnancy rates.

What is known already: Previous studies have indicated that the use of techniques associated with fertility awareness-based methods for contraception may enhance pregnancy rates for women trying to conceive. Such studies have so far mainly treated various verisons of the so-called Billings method and the sympto-thermal method. Several previous studies also show that the use of hormonal contraceptives may instead reduce the short-term probabilities to conceive. Most studies do not find any long-term effect of hormonal contraceptives on fecundity.

Study design, size, duration: The study is a real-life prospective observational study of women who use a mobile fertility monitoring application (Natural Cycles) in attempting to become pregnant. A total of 2934 women planning a pregnancy using the mobile application Natural Cycles between August 2014 and June 2016 were included. Of these women 1638 were previous users of hormonal contraceptives and 1296 had previously used the fertility awareness-based method provided by the Natural Cycles application to prevent pregnancies.

Participants/materials, setting, methods: Users were included if they registered as users of the mobile contraceptive app with the intent of planning a pregnancy between August 2014 and June 2016. Comparisons were performed using two complementary methods: We calculated the average Time to Pregnancy (TTP) for all women who became pregnant during the time of the

study, and performed Kaplan-Meier life-table analysis to analyze the cumulative probabilities of pregnancy including all women who entered the study.

Main results and the role of chance: We found an average Time To Pregnancy of 2.3 (95% CI: 2.1-2.4) cycles for the women who had used Natural Cycles to prevent pregnancies, compared to 3.7 (95% CI: 3.4-3.9) for women who used hormonal contraceptives prior to attempting to become pregnant. We used Kaplan-Meier life-table analysis to compare the time to reach 30% cumulated pregnancy probability for the two groups and found the time for women previously on hormonal contraceptives to be 1.6 (95% CI: 1.5-1.8) times longer than the time for women previously using Natural Cycles. When comparing 13-cycle cumulated pregnancy probabilities there were no significant differences between the two groups.

Limitations, reasons for caution: The results do not provide a comparison of neither method to other non-hormonal method of contraception. The study population only contains women who decided to use an application for fertility monitoring, which may lead to a selection bias compared to the average population.

Wider implications of the findings: The result is likely widely applicable to women who uses fertility awareness methods prior to planning a pregnancy. The results presented in this study may be of interest to women planning to become pregnant in the near future as well as for healthcare professionals counseling women on contraception and fertility.

Trial registration number: Not applicable.

P-333 Epigenetic changes in human cumulus cells during reproductive aging

E. Molinari[1], S. Horvath[2], D.T.S. Lin[3], M.S. Kobor[4], P. Patrizio[5]

[1]*New England Fertility Institute, Embryology Lab, Stamford, U.S.A.*
[2]*UCLA, Dept of Human Genetics, Los Angeles, U.S.A.*
[3]*UBC, Department of Medical Genetics, Vancouver, Canada*
[4]*UBC, Department of Medical Genetics, Department of Medical Genetics, Canada*
[5]*Yale University, Obstetrics and Gynecology, New Haven, U.S.A.*

Study question: Oocyte aging is a common cause of infertility and still the mechanisms involved are unknown. Could age-related changes in DNA methylation (DNAmAge) of cumulus cells explain the reproductive decline?

Summary answer: We found suggestive evidence that chronological age correlates with DNAmAge ($r = 0.38$, $p = 0.074$). Epigenetic age acceleration exhibited moderately high correlations with variables measuring fertility.

What is known already: The study of the epigenetic profile of a tissue has been proven to reliably provide information regarding the age of the derived organ, through the analysis of 353 CpG islands across the entire human genome. The epigenetic clock algorithm identifies the discrepancies between chronological age and biological age, so called age acceleration rate (AgeAccel). Conditions such as chronic diseases, viral infection and chromosomal anomalies show an increased AgeAccel compared to healthy individuals. Our study aimed at deciphering AgeAccel in follicles of women undergoing in vitro fertilization.

Study design, size, duration: Thirty-two women undergoing IVF/ICSI were selected for the study (exclusion criteria: endometriosis, PCOS, use of PGD). Cumulus cells were removed from oocytes and pooled for each individual patient. Patient's ages ranged 24-45 y.o. (mean 36.8)

Participants/materials, setting, methods: Total DNA from cumulus cells was extracted and used for bisulfite conversion (Zymo Research). Genomewide DNA methylation profiling was carried out with 160 ng bisulfite converted DNA, using the Infinium Methylation BeadChips (Illumina) and hybridized to the Illumina Infinium 450 K Human Methylation Beadchip.

Main results and the role of chance: AgeAccel is inversely correlated to good markers of patient's prognosis, such as AMH ($r = -0.24$), number of oocytes collected ($r = -0.33$), oocyte maturity ($r = -0.31$), fertilization ($r = -0.22$) and cleavage ($r = -0.25$) and positively correlated to amount of administered gonadotropins ($r = 0.19$)

Limitations, reasons for caution: This study focused almost exclusively on assessing the epigenetic differences in CC across a population of patients undergoing IVF/ICSI. These epigenetic findings were not correlated with embryonic development and clinical outcome.

Wider implications of the findings: Our data confirms the hypothesis of a link between follicle senescence, cumulus cells and oocyte aging. The use of the age acceleration clock could, on a larger and more diverse cohort of patients, predict weather also other conditions, such as endometriosis and PCOS could be associated with follicular aging.

Trial registration number: N/A.

P-334 Effects of dietary AGE (Advanced Glycation End product) on ovarian microenvironment and oocyte quality

G. Di Emidio, G. Rossi, M. Placidi, S.J. Santini, A.M. D'Alessandro, S. Falone, F. Amicarelli, C. Tatone

University of L'Aquila, Dept. of Life- Health and Environmental Science, L'Aquila, Italy

Study question: Does the ovary activate an effective adaptive response to counteract the toxicity derived from dietary AGEs?

Summary answer: The ovary activates an adaptive response, which counteracts AGE accumulation but does not prevent toxic effects of dietary AGE on growing follicles and mature gamete.

What is known already: The levels of advanced glycation end products (AGEs) are increased during aging and under conditions of impaired glucose metabolism and/or oxidative stress (OS), promoting insulin resistance and other endocrine abnormalities. AGE deposition may be also ascribed to exogenous factors, such as tobacco smoking and diet. In the ovary, AGE formation has been associated to reproductive aging and polycystic ovarian syndrome (PCOS). *In vitro* exposure to methylglyoxal (MG), the main precursor of AGE, severely affects oocyte maturation, whereas *in vivo* ovarian and oocyte toxicity of MG is still unknown.

Study design, size, duration: To study the effects of dietary AGE (dAGE), 4-week-aged female CD1 mice received water ($n = 9$) or 100 mg/kg MG ($n = 9$) by gastric administration for 28 days. This treatment induces increased serum MG levels (Ghosh et al., 2006). Six mice per group were sacrificed 48-h after the last administration and ovaries were collected for further analysis. Three mice were sacrificed 15-h after induction of superovulation by PMSG-hCG protocol and MII oocytes were isolated from ampullae.

Participants/materials, setting, methods: The number of ovarian follicles was recorded in ovaries stained by ematossilin/eosin. The abundance of MG-AGEs, sirtuins (SIRT1, SIRT3), catalase (CAT), mitochondrial superoxide dismutase (SOD2), PGC1α, glyoxalase 1 (GLO1) were analysed by Western blot (WB). Spindles and chromosomes of MII oocytes were stained by immunofluorescence and digital images were analysed by ImageJ to obtain measurements of spindle dimensions (length, equator and pole width). Statistical analysis was performed by Sigma-Stat software.

Main results and the role of chance: Analysis of follicle population revealed a reduced number of primary and secondary follicles in dAGE group. Biochemical investigation demonstrated similar levels of ovarian MG-AGEs in the two groups. Nevertheless dAGE ovaries displayed an increase of SIRT1, an OS sensor, together with up-expression of CAT and SOD2. Expression of the mitochondrial sirtuin SIRT3 and PGC1α, the main regulator of mitochondrial biogenesis, was also increased. Finally, enhanced protein expression of GLO1, the main ovarian AGE detoxifying enzyme, was observed in dAGE group. Although similar ovulation rate were recorded in control and dAGE mice, spindle analysis showed that dAGE oocytes exhibited abnormal spindle size resembling those previously found in low quality oocytes (Sanfins et al, 2003).

Limitations, reasons for caution: The results on this animal model may not fully extrapolate to humans.

Wider implications of the findings: Present results suggest that AGE intake induces ovarian oxidative stress and triggers an adaptive response, which prevents ovarian AGE accumulation. Nevertheless, dAGE leads to loss of growing follicles and production of low quality oocytes. These results contribute to the knowledge of mechanisms underlying the reduced fertility in PCOS and diabetes.

Trial registration number: not required.

P-335 Bisphenol S (BPS) affects meiotic spindle formation and causes DNA damage: Implications for female infertility

J. Nevoral[1], M. Jeseta[2], T. Zalmanova[3], K. Hoskova[3], P. Klein[1], S. Prokesova[4], M. Stiavnicka[1], J. Moravec[1], P. Hosek[1], J. Zakova[2], E. Koutna[1], J. Petr[3], M. Kralickova[1]

[1]*Faculty of medicine in Plzen- Charles University in Prague, Biomedical Center, Plzen, Czech Republic*

[2]University Hospital and Masaryk University- Obilni trh 11- 602 00 Brno- Czech Republic, Department of Obstetrics and Gynecology-, Brno, Czech Republic
[3]Institute of Animal Sciences- Prague-Uhrineves- Czech Republic, Biology of reproduction, Prague, Czech Republic
[4]Czech University of Life Sciences Prague- Czech Republic, Department of Veterinary Sciences, Prague, Czech Republic

Study question: Does BPS occur in human follicular fluid? If yes, is BPS able to influence chromosome alignment and spindle formation in mouse oocyte?

Summary answer: BPS was measured in follicular fluid of women underwent ART. Accordingly, BPS in vivo treatment of mice impairs the quality of the matured oocyte.

What is known already: BPS represents the main substituent of earlier widely-used bisphenol A (BPA). In accordance with BPA detection in human follicular fluid and negative effects of both BPA and BPS is known so far, we assumed BPS presence in human follicular fluid and its negative effect on oocyte quality. Detrimental effects of BPS on oocytes were described on pig model in vitro only. On the other hand, BPS levels in human follicular fluid were not determined and influence of BPS on oocytes in vivo remains unknown.

Study design, size, duration: 35 samples of human follicular fluid were obtained from April to November 2017. Subsequently, eight-week-old ICR mice (n = 25) were treated with BPS in four different concentrations for 7 days per os. When the experiment was terminated, oocytes were isolated and matured in vitro. In total, the experiments included 127 matured oocytes.

Participants/materials, setting, methods: The samples of follicular fluid, obtained from patients of ART clinic were digested by β–glucuronidase and subjected to derivatization by 1-methylimidazol-2-sulfonyl chloride, followed by BPS measurement by LC-MS. Eight-week-old ICR mice were exposed to 0.001–100 ng BPS/g BW/day per os for 7 days. Isolated oocytes were in vitro maturated followed by TUNEL assay or spindle α-tubulin immunostaining. Oocytes were analysed by confocal microscope (Olympus, Germany) and signal intensity measurement (ImageJ, NIH, USA).

Main results and the role of chance: BPS levels were detected in samples of human follicular fluid of patients of the ART clinic, with values 3.5 ± 0.77 ng. ml-1 (median ± S.E.M.; LOD: 0.19 ng/ml, LOQ 0.65 ng/ml). The additional experiment, using mouse in vivo exposure, proved the negative impact on female reproduction. BPS treatment of mice disrupted DNA stability of matured oocytes. There was observed 4.7, 7.0 and 5.8-fold TUNEL signal intensity in metaphase chromosomes after dosing 0.001, 0.1, 100 ng BPS/g BW/day, respectively. Moreover, BPS exposure showed significantly increased the incidence of malformed spindle microtubules and chromosome misalignment. Individual BPS doses seemed to have a specific pattern of spindle abnormalities, such as extended shapes and barrel-shaped spindle in 0.001 and 10 ng BPS/g BW/day, respectively.

Limitations, reasons for caution: With respect to the observation of BPS levels in the follicular fluid, we analysed the oocyte quality after mouse in vivo exposure. Considering the results of decreasing oocyte quality arise from an animal model, it would be appropriate to evaluate the BPS effect in human oocytes.

Wider implications of the findings: Currently, the BPS exposure on mankind rise as the BPS becomes widely used, as shown with detection of BPS in follicular fluid. Moreover, concentrations of BPS closely resemble those of harmful BPA. Our findings show that these low doses of BPS significantly impact female reproduction.

Trial registration number: The sample colection and experiments with mice were performed in accordance with the Ethical Committee at Faculty Hospital in Brno and Act No 246/1992 Coll.

P-336 Circadian rhythm disruption in polycystic ovary syndrome

F. Wang[1], Y. Wu[1], F. Qu[2]

[1]Women's Hospital-School of Medicine-Zhejiang University, Department of Obstetrics and Gynecology, Hangzhou, China
[2]Women's Hospital-School of Medicine-Zhejiang University, Department of Traditional Chinese Medical Gynecology, Hangzhou, China

Study question: Is circadian rhythm disruption involved in the pathogenic mechanism of polycystic ovary syndrome (PCOS)?

Summary answer: The chronodisruption, typically attributable to shift work, may contribute to the development of PCOS.

What is known already: Although the underlying etiology remains unclear, aberrant light–dark cycles greatly impair the ovarian function.Despite emerging evidence of a high prevalence of sleep disorders in patients with PCOS, there is limited epidemiological data concerning the association between PCOS risk and circadian disruption by sleep disturbances or night shift work.

Study design, size, duration: We performed a multicenter, questionnaire-based survey to explore the link between night shift work and PCOS risk in 436 PCOS cases and 715 controls between June 2016 and May 2017.Moreover, we conducted a series of experiments to investigate the roles of ovarian circadian disruption in PCOS pathogenesis.

Participants/materials, setting, methods: Firstly, the survey was conducted over twelve hospitals in mainland China. Only women aged 21–45 without any sleep disorders, caused by neurological, psychiatric or respiratory disorders etc., were recruited. Patients were diagnosed with PCOS according to the Rotterdam Consensus.The controls were healthy women who had participated in a health screen in these hospitals. Secondly, PCOS patients and women with tubal blockage undergoing in vitro fertilization (IVF) were recruited, GCs and follicular fluids were collected.

Main results and the role of chance: After adjusting for potential confounders, night shift workers had a significantly increased risk of PCOS compared with day workers (OR = 1.80; 95%CI = 1.18–2.75; Table 2). This association was also observed among those with rotating, but not permanent, night shifts ($OR_{(Rotating\ vs.\ day\ work)}$ = 2.00, 95%CI = 1.16–3.44; $OR_{(Permanent\ vs.\ day\ work)}$ = 1.54, 95% CI = 0.80–2.95). Compared with day workers, participants that worked night shifts for a longer period of time (more than 2 years) had a higher PCOS risk (OR = 2.08; 95%CI = 1.15–3.73). However, those that had worked night shifts for a shorter period of time (less than 2 years) did not have an increased risk of PCOS (OR = 1.56; 95%CI = 0.86–2.80). In addition, we found that in GCs of PCOS women, the overexpression of core clock gene PER1 suppressed the transcriptional activity of AR through combination, and altered androgen metabolism in GCs contributing to AR-associated hyperandrogenism.

Limitations, reasons for caution: Our survey is a retrospective investigation, further verification is required, particularly studies that evaluate individuals of different ethnicities using a prospective observational technique.The GCs used in the present study were collected from patients undergoing IVF, thus it is of significance to further confirm our findings in unstimulated and non-luteinized GCs.

Wider implications of the findings: Understanding the role of circadian rhythm disruption in PCOS could help to intervene the infertility resulted from irregular light–dark cycles common to modern-day 24-hour society.

Trial registration number: Not applicable.

POSTER VIEWING
Female infertility

P-337 Estrogen receptor 1 polymorphism (A>G, rs12199722) is associated with recurrent implantation failure

L. Vagnini[1], A. Renzi[1], B. Petersen[1], C.G. Petersen[1,2], A.L. Mauri[1,2], M.C. Mattila[2], V.A. Comar[2], J. Ricci[2], F. Dieamant[1,2], J.B.A. Oliveira[1,2], R.L. Baruffi[1,2], J.G. Franco Jr[1,2]

[1]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil
[2]Centre for Human Reproduction Prof. Franco Jr, Research, Ribeirao Preto, Brazil

Study question: Is there an association between any Single Nucleotide Polymorphism (SNP) in the estrogen receptor 1 (ESR1) gene and recurrent implantation failure (RIF)?

Summary answer: ESR1 polymorphism (A>G, rs12199722) is associated with RIF. Women with A/G genotype had a 60% decrease in the chance of being included in RIF group.

What is known already: Estrogen, as a crucial hormone during pregnancy, acts through its receptors alpha and beta, which are encoded by the ESR1 and ESR2 genes, respectively. These receptors are involved in reproduction and may play important roles in RIF. The uterus is a primary target of oestrogen for various functions during the reproductive cycle and pregnancy. Estrogen binds to the receptor alpha, which modulates uterine events preparing the endometrium for embryo fixation and implantation. Since genetic factors appear to be highly associated with RIF, SNPs in the ESR1 gene encoding the receptor alpha can be used to predict RIF.

Study design, size, duration: A cross-sectional study was performed between 2015 and 2017, comparing 48 women presenting RIF (two or more failed IVF/ICSI attempts and at least five or more good-morphological-quality embryos transferred) versus 2 control groups: 63 women who became pregnant in the first IVF/ICSI attempt (control group I) and 68 fertile women who had at least 2 live births and no history of miscarriage or infertility treatment (control group II).

Participants/materials, setting, methods: Genomic DNA was extracted from peripheral blood samples taken from RIF and control groups. DNA was sequenced on MiSeq(Illumina) to search for SNPs in the ESR1 gene. SNPs found by Next-Generation Sequencing were analysed to find a possible association with RIF. The A>G polymorphism (rs12199722) was identified and subsequently validated by Real Time PCR. Frequencies of genotypes and alleles were compared using Fisher's exact test. An association with RIF was calculated by logistic regression analysis.

Main results and the role of chance: Our results showed an association between A/A genotype of ESR1 gene (rs12199722) and women presenting RIF. Patients with A/A genotype had 3.0-fold increase in the chance of being included in the RIF group. On the other hand, the presence of A/G genotype was associated with a 60% decrease in the chance of being included in the RIF group. A comparison of genotype and allele frequencies of ESR1 polymorphism (A>G, rs12199722) among women with RIF and two control groups are shown in Table 1. The association between each genotype and RIF is in Table 2.

Table I Genotype and allele frequencies of ESR1 polymorphism(A>G, rs12199722).

ESR1 (rs12199722)	RIF (%) n = 48	Control group I (%) n = 63	P	RIF (%) n = 48	Control group II (%) n = 68	P
Genotype						
AA	64.6	39.7	0.02	64.6	35.3	0.008
AG	29.2	55.5		29.2	50.0	
GG	6.2	4.8		6.2	14.7	
Allele						
A	79.2	67.5	0.05	79.2	60.3	0.002
G	20.8	32.5		20.8	39.7	

Table II Logistic Regression between ESR1 polymorphism(A>G, rs12199722) and RIF.

ESR1 (rs12199722)	OR (95% CI)	P
AA	3.0 (1.53-6.08)	0.002
AG	0.4 (0.18-0.75)	0.006
GG	0.6 (0.16-2.22)	0.45

Limitations, reasons for caution: Since the basic idea of performing a test is to increase the chance of obtaining a correct diagnosis, further validation of the ESR1 polymorphism (A>G, rs12199722) is required (e.g., increasing the number of cases, expanding to different ethnic groups) to provide more information regarding its potential use to predict RIF.

Wider implications of the findings: Our results, based on two control groups, showed for the first time evidence that ESR1 polymorphism(A>G, rs12199722) can be used as a genetic marker to predict RIF allowing physicians to provide a better risk analysis for each patient, helping to make assertive decisions, improving the chances of a woman becoming pregnant.

Trial registration number: Merck Grant for Fertility Innovation (GFI-2014-16). The funders had no role in study design, data collection and analysis, or preparation of the abstract.

P-338 Analysis of 215,212 ovulation induction (OI) and intrauterine insemination (IUI) cycles reveals the high rate of multiple gestations in patients across age groups and diagnoses

K. Hunter Cohn[1], C. Wellock[1], B.T. Miller[2], M. Hinckley[3], J.N. Gutmann[4], C. Benadiva[5], J.C. Nulsen[5], G. Letterie[6], J. Hirshfeld-Cytron[7], P. Yurttas Beim[1]

[4]*Reproductive Medicine Associates of Philadelphia, Reproductive Endocrinology, Philadelphia, U.S.A.*
[5]*University of Connecticut School of Medicine, The Center for Advanced Reproductive Services, Farmington, U.S.A.*
[6]*Seattle Reproductive Medicine, Reproductive Endocrinology, Seattle, U.S.A.*
[7]*Fertility Centers of Illinois, Reproductive Endocrinology, Highland Park, U.S.A.*

Study question: What are the ongoing pregnancy rates (OPR) and multiple gestation rates (MGR) associated with different non–*in vitro* fertilization (non-IVF) treatments?

Summary answer: Non-IVF treatment yielded OPR of 3.4%–19.0% and MGR of 3.5%–25.5%, with higher-order multiple (HOM) rates of 3.3%–6.4% in patients younger than 40 using gonadotropins.

What is known already: Non-IVF treatments with OI using oral medications (clomiphene citrate or letrozole) or injectable gonadotropins with IUI or timed intercourse (TI) are frequently used as first-line fertility treatments because of lower up-front costs compared to IVF. Since non-IVF treatments often lead to multiple birth and consequently high neonatal costs, characterization of pregnancy and multiples rates resulting from non-IVF treatments is needed to properly evaluate the cost-effectiveness of these treatment options. A study of this magnitude has been hindered to date by the lack of outcome tracking for non-IVF treatments in data registries in both the United States and Europe.

Study design, size, duration: We performed a retrospective analysis of cycles that used the OI medications clomiphene citrate or letrozole (Orals) and/or injectable FSH or hMG (Gnd) with IUI or TI with partner semen. We included 215,212 cycles from 77,303 patients treated at 13 fertility centers located within the United States. Cycles were performed between 2002 and 2017.

Participants/materials, setting, methods: We included all women who were treated with OI or IUI that were 18–45 years old, and excluded cycles utilizing donor sperm. Patients were treated according to standard clinic protocols for OI and IUI. Ongoing pregnancy outcomes were determined by the presence of a fetal heartbeat (FH) upon discharge to obstetrical care. Multiple gestations were determined by the number of FHs detected by ultrasound, and classified as either twins or HOMs (3 or more FHs).

Main results and the role of chance: The overall OPR was 11.1%, with 10.7% twin and 1.5% HOM. The OPR and MGR by age and treatment type are shown in Tables 1 and 2. Notably, the HOM rate was as high as 3.3%–6.4% in patients younger than 40 who used Gnd.

Table I Ongoing pregnancy % (N of cycles)

	<30	30–34	35–39	40–45
Orals+TI	11.2%(7831)	10.1%(16,113)	6.9%(11,922)	3.4%(5902)
Orals+IUI	11.7%(10,842)	11.1%(36,850)	9.7%(33,053)	4.9%(12,738)
Gnd+Orals+TI	14.6%(623)	12.9%(1472)	8.9%(1401)	3.9%(908)
Gnd+Orals+IUI	15.9%(2751)	14.8%(10,271)	12.6%(11,793)	6.9%(7553)
Gnd+TI	18.1%(867)	18.2%(1566)	11.4%(1257)	5.3%(1122)
Gnd+IUI	19%(3059)	17.3%(10,767)	14.2%(12,927)	6.9%(11,624)

Table II Multiple gestation % of ongoing pregnancies (N of cases)

	<30	30–34	35–39	40–45
Orals+TI: Twins	8.6%(75)	7.7%(126)	7.3%(60)	3%(6)
Orals+TI: HOM	0%(0)	0.7%(11)	0.6%(5)	0.5%(1)
Orals+IUI: Twins	7.9%(100)	8.9%(365)	8.7%(279)	6.8%(42)
Orals+IUI: HOM	0.9%(12)	0.6%(23)	0.7%(24)	0.3%(2)
Gnd+Orals+TI: Twins	17.6%(16)	13.7%(26)	11.3%(14)	14.3%(5)
Gnd+Orals+TI: HOM	2.2%(2)	1.1%(2)	1.6%(2)	2.9%(1)
Gnd+Orals+IUI: Twins	14.8%(65)	12.7%(194)	13.1%(194)	8.9%(46)
Gnd+Orals+IUI: HOM	1.4%(6)	1.7%(26)	0.9%(14)	1.2%(6)
Gnd+TI: Twins	19.1%(30)	13.7%(39)	11.9%(17)	11.7%(7)
Gnd+TI: HOM	6.4%(10)	5.3%(15)	4.2%(6)	1.7%(1)
Gnd+IUI: Twins	16.6%(96)	16.9%(315)	16.6%(306)	12.4%(100)
Gnd+IUI: HOM	3.6%(21)	4%(74)	3.3%(61)	1.6%(13)

Limitations, reasons for caution: This retrospective dataset included a variety of treatment and monitoring protocols used at multiple clinics over a large time range. In addition, the observed rates were of all treated patients, so comparison of rates between treatments, in particular TI to IUI, should be the subject of a subsequent investigation.

Wider implications of the findings: This is the first large scale study to date of the health burden associated with non-IVF fertility treatments. We observed that these treatments result in a significant rate of multiple births, including HOMs. This study sets the foundation for future cost-effectiveness studies that can improve policy-making around fertility care.

Trial registration number: N/A.

P-340 External validation of a dynamic prediction model for repeated predictions of natural conception

R. Van Eekelen[1], D.J. McLernon[2], M. Van Wely[1], M.J.C. Eijkemans[3], S. Bhattacharya[4], F. Van der Veen[1], N. Van Geloven[5]

[1]Academic Medical Center, Centre for Reproductive Medicine, Amsterdam, The Netherlands
[2]University of Aberdeen, Medical Statistics Team, Aberdeen, United Kingdom
[3]University Medical Center Utrecht, Department of Biostatistics and Research Support, Utrecht, The Netherlands
[4]Unversity of Aberdeen, Institute of Applied Health Sciences, Aberdeen, United Kingdom
[5]Leiden University Medical Center, Department of Biomedical Sciences, Leiden, The Netherlands

Study question: How well does a previously developed dynamic prediction model perform in an external, geographical validation in terms of predicting the chances of natural conception at various points in time?

Summary answer: The dynamic prediction model performs well in an external validation on a Scottish cohort.

What is known already: We developed a dynamic prediction model for natural conception that is able to update predictions of natural conception when couples return to their clinician after a period of unsuccessful expectant management. However, it is not known how well this model performs in an external population for clinical use.

Study design, size, duration: A record-linked registry study including the long term follow up of all couples who were considered unexplained subfertile following a fertility work up at the Aberdeen Fertility Clinic in the Grampian region of Scotland between 1998 and 2011. Couples with anovulation, uni/bilateral tubal occlusion, mild/severe endometriosis or impaired semen quality according to WHO criteria were excluded.

Participants/materials, setting, methods: The endpoint was time to natural conception, leading to an ongoing pregnancy. Follow up was censored at the start of treatment, at the change of partner or at the end of study (31st of March, 2012). The performance of the van Eekelen model was evaluated in terms of calibration and discrimination at various points in time. Additionally, we assessed the clinical utility of the model in terms of the range of the calculated predictions.

Main results and the role of chance: Of a total of 1214 couples with a median follow up of 14 months after the fertility workup, 397 (33%) couples conceived naturally leading to an ongoing pregnancy. Using the dynamic prediction model, the mean probability of natural conception over the course of the first year after the workup was estimated at 25% (observed: 22%), After half a year, one year and one and a half years of expectant management after completion of the fertility workup, the average probability of conceiving naturally over the next year was estimated at 18% (observed: 15%), 14% (observed: 14%) and 11% (observed: 12%).

Calibration plots showed good agreement between predicted chances and the observed fraction of ongoing pregnancy within risk groups. Discrimination was moderate with c statistics similar to those in the internal validation, ranging from 0.60 to 0.64. The range of predicted chances was sufficiently wide to distinguish between couples having a good and poor prognosis with a minimum of zero at all times and a maximum of 55% over the first year after the workup, which decreased to maxima of 43% after half a year, 34% after one year and 29% after one year and a half after the workup.

Limitations, reasons for caution: The primary analysis showed a slight overestimation of conception by approximately 3 percentage points on group level in the first year post fertility workup and after half a year of expectant management. This is likely attributable to the difficulty in identifying the exact date of completion of the fertility workup.

Wider implications of the findings: The van Eekelen model is a valid tool in clinical practice to counsel couples with unexplained subfertility on their individualised chances of conception at various points in time, notably when couples return to the clinic after a period of unsuccessful expectant management.

Trial registration number: Not applicable.

P-341 Effects of Vitamin D supplementation on Assisted Reproduction Technology (ART) outcomes: an interim analysis of a randomized double-blind multicenter placebo-controlled trial

V. Sarais[1], S. Ferrari[2], M. Reschini[2], A. Paffoni[2], G. Cermisoni[3], S. Signorelli[4], E. Papaleo[4], P. Viganò[3], E. Somigliana[5]

[4]Centro Scienze Natalità- IRCCS San Raffaele Scientific Institute- 20132 Milan- Italy-, Infertility Unit, milano, Italy
[5]Infertility Unit- Fondazione IRCCS Ca' Granda- Ospedale Maggiore Policlinico- Via M. Fanti 6- 20122- Milan-Italy - University of Milan- Via della Commenda 10- 20122- Milan- Italy, Infertility Unit, milano, Italy

Study question: Does vitamin D supplementation affect clinical pregnancy rate (CPR) per started cycle in women undergoing ART procedures?

Summary answer: No significant differences were found in CPR. A significantly higher top quality embryo rate was observed in women allocated to vitamin D.

What is known already: Several observational data from IVF cycles suggest a possible beneficial effect of vitamin D on the rate of success of the procedure. According to a recent metanalysis, the ORs of clinical pregnancy in vitamin D sufficient women was 1.33 (95%CI: 1.08-1.65) (Chu *et al.*, 2018). However, a causal relation remains to be demonstrated and interventional studies are warranted. To date, only one randomized controlled trial on the potential benefit of vitamin D for IVF has been published (Aflatoonian *et al.*, 2014). No significant benefits emerged but the sample size (n = 106) was insufficient for meaningful conclusions.

Study design, size, duration: Eligible women with a serum vitamin D level <30 ng/ml were recruited. The sample size (630 women) was calculated considering a 10% difference in CPR between the supplemented and not supplemented populations. The first visit for recruitment was 10/10/2016. Recruited women received 600,000 IU of Vitamin D or placebo (in a single oral administration) at the time of randomization. Ovarian hyperstimulation initiated within three months after randomziation.

Participants/materials, setting, methods: All participants and physicians managing the patients were blinded to trial intervention allocation. The allocation sequence was computer-generated and blinded to the investigators and participants. Inclusion criteria of women were: age 18-39 years, less than 3 previous ART attempts, body mass index between 18 m^2/Kg and 25 m^2/Kg. Exclusion criteria were: poor responders according to Bologna criteria, ART freezing-cycles. Eligible women signed an informed consent and provided a blood sample for vitamin D assessment.

Main results and the role of chance: Since the start of the study, 267 women were recruited (n = 136 women were administered vitamin D and n = 131 women placebo). No differences were observed in duration of ovarian hyperstimulation (p = 0.29) and total dosage of gonadotropins administered (p = 0.21) between the two groups. The mean (±SD) number of retrieved oocytes was 8.7 ± 6.4 in vitamin D group and 7.6 ± 4.6 in the placebo group (p = 0.09). No significant differences were found in the total number of follicles > 16 mm (p = 0.24), oocytes used (p = 0.46) and fertilization rate (p = 0.84). Cleavage rate and number of total embryos on day 3 were not different between vitamin D and placebo group (respectively p = 0.27 and p = 0.97). A statistically significant higher top quality day 3 embryos rate was found in the supplemented group (respectively 60% compared to 43%, p = 0.03). Blastulation rate was not different between the two groups (vitamin D treatment 50% and placebo 44%, p = 0.72). Due to the increased strategy to freeze embryos for clinical conditions, clinical pregnancy rate was calculated on a lower number of women (vitamin D supplemented n = 77 and placebo group n = 82) and was not different between the groups (p = 0.74).

Limitations, reasons for caution: This is a planned interim analysis performed in order to evaluate preliminary results mostly on embryological outcomes. The sample size is not powered enough to detected differences in CPR per started cycle.

Wider implications of the findings: This study can potentially influence the clinical practice of infertility treatment. Vitamin D supplementation is a simple and cheap intervention and is free of relevant side effects. It may also have beneficial effects on pregnancy outcome.

Trial registration number: EUDRACT 2015-004233-27

P-342 Only patient age - and not stimulation or relationship status - affects IUI outcome in 13-year single-centre series of 8995 consecutive cycles

E. Linara, J.J. Wang, G. Lamanna, S. Nair, N. Macklon, K. Ahuja

The London Women's Clinic, Embryology, London, United Kingdom

Study question: Are clinical outcomes in donor insemination cycles affected by patient age, ovarian stimulation, or relationship status?

Summary answer: Clinical outcomes are strongly associated with patient age. Ovarian stimulation, or relationship status did not significantly affect pregnancy outcomes in almost 9000 consecutive IUI cycles.

What is known already: It is well known that age affects fertility in both natural and assisted conception, with patient age to be inversely and significantly associated with positive pregnancy outcomes. Despite the improvements in semen preparation methods and controlled ovarian stimulation, the success of IUI is still lower than what is reported for other assisted reproduction procedures and we know that it is affected by many factors. Important prognostic indicators of success with IUI include the patient's age, the cause and duration of infertility, methods of ovarian stimulation, number of cycles, ovarian reserve and male factor infertility.

Study design, size, duration: Our analysis is a retrospective observation study of data collected from 8995 consecutive treatment cycles of intrauterine donor insemination performed at the London Women's Clinic between January 2004 and December 2016. The aim of the study was to examine the efficacy of IUI effectiveness in relation to patient age, ovarian stimulation, and relationship status. Statistical analysis was performed using STATA.

Participants/materials, setting, methods: Between 2004 and 2016, 3406 women attended the London Women's Clinic (LWC) for donor insemination. 1018 women were in heterosexual relationship, 4265 were in same-sex relationship, and 3712 were single. 58% of cycles were natural; the remainder stimulated (42%). The cross-section of patients - with a high number of lesbian and single women - reflects a clinical focus of the LWC and socio-legal change in the acceptance and parental rights of individuals in the UK.

Main results and the role of chance: The highest live birth rate (LBR) was found in women aged <35 years (n = 2948 cycles) with a LBR of 12.6% per cycle. Women aged 35-37 years (n = 2204 cycles) had a LBR of 10% per cycle and those aged 38-39 years (n = 1544 cycles) had a LBR of 8% per cycle. In women aged 40-42 years (n = 1621 cycles) LBR declined to 5% per cycle, while no pregnancy was observed in women aged ≥45 years.

LBRs were affected by relationship status with single women having significantly different results compared with the other groups, but this difference was fully explained after adjustment for age (p<0.000).

Single women (n = 3712) had a mean age of 39 years and a LBR per cycle of 7%, women in heterosexual relationships (n = 1018) a mean age of 34 years and a LBR of 10% per cycle, and those in same-sex relationships (4265) a mean age of 35 years and a LBR of 11% per cycle.

There was a fairly even distribution of non-stimulated (n = 5212) and stimulated cycles (n = 3783) and we found no statistically significant difference in the outcome (p = 0.70). LBR was 8.7% in non-stimulated natural cycles and 9.4% in stimulated cycles.

Limitations, reasons for caution: This study uses a large sample size of patients and is adequately powered to detect medium-size effects. The data are observational and were retrospectively analysed though so unknown confounders were not assessed. Throughout the study period stimulation protocols were modified and LBRs were calculated in varying numbers of cycles.

Wider implications of the findings: Our study has implications for clinical practice and patient counselling, with outcome following IUI dependent mainly on patient age and only marginally on ovarian stimulation and relationship status.

Trial registration number: not applicable.

P-343 Vascular endothelial growth factor polymorphism (C>T, rs3025010) can predict recurrent implantation failure

A. Renzi[1], L. Vagnini[1], B. Petersen[1], C.G. Petersen[1,2], A.L. Mauri[1,2], M.C. Mattila[2], V.A. Comar[2], J. Ricci[2], F. Dieamant[1,2], J.B.A. Oliveira[1,2], R.L.R. Baruffi[1,2], J.G. Franco Jr[1,2]

[1]*Paulista Centre for Diagnosis- Research and Training, Research, Ribeirao Preto, Brazil*

[2]*Centre for Human Reproduction Prof Franco Jr, Research, Ribeirao Preto, Brazil*

Study question: Is it possible single nucleotide polymorphisms (SNPs) of the vascular endothelial growth factor (VEGF) gene to predict recurrent implantation failure (RIF)?

Summary answer: VEGF polymorphism (C>T, rs3025010) can predict RIF. Women with T/T genotype had a 60% decrease in the chance of being included in RIF group.

What is known already: VEGF is involved in embryonic development, decidual vascularization, fetal and placental angiogenesis and blastocyst invasion. This gene located on chromosome 6, contain eight exons and seven introns, which can form different isoforms by alternative splicing. There are several reports showing that polymorphisms in this gene can affect the expression and function of the protein, as well as serum levels of VEGF that could lead to implantation failure. The rs3025010 VEGF polymorphism site located in the intron region has been reported to be associated with another SNP in the promoter region (rs1570360), both related to implantation.

Study design, size, duration: A cross-sectional study was performed between 2015/2017 comparing 48 women presenting RIF (two or more failed IVF/ICSI attempts and at least five or more good morphological quality embryo transferred) (RIF group) with 68 fertile women who had at least 2 live births and no history of miscarriage or infertility treatment (control group).

Participants/materials, setting, methods: Genomic DNA was extracted from peripheral blood samples taken from RIF and control groups. The genomic DNA was sequenced on MiSeq system (Illumina) to search for SNPs in VEGF gene. The SNPs found by Next Generation Sequencing were analysed to find possible association with RIF. The C>T polymorphism (rs3025010) was identified and confirmed by Real Time PCR using the allelic discrimination method. Differences in genotype were compared using Fisher's exact test and logistic regression.

Main results and the role of chance: Our results showed an association between VEGF C/C genotype (rs3025010) and increased prevalence of RIF as well as T/T genotype and fertile women. Distribution of genotype and allele frequencies of RIF and control groups are represented in Table 1. These findings have been corroborated by logistic regression analysis where patients with C/C genotype had 2.8-fold increase in the chance of being included in the RIF group and patients with T/T genotype had a 60% decrease in the chance of being included in the RIF group (Table 2).

Table I Genotype and allele frequencies of VEGF polymorphism (C>T,rs3025010).

VEGF (rs3025010)	RIF group (%) n = 48	Control group (%) n = 68	*P*-value
Genotype			
CC	27.1	1.8	0.03
CT	39.6	32.3	
TT	33.3	55.9	
Allele			
C	46.9	27.9	0.003
T	53.1	72.1	

Table II Logistic Regression between VEGF polymorphism (C>T,rs3025010) and RIF.

VEGF (rs3025010)	OR (95% CI)	*P*-value
CC	2.8 (1.05-7.38)	0.04
CT	1.4 (0.63-2.96)	0.42
TT	0.4 (0.18-0.85)	0.02

Limitations, reasons for caution: Since the basic idea of performing a test is to increase the chance of attaining a correct diagnosis, further validation of the VEGF polymorphism (C>T, rs3025010) is required (i.e., increasing the number of cases; expanding to different ethnic groups) to provide more information regarding its potential use to predict RIF.

Wider implications of the findings: The ability to predict RIF using the VEGF polymorphism (C>T, rs3025010) can enable physicians to provide a better risk analysis to each patient, helping make assertive decisions, improving the chances of a woman to get pregnant, encouraging her to undergo additional cycles of ART.

P-344 A new biochemical approach to detect oxidative stress in infertile women undergoing assisted reproductive technology procedures

R. Fucci[1], C. Giachini[2], M. Becatti[2], A. Mannucci[2], R. Picone[1], F. Bertocci[1], P. Falcone[1], E. Borrani[1], M.G. Servidio[1], L. Badolato[1], L. Criscuoli[1], C. Fiorillo[2], M.E. Coccia[2]

[1]Careggi University Hospital, Assisted Reproductive Technology, Florence, Italy
[2]University of Florence, Experimental and Clinical Biomedical Sciences "Mario Serio", Florence, Italy

Study question: To compare blood and follicular fluid (FF) redox status in infertile women versus age-matched controls undergoing in vitro fertilization (IVF) and to establish its connection with the IVF outcome.

Summary answer: Blood oxidative stress reflects FF oxidative stress; it is significantly increased in infertile women compared to controls and correlates with IVF outcomes.

What is known already: Studies performed so far indicate that oxidative stress – characterized by an overabundance of reactive oxygen species (ROS) or/and a deficiency of antioxidants – negatively affects reproductive potential. The influence of oxidative stress (OS) on ART outcome is related to its negative impact on gamete quality and early embryo development, as reported by several studies. However, a clinically reliable, biologically accurate indicator of oxidative stress condition does not yet exist and is still difficult to identify. Antioxidant therapy can restore the redox balance and therefore potentially improve implantation, pregnancy and live birth rate and time to pregnancy.

Study design, size, duration: The study population included 45 women with female factor infertility (excluding tubal factor) and 45 age-matched controls (women from couples with pure male factor or tubal factor) undergoing ART. The biological samples used for the planned investigations were: i) blood (both plasma and leukocyte subpopulations); ii) follicular fluid (FF), including granulosa cells.

Participants/materials, setting, methods: ROS assessment (blood/granulosa cells) was performed by Cytofluorimetric analysis. OS markers (plasma/FF) were assessed by fluorometric lipid peroxidation markers (MDA) estimation. Total antioxidant capacity (plasma/FF) was performed by fluorimetric ORAC assay. Measurements of outcomes were based on the evaluation of: rate of retrieved MII oocytes, fertilization, implantation and pregnancy rates. Statistical analysis were used to correlate OS markers between blood and follicular samples and its association with embryo development and ART outcome.

Main results and the role of chance: In this study we assessed redox status in blood, follicular fluid (FF) and granulosa cells from 45 infertile women and 45 controls undergoing ART. Oxidative stress markers in blood and in granulosa cells resulted significantly ($p<0.001$) increased in infertile patients compared to controls. Moreover, we observed: i) a significant increase of OS markers in blood and in granulosa cells in infertile patients compared to controls ($p<0.001$); ii) a significant correlation between blood and FF redox markers, indicating that blood oxidative stress reflects FF oxidative stress; iii) an association between oxidative stress parameters and the considered IVF outcomes (rate of oocyte at metaphase II and fertilization rate).

Limitations, reasons for caution: Not applicable.
Wider implications of the findings: The non-invasive evaluation of oxidative stress will allow the selection of patients who could benefit from antioxidant therapy to restore redox balance before starting the IVF treatment. The improved redox environment would increase the ART efficiency, allowing the quicker achievement of a successful pregnancy.
Trial registration number: Not applicable.

P-345 Reproductive outcomes in patients with a history of retained products of conception after delivery versus abortion

H. Ganer Herman, Z. Kogan, D. Tairy, M. Ben Zvi, R. Kerner, S. Ginath, J. Bar, Y. Mizrachi, R. Sagiv

Edith Wolfson Medical Center, Obstetrics & Gynecology, Holon, Israel

Study question: In the assessment of infertile patients - does a history of retained products of conception (RPOC) entail a similar prognosis following delivery and abortion?
Summary answer: Following hysteroscopy for RPOC after delivery and abortion similar reproductive outcomes were observed. However, following delivery, subsequent pregnancies entailed a higher rate of abnormal placentation.
What is known already: RPOC are associated with the formation of intrauterine adhesions and subsequent infertility, while hysteroscopic treatment is associated with less adhesions as compared to curettage. A single study to date compared post-partum and post abortion RPOC, and noted no difference in fertility and pregnancy outcomes between cases following delivery and first trimester abortion. However, study patients were not uniformly treated with hysteroscopy, now the gold standard for RPOC.
Study design, size, duration: This is a cohort of operative hysteroscopies performed between 2011-2015 for suspected RPOC. Variables were compared between cases following delivery (n = 85), and following abortion (n = 96).
Participants/materials, setting, methods: Patients included underwent an operative hysteroscopy at our university hospital due to RPOC, during which confirmed trophoblastic tissue was removed. Computerized files were reviewed. For patients who did not deliver at our institution following the hysteroscopy – a telephone survey was performed, during which we inquired regarding infertility or subsequent pregnancies.
Main results and the role of chance: A history of infertility following hysteroscopy, defined as at least one year of failure to conceive, was noted in 11 patients (11.8%) in the post abortion group, four of whom were receiving assisted reproductive treatment, as compared to two patients (2.3%) in the post-delivery group, one of whom was receiving assisted reproductive treatments (p = 0.01). None of the cases were attributed to mechanical female factor (intrauterine adhesions). A similar rate of patients in both groups had experienced an abortion since their hysteroscopy. In the post-delivery group – 34 patients delivered following hysteroscopy (40.0%) for a total of 36 deliveries, while in the post-abortion group 37 delivered (39.7%) a total of 42 deliveries. Deliveries in the post-delivery group were notable for a higher rate of abnormal placentation – 30.5% - including low lying placenta and placenta accreta. A significant rate of vaginal deliveries in both groups entailed manual removal of the placenta or manual exploration of the uterine cavity (23.5% and 10.5%, p = 0.20).
Limitations, reasons for caution: The study is retrospective and data obtained was that available in patient files and through telephonic survey. In addition, the post abortion group included missed abortion and termination of pregnancy, and medically and surgically treated cases. These entities may entail different outcomes, but were not powered for seperate analysis.
Wider implications of the findings: In the assessment of infertility patients, a history of past RPOC following delivery or abortion entails a similar prognosis, and warrant a similar suspicion for intrauterine adhesions. During pregnancy follow up – cases of RPOC following delivery necessitate careful attention to placentation.
Trial registration number: Not applicable.

P-346 Predicting the cumulative chance of live birth over multiple complete cycles of in vitro fertilization (IVF): an external validation study

J. Leijdekkers[1], M.J.C. Eijkemans[2], H.L. Torrance[1], S.C. Oudshoorn[1], T.C. Van Tilborg[1], D.J. McLernon[3], B.W.J. Mol[4], S. Bhattacharya[5], F.J.M. Broekmans[1]

[1]*University Medical Centre Utrecht- University Utrecht, Reproductive Medicine, Utrecht, The Netherlands*
[2]*University Medical Centre Utrecht- University Utrecht, Julius Centre for Health Sciences and Primary Care, Utrecht, The Netherlands*
[3]*Institute of Applied Health Sciences- University of Aberdeen, Medical Statistics Team, Aberdeen, United Kingdom*
[4]*Monash University, Obstetrics and Gynaecology, Clayton, Australia*
[5]*University of Aberdeen, Institute of Applied Health Sciences, Aberdeen, United Kingdom*

Study question: Are the published pre-treatment and post-treatment McLernon models, predicting cumulative live birth rates (LBR) over multiple complete IVF cycles, valid in a different context?
Summary answer: With minor recalibration of the pre-treatment model, both McLernon models accurately predict cumulative LBR in a different geographical context and a more recent time period.
What is known already: Previous IVF prediction models have estimated the chance of live birth after a single fresh embryo transfer, thereby excluding the important contribution of embryo cryopreservation and subsequent IVF cycles to cumulative LBR. In contrast, the recently developed McLernon models predict cumulative LBR over multiple complete IVF cycles at two certain time points: a) before initiating treatment using baseline characteristics (pre-treatment model) and b) after the first IVF cycle adding treatment related information to update predictions (post-treatment model). Before these models are used in clinical practice, their predictive performance needs to be validated in an independent cohort.
Study design, size, duration: External validation study in an independent prospective cohort of 1515 Dutch women who participated in the OPTIMIST study (NTR2657) and underwent their first IVF treatment between 2011 and 2014. Participants underwent a total of 2882 complete treatment cycles, defined as all fresh and frozen thawed embryo transfers resulting from one episode of ovarian stimulation. The follow up duration was 18 months after inclusion, and the primary outcome was ongoing pregnancy leading to live birth.
Participants/materials, setting, methods: Model performance was evaluated up to three complete treatment cycles, using the linear predictor as described by McLernon to calculate the probability of live birth. Discrimination was expressed by the c-statistic and calibration was depicted graphically in a calibration plot. In contrast to the original model development cohort, antimullerian hormone (AMH), antral follicle count (AFC) and body weight were available in the OPTIMIST cohort and evaluated as potential additional predictors for further model improvement.
Main results and the role of chance: Applying the McLernon models to the OPTIMIST cohort, the c-statistic of the *pre-treatment model* was 0.62 (95% CI 0.59-0.64) and of the *post-treatment model* 0.71 (95% CI 0.69-0.74). The calibration plot of the *pre-treatment model* indicated slight overestimation of the cumulative LBR. To improve calibration, the *pre-treatment model* was adjusted by subtracting 0.40 from the intercept. The *post-treatment model* calibration plot revealed accurate cumulative LBR predictions. After addition of AMH, AFC and body weight to the McLernon models, the c-statistic of the *updated pre-treatment model* improved slightly to 0.66 (95% CI 0.64-0.68), and of the *updated post-treatment model* remained at the previous level of 0.71 (95% CI 0.69-0.73).

As example for clinical application, using the recalibrated pre-treatment model, a woman aged 30 years with 2 years of primary infertility who starts ICSI treatment for male factor infertility has a probability of success of 0.39 in the first ICSI cycle, increasing to 0.71 over 3 complete cycles. Then using the post-treatment model, if this woman had 10 oocytes retrieved in the first cycle, embryos cryopreserved and a single fresh cleavage stage embryo transfer, the cumulative probability of success rises to 0.83 over 3 cycles.

Limitations, reasons for caution: The OPTIMIST study contained two randomized controlled trials (RCT) evaluating the effectiveness of gonadotropin dose individualization on basis of the AFC. The strict dosing regimens, the RCT in- and exclusion criteria and limited follow up time of 18 months might have influenced model performance in this independent cohort.

Wider implications of the findings: The McLernon prediction models can be introduced in clinical practice, after local recalibration, to inform patients and to complement clinical reasoning. These new counselling tools are the first to offer an objective and personalized estimate of the cumulative probability of live birth over multiple complete IVF cycles.

Trial registration number: Not applicable.

P-347 Pretreatment with coenzyme Q10 improves ovarian response and embryo quality in low-prognosis young women with decreased ovarian reserve: a randomized controlled prospective study

Y. Xu, X. Zhen

Peking University Third Hospital, Reproductive Center, Beijing, China

Study question: Is there any effect of anti-oxidant treatment with coenzyme Q10 (CoQ10) on ovarian response and embryo quality in young low-prognosis patients with POR?

Summary answer: Women in CoQ10 group had more retrieved oocytes, higher fertilization rate and more high-quality embryos, less cancelled embryo transfer, more available cryopreserved embryos.

What is known already: It has been suggested that poor responders could assist in evaluation of optimal management strategies for these patients. CoQ10 acts as an antioxidant by inhibiting lipid peroxidation and DNA oxidation, Several animal studies have demonstrated that CoQ10 protects ovarian reserve, counteracts physiological ovarian ageing by restoring mitochondrial function In the clinical setting, led to better response to ovulation induction and decreased odds of fetal aneuploidy in 35–43-year-old women. To date, however, no study has investigated whether CoQ10 pretreatment could improve the ART treatment outcomes in young subpopulation of poor responders in a randomized setting.

Study design, size, duration: A prospective, randomized controlled study included 186 consecutive patients with POR stratified according to the POSEIDON classification group 3 (age < 35, poor ovarian reserve parameters). The participants were randomized to the CoQ10 pre-treatment for 60 days preceding IVF-ICSI cycle or no pre-treatment. The number of high quality embryos was a primary outcome measure.

Participants/materials, setting, methods: This was a prospective randomized controlled study conducted at the Reproductive Medical Center of the Peking University Third Hospital, a tertiary university hospital and a center of excellence in Reproductive Medicine in China. The study is reported according to the CONSORT guidelines.

Main results and the role of chance: A total of 169 participants were evaluated (76 CoQ10 and 93 controls) and 17 women were excluded due to low compliance with CoQ10 administration. The baseline demographic and clinical characteristics were comparable between the groups. CoQ10 pretreatment resulted in significantly lower gonadotrophin requirements and higher peak E2 levels. Women in CoQ10 group had increased number of retrieved oocytes (4, IQR 2-5), higher fertilization rate (%) and more high-quality embryos (1, IQR 0-2); $p<0.05$. Significantly less women treated with CoQ10 had cancelled embryo transfer because of poor embryo development than controls (8.33% vs. 22.89%, $p = 0.04$) and more women from treatment group had available cryopreserved embryos (18.42% vs. 4.3%, $p = 0.012$). The clinical pregnancy and live birth rates per embryo transfer and per one complete stimulation cycle tended to be higher in CoQ10 group, but did not achieve statistical significance.

Limitations, reasons for caution: The important limitation of our study was its small sample size and we were unable to detect significant differences in clinical outcomes.

Wider implications of the findings: Pretreatment with CoQ10 improves ovarian response to stimulation and embryological parameters in young women with poor ovarian reserve in IVF-ICSI cycles. Further work is required to determine whether there is an effect on clinical treatment endpoints.

Trial registration number: Chinese Clinical Trial Registry (trial registration number: ChiCTR-IPR-17010945).

P-348 Investigating the effect of lifestyle risk factors upon the number of aspirated and mature oocytes in in vitro fertilization cycles: interaction with antral follicle count

L. Joelsson[1], E. Elenis[1], K. Wanggren[2], A. Berglund[3], A. Nyman Eliadou[4], C. Cesta[4], S. Mumford[5], R. White[6], T. Tyden[1], A. Skalkidou[1]

[3]*National Centre for Knowledge on Men's Violence, National Centre for Knowledge on Men's Violence, Uppsala, Sweden*
[4]*Karolinska institute, Inst of Medical Epidemiology & Biostatistics, Stockholm-, Sweden*
[5]*Eunice Kennedy Shriver National Institute of Child Health and Human Development- National Institutes of Health, Epidemiology Branch- Division of Intramural Population Health Research, Bethesda- Maryland-, U.S.A.*
[6]*Norwegian Institute of Public Health, Norwegian Institute of Public Health, Oslo, Norway*

Study question: Is there a cumulative effect of smoking and Body mass Index on the reproductive outcomes after the first completed IVF cycle. Is there any possible interaction with antral follicle count.

Summary answer: There is an independent and a cumulative effect of smoking and BMI on the number of aspirated oocytes and mature oocytes in fresh IVF treatment-cycles.

What is known already: There is evidence demonstrating that lifestyle factors have a detrimental effect on fertility, however the data examining the effects of lifestyle changes on fertility treatment outcomes are limited. Furthermore, little is known about the cumulative impact of these unhealthy factors. Despite the lack of clear preconception guidelines intended for people seeking fertility treatment, most patients undergoing IVF treatment are willing to modify their lifestyle behavior. It is therefore crucial that they are aware of the precise lifestyle changes they can implement in order to enhance the likelihood of IVF success.

Study design, size, duration: Cohort study based on 2 different prospective cohorts. In total, 242 participants (hypothesis generating cohort) from the 'Lifestyle study cohort" in which data collection started in May 2013 and ended in September 2015. In addition, 432 participants (validation cohort) from the 'UppSTART cohort" starting their first fresh IVF cycle between September 2011 and December 2013 were included. Both public and private fertility clinics in mid-Sweden region were included in both studies.

Participants/materials, setting, methods: Number of aspirated oocytes, number of mature oocytes, number of embryos created, number of utilizable embryos and proportion of mature oocytes were the main outcome measures. The lifestyle factors considered were age, body mass index (BMI), smoking, alcohol consumption, daily caffeine consumption, physical activity score and history of depression. A regression model were performed to identify potential risk factors in the 'Lifestyle study cohort". The results were then validated in the UppStART cohort.

Main results and the role of chance: The median age of the population at cycle start was lower in the 'Lifestyle study" cohort 31.1 (IQR = 6.8) years compared to the 'UppStART study" validation cohort 34.0 (6.0) years. However, there were more women with university education in the 'UppStART study" validation cohort compared to the 'Lifestyle study" cohort.

Significant risk factors were identified in the 'Lifestyle study cohort": smoking and BMI. Women with both risk factors had (on average) 25% less aspirated oocytes than women without risk factors (IRR of 0.75,95% CI 0.61–0.94). Women with these risk factors had also an IRR of 0.78 (95% CI: 0.62–0.98) for the proportion of mature oocytes (in relation to the total number of aspirated oocytes), meaning that they would (on average) have 22% fewer mature oocytes than women with no risk factors. For the outcome of proportion of mature oocytes (in relation to the total number of aspirated oocytes), the number of risk factors was found to have a borderline significant interaction with

AFC (p = 0.099): the larger the value of AFC, the less harmful the effect of the risk factors.

Limitations, reasons for caution: The relatively small sample size, especially in the 'Lifestyle study", might introduce some problems with statistical power. This might be reflected in the borderline statistical significance of some of the results, where, on the other hand, notable and stable trends are demonstrated.

Wider implications of the findings: These negative lifestyle factors are easy to detect at an early stage of the assessment process and might allow for optimization of the treatment outcome. The results provide evidence on the significance of preconception guidance for the optimization of the treatment.

Trial registration number: Not relevant.

P-349 Outcome of Progestin-primed ovarian stimulation protocol vs. ultra-long protocol in patients with a first IVF/ICSI cycle: a randomized clinical trail

X. Qianwen, K. Yanping

Shanghai ninth hospital affiliated to jiaotong University, Department of Assisted Reproduction, Shanghi, China

Study question: Could Progestin-primed ovarian stimulation protocol or ultralong protocol be a preferred alternative for infertile women during IVF/ICSI.

Summary answer: Both regimens can get similar top-quality embryos with good developmental potential. They all have their benefits and are irreplaceable.

What is known already: Ultralong protocol with fresh embryo transfer is a typical ovarian stimulation regimen using a depot of long acting GnRH agonist. It is well recognized and widely used. Progestin-primed ovarian stimulation (PPOS) based on a freeze-all strategy is a new ovarian stimulation regimen that uses progestin as an alternative to a GnRH-a for preventing a premature LH surge. Ultralong protocol has some weakness of being increased procedure complexity, higher fees, and greater risk of ovarian hyperstimulation syndrome (OHSS) in addition to its benefits. There is an unmet need for new ovarian stimulation protocols with improved efficacy and user convenience.

Study design, size, duration: A prospective RCT including 260 patients was performed between 1 July 2017 to 31 December 2017. Computerized randomization was conducted to assign participants at a 1:1 ratio into two treatment groups: PPOS (130 patients) or ultralong protocol (130 patients) followed by their first IVF/ICSI with fresh/frozen embryo transfer. The primary outcome was the number of top-quality embryos. The sample size was chosen to detect a difference of two oocytes with a power of 85%.

Participants/materials, setting, methods: Patients with normal ovarian reserve undergoing their first IVF/ICSI procedure were included. MPA and HMG was simultaneously administered at menstrual cycle 3 in PPOS group. Oocyte maturation was co-triggered by a GnRHa and hCG(1000IU). In the ultralong protocol group, pituitary down-regulation was obtained in early follicle phase, Ovarian stimulation started after 35 days and hCG(5000IU) was used to trigger. Only the first embryo transfer cycle was followed-up. The embryological and clinical outcomes were measured.

Main results and the role of chance: Basic characteristics, such as age, BMI and infertility duration, in both groups were comparable. There was no significant difference in the number (mean ± SD) of top-quality embryos [3.9 ± 3.0 for PPOS vs 3.4 ± 2.5 for ultralong protocol] or the number of oocytes retrieved [11.8 ± 6.5 for PPOS vs 11.1 ± 5.7 for ultralong protocol] between the groups. During the whole process of ovarian stimulation, the LH level in the PPOS group was always higher than that in the ultralong protocol group but lower HMG dosage was administrated in the PPOS group [2027.9 ± 333.9 for PPOS vs 2689.0 ± 624.9 for ultralong protocol, P = 0.00]; however, no patient from either group experienced a premature LH surge. Besides, there was no moderate or severe ovarian hyperstimulation syndrome during the ovarian stimulation in PPOS group while three patients suffered it in the ultralong protocol group. No significant difference was found in the clinical pregnancy rate of the first embryos transfer cycle between the two groups (P = 0.89): 56.5% for the PPOS group (65/115) versus 57.4% for the ultralong protocol group (70/122).

Limitations, reasons for caution: Patients and physician were not blinded to the study. Moreover, some patients had not finish their first embryo transfer cycle at the end of the trial. It would be better if the live birth rates were observed in the follow up period and the result could be demonstrated.

Wider implications of the findings: PPOS effectively reduces the HMG dosage and the incidence of moderate and severe OHSS during COH while having a weakness to use freeze-all strategy only. It can be an alternative of the treatments for infertile woman undergoing IVF as well as traditional protocols.

Trial registration number: ChiCTR-INR-17012089.

P-350 Arterial stiffness during controlled ovarian hyperstimulation and early pregnancy in women exposed to assisted reproduction

P. Saldeen[1], E. Von Wowern[2], P. Olofsson[3]

[1]*Nordic IVF Malmö, Nordic IVF Malmö, Limhamn, Sweden*
[2]*Institution of Clinical Sciences Malmö- Lund University, Department of Obstetrics and Gynecology- Skåne University Hospital, Malmö, Sweden*
[3]*Institution of Clinical Sciences Malmö- Lund University, Cura Mödravård, Malmö, Sweden*

Study question: To study the effects of controlled ovarian hyperstimulation (COH) for in vitro fertilization (IVF), and early pregnancy, on arterial stiffness determined by digital pulse wave analysis (DPA).

Summary answer: We found an increased systemic arterial stiffness, assessed by DPA, in luteal phase of IVF but no change during ovarian stimulation or in early pregnancy.

What is known already: Among female sex hormones, estrogen has a vasodilatory effect whereas the vascular effect of progesterone is not yet fully determined. A person's vascular condition can be expressed in terms of arterial stiffness, as measured by pulse wave analysis. Photoplethysmographic DPA is an operator-independent method to estimate arterial stiffness and endothelial function in large and small arteries, and changes in DPA parameters towards increased stiffness have shown good correlations with age and cardiovascular pathology and morbidity. To our knowledge, there are no previous studies investigating the effects of IVF and COH on arterial stiffness.

Study design, size, duration: Prospective observational longitudinal study including 68 women, starting before conception and performed during COH and IVF treatment until the seventh gestational week.

Participants/materials, setting, methods: 68 women planned for IVF treatment were asked to participate. The women were examined with DPA at first visit to the clinic (baseline), during IVF stimulation, after embryo transfer, and in early pregnancy. Heart rate, mean arterial pressure (MAP) and DPA variables cardiac ejection elasticity index (EEI), *b/a,* dicrotic index (DI), *d/a*, and the global variable aging index (AI), were measured. The ovarian response to gonadotropin stimulation was estimated with ovarian stimulation index (OSI).

Main results and the role of chance: Heart rate was significantly increased at all measuring points ($p \leq 0.003$) but MAP only at embryo transfer ($p = 0.007$). DPA variables representing large arteries (EEI, *b/a*) and peripheral arteries (DI, but not *d/a*), and AI, all indicated increased arterial stiffness at embryo transfer compared with baseline ($p \leq 0.035$). No DPA variable was significantly changed during stimulation or at pregnancy measurements. Independent of the influence of age, basal measurements of *b/a* and AI indicated higher arterial stiffness in poor ovarian responders.

Limitations, reasons for caution: The stimulation measurements, which showed no significant DPA variable changes, may have been performed too early during the stimulation (stimulation day 7), before the full effect of stimulation had been reached. Baseline measurements were obtained without considering the menstrual cycle.

Wider implications of the findings: We expected a vasodilatory effect of COH since estrogen is a vasodilator, but found the opposite. The unexpected findings could be a progesterone effect, or activation of the renin-angiotensin-aldosterone-system (RAAS), eclipsing the estrogen effects. The association between arterial stiffness and poor ovarian response, independent of age, deserves further exploration.

Trial registration number: The study was approved by Regional Research Ethics Committee in Lund, Sweden, Dnr 2014/648.

P-351 Identification of empty follicles or oocyte-containing follicles by ultrasound images using K-means method and principal component analysis assessing several parameters with artificial intelligence

H. Matsubayashi[1], K. Kitaya[1], Y. Takaya[1], R. Nishiyama[1], K. Yamaguchi[1], N. Kim[1], K. Sakaguchi[2], M. Doshida[2], T. Takeuchi[2], T. Ishikawa[1]

[1]Reproduction Clinic Osaka, Obstetrics and Gynecology, Osaka, Japan
[2]Reproduction Clinic Tokyo, Obstetrics and Gynecology, Tokyo, Japan

Study question: To investigate whether we can identify the existence of oocytes from ovarian follicles by ultrasound images using artificial intelligence (AI).

Summary answer: We can retrospectively classify ovarian follicles with or without oocytes by ultrasound images using K-means method and principal component analysis assessing several parameters with AI.

What is known already: We cannot distinguish follicles with or without oocytes using ultrasound, because a diameter of oocyte is below minimum detection levels of usual ultrasound devices. When we choose 8 MHz as a frequency of ultrasound, minimum detection levels are estimated to be 0.2 mm and 0.48 mm with a simple calculation and in consideration with distance-based resolution, respectively. Therefore, physicians and patients cannot speculate how many oocytes could be retrieved before oocyte retrieval, or whether a follicle would be empty in a cycle with timed intercourse or intrauterine insemination. New idea to detect oocytes by ultrasounds has been desired.

Study design, size, duration: We hypothesized the follicles with oocyte might be more rigid (i.e. less elastic) than those without oocytes, because the former has thicker follicle membrane as cumulus-oocyte-complex. If they were, deformity patterns with or without oocytes might be different when a needle was going to insert into the follicles. With a similar concept, elastography has been utilized for prediction of breast cancer. We performed a pilot study in a single center on October in 2015.

Participants/materials, setting, methods: With informed consent, 3 patients participated in the study. Ultrasound (B-mode) moving images were recorded throughout the oocyte retrieval under anesthesia, each follicle was aspirated separately using different syringe followed by confirmation with microscopy. Aspirated follicles and moving images were numbered in numerical order. The image data of 16 follicles (11 contained oocytes, 5 did not) were analyzed with AI in order to distinguish the differences with or without oocytes using several parameters, retrospectively.

Main results and the role of chance: We chose six parameters from the moving images when a needle was going to insert into the follicles: #1: Circularity of outline of the follicles ($C = 4\pi S/L^2$, where S is the area surrounded by the outline of the follicles and L is the perimeter of the outline), #2: Angle formed between the two lines defined by the two points just before piercing the follicles ($\theta_{1/\sqrt{2}} = D_{1/\sqrt{2}}$, where D is the distance between the convex hull and the outline for each angle, and $D_{1/\sqrt{2}}=D_{max} \times 1/\sqrt{2}$), #3: $\theta_{0.01} = D_{0.01}$ where D = 0.01 mm, #4: D_{max} difference between just before piercing the follicles and 1 mm in front of piercing the follicles ($D_{max}{}^{diff}$), #5: $\theta_{1/\sqrt{2}}$ difference between just before piercing the follicles and 1 mm in front of piercing the follicles ($\theta_{1/\sqrt{2}}{}^{diff}$), #6: $\theta_{0.01}$ difference between just before piercing the follicles and 1 mm in front of piercing the follicles ($\theta_{0.01}{}^{diff}$). By K-means method and principal component analysis with AI, oocytes-containing follicles can be predicted in 8/10 and empty follicles can be predicted in 5/6.

Limitations, reasons for caution: This was a retrospective pilot study with a sample size, and was a single-center study. Moreover, this method requires needle aspiration. Further prospective studies in large samples size without needles are needed.

Wider implications of the findings: We can retrospectively classify ovarian follicles with or without oocytes by ultrasound images with AI. If we could prospectively recognize ovarian follicles with or without oocytes by ultrasound image only (without needles), we could predict retrieval oocyte number and locations of empty follicles at daily office gynecology.

Trial registration number: N/A.

P-352 Is the follicular flushing usefull for poor ovarian response, a prospective controlled randomised trial

C. Calabre[1], E. Schuller[1], C. Celebi[1], N. Meyer[2], I. Lichtblau[1], O. Pirrello[1]

[1]CMCO Schiltigheim, Strasbourg fertility unit- CMCO, Schiltigheim, France
[2]Faculté de medecine de Strasbourg, Laboratoire de biostatistiques, strasbourg, France

Study question: Does follicular flushing with a double-lumen needle improve the number of oocytes collected in a poor responder population?

Summary answer: Follicular flushing does not improve, number of oocytes collected, numbers of top embryos, oocyte quality and pregnancy rate and could decrease the number of oocytes collected.

What is known already: Follicular flushing in poor ovarian response is a usual practice but benefit is unproved. No strong statistical power prospective randomised study has been produced at this time.

Study design, size, duration: A monocentric controlled randomised prospective study leaded in Strasbourg fertility unit from March 2011 to June 2016. We compared two technics of oocyte retrieval: direct aspiration with a single lumen aspiration needle vs flushing method with a double lumen aspiration needle (EchoTip® Cook® Double Lumen Aspiration Needle K-OPSD-1735-B-L).

Participants/materials, setting, methods: Patients with 4 or less follicles bigger than 14 mm on ovulation induction day in IVF cycle were included. Patients were randomized between a FLUSH group with a double-lumen needle with flushing and a NO FLUSH group with a classic single-lumen needle without flushing. The primary outcome was the number of oocyte collected. The secondary criteria was the pregnancy rate and the number of embryos.

Main results and the role of chance: 250 patients were included: 125 patients were included in the FLUSH group and 125 in the NO FLUSH group. The two groups were comparable about Age, BMI, FSH and AMH before stimulation and number and follicle and oestradiol on ovulation induction day. The number of oocytes retrieval was highest in the NO FLUSH group (2.35 in the flush group versus 3.43 in the non flush group, p<0,001), as the number of meta II oocytes (p = 0,003).

Limitations, reasons for caution: Several operators participated to this study, each one had some differences in their own practice of flushing even if the amont of flushing medium was standardised. Those differences of practice could be a bias to interpret our results.

The volume of flushing fluid was limited that's why for some patients included in FLUSH GROUP, few oocytes were not collected by flushing procedure.

Wider implications of the findings: Follicular flushing with double-lumen needle for poor responder patients doesn't increase the number of oocyte collected.

Trial registration number: PRI 2010 HUS n°4781 **2010-A00589-30**

P-353 Circulating microRNAs as biomarkers for controlled ovarian stimulation

M.G.F. Mulato[1], R.C.S. Figueira[2], D.P.A.F. Braga[3], B.F. Zanetti[4], A.S. Setti[4], M.V. Geraldo[1], E. Borges Jr.[5]

[1]Universidade Estadual de Campinas, Departamento de Biologia Estrutural e Funcional- Instituto de Biologia, Campinas, Brazil
[2]Fertility Medical Group, IVF Laboratory, Sao Paulo, Brazil
[3]Fertility Medical Group, Scientific Department, Sao Paulo, Brazil
[4]Instituto Sapientiae - Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific Department, Sao Paulo, Brazil
[5]Fertility Medical Group, Clinical Department, Sao Paulo, Brazil

Study question: Are circulating microRNAs (miRNAs) able to predict the response to controlled ovarian stimulation (COS) in patients undergoing assisted reproduction cycles?

Summary answer: The presence of specific miRNAs in serum may be a tool to predict the ovarian response to COS.

What is known already: Most assisted reproduction cycles use COS before oocyte pick up, to increase the number of embryos. However, the optimal

stimulation protocol has not been established. The need for COS individualization to attain an optimal oocyte yield while minimizing the risk of an excessive response, has been recognized. Therefore, the development of tolls to predict the response to COS is extremely important. MiRNAs are small non-coding RNAs that can be detected in the extracellular environment. Circulating miRNAs emerged as diagnostic and prognostic markers of several diseases; however, its utility as a biomarker of response to COS is still unknown.

Study design, size, duration: This study included 15 serum samples split into three groups, and polled together, according with the response to COS: poor response: < 4 retrieved MII oocytes (Poor, n = 5), normoresponse: ≥ 4 and < 25 retrieved MII oocytes (NR, n = 5), and hyper response: ≥ 25 oocytes (Hyper, n = 5).

Participants/materials, setting, methods: Serum samples were collected from patients < 36 years-old, body mass index (BMI)>18,5 and <25 Kg/m^2, prior to the COS for intracytoplasmic sperm injection (ICSI), in a private university-affiliated IVF center, between January/2017 and June/2017. Patients presenting endometriosis grades III and IV were excluded. Circulating RNA was extracted, cDNA was synthesized and large-scale analysis of miRNA was performed (miScript miRNome qPCR Array, QIAGEN). The cel-miR-39 was spiked-in to calibrate the gene expression analysis.

Main results and the role of chance: A total of nine miRNAs were differentially detected in serum from the pool of patients who presented hyper response, in comparison with the pool of patients who responded normally (NR). Four miRNAs were exclusively detected in patients on the Hyper group, with undetectable levels in the NR and Poor groups. On the other hand, five miRNAs were differentially detected in patients with poor response, four of them exclusively detected in patients from Poor group. Moreover, we identified the absence of one miRNA in Poor group, with normal detection levels in NR and Hyper groups. These findings suggest these miRNAs could be explored as specific serum predictive markers for poor or hyper response to COS.

Limitations, reasons for caution: These analyses were performed in pooled samples. The next step includes the validation of these candidate miRNAs in a larger cohort of samples and the correlation with clinical data from the patients.

Wider implications of the findings: Individual heterogeneity in ovarian response limits the implementation of individualized COS protocols. Currently, there is no consensus regarding the factors to be considered when determining the gonadotropin dose in individualized protocols. Detection of specific circulating miRNAs prior to the treatment could guide the COS and improve the outcomes of IVF.

Trial registration number: None.

P-354 Vitamin D deficiency leads to increased insulin resistance and advanced glycation end-product (AGE) accumulation and decreased DHEA-S levels and oocyte maturation rates

T. Nishihara[1], T. Inoue[2], Y. Morimoto[3]

[1]HORAC Grand Front Osaka Clinic, Department of culture environment, Osaka, Japan
[2]HORAC Grand Front Osaka Clinic, Medical doctor, Osaka, Japan
[3]HORAC Grand Front Osaka Clinic, Chief Executive Officer, Osaka, Japan

Study question: Is vitamin D deficiency associated with hormone levels, oxidative stress, insulin resistance, advanced glycation end-products (AGEs), and the outcome of IVF-ET in infertile patients?

Summary answer: Vitamin D deficiency has been associated with increased insulin resistance and AGE accumulation and decreased DHEA-S levels and oocyte maturation rates.

What is known already: Vitamin D is necessary for maintaining calcium homeostasis and promoting bone metabolism. However, vitamin D deficiency is still common in the general population, particularly in women of reproductive age. Vitamin D receptors are expressed in a number of tissues including the skeleton and parathyroid glands as well as reproductive tissues. Vitamin D has been shown to exert effects on female reproduction.

Study design, size, duration: The present study enrolled 510 infertility women who received IVF treatment at the HORAC Grand Front Osaka Clinic between July 2016 and August 2017. Patients were divided into two groups based on their serum 25-hydroxyvitamin-D3 [25(OH)D] levels: Group A < 20 ng/ml and Group B ≥ 20 ng/ml, and follicular fluid 25(OH)D levels: Group C < 20 ng/ml and Group D ≥ 20 ng/ml. This study was approved by the local Ethics Committee.

Participants/materials, setting, methods: Vitamin D insufficiency and deficiency corresponded to 25(OH)D levels < 30 and < 20 ng/ml, respectively. Serum 25(OH)D, AMH, basal FSH, testosterone, and DHEA-S were measured at a commercially available laboratory. Reactive oxygen metabolite (d-ROM) and biological antioxidant potential (BAP) levels were measured as indicators of the degree of oxidative stress. AGEs were measured using the AGE Reader. A follicular fluid sample was obtained from preovulatory follicles ≥ 18 mm in diameter.

Main results and the role of chance: The numbers (%) of women with a vitamin D deficiency and insufficiency were 337 (66.1%) and 141 (27.6%), respectively. No significant differences were observed in age (38.4 ± 4.7 vs. 38.1 ± 5.0 years) or BMI (21.1 ± 4.1 vs. 21.0 ± 3.8 in kg/m^2) between groups A (n = 337) and B (n = 173). DHEA-S was significantly lower in group A than in group B (165.9 ± 90.4 vs. 188.1 ± 115.4 μg/dL, $p < 0.05$). HOMA-R was significantly higher in group A than in group B (1.81 ± 1.5 vs. 1.28 ± 0.6, $p < 0.01$). AGEs were significantly higher in group A than in group B (213.6 ± 60.5 vs. 192.9 ± 29.4 AU, $p < 0.01$). However, no significant differences were observed in AMH, testosterone, basal-FSH, PRL, d-ROM, or BAP. Oral vitamin D supplementation increased follicular fluid 25(OH)D levels in deficiency and insufficiency cases (from 16.0 ng/mL to 29.7 ng/mL, $p < 0.01$). Oocyte maturation rates were significantly lower in group C than in group D (73.7 vs. 83.1%, $p < 0.05$). However, no significant differences were observed in the rate of fertilization, good quality embryos, blastocysts, or good quality blastocysts.

Limitations, reasons for caution: The vitamin D status fluctuates and may be influenced by several external factors such as sun exposure, seasonality, and diet. Therefore, the limitation of the present study is that vitamin D levels may have varied.

Wider implications of the findings: The present results demonstrated that serum vitamin D levels are increased by oral vitamin D supplementation and this may have a significant impact on insulin resistance, DHEA-S levels, AGE accumulation, and oocyte maturation. A vitamin D deficiency may be involved in the pathogenesis of infertility.

Trial registration number: Not applicable.

P-355 Factors associated with livebirth in couples undergoing their first ICSI cycle: an internally validated prediction model

E. Kalafat, B. Berker, A. Gokce, E. Sukur, B. Ozmen, M. Sonmezer, C. Atabekoglu, R. Aytac

Ankara University, Obstetrics and Gynecology, Ankara, Turkey

Study question: What factors are associated with livebirth in couples without children undergoing ICSI cycles for the first time?

Summary answer: Our seven-parameter model shows good precision and calibration for the prediction of live birth and can be reliably used for estimation and counseling.

What is known already: Predictive models are useful for counseling patients and guiding treatment decisions. Most prediction models rely on demographic and ovarian reserve parameters without incorporating cycle specific information which can be vital. The precision of the existing models is most often suboptimal for clinical use. Also, there is a paucity of information about the variables which are most useful predicting success in the first ICSI cycles.

Study design, size, duration: This was a cohort study including ICSI cycles managed at Ankara University, Department of Reproductive Health and Infertility between years 2010 and 2017. A total of 488 women were included.

Participants/materials, setting, methods: Couples with no prior children undergoing their first ICSI cycles using fresh embryos were included in the study. Exclusion criteria consisted patients with secondary infertility, younger than 45 years, and cycles in which more than two embryos were transferred. The cohort was partitioned for model building (n:305) and internal validation via bootstrapping. The prediction model was built using a variable selection approach, and parameter estimates were obtained using Bayesian logistic regression with a vague prior.

Main results and the role of chance: A total of 488 women with a live birth rate of 27.9% were included. The model variables consisted female age ≥38

years (OR:0.05,95% CrI:0.00-0.44), baseline luteinizing hormone (LH) levels above 6mIU/mL (OR:2.46,95% CrI:1.33-4.52) and antral follicle count below 5 (OR:0.13,95% CrI:0.02-0.60), duration of induction cycle longer than 10 days (OR:2.31,95% CrI:1.18-4.61), endometrial thickness at the day of transfer greater than 9 mm (OR:2.16,95% CrI:1.02-4.75), transferred embryo grade and count. The model showed good precision (AUC: 0.76) and good calibration (Hosmer-Lemeshow test, P = 0.624) in the internal validation cohort. The baseline model without using cycle specific information also showed modest precision (AUC:0.68).

Limitations, reasons for caution: Our cohort size is smaller than optimal, and some parameter estimates may be unreliable despite using a Bayesian framework with Markov Chain Monte Carlo simulations. An external validation study is required for the generalization of these results to broader populations.

Wider implications of the findings: Our model uses variables which are easily obtained and widely recorded during ICSI cycles worldwide. If proven to be stable in external validation studies, our model offers the highest precision reported up to date.

Trial registration number: Not applicable.

P-356 Cheaper, simpler, better: oral desogestrel versus antagonist injections for LH suppression in corifollitropin-stimulated cycles in the same oocyte donor. A crossover study

F. Martinez, D. Rodriguez, E. Clúa, J. Rodriguez-Purata, I. Rodríguez, P.N. Barri, B. Coroleu

Hospital Universitario Dexeus, Obstetrics- Gynaecology and Reproduction, Barcelona, Spain

Study question: Is the ovarian response to Corifollitropin (CFT) among oocyte donors (OD) different when treated with oral Desogestrel (DSG)or subcutaneous injections of antagonist (ANT) for LH suppression?

Summary answer: Donors response to CFT-DSG compared to CFT-ANT was similar in number of oocytes and pregnancy rates in recipients, with less injections and lower medication costs.

What is known already: A single injection of CFT replaces the first seven daily injections of any rFSH preparation. Initiating CFT seven days after discontinuation of the oral combined contraceptive pill (OCP) instead of 5 days, results in a significant reduction of the additional consumption of rFSH in oocyte donors(OD) on an antagonist protocol. Patients showed high degree of satisfaction and preference for this preparation. A new form of controlling the endogenous LH peak has been put forward: the so-called "progesterone protocols". DSG is a progestogen-only pill (POP) that at a dose of 75 mcg inhibits ovulation by suppressing endogenous LH peak.

Study design, size, duration: An observational cross-over study, including 35 donors treated at a private, university-based IVF centre between Feb'15 and May'17. Recruited donors had undergone two stimulation cycles within <20 months under CFT. Exclusion criteria: AFC >20, hypersensitivity to CFT, presence of ovarian cysts or enlarged ovaries, risk or history of ovarian hyperstimulation syndrome (OHSS). Fifty-four corresponding recipients of freshly donated oocytes were analysed (29 in the CFT-ANT group and 25 in the CFT-DSG group).

Participants/materials, setting, methods: Healthy donors, pre-treated with OCP and CFT. On stimulation day 8, daily FSH doses were added if needed. In CFT-ANT cycles, daily antagonist was administered since follicle >14 mm until trigger. Subsequently, in CFT-DSG cycles, donors received daily DSG starting right after OCP until trigger. All donors were triggered with a GnRH agonist bolus. Outcomes of both cycles and clinical pregnancies among corresponding recipients were compared. Paired statistical test was used to compare variables.

Main results and the role of chance: Mean donors age was 25.94 ± 5.37 years, mean basal AMH was 3.57 ± 2.07 ng/mL, and mean AFC was 19.35 ± 5.07. Interval between both treatment cycles was 0.91 ± 0.70 months.

Compared to CFT-ANT cycles, cycles under CFT-DSG received less number of injections (10.34 ± 2.83 vs 5.03 ± 2.12, p<0.05), a lower total supplementary rFSH dose (497.4 ± 338.9 IU vs 442.9 ± 332.8 IU, p<0.05); all this translated in a lower total cost of medication (1018.6 ± 191.0€ vs. 813.8 ± 145.9€, p<0.05).

Compared to CFT-ANT, donors treated with CFT-DSG had significantly higher mean serum estradiol at trigger (1505.4 vs 2406.0 pg/ml, p<0.05). There were no differences in the total number (17.4 ± 7.5 vs 18.6 ± 89.0) and mature oocytes retrieved (14.1 ± 6.9 vs. 15.9 ± 8.1). There were no cycles cancelled due to low ovarian response or premature LH rise prior to GnRH trigger. There were no cases of OHSS.

The average number of embryos transferred was 1.3 ± 0.7 in the CFT-ANT group vs. 1.1 ± 0.6 in the CFP-DSG group(p> 0.05). Clinical pregnancy rate/embryo transfer was similar between groups: 52.0% vs. 58.6% respectively (p>0.05).

Limitations, reasons for caution: No cycles were cancelled due to low ovarian response and it should be interpreted with caution. Given that included patients were OD that had undergone both treatment cycles, with good ovarian reserve markers, and none previous cancelled cycles.

Wider implications of the findings: In OD programs, treatment cost savings are important, but so are patient safety, comfort and compliance, and clinical results among recipients. The main advantage of this strategy is its simplicity, an aspect of utmost importance in the management of ODs. This information could be useful for PGS and fertility preservation.

Trial registration number: The study was in clinicaltrials.gov (Trial number: NCT03354494).

P-357 A multivariate logistic regression model for embryo selection improves pregnancy outcomes in frozen-thawed embryo transfer

T. Habara[1], Y. Miyagi[2], R. Hirata[3], N. Yoshioka[3], S. Terada[3], N. Hayashi[3]

Study question: Can a validated model, based on biological variables, be developed to predict successful pregnancy outcomes in frozen-thawed embryo transfer (FET)?

Summary answer: Our logistic model with six variables shows good performance on validation of the values for the prediction of pregnancy in single-blastocyst transfers.

What is known already: Although three morphological parameters have routinely been used to select the best blastocyst for transfer (degree of blastocoele expansion and appearance of the trophectoderm (TE) and the inner cell mass (ICM)), their independent ability to predict pregnancy outcomes remains unclear. A simple scoring system derived from a mathematical model that can be easily implemented in clinical practice has not been previously described for the prediction of ongoing viability.

Study design, size, duration: We performed a retrospective cohort study. Retrospective evaluation of data extracted from implantation data originating from 4717 blastocyst transfers conducted at a single clinic between January 2012 and December 2015 in phase I. Data from 490 FETs were collected between January 2016 and February 2017 in phase II.

Participants/materials, setting, methods: We obtained the regression functions for the establishment of pregnancy for each factor of the ASEBIR embryo assessment system (Hum Reprod, 2011) and of conventional clinical information, which were statistically related to the establishment of pregnancy confirmed by univariate analysis. A multivariate logistic regression was conducted, which was not affected by multicollinearity, which provided the probability of the establishment of pregnancy with calculated values from actual data from the regression functions.

Main results and the role of chance: In phase I of the study, 4717 single-blastocyst transfers were performed that resulted in 1826 pregnancies (38.7% of the women). The prediction model, built after multivariable logistic regression analysis, demonstrated that blastocyst diameter (odds ratio (OR) 271.03, 95% confidence interval (CI): 62.93-1167.34), ICM (OR 4.36, 95% CI: 1.22-15.59), and TE (OR 3.03, 95% CI: 1.12-8.22) were predictive factors for successful pregnancy outcomes. Cryopreservation day (OR 14.40, 95% CI: 2.03-102.18), ET attempt (OR 11.18, 95% CI: 2.06-60.63), and female age (OR 11.16, 95% CI: 4.89-25.51) were predictive for unsuccessful pregnancy

outcomes. The area under the receiver operating characteristic curve for the model for successful pregnancy outcomes was 0.692 (95% CI: 0.669-0.716). Sensitivity and specificity were 0.611 and 0.667, respectively; positive and negative predictive values were 0.540 and 0.729, respectively. In phase II, a validation study (n = 490) showed that the application of this logistic model was associated with a significantly higher ongoing clinical pregnancy rate (54.2% versus 43.4%) with an odds ratio of 1.62 (95% CI: 1.12-2.36, P = 0.011).

Limitations, reasons for caution: In this study, the morphokinetic variables provided by time-lapse incubators could not be assessed, and embryo evaluation was limited to distinct time-point observations. The interpretation of our findings is limited by the retrospective nature of the analysis and the potential for unmeasured confounding.

Wider implications of the findings: This prediction model incorporates readily available data that are routinely collected in clinical practices and have been shown to significantly improve pregnancy outcomes. Further study is required to add morphokinetic information and thereby improve implantation rates.

Trial registration number: Not applicable.

P-358 Patients with Inflammatory Bowel Disease (IBD) have similar reproductive outcome compared to the general infertile population

C. Hernandez-Nieto[1], L. Sekhon[1], D. Gounko[1], J. Lee[1], M. Luna[1], E. Cervantes[1], A. Copperman[1,2], B. Sandler[1,2]

[1]Reproductive Medicine Associates of New York, Reproductive endocrinology and Infertility, New York, U.S.A.
[2]Icahn School of Medicine at Mount Sinai Hospital, Reproductive endocrinology and Infertility, New York, U.S.A.

Study question: Is reproductive outcome compromised in patients with IBD who undergo IVF with transfer of single euploid blastocyst?

Summary answer: IBD Patients who pursue a single euploid embryo transfer have similar odds of implantation, clinical pregnancy and pregnancy loss compared to the general infertile population.

What is known already: Often, women with IBD experience challenges to family building throughout the course of their reproductive years. Patients may encounter decreased fertility and fecundity associated with pelvic adhesive disease from surgery and/or by the disease itself. IBD has been postulated to cause infertility due to an adverse autoimmune influence on embryo quality and/or endometrial receptivity. Currently, there is limited data assessing the implantation rate in IBD patients following IVF. This study aims to evaluate embryo transfer outcome in IBD patients who undergo transfer of screened embryos.

Study design, size, duration: This was a retrospective cohort study of patients who underwent IVF with preimplantation genetic testing and subsequent euploid single embryo transfer (SET) of a vitrified-warmed blastocyst in a synthetically prepared endometrial cavity from Jan 2012 to January 2018. Trophectoderm biopsies (Day 5-6) were analyzed by Next-Generation Sequencing or quantitative Polymerase Chain Reaction (qPCR). A sample size of 36 patients per group was needed to detect a 25% difference in implantation rates with 80% power (alpha = 0.05).

Participants/materials, setting, methods: Natural language processing was used to identify from the electronic medical records a cohort of women with the diagnosis of IBD. A matched 3:1 ratio cohort of control subjects were identified using a propensity-score matching algorithm based on oocyte age, BMI, and ovarian reserve markers. Cases involving the transfer of fresh and/or multiple embryos were excluded. Also, uterine factor infertility, ovum donation, recurrent pregnancy loss, recurrent implantation failure and severe male factor infertility were excluded.

Main results and the role of chance: Of 3274 euploid, single, vitrified-thawed blastocyst transfers included, 38 patients with an IBD diagnosis were compared to 114 control patients. IBD and control patients had a similar implantation rate (71.0% vs. 78.0% (p = 0.68)), clinical pregnancy rate (50.0% vs 60.5% (p = 0.68)) and pregnancy loss rate (37% vs 25.8% (p = 0.25)) respectively. An IBD diagnosis was not found to significantly modify the odds of implantation (adjusted OR = 0.6 [CI 95% -1.2–0.8]) after the data was evaluated using a GEE model that accounted for patients who underwent multiple cycles and controlled for oocyte age, body mass index, anti-müllerian hormone, basal antral follicle count and endometrial thickness at embryo transfer. Additionally, the odds of implantation were not altered by IBD patients having an ulcerative colitis or Crohn's disease diagnosis. (OR = 0.4 CI95% 0.1 – 1.9).

Limitations, reasons for caution: We acknowledge the potential weakness of this study. The retrospective nature of the study might create a possible selection bias. The study's current results must therefore be considered with some caution. Larger, well-controlled studies are needed to verify the study's findings.

Wider implications of the findings: Patients who suffer from Inflammatory bowel disease have comparable embryo transfer outcomes to the general infertile population when pursuing a euploid, single, cryo-thawed embryo transfer. Patients and physicians can be reassured that an IBD diagnosis does not appear to adversely impact embryo quality and endometrial receptivity.

Trial registration number: This study was approved by the Western Institutional Review Board (Study Number: 1167398).

P-359 Association of follicular fluid levels of adrenomedullin 2, vascular endothelial growth factor and its soluble receptors with ICSI outcome

Z. Latifi[1], H.R. Nejabati[2], A. Ranjbaran[1], T. Ghasemnejad[3], K. Hamdi[1], H. Hajipour[1], N. Raffel[4], Z. Bahrami-asl[1], P. Hakimi[1], A. Mihanfar[2], A. Ghasemzadeh[1], L. Farzadi[1], M. Nouri[1], A. Fattahi[1]

[1]Tabriz University of Medical Sciences, Department of Reproductive Biology, Tabriz, Iran
[2]Tabriz University of Medical Sciences, Department of Biochemistry and Clinical Laboratories, Tabriz, Iran
[3]Tabriz University of Medical Sciences, Department of Medical Genetic, Tabriz, Iran
[4]Erlangen University Hospital- Friedrich-Alexander University Erlangen-Nuremberg, Department of Obstetrics and Gynecology, Erlangen, Germany

Study question: Association between follicular fluid (FF) levels of adrenomedullin 2 (ADM2), vascular endothelial growth factor (VEGF) and its soluble receptors with ICSI outcome.

Summary answer: The FF ADM2 could be a potential predictive marker for ovarian non-responders with cutoff value of 348.55 (pg/ml).

What is known already: ADM2 and VEGF are involved in ovarian function especially angiogenesis, follicular development, and ovulation. VEGF action could be antagonized by its soluble receptors, soluble fms-like tyrosine kinase-1 (sFlt-1) and soluble VEGF receptor 2 (sVEGFR-2), via decreasing its free form, thereby decreasing angiogenesis. It has been reported that sFlt-1 and sVEGFR-2 have low expression in post-selected follicles (POF) compared with preselected follicles (PRF). However, after dominant follicle selection, sVEGFR-2 expression increases while sFlt-1 expression reduces along with the days of cycle.

Study design, size, duration: Ninety non-smoker women aged from 20-40 years with fallopian tube obstruction, idiopathic infertility and male factor infertility (varicocele and oligospermia) were enrolled in this study. The long GnRH agonist–recombinant FSH protocol was used for all patients and a single FF aspiration without blood was done. All patients were treated with ICSI and were categorized as non-, poor-, normo- and high-responders according to the retrieved oocytes number.

Participants/materials, setting, methods: The fertilization rates were determined by dividing the number of fertilized oocytes with the number of mature oocytes and the clinical pregnancy was evaluated by existence of the intrauterine gestational sac via transvaginal ultrasound. Implantation rate was defined as the quantity of visible sacs per number of transferred embryos. FF ADM2, VEGF, sFlt-1 and sVEGFR-2 levels were determined by ELISA kits and the VEGF/sFlt-1 and VEGF/sVEGFR-2 ratios were also calculated.

Main results and the role of chance: In the present study, for first time existence of ADM2 in FF was reported; its mean level was 62.2 ± 66.86 pg/ml. Also, it was found that age of the patients was significantly correlated with ADM2 (r = 0.268, p = 0.049). ADM2 level was positively correlated with VEGF and sVEGFR-2 levels (r = 0.586, p = 0.001 and r = 0.482, p = 0.001, respectively). Our results showed that the levels of ADM2 in FF were significantly higher in ovarian non-responders in comparison to patients with poor-,

normo- and high- ovarian responses (p<0.05). Also, the FF levels of VEGF, and sVEGFR-2 were significantly higher in the non-responders than in poor-responder patients (p<0.05). We found no significant association between FF levels of ADM2, VEGF and sVEGFR-2 with clinically pregnant. Based on receiver operating characteristic (ROC) analyses, cutoff value for ADM2 as a non-responder predictor was 348.55 (pg/ml) with sensitivity and specificity of 67.7 % (CI, 67.21–68.25%) and 94.6% (CI, 94.11–95.08%), respectively.

Limitations, reasons for caution: It is a preliminary report covering existence of ADM2 in FF and further studies are required to clarify mode of action of ADM2 in ovarian angiogenesis. The number of subjects was almost low and there may have been other confounding factors that we were unable to account for.

Wider implications of the findings: We found higher FF levels of ADM2 in non-responder women and proposed ADM2 as a potential predictive marker for non-responders. Besides, positive correlations of ADM2 with VEGF and sVEGFR-2 were obtained, what could be considered as an important clue regarding the roles of ADM2 in ovarian angiogenesis.

Trial registration number: Not applicable.

P-360 Bacterial infection other than Chlamydia associated to tubal factor of infertility suggests new approach

R. Piscopo[1,2], J. Ueno[3,4], R. Guimaraes[2], F. Ikeda[4,5], Z. Jarmy-Di Bella[6], M. Girão[6], M. Samama[5,6]

[4]*Hospital Sirio Libanes, Hysteroscopy, Sao Paulo, Brazil*
[5]*Instituto Gera de Medicina Reprodutiva, Clinical, Sao Paulo, Brazil*
[6]*Universidade Federal de São Paulo – Escola Paulista de Medicina UNIFESP-EPM, Gynecology, Sao Paulo, Brazil*

Study question: Is the presence of endocervical bacteria associated to hysterosalpingography outcomes in patients screened for infertility?

Summary answer: Endocervical bacterial is associated to tubal factor infertility and most prevalent etiologic agents were Ureaplasma and Mycoplasma, suggesting that not only Chlamydia must be screened.

What is known already: It is known that microorganisms infecting vaginal flora as Chlamydia trachomatis and Neisseria gonorrhoeae cause pelvic inflammatory disease (PID) in at least 50% of cases. A strong association exists between chlamydia infection and tubal factor infertility, leading PID-related morbidity (i.e., infertility and ectopic pregnancy) and is a substantial public health problem worldwide. Considering the uterine and tubal factors are responsible for 20% of infertility causes, the hysterosalpingography is part of infertility investigation. Besides that, in developing countries, the female infertility by infection as Chlamydia trachomatis is highly prevalent and correlated to tubal alterations.

Study design, size, duration: Cross sectional study reviewed 156 clinical charts of women who underwent infertility investigation during 2016 and 2017 in a private reproductive medicine center in Brazil. The inclusion criteria were women who had hysterosalpingography realized and collected endocervical secretion for bacteria screening.

Participants/materials, setting, methods: Women had complete infertility investigation including anamneses, serum hormone measurements, transvaginal ultrasound, hysteroscopy and biopsy if necessary, hysterosalpingography and endocervical bacteria screening. The hysterosalpingography results were classified as normal tubal or abnormal tubal and endocervical bacteria's screened were Chlamydia Trachomatis, Neisseria Gonorrhea, Ureaplasma Urealíticum, Mycoplasma Hominies and Gardnerella by using PCR. Patients with bacteria positive received antibiotic treatment before IVF cycle.

Main results and the role of chance: Patients were 22 to 48 years of age (36.3 ± 4.6), had a mean of 4.3 years of infertility time, basal FSH of 9.4 ± 14.5 and anti-mullerian hormone of 2.2 ± 2.0. The hysterosalpingography was abnormal in 53.2% of patients, which determined tubal factor of infertility. The prevalence of endocervical bacteria's was 20.5%, as Chlamydia Trachomatis 3.2%, Neisseria Gonorrhea 0.0%, Ureaplasma Urealíticum 7.7%, Mycoplasma Hominies 5.1%, Gardnerella 2.6%, other bacteria 9.6% (Staphylococcus Epidermidis, Streptococcus Agalactiae, Enterococcus Faecalis, and Escherichia Coli). Patients presenting abnormal hysterosalpingography had a higher prevalence of endocervical bacteria (27.7%) compared to normal hysterosalpingography (12.3%; p = 0.014), independently of the type of bacteria. From women with endocervical bacteria positive (n = 32), 34.4% presented more than one type of bacteria positive, and from those, 81.8% (9/11) had tubal factor of infertility.

Limitations, reasons for caution: The number of cycles included in this study is relatively small and larger prospective studies should be carried out to confirm the results. The prevalence of each bacteria individually analyzed in this study was low and it was not possible to correlate each one with hysterosalpingography outcomes.

Wider implications of the findings: The prevalence of endocervical bacterial infection was higher among patients with tubal factor infertility, supporting the association between bacterial infection (other than Chlamydia) and tubal factor. The prevention of complications associated with bacterial infection is an indication for screening at the time of IVF and even at gynecological routine.

Trial registration number: not applicable.

P-361 Progesterone dose adjustment and transfer postponement in patients with low progesterone levels following hormonal replacement therapy for frozen thawed embryo transfer

I. Cedrin - Durnerin[1], L. Laup[1], M. Comtet[1], C. Vinolas[1], A. Seroka[1], B. Dagher Hayeck[1], C. Herbemont[2], C. Sifer[2], M. Grynberg[1]

[1]*Hôpital Jean Verdier, Service médecine de la reproduction et préservation de la fertilité, Bondy, France*
[2]*Hôpital Jean Verdier, Laboratoire de biologie de la reproduction, Bondy, France*

Study question: Is progesterone (P) dose adjustment and postponement of frozen thawed embryo transfer (FET) effective to improve outcome in patients with low P levels following hormonal replacement therapy?

Summary answer: Dose adjustment to obtain serum P levels >10 ng/ml and transfer postponement accordingly gave similar outcome to those of normal P and 'in phase" transfers.

What is known already: Several studies have demonstrated that, in HRT cycles, low serum P levels on the day of FET were associated with decreased pregnancy and live birth rates. However, in our hands, P dose adjustment after ET to obtain P levels >10 ng/ml was ineffective to correct impaired outcome. Therefore, we decided to measure serum P levels and adjust P dose to obtain a serum P level >10 ng/ml prior to ET and to postpone ET by one or two days accordingly.

Study design, size, duration: This retrospective study included data from March to October 2017 obtained in a cohort of 139 patients, undergoing FET following HRT. Endometrial preparation was achieved by sequential administration of vaginal estradiol until endometrial thickness >7 mm, followed by transdermal estradiol combined with 600 mg/day vaginal micronized P (200 mg three times a day).

Participants/materials, setting, methods: This study was conducted in a university hospital. Serum P was measured on D2 following exogenous P introduction in the evening (referred as D0). When P levels were >10 ng/ml, ET was performed on D2, D3 or D5 depending on embryo stage at cryopreservation. When P levels were <10 ng/ml, P dose was increased to 1200 mg/day. Serum P level was checked one day later and the next day if necessary. ET was postponed accordingly.

Main results and the role of chance: Mean serum P level on D2 was 12.1 + 3.52 ng/ml and serum P <10 ng/ml were observed in 28% of cycles. Cycles were cancelled in 11 patients because of inability to obtain P >10 ng/ml despite increased progesterone supplementation (n = 5) or failure in performing P measurement timely (n = 6). ET was postponed in 26 patients after P dose adjustment until reaching serum P values beyond 10 ng/ml. This strategy led to similar positive pregnancy test (42.3 % vs 43.1 %, NS), heartbeat activity at 6 weeks (30.7 % vs 27.5 %, NS) and ongoing pregnancy rates at 12 weeks (26.9 % vs 25.7 %, NS) when compared with 102 'in phase" transfers performed in patients with P >10 ng/ml at first evaluation.

Limitations, reasons for caution: The number of treated patients has to be extended to confirm these preliminary data.

Wider implications of the findings: These results suggest that serum P measurement prior to ET and further adjustment of exogenous P dose and postponement of transfer might optimise the outcome of FET cycles performed using HRT.

Trial registration number: not applicable.

P-362 Mitochondrial function in granulosa cells of preovulatory follicles may be diminished in infertile women with polycystic ovary syndrome

C.H. Kim[1], J.W. Moon[2], H.J. Kim[1], S.H. Kim[1], H.D. Chae[1], B.M. Kang[1]

[1]Asan Medical Center- University of Ulsan, Dept. of Ob/Gyn, Seoul, Korea- South
[2]M fertility center, Gynecology, Seoul, Korea- South

Study question: Could polycystic ovary syndrome (PCOS) affect the mitochondrial function in granulosa cells (GCs) of preovulatory follicles?

Summary answer: Mitochondrial function in GCs of preovulatory follicles may be diminished in infertile women with PCOS.

What is known already: Several problems in patients with PCOS undergoing IVF have been reported including decreased fertilization rates, abnormal embryo development, high incidence of miscarriage and increased likelihood of ovarian hyperstimulation syndrome (OHSS). In addition, Infertile women with PCOS frequently have higher concentrations of inflammatory cytokines such as tumor necrosis factor (TNF)-alpha and androgens in follicular fluid (FF). These unfavorable intrafollicular environment may have a negative effect on the mitochondrial function in GCs. However, the study on the mitochondrial activity in GCs of infertile patients with PCOS undergoing COS for IVF has not been reported.

Study design, size, duration: This retrospective study included 51 infertile patients with PCOS (PCOS group) and 95 infertile patients with normal ovulatory cycle (control group) who underwent IVF/ICSI in controlled ovarian stimulation (COS) cycles between June 2015 and December 2016.

Participants/materials, setting, methods: IVF cycles in which GnRH antagonist protocol was used for controlled ovarian stimulation (COS) were included for this study. FF from at least 2 follicles (range 17-21 mm) at oocyte retrieval was collected. IVF results and relative amounts of succinate dehydrogenase complex subunit A (SDHA) and peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1alpha) mRNA in GCs were compared between the two groups. The expression of *SDHA* and *PGC-1alpha* mRNAs was analyzed by realtime RT-PCR.

Main results and the role of chance: Patients' age and infertility duration were similar in the two groups. In the PCOS group, total dose of recombinant human FSH (rhFSH) used for COS was significantly lower and the number of oocytes retrieved was significantly higher than in the control group. However, number of embryos fertilized was comparable between the two groups. FF TNF-alpha and IL-6 concentrations at oocyte retrieval were significantly higher in the PCOS group ($P<.001$, $P<.001$). Relative amount of *SDHA* mRNA in GCs was significantly lower in the PCOS group of 4.58 ± 2.87 compared with 9.62 ± 3.90 in the control group ($P<.001$). Relative amount of *PGC-1alpha* mRNA in GCs was also significantly lower in the PCOS group ($P<.001$).

Limitations, reasons for caution: This study have limitations to evaluate the mitochondrial function due to a small numbers of sample available and marker genes investigated and its retrospective nature. Therefore these results should be taken with caution until well-designed controlled studies will be presented.

Wider implications of the findings: Mitochondrial function in GCs may be impaired in infertile women with PCOS and these results may be associated with the unfavorable intrafollicular environment including higher levels of FF pro-inflammatory cytokines.

Trial registration number: None.

P-363 Expression of various genes in granulosa cells derived from women undergo IVF procedures

M. Wasserman[1], I. Har-Vardi[2], E. Levitas[2], E. Priel[1]

[1]Ben Gurion University of the Negev, Microbiology- Immunology & Genetics- Faculty of Health Sciences, Beer-Sheva, Israel
[2]Ben Gurion University of the Negev, - Faculty of Health Sciences- Fertility and IVF unit- Obs/Gyn- Soroka University medical center, Beer-Sheva, Israel

Study question: Do telomerase and topoisomerase expression and activity in luteinized granulosa cells derived from woman undergoing IVF treatments correlate with woman infertility?

Summary answer: The results show variations and correlations between enzymes activities and expressions with women's age, cause of infertility and estrogen levels with/without telomerase activating compounds.

What is known already: Telomerase (Telo) and topoisomerase (Topo) are nuclear enzymes with essential activities needed for maintaining the normal functions and survival of cells and tissues in organisms.

Granulosa cells (GCs) are somatic cells, surrounding each developing oocyte, required for the development and functionality of ovarian follicle in vivo. These enzymes exist in all living organisms, in which they play a crucial role in genomic stability. Little is known about in their functions and activities in developing GCs. Thus, deep understanding of the enzymes participating in the maintenance of oocytes and GCs quality and functionality is important for improving human fertility.

Study design, size, duration: GCs were collected from 80 IVF patients following oocyte retrieval and formal consent. The GCs were immediately subjected to protein or RNA extract procedures or incubated for various intervals with/without AGS (telomerase activating compounds).

The extend of the activity and expression of the enzymes and other genes (markers of GCs) in the GCs of each woman were correlates to various parameters including woman age, cause of infertility, number of oocytes and estrogen levels.

Participants/materials, setting, methods: GCs were collected and isolated from follicular fluids of patients undergoing IVF treatments. In some experiments GCs were treated with telomerase activating compounds (AGS) Telomerase activity was determined in whole cells (WC) and DNA bound (DB) extracts using TRAP assay. Topoisomerase I activity was assayed by the relaxation of supercoiled DNA plasmid. The expressions of the enzymes and other relevant genes were examined by RT-PCR using specific primers.

Main results and the role of chance: Variations in telo and topo I activities in the GCs derived from the examined women were detected. A negative correlation between topo I or telo activities and blood estrogen levels was observed. The patients were divided into two groups according to the cause of infertility. Low but not significant, telo activity was observed within the group diagnosed as "female infertility" and not in "male infertility" group. An increase in Telo expression with AGS, was shown in older women–in female infertility group, while in male infertility group, the increase in Telo expression was determined in all ages.

Specific GCs genes expression (known as markers for GCs: CAMTA1, UNC-5, 3bhsd, B4galt 2), showed different expression pattern due to the presence/absence of AGSs. We found that the expression pattern of CAMTA and B4galt 2 in correlation with woman age, was the opposite to that observed for telo, but 3bhsd expression was very similar to Telo expression. No dependency with woman age was observed for the expression of Unc5 and STAR genes in GCs. Generally, Telo expression decreases with woman's age, but in the presense of AGS's, Telo expression was increased, especially in older women.

Limitations, reasons for caution: The Gcs in our experiments were derived from woman exposed to gonadotropins and maturating oocyte agents therefore they represent the state of luteinized GSc.

Wider implications of the findings: Telomerase and topoisomerase are nuclear enzymes.

Deep understanding of the enzymes participating in maintenance of oocytes and GCs quality and functionality is important for the design of strategies to treat human infertility. Identification of GCs response to AGS compounds, could provide a new and promising insights into IVF procedures.

Trial registration number: All the human samples used in this study were approved by Helsinki committee no. 0003-15-SOR

P-364 Anti-Mullerian hormone can predict pregnancy, live birth and miscarriage?

T. Inoue[1], N. Nakayama[2], N. Terawaki[1], R. Kawabe[1], Y. Asai[1], T. Himeno[1], Y. Morimoto[1]

[1]HORAC GRAND FRONT OSAKA CLINIC, medical, Osaka, Japan

[2]HORAC Grand Front Osaka clinic, reproductive technology, Osaka, Japan

Study question: Is the serum Anti-Mullerian hormone (AMH) level in infertile women associated with the outcome of fertility treatment?

Summary answer: AMH cannot be a predictive value for pregnancy, live birth or miscarriage 1 to 1.5 years after starting fertility treatment.

What is known already: AMH is an established marker of ovarian reserve and a good predictor of ovarian response for controlled stimulation, and previous research has shown that AMH is associated with implantation and clinical pregnancy rate effectuated from assisted reproductive medicine treatments. However, it is still uncertain whether AMH can predict the final outcome of every type of fertility treatment.

Study design, size, duration: This retrospective cohort study was designed to identify the correlation between serum AMH levels and fecundity by reviewing infertile couples' medical records. Four hundred and eighty-one women had the AMH test at their first consultation visit from January 2015 until June 2016. The history of 477 women who received any kind of fertility care was examined only if the couples reached clinical pregnancy, live birth, or miscarriage by June 2017.

Participants/materials, setting, methods: This study was performed at a private fertility clinic located in Japan's second city, Osaka. AMH was measured by an enzyme-linked immunosorbent assay (gen II). The couples suffered from various causes of infertility and underwent different fertility treatments including, timed intercourse direction, intrauterine insemination, assisted reproductive technology, and/or alternative medicine. The data was analyzed with the Games-Howell multiple comparisons procedure.

Main results and the role of chance: The average age of the women was 38.9 (SD = 4.6, range 25-49), and the average AMH was 2.4 (SD = 2.4, 0-33.8) ng/mL. Two hundred and forty-one were younger than 40 years old (group I), and two hundred and thirty-six women were in their forties (group II). The data was analyzed according to their AMH levels, a: <0.1, b: 0.1-0.49, c: 0.5-0.99, d: 1.0-1.49, e: 1.50-1.99, f: 2.0-2.49, g: 2.5-2.99, h: 3.0-3.99, i: 4.0-4.99, j: ≥5.0 ng/mL. The pregnancy rate, the live birth rate including the ongoing pregnancy rate after the 12th week of gestation, and the miscarriage rate were compared among different AMH sub-groups (a-j) at the point of 1 to 1.5 years after their first visit. The pregnancy rate in group I was a: 0.31, b: 0.53, c: 0.46, d: 0.52, e: 0.57, f: 0.62, g: 0.60, h: 0.77, i: 0.59, j: 0.66. The live birth rate was a: 0.23, b: 0.40, c: 0.38, d: 0.41, e: 0.54, f: 0.58, g: 0.47, h: 0.65, i: 0.53, j: 0.58. No significant difference was found among the AMH dependent subgroups. This trend was the same in the elderly group (II). The analysis on miscarriage rates showed no relation between AMH and miscarriage development.

Limitations, reasons for caution: Small sample size. There is possible dispersion of the cause of infertility, the patients' back ground and treatment policy.

Wider implications of the findings: AMH is not associated with the outcome of fertility treatment. Low AMH doesn't necessarily mean a poor prognosis of fertility treatment. With adequate management for poor ovarian responders we anticipate just under 40% of infertile couples can achieve conception.

Trial registration number: not applicable.

P-365 A personalized maturation trigger administered 36 hours before IUI improves the pregnancy rates

T. Horikawa, K. Nakagawa, A. Moriyama, R. Sugiyama, K. Nakao, K. Kuroda, S. Takamizawa, R. Sugiyama

Sugiyama Clinic Shinjuku, Reproductive Medicine, Tokyo, Japan

Study question: If a maturation trigger of human chorionic gonadotropin (hCG) is administered 36 hours before intrauterine insemination (IUI), will this improve the pregnancy rate?

Summary answer: A maturation trigger of hCG administered 36 hours before intrauterine insemination (IUI) improves the pregnancy rate.

What is known already: In ART treatment, 36 hours is accepted as the optimal duration between a maturation trigger and oocyte pick-up (OPU) in order to obtain mature oocytes. With a shorter duration, the chances for immature oocyte obtainment rate are higher; when the duration is longer, the ovulation rate becomes higher. Therefore, approximately 36 hours following the maturation trigger could be a suitable duration for both ovulation and fertilization naturally without ART. In our country, self-injection kits with a prefilled syringe containing either recombinant-human chorionic gonadotropin (r-hCG) syringe or Gonadotropin-releasing hormone agonist (GnRH-a) are available as maturation triggers.

Study design, size, duration: This was a retrospective cohort study of total 425 patients who received IUI form the husband's semen in our clinic between January and April 2017. The patients were classified into one of three groups: the r-hCG group included 73 patients who received r-hCG 36 hours before IUI; the u-hCG group included 233 patients who received urinary-hCG 24 hours before IUI; and, the GnRH-a group included 119 patents, who received GnRH-a 36 hours after IUI.

Participants/materials, setting, methods: Some patients were received Clomiphen citrate or recombinant follicle stimulating hormone (r-FSH) as ovarian stimulation, but others received no drugs for stimulation. Luteal support was not performed for all participants. Factors that included male infertility and advanced maternal age of the female partner were excluded in this study. A clinical pregnancy was defined as the confirmation of a gestational sac via ultrasound. The clinical pregnancy and miscarriage rates were evaluated for the three groups.

Main results and the role of chance: The mean age of the patients in the r-hCG, u-hCG and GnRH-a groups were 36.5, 36.1 and 35.7, respectively, and there were no significant differences. The mean number of previous IUI attempts (times) and the percentage of stimulated cycles in the r-hCG, u-HCG and GnRH-a groups were 1.2 and 19.2%, 1.4 and 15.5%, and 1.6 and 20.2%, respectively, with no significant differences among the three groups. The clinical pregnancy rate in the r-hCG group was 16.4%, which was significantly higher than that for the u-hCG group (8.2%, $p<0.05$). But there were no significant differences between the r-hCG and GnRH-a groups (20.2%). The miscarriage rates for the r-hCG, u-hCG, and GnRH-a groups were 0, 26.7, and 36.8%, respectively, with no other significant differences among the three groups.

Limitations, reasons for caution: This study was not a randomized controlled trial. The r-hCG has only been available since March 2017. Prior to that, u-hCG wss the only agent available for hCG preparation.

Wider implications of the findings: The miscarriage rate in the GnRH-a group tended to be higher than that in the r-hCG group. One of the reasons could involve the half-life of each agent, because r-hCG shows a longer half-life than GnRH-a. Nobody received luteal support, which suggested that r-hCG might support the luteal phase.

Trial registration number: This study had no RCT status, and was not assigned a trial registration number.

P-366 Impact of yoga- and meditation-based lifestyle intervention on depression and quality of life in infertile couples: a randomized controlled trial

M. Tolahunase[1], R. Kumar[2], R. Sagar[3], R. Dada[1]

[1]*All India Institute of Medical Sciences, Lab for Molecular Reproduction and Genetics-Department of Anatomy, New Delhi -110029, India*

[2]*All India Institute of Medical Sciences, Department of Urology, New Delhi -110029, India*

[3]*All India Institute of Medical Sciences, Department of Psychiatry, New Delhi -110029, India*

Study question: What is the impact of yoga- and meditation-based lifestyle intervention (YMLI) on depression severity, quality of life, and accelerated cellular aging in infertile couples with major depressive disorder (MDD)?

Summary answer: A brief 12-week YMLI significantly decreases depression severity, increases the quality of life, and reverses the biological aging in infertile couples with major depressive disorder.

What is known already: Depression and Infertility are comorbid and significantly affect pregnancy outcomes. Modern lifestyle factors, including the psychological stress of infertility and treatment failures, contribute to depression. The depression-related accelerated cellular aging that includes neurodeficits,

regulatory feedback dysfunctions, affect reproductive functions and quality of life in both infertile men and women. In addition, it can lead to poor quality gametes and severe complications in the offspring like neurodevelopmental disorders and cancers. Targeted interventions are needed to increase the success of pregnancy and healthy offspring.

Study design, size, duration: A randomized clinical trial of 12−week YMLI for infertile couples (n = 80 couples) with MDD was designed to evaluate the impact on depression severity, quality of life, and systemic biomarkers of cellular aging.

Participants/materials, setting, methods: Infertile couples with MDD were randomly assigned to a 12−week yoga intervention group (n = 40) or to a control group (n = 40). Clinical parameters and blood samples were collected before and after the intervention.Assessment of depression severity was by Beck Depression Inventory–II scale (BDI-II)], and quality of life was by abbreviated 26 item version of World Health Organization Quality-of-Life Scale (WHOQOL−BREF). Systemic biomarkers of cellular aging were assessed as per manufacturer protocols.

Main results and the role of chance: YMLI led to a significant decrease [difference between means, (95% CI)] in BDI-II score [-5.83 (-7.27, -4.39), p < 0. 001]. There was significant improvement in all domains of the quality of life: physical [11.3 (4.2 to 21.3), p < 0. 001]; psychological [13.2 (3.9 to 22.4), p < 0. 001]; social [4.6 (1.6 to 12.3), p < 0. 033]; and environment [3.4 (1.1 to 7.8), p < 0. 039]. There were significant improvements in the 12-week levels of the systemic biomarkers of accelerated aging in yoga group compared to control group [decrease in ROS, 8OH2dG, cortisol, and IL-6, and, increase in TAC, COX2 activity, telomerase activity, BDNF, serotonin, melatonin, and sirtuin 1) (all P<0.05). Although YMLI did not differentially improve telomere length (P = 0. 084), telomere length was maintained. These findings were in parallel with the significant reduction in BDI-II scores and increase in WHOQOL-BREF scores.

Limitations, reasons for caution: Interpretation of the study findings will be more precise only after further studies of the impact of YMLI on pregnancy outcomes in infertile couples with MDD and their future offspring become available. It should also be noted that chronological age is an independent risk for infertility.

Wider implications of the findings: Reversal of depression associated accelerated aging by YMLI in infertile couples with MDD improve all domains of the quality of life. YMLI induced improvement in neural networks and integrative mechanisms contribute to improvement in both male and female reproductive systems, gametes, pregnancy outcomes, and future offspring.

Trial registration number: Clinical Trial Registry of India (CTRI) REF/2014/09/007532

P-367 Live birth rate in Turner syndrome patients after oocyte donation: a matched-cohort study over a 10-years period

E. Milego[1], D. García[2], P. Giménez-Bonafé[1], R. Vassena[2], A. Rodríguez[2]

[1]Barcelona University, Faculty of Medicine, Barcelona, Spain
[2]Clínica EUGIN, Assisted Reproduction, Barcelona, Spain

Study question: Is the live birth rate in Turner syndrome women after oocyte donation (OD) comparable to that of oocyte recipients without Turner syndrome?

Summary answer: The live birth rate in Turner syndrome patients after IVF with donated oocytes (OD) is 35.4%, comparable to other women accessing this treatment.

What is known already: Turner syndrome is one of the most common female chromosomal abnormalities with gonadal dysgenesis, due to a total or partial (mosaicism) absence of one X chromosome. Turner syndrome usually causes infertility and gestational complications, thus spontaneous pregnancies in these women are rare, and pregnancy outcomes involve an increased risk of miscarriage and stillbirths. Assisted reproduction techniques, especially OD, can give women with Turner syndrome the possibility to become pregnant and delivery healthy children.

Study design, size, duration: Retrospective matched (1:2) cohort study including 252 OD patients. The exposed group ("Turner", n = 84) were women affected by Turner syndrome performing their first fresh embryo transfer (ET) between 2010 and 2017. The non-exposed group ("no-Turner"; n = 168) were women without chromosomal alterations also performing their first ET in the same time period. Endometrial preparation was performed with estrogens, administered either orally or transdermally, while oocyte donors were stimulated using GnRH antagonist protocol triggered with GnRH-agonist.

Participants/materials, setting, methods: Turner women in this study had different karyotypes: 45,X (4 women, 4.8%) and several mosaics such as 45,X/46,XX and 45,X/46,XY. No-Turner women required OD mainly due to age. Cases and controls were matched by date of ET, number of embryos transferred, and developmental stage of the embryo at the time of ET. Differences in reproductive outcomes between groups were assessed using Chi-square tests. Additionally, we analyzed the subset of 147 cycles with single ET (SET).

Main results and the role of chance: Women in the Turner group were on average 32.2 years old (SD 4.8, range 22-43), while women in the no-Turner group were 41.8 (SD 4.3, range 25-50). All other parameters were similar in both groups: mean BMI was 23.9 (SD 4.2), mean number of mature oocytes (MII) assigned to each woman was 7.3 (SD 1.5, range 4-14), and they were fertilized with partner's sperm in 86.8% of cases. ET was performed on day 2-4 in 165 (66.7%) cases, with 1 embryo transferred in 147 (58.3%) of cycles.

Reproductive outcomes were slightly higher in the Turner group, although not statistically significant. Biochemical pregnancy rate was 54.9% vs. 47.2% (p = 0.28). Clinical pregnancy rate was 39.5% vs. 37.7% (p = 0.82). Ongoing pregnancy rate was 36.3% vs. 30.6% (p = 0.38), and live birth rate was 35.4% vs. 29.6% (p = 0.36). Comparable results were obtained when analyzing the subset of SET: biochemical pregnancy rate was 57.5% vs. 50.5% (p = 0.44); clinical pregnancy rate 43.5% vs. 38.3% (p = 0.56); ongoing pregnancy rate 40% vs. 30.4% (p = 0.27); live birth rate 38.6% vs. 29.7% (p = 0.30).

Limitations, reasons for caution: Women in the Turner group were on average 10 years younger; however reproductive outcomes are not affected by the patient's age when donated oocytes are used, and the mean donor age was 26 in both groups.

Wider implications of the findings: OD is an assisted reproduction technique that offers excellent results in women with Turner syndrome, especially in single ET, which is the recommended treatment option for these patients.

Trial registration number: Not applicable.

P-368 National U.S. utilization patterns and live birth rates of various ovarian stimulation protocols for IVF

S. Darmon, D. Barad, N. Gleicher, V. Kushnir

Center for Human Reproduction, n/a, New York- NY, U.S.A.

Study question: How does the U.S. utilize various ovarian stimulation protocols for in vitro fertilization (IVF) and what are resulting live birth rates?

Summary answer: Paradoxically, minimal stimulation, natural cycles and *in vitro* maturation (IVM) are utilized primarily in poor prognosis patients, where their utility is the lowest.

What is known already: Alternative ovarian stimulation protocols for IVF have grown in popularity. Yet, patient populations best suited for these protocols have not been defined.

Study design, size, duration: This is a retrospective study of aggregate data published by the Society for Assisted Reproductive Technologies (SART) for autologous IVF cycles performed in the U.S. during 2014 and 2015.

Participants/materials, setting, methods: IVF cycles were stratified based on ovarian stimulation protocols and included 205,705 conventional stimulations, 4,397 minimal stimulations, 2,785 natural cycles and 514 in vitro maturation (IVM) cycles. The main outcome measures were utilization patterns and age-specific live birth rates for the different ovarian stimulation protocols.

Main results and the role of chance: With advancing female age, utilization of conventional stimulation protocols decreased, while minimal stimulation and natural cycle IVF increased. LFOR diagnoses were in all age groups less prevalent in patients undergoing conventional stimulation than with all other protocols. Live birth rates were uniformly the highest with conventional stimulation at 42.4%, 33.1%, 22.1%, 11.7% and 3.9% for ages <35, 35-37, 38-40, 41-42 and

>42, respectively. Moreover, pars in live birth rates between conventional stimulation and other protocols widened with advancing age from 1.6-3.9-fold among women <35 years to 4.4-6.6-fold among women > 42 years.

Limitations, reasons for caution: Current U.S. national IVF outcome reporting allows for only limited interpretation of data: One such limitation is absence of a standardized definition of what represents minimal stimulation. Another limitation is that SART reports only present aggregate data. Our ability to adjust for confounding patient characteristics was, therefore, limited.

Wider implications of the findings: Conventional stimulation protocols still represent the gold standard of care. Alternative protocols should only be used in younger patients with normal FOR if specific indications exist which negate lower pregnancy and live birth chances but should be avoided in older women and in younger patients with LFOR.

Trial registration number: not applicable.

P-369 Is there a difference between blastocyst formation and cumulative pregnancy rates between cycles of recipients who received fresh or vitrified eggs from the same donor?

B. Barros[1], A.P. Aquino[2], R. Mazzeto[3], T. Bonetti[4], A.R. Lorenzon-Ojea[5], E. Motta[6], T. Domingues[2]

[1]Huntington Medicina Reprodutiva, Embryology Department, Sao Paulo / SP, Brazil
[2]Huntington Medicina Reprodutiva, Clinical Medicine Department, São Paulo- SP, Brazil
[3]Huntington Medicina Reprodutiva, Embryology Department, São Paulo- SP, Brazil
[4]Federal University of São Paulo, Gynecology Department, São Paulo- SP, Brazil
[5]Huntington Medicina Reprodutiva, Scientific Coordination, São Paulo- SP, Brazil
[6]Huntington Medicina Reprodutiva/Federal University of São Paulo, Clinical Medicine Department/Gynecology Department, São Paulo- SP, Brazil

Study question: Do frozen-thawed oocytes affect the blastocyst formation and pregnancy rate compared to fresh oocytes from the same donor in *in vitro* fertilization (IVF) cycles?

Summary answer: Frozen-thawed oocytes do not affect blastocyst formation and pregnancy rates in donation cycles when compared to fresh oocytes from the same donor.

What is known already: An efficient oocyte cryopreservation method is mandatory to establish a successful egg-banking program. There are increasing reports showing good clinical outcomes after oocyte cryopreservation, but there is still a lack of large controlled studies evaluating the effectiveness of oocyte cryo-banking. Although previous studies suggest that vitrified oocytes result in similar pregnancy rates when compared to fresh oocytes, no data is available regarding blastocyst formation and pregnancy rates from the same oocyte donor.

Study design, size, duration: Cross-section study from an oocyte donation program, including 20 oocyte donors, that obtained ≥14 MII oocytes/cycle and divided into 49 different recipient's, 20 receiving fresh and 29 frozen eggs, from 2013 to 2017.

Participants/materials, setting, methods: All oocyte donors (23.5 ± 2.91 years old) were stimulated using the same protocol. Recipient's patients (42.04 ± 4.14 years old) received at least 07 mature oocytes from fresh (n = 20) or frozen-thawed (n = 29) cycles, according to uterine synchronization. For all recipients, fertilization were carried out with ICSI and the embryos produced within the cycle were transferred on blastocyst stage (2.02 ± 0.59).

Main results and the role of chance: There was no difference between fresh and frozen-thawed oocyte cycles rates for fertilization (83.21% vs 81.57%, p = 0.6765), D3 embryo formation (93.44% vs 94.42%, p = 0.6038), top quality D3 embryo (total TQ D3/total D3 embryos: 46.24% vs 42.14%, p = 0.3719), blastocyst formation (55.78% vs 54.59%, p = 0.8324), top quality blastocyst (total TQ Blastocyst/total Blastocyst: 67.69% vs 62.99%, p = 0.5945), pregnancy (75.86% vs 65.52%, p = 0.5648) and implantation (48.15% vs 44.44%, p = 0.7074). Paired T-test or Fisher´s test was applied as appropriated.

Limitations, reasons for caution: The egg donation is usually performed by healthy and young woman (≤29 years) and could be speculated that oocytes from women below 30 years old may be more resistant to vitrification than those from women of advanced age. Moreover, male factor was not considered.

Wider implications of the findings: Using eggs from the same donor to fresh or frozen-thawed cycles produce an excellent clinical outcome. Moreover, a consistent egg vitrification program could be extended to accumulate oocytes from successive stimulations from the same donor, decreasing risk of ovarian hyperstimulation and improving fertility preservation and/or oocyte donation program outcomes.

Trial registration number: Not applicable.

P-370 Dual triggering with GnRH agonist plus hCG versus triggering with hCG alone for IVF/ICSI outcome in GnRH antagonist cycles

C.H. Chen[1], C.R. Tzeng[1], P.H. Wang[2], W.M. Liu[1], H.Y. Chang[3], H.H. Chen[1], C.H. Chen[1]

[1]Taipei Medical University Hospital, Department of Obstetrics and Gynecology, Taipei, Taiwan R.O.C.
[2]Taipei Veterans General Hospital, Department of Obstetrics and Gynecology, Taipei, Taiwan R.O.C.
[3]Taipei Medical University, Department of Biochemistry and Molecular Cell Biology-School of Medicine- College of Medicine, Taipei, Taiwan R.O.C.

Study question: Is dual triggering with GnRH agonist plus hCG as efficacious as hCG triggering in terms of oocyte and pregnancy outcomes?

Summary answer: Results indicate comparable or significantly improved outcomes with the use of GnRH agonist plus hCG as compared with hCG alone for triggering of oocyte maturation.

What is known already: Final oocyte maturation triggering in *in vitro* fertilization cycles using GnRH antagonist protocols is conventionally achieved with hCG, which is associated with an increased risk of ovarian hyperstimulation syndrome (OHSS). Triggering with GnRHa has been used as an alternative to hCG; however, previous findings indicate poorer pregnancy outcomes with this method.

Study design, size, duration: A comprehensive literature search was performed to identify randomized controlled trials comparing IVF outcomes between women receiving combined administration of hCG with GnRHa and those receiving hCG alone for triggering of final oocyte maturation.

Participants/materials, setting, methods: Meta-analysis.

Main results and the role of chance: Four studies including 527 patients eligible for inclusion in meta-analysis were identified. No significant difference in the number of mature oocytes or fertilized oocytes retrieved was found between groups. Clinical pregnancy rate with dual triggering was significantly higher as compared with hCG-alone triggering (pooled OR = 0.48, 95% CI: 0.31 to 0.77, P = 0.002), but there was no significant difference in the ongoing pregnancy rate between groups (pooled OR = 0.88, 95% CI: 0.29 to 2.66, P = 0.826).

Limitations, reasons for caution: Only 4 studies were eligible for inclusion and the quality of the studies was only moderate overall.

Wider implications of the findings: None.

Trial registration number: None.

P-371 Relationship between pregnancy rate and post sperm wash motile sperm count in IUI cycles: perspective from a developing country

J. Sneha[1], A. Sadashivan[2]

[1]NU Hospitals- Bangalore, Reproductive Medicine, Bengaluru, India
[2]Nu Hospitals- Bengaluru, Reproductive Medicine, Bengaluru, India

Study question: What is the least total Motile sperm count in a post wash IUI semen sample for a reasonable pregnancy rate?

Summary answer: No pregnancies occured when the total motile sperm count of the post wash semen sample was < 10million.

What is known already: IUI is an efficacious, cost effective treatment of infertility. In developing country like India where IVF is not covered by health insurance, the affordability of common man for IVF is low. Also there are various societal taboos associated with IVF. Hence, we are expected to offer IUI

for those with higher degrees of male factor infertility. The quality of sperms is an important determinant of outcome. KoyunOk et al, suggested that an average post-wash total motile sperm count of 10×10^6 may be a useful threshold value for IUI success, but more studies are needed to determine a cut-off value.

Study design, size, duration: It was a prospective observational study carried out between November 2015 and November 2017. The sample included 422 consecutive IUI cycles. All IUI cycles using husband sperm were included and those using donor sample were excluded. Post sperm wash motile sperm count(PMSC) was calculated as Post sperm wash (Total sperm count x Percentage motility)

Participants/materials, setting, methods: The patients underwent standard protocol of ovulation induction using clomifene and gonadotropins as per institutional protocol. Follicular monitoring was done using Mindray Resona 6 using 7.5 MHz transvaginal probe.Ovulation trigger with purified urinary HCG 10,000 units was given and IUI done 36-40 hours later. The ovulation was checked prior to IUI and done only if follicles had ruptured. Semen sample was collected by masturbation and processed by WHO prescribed density gradient method and IUI done.

Main results and the role of chance: In the 422 patients included in the study, the range of female partner age and male partner age (mean) was 18-38 yrs(29.8) and 23-42 yrs(31.3) respectively.312 and 110 patients had primary and secondary infertility respectively. The number of patients with PMSC <10,10-20,20-30,30-40,40-50,>50 million was 43,51,77,103,80,68 respectively and number of pregnancies(pregnancy rate) was 0(0%),17(33.3%),15 (19.4%),21(20.3%),17(21.3%),24(35.2%) respectively. Out of the 422 patients who underwent IUI, 94 conceived, making pregnancy rate 22.2%.

There were no pregnancies when the total motile sperm count of the inseminated sample was < 10million. However, the motile sperm count >10 million gives good pregnancy rate. This can be used to explain prognosis to patients undergoing IUI and counsel them for other options such as IVF/ICSI in the subsequent cycle.

Limitations, reasons for caution: The study has a low sample size and is an observational study. It is a single centre study.

Wider implications of the findings: Further multicentre studies with larger number including the combined impact of post wash motility/morphology must be carried out. This can be used to define criteria for explaining the limitations of IUI treatment and next step to offer after IUI fails: whether to go ahead with IUI or offer IVF/ICSI.

Trial registration number: RM003

P-372 Pain scores during oocyte retrieval: a retrospective cohort study comparing three different protocols

I. Roest[1], E. Buisman[2], J. Smeenk[3], J.W. Van der Steeg[2], C. Koks[1]

[1]*Maxima Medical Centrum, Gynaecology, Veldhoven, The Netherlands*
[2]*Jeroen Bosch Hospital, Gynaecology, 's-Hertogenbosch, The Netherlands*
[3]*Elisabeth-TweeSteden Hospital, Gynaecology, Tilburg, The Netherlands*

Study question: Pain scores during oocyte retrieval in three Dutch clinics: a comparison of oral analgesics with intravenous or intramuscular opioids.

Summary answer: The lowest pain scores were achieved by intramuscular administration of alfentanil, followed by intravenous fentanyl and, finally, non-sedative oral analgesics.

What is known already: No particular method is superior in providing effective conscious sedation and analgesia for pain relief during oocyte retrieval, as described in a 2013 Cochrane review (Kwan, et al.). Conscious sedation is most commonly used for pain relief in the USA and UK, whereas pain protocols in the Netherlands vary from oral analgesics to various administration methods of opioids or a paracervical block. Comparison of these methods has never been done before. We aimed to compare these methods and thereby identify the most effective and convenient pain relief protocol, ultimately enabling the creation of a uniform protocol across the Netherlands.

Study design, size, duration: A retrospective cohort study was conducted in three hospitals in the Netherlands. A total of 2.134 oocyte retrievals between May 2012 and May 2017 were included in the analysis. Each clinic has a different protocol for pain relief during oocyte retrieval: clinic 1. oral analgesics (1000 mg paracetamol and 500 mg naproxen), clinic 2. intramuscular opioids (0.01 mg/kg alfentanil), clinic 3. intravenous opioids (50ug fentanyl). We excluded patients where pain relief was not given according to local protocol.

Participants/materials, setting, methods: In all three clinics, pain scores were registered during every oocyte retrieval on a scale from 0 to 10. Clinic one and three used the numerical rating scale, clinic two used the visual analogue scale. Pain scores and additional variables, such as female demographics, treatment type and cycle (in vitro fertilisation or intracytoplasmic sperm injection) and oocyte number were recovered from the national electronic fertility database or from the local electronic file.

Main results and the role of chance: A mixed linear model was performed, since some patients had had multiple follicle punctures. Mean pain scores and their 95% confidence intervals were: 5.6 (5.3-5.8) in the oral analgesics group, 5.1 (5.0-5.3) in the intravenous opioids group and 4.0 (3.9-4.2) in the intramuscular opioids group. Furthermore, age, number of oocytes and number of previous retrievals had a significant effect on pain scores. A lower age, higher number of follicles and having undergone a retrieval in the past were associated with higher pain scores. The largest effect was found on having undergone a previous oocyte retrieval, the mean pain score increases with 0.28 (95% CI 0.17-0.38) per previous puncture. In view of the large size of the participant population it is unlikely that outcomes are the result of chance.

Limitations, reasons for caution: Potential limitations of this study include; the retrospective design, the use of only one type of analgesia per centre for comparison and the use of verbal and visual pain scores (although both using a scale from 0 to 10 with whole numbers).

Wider implications of the findings: Acceptable pain scores were demonstrated following intramuscular administration of opioids during oocyte retrieval. The use of intramuscular alfentanil is unaccustomed for this procedure worldwide, but could be a cost effective and less invasive alternative for conscious sedation. Further research is needed to compare post-procedure pain, side effects and patient satisfaction.

Trial registration number: *N17.059*, trial registration number from the local Medical Ethical Committee.

P-373 Embryo implantation failure as a prognostic factor of ART outcomes: An evaluation of 3315 ART cycles

R.L. Baruffi[1,2], C.G. Petersen[1,2], A.L. Mauri[1,2], L. Vagnini[2], A. Renzi[2], B. Petersen[2], M.C. Mattila[1], V.A.A. Comar[1], A. Nicoletti[1], F. Dieamant[1,2], J.B.A. Oliveira[1,2], J.G. Franco Jr[1,2]

[1]*Centre for Human Reproduction Prof Franco Jr, Research, Ribeirao Preto, Brazil*
[2]*Paulista Center for Diagnosis Research and Training, Research, Rlibeirao Preto, Brazil*

Study question: Can the number of previous implantation failures (NIF) alone be a useful tool for predicting the outcomes of ART cycles?

Summary answer: An increase in NIF is associated with a worsening of ART outcomes but is closely related to patient age.

What is known already: As one of the main reasons for the high rate of abandoning ART programmes, implantation failure (IF) is a challenging condition. Adjuvant treatments and diagnostic investigations to improve the chances of pregnancy have been proposed. However, the use of IF alone as a prognostic factor for ART outcomes has not been evaluated.

Study design, size, duration: A single-centre prospective-cohort study on data from 3315 couples submitted to IVF/ICSI cycles (one per couple) was conducted. Only fresh embryo transfers were considered. The couples were categorized into three groups according to female age: ≤35 years, 36–39 years and ≥40 years. The NIF of each couple was recorded at the first appointment. Exclusion criteria included abnormal karyotype, uterine defects, evidence of hydrosalpinx, infections, endocrine problems, coagulation defects or thrombophilia and autoimmune defects.

Participants/materials, setting, methods: Potential confounding factors, including age, aetiologies, duration/type of infertility, type of ovarian stimulation, endometrial thickness, and number/quality and development stage of the transferred embryo, were included as variables. NIF was correlated with the presence or absence of clinical pregnancy (CP) and live birth (LB). Simple logistic regression (considering only the independent variable NIF), multiple logistic

regression (considering other cycles variables together with NIF) and ROC curve analysis were used to evaluate the results.

Main results and the role of chance: Simple logistic regression revealed that the likelihoods of CP and LB were significantly (P<0.0001) associated with NIF. Multiple logistic regression confirmed this results, although to a smaller degree. However, this influence of NIF seemed to be important only in younger women (≤35 years). In older age groups, an influence of NIF on clinical pregnancy and live birth was not observed (Table 1). In the younger group (≤35 years), for the probability of CP and LB occurrence, the ROC curve set the threshold at ≤1 for the best prognostic value.

Table 1 Regression analysis. OR:odds ratio CI: confidence interval.

	Simple Regression			Multiple Regression		
Total (3315)	**OR**	**95%CI**	***P***	**OR**	**95%CI**	***P***

≥40 years (n: 694)						
CP (n: 119)	0.96	0.88-1.04	0.31	0.94	0.86-1.03	0.19
LB (n: 66)	0.99	0.90-1.10	0.94	0.98	0.88-1.10	0.78

Limitations, reasons for caution: Including the number of transferred embryos can change the results.

Wider implications of the findings: This study highlights the importance of NIF alone in the prognosis of clinical outcomes after IVF/ICSI cycles. Changes in therapy with inclusion of procedures that may enhance the results (e.g., increasing the number of embryos transferred, PGS, time lapse) would be advisable in young patients with ≥2 IF.

Trial registration number: The local ethics committee authorised this study.

P-374 In vitro fertilization (IVF) outcomes after dramatic weight loss linked to bariatric surgery: a case-control study

V. Grzegorczyk Martin[1], A. Finet de Bantel[2], E. Bonnet[3], I. Cédrin-Durnerin[4], M. Merzouk[5], J. Roset[1], C. Avril[1], R. Wainer[5], P. Landais[6]

[5]*CHI poissy Saint germain, Médecine de la reproduction, Poissy, France*
[6]*Universite Montpellier, Clinical research university Institute, Montpellier, France*

Study question: Do women having undergone bariatric surgery achieve similar IVF outcomes as compared to women matched at the first IVF for age and body mass index?

Summary answer: Cumulative live birth rates are comparable, even after adjustment for confounding variables. Smaller weight for gestational age was observed in newborns of bariatric surgery group.

What is known already: Bariatric surgery leads to long term significant weight loss, improves spontaneous fertility, obstetrical and neonatal prognosis but increases incidence of newborn's small weight for gestational age. So far, articles concerning IVF outcomes after bariatric surgery are sparse; they included small cohorts, ranging from 5 to 40 cases, comparing IVF results both before and after surgery, or cases to obese and normal-weight patients. This is the first and the largest study matching bariatric surgery patients undergoing IVF to patients of similar Body Mass Index (BMI) and age and without a history of significant weight loss.

Study design, size, duration: This case-control study was performed from the retrospective analysis of three IVF center databases. Data from 10,287 IVF/ICSI cycles between January 1st, 2012 and December 31st, 2016 were extracted and analyzed, and all patients were followed until the pregnancy issue including newborn's state of health. Inclusion criteria for all cases were women aged 18 to 43 years old with a previous history of bariatric surgery and undergoing their first IVF cycle during this time frame.

Participants/materials, setting, methods: Each case was matched with two following controls of the same IVF centre, of similar BMI (±2 kg/m^2) and age (±2 years) and without a history of significant weight loss. A total of 249 women were included: 83 cases and 166 controls.The main outcome measure was the cumulative live birth rate after the first IVF cycle; secondary outcomes were number of mature oocytes and embryos obtained in the first IVF cycle and neonatal outcomes.

Main results and the role of chance: No significant difference in cumulative live birth rates was found between cases and controls (22.9% vs. 29.5%, respectively, p = 0.339), nor was any significant difference observed in cumulative pregnancy rates (36.1% vs. 38.6% respectively p = 0.817). Average number of mature oocytes (6.9 ± 4.9 vs 7.4 ± 4.9, p = 0.189) and embryos (4.4 ± 4.2 vs. 4.9 ± 3.8, p = 0.239) were similar between both groups. A lower BMI and higher number of good-quality embryos appeared to have a significant positive impact on the occurrence of live birth in both groups. However, multivariate conditional logistic regression analysis showed no significant difference in cumulative live birth rates after adjustment for potential confounding factors.

Additionally, miscarriage rates were found to be 41% in cases and 33% in controls (p = 0.613), and a significantly smaller weight for gestational age was observed in newborns of cases versus controls (2849 g±687 vs 3170 g±863; p = 0.002).

Limitations, reasons for caution: This is the largest study concerning live birth results in IVF bariatric surgery patients and the first to match IVF patients having undergone bariatric surgery to patients of similar BMI and age. Nonetheless, the sample size remains limited and further studies, with prospective inclusion, are needed to confirm these conclusions.

Wider implications of the findings: Bariatric surgery allowed IVF prognosis of patients with previously morbid obesity to be similar to that of comparable age and BMI women. Higher BMI negatively impacts live birth occurrence. Smaller weight for gestational age necessitates investigations concerning impact of surgery types and fresh versus frozen embryo transfers on neonatal outcomes.

Trial registration number: This study was approved by our Institutional Review Board (IRB) and registered in clinicaltrial.gouv under the number NCT02884258

P-375 Pregestational thyrotropin level and reproductive outcome of in vitro fertilisation in healthy euthyroid women

D. Grove-Laugesen[1], E. Ebbehøj[1], C. Aaskov[2], U.B. Knudsen[3]

[1]*Aarhus University Hospital, Department of Endocrinology and Internal Medicine, Aarhus C, Denmark*
[2]*Aarhus University, Clinical Institute, Aarhus, Denmark*
[3]*Regionshospitalet Horsens, The Fertility Clinic, Horsens, Denmark*

Study question: Does pregestational thyrotropin (TSH) level above 2.5 mIU/L predict delivery rates in euthyroid healthy women undergoing first in vitro fertilization (IVF)?

Summary answer: In euthyroid women TSH above as compared to below 2.5 mIU/L was associated with lower odds for clinical pregnancy and delivery.

What is known already: Thyroid hormones (TH) are vital for achieving and maintaining pregnancy. Pregnancy inflicts a vast increase in demands for TH. This impact is even greater in the setting of fertility treatment due to ovarian hyperstimulation. Elevated TSH in early pregnancy is associated with increased risk of miscarriage. Current guidelines recommend levothyroxine supplementation in women with elevated TSH undergoing IVF procedures, aiming at TSH 2.5 mIU/L. However, data on impact of pregestational TSH above 2.5 mIU/L in euthyroid women on success of IVF is sparse.

Study design, size, duration: This is a retrospective cohort study of 623 women comparing success of first IVF according to pregestational level of TSH above or below 2.5 mIU/L.

Participants/materials, setting, methods: Women with first referral for fertility treatment at Aarhus University Hospital, Denmark, January 1st 2012 until March 31th 2014 were included. Exclusion criteria were chromosomal abnormalities, comorbidity, prior levothyroxine (LT4) treatment, and lack of TSH measurement. TSH and anti-thyroperoxidase-antibodies (TPOab) were measured as part of infertility work-up. Impact on success of IVF was assessed using logistic regression adjusted for BMI, smoking, age, fertility status, and initiation of LT4. P-values of <0.05 were considered significant.

Main results and the role of chance: Overall live birth rate was 27.0 % (n = 168). 14.5 % (73) miscarried, 24.5 % (59) before week 8 of gestation. 18.3 % (114) had TSH above 2.5 mIU/L. Baseline demographics according to grouping of TSH showed no differences in age, BMI, history of smoking, fertility status or infertility diagnosis. However, women with TSH above 2.5 mIU/L had lower change of clinical pregnancy (21.1 % vs 31.0 %, p = 0.035) and delivery (18.4 % vs 28.9%, p = 0.023), despite comparable chance of conception (22.2% vs 39.9%, p = 0.19). These associations were confirmed in the adjusted analysis with odds ratio for clinical pregnancy 0.49 (95% CI: 0.27-0.90, p = 0.022) and odds ratio for delivery 0.54 (95% CI: 0.29-1.00, p = 0.049), comparing TSH above vs below 2.5 mIU/L. In crude analysis odds for any pregnancy loss was significantly higher among women with TSH above2.5 mIU/L, but not in the adjusted analysis.

TPOab was only available in a subcohort. In subanalysis adding TPOab to the adjusted regression analysis, the adverse impact of TSH on success of IVF remained regarding clinical pregnancy. In line with this finding, odds for early pregnancy loss was higher in women with TSH above 2.5 mIU/L (OR 3.43 (95% CI:1.03-11.40, p = 0.044).

Limitations, reasons for caution: TPOab are associated with increased risk of miscarriage. TPOab were available only in a subcohort. However women with or without available sample were comparable, and a subanalysis adjusted for TPOab displayed similar adverse impact of TSH above 2.5 mIU/L as in our main analysis indicating validity of our findings.

Wider implications of the findings: RCTs show improved IVF outcome when treating pregestational TSH above 4.0 or 4.5 mIU/L with LT4. Our data, though retrospective, suggests adverse IVF outcomes with TSH above 2.5 mIU/L. Future intervention studies should clarify whether additional improvement of reproductive success in IVF is obtainable treating pregestational TSH above 2.5 mIU/L.

Trial registration number: None.

P-376 Double embryo obtaining using the 1st polar body transfer technique: is it a fact or a myth?

I. Ilyin[1], N. Buderatskaya[2], J. Gontar[3], O. Parnitskaya[2], E. Ilyina[4], E. Kapustin[4], S. Lavrynenko[2], Y. Lakhno[3], M. Yaroshyk[3], N. Kazachkova[3]

[1]Reproductive Genetics Institute, IVF Department, Kyiv, Ukraine
[2]Medical Center IGR, Embryology, Kyiv, Ukraine
[3]Medical Center IGR, Diagnostic Laboratory, Kyiv, Ukraine
[4]Medical Center IGR, ART department, Kyiv, Ukraine

Study question: Could transfer of the patient's 1st polar body (PB) to donor oocyte cytoplasm be used to obtain viable embryos?

Summary answer: The 1st PB transfer technique can be used to double the number of embryos suitable for embryos transfer.

What is known already: Mainly the increase of oocytes number in patients with poor response are conducted in stem cells studies. But the 1st PB transfer technique, which is mainly applied in case of oocyte cytoplasm donation, could be used to double oocyte number for further fertilization.

Study design, size, duration: The study was performed in the Medical Centre IGR from March 2017 to January 2018. It involved 60 oocytes in each group (groups A and B) obtained from 16 patients and 11 donors, respectively. The mean age of oocyte donors and patients was 28.2 ± 2.4 and 40.4 ± 3.9 years, respectively. We evaluated embryos' euploidy and the number of zygotes and viable embryos at 48, 72, 96 and 120 hours after fertilization.

Participants/materials, setting, methods: Oocytes obtained from 16 patients with poor response. Donor oocytes had been pre-enucleated and modified by the transfer of patient's 1stPB with further fertilization. The procedure was carried out using Nikon Ti Eclipse(Japan) inverted microscope, Saturn 3 laser console(UK). Blastocyst biopsy was performed for the preimplantation genetic screening (PGS), samples were diagnosed using Ion S5 by Thermo Fisher Scientific(USA). Statistical analysis was carried out using Shapiro-Wilk test for normality, Chi-square test.

Main results and the role of chance: The number of normal fertilized oocytes in both groups was comparable and reached 46 (76.7%) zygotes in group A and 45 (75.0%) zygotes in group B. Nine oocytes (15.0%) in group A had abnormal fertilization pattern and 5 oocytes (8.3%) degraded after ICSI, whilst 14 oocytes (23.3%) in group B had abnormal fertilization and 1 oocyte (1.7%) degraded after sperm injection. Then embryos developed as follows: in 48 hours after fertilization there were 41 (68,3%) and 49 (81.7%) embryos, in 72 hours - 39 (65.0%) and 47 (78.3%), in 96 hours - 33 (55.0%) and 40 (66.7%), in 120 hours – 27 (45.0%) and 30 (50.0%) embryos, where 16 (59.3%) and 20 (66.7%) blastocysts were of high quality (5AA) in group A and group B, respectively, and there was no statistically significant difference between the groups (p>0.05). Embryos distribution by euploidiy/aneuploidy was as follows: group A –1:1 (12 euploid and 12 aneuploid embryos), group B – 1:2 (8 euploid and 16 aneuploid embryos). Next combinations of embryos' chromosome sets (obtained from patients oocytes and modified donor oocytes) were detected: euploidy/euplody (5 pairs), euploidy/aneuploidy (4 pairs), euploidy/mosaic (2 pairs), euploidy/polyploidy (1 pair), aneuploidy/euploidy (3 pairs), aneuploidy/polyploidy (2 pairs), aneuploidy/aneuploidy (7 pairs).

Limitations, reasons for caution: The 1st PB chromosome set corresponds to the oocyte nucleus and and unequal meiosis-I will result in two aneuploid embryos But the availability of two euploid oocytes obtained by transfer doesn't guarantee the presence of a normal embryo's chromosomal set, since two different spermatozoa are used for fertilization.

Wider implications of the findings: The 1st PB transfer is useful to increase the patient's chances of having a biologically native child and avoiding the oocytes donation. Also the use of this technique makes it possible to detect quantitative chromosomal abnormalities of embryos introduced by spermatozoa, in particular polyploidy and mosaicism, without any additional analyses.

Trial registration number: Not applicable.

P-377 Predictive factors for pregnancy after controlled ovarian stimulation and intrauterine insemination: A retrospective analysis of 4146 cycles

A. Michau[1], H. El Hachem[2], J. Galey[1], S. Le Parco[1], S. Perdigao[1], B. Guthauser[1], A. Rousseau[1], M. Dahoun[1], C. Guillaume[1], N. Tabchouri[1], I. Hammoud[1]

[1]ART Center, Institut Mutualiste Montsouris (IMM) 42 boulevard Jourdan, 75014 Paris, France
[2]Department of Obstetrics and Gynecology, Clemenceau Medical Center, Lebanon

Study question: What are the predictive factors for clinical pregnancy (CP) and live birth (LB) in intrauterine insemination (IUI) cycles following controlled ovarian stimulation (COS)?

Summary answer: Age <38, anovulatory infertility, ≥2 preovulatory follicles, total motile sperm count ≥5 million, and IUI cycle rank ≤3 are associated with a good outcome.

What is known already: IUI is a widely used infertility treatment in various indications, and is frequently offered first-line because it is simple, non-invasive, has a low cost and minimal risk of complications. However, its overall efficiency remains questioned, whether in natural cycles or following COS. Despite being

recommended by many international societies, it is sometimes overlooked in favor of *in vitro* fertilization (IVF), which offers higher success rates, but at a considerably higher cost. Studies have shown that many factors can affect outcomes, such as age and cause of infertility, but the impact of many other variables remains unknown.

Study design, size, duration: A retrospective unicentric study at the department of reproductive medicine of Institut Mutualiste Montsouris, a university affiliated private IVF center in Paris, France, between January 2009 (date when patient data became computerized) and December 2016.

Participants/materials, setting, methods: Patients aged 18 to 43 years who had an IUI following COS with gonadotropins were included. Donor cycles were excluded. Cycles were monitored by transvaginal ultrasounds and hormone assays. Ovulation was triggered with hCG when 1-3 follicles reached >16 mm with an endometrial thickness >7 mm, and insemination performed 36 h later. When serum LH was >10 IU/L, IUI was performed the day after hCG. Statistical analysis was performed using Chi square and logistic regression.

Main results and the role of chance: 4146 cycles (1312 couples) were included. Mean age was 34.7 ± 4 years. CP rate (CPR) and LB rate (LBR) were 11.5% and 8.1%, respectively. CPR/cycle was significantly higher in women <38 years compared to ≥38 years (12.6% versus 8.3%, p = 0.0001), in cycles with ≥2 preovulatory follicles (>16 mm) compared to 1 follicle (14.4% versus 11%, p = 0.01), and when TMSC was ≥5 million compared to <5 million (12.4% versus 7.7%, p = 0.0002). LBR/couple was 39% for anovulatory infertility (WHO group II), significantly higher (p<0.05) than unexplained infertility (28.6%), mixed (23.4%), male factor (20.1%), unilateral tubal (14.2%), low ovarian reserve (13.2%), and endometriosis (stage I and II) (11.1%). However, it was comparable to cervical factor infertility (29.3%, p = 0.11). Multivariate analysis showed the following factors were associated with CP: Cycle rank ≤3 (Odds ratio (OR) = 1.5, 95% CI: 1.2-1.9, p<0.001), age <38 years (OR = 1.5, 95% CI: 1.2-2, p<0.001), ≥2 preovulatory follicles (OR = 1.4, 95% CI: 1.1-1.8, p = 0.004), TMSC ≥5 million (OR = 1.8, 95% CI: 1.3-2.4, p<0.001). Compared to anovulatory infertility, endometriosis, low ovarian reserve, unilateral tubal, and male factor were associated with a lower CPR (OR = 0.3, 95% CI: 0.1-0.5, p<0.001; OR = 0.4, 95% CI: 0.3-0.7, p<0.001; OR = 0.5 95% CI: 0.3-0.9, p = 0.01; OR = 0.6, 95% CI: 0.4-0.8, p = 0.002 respectively).

Limitations, reasons for caution: The main limitation of our study is the unicentric retrospective design, although the large number of cycles and the fact that only COS with gonadotropins was included make the findings interesting. Moreover, a cost analysis would have been relevant in order to compare the efficacy of IUI and IVF.

Wider implications of the findings: Our study confirms that IUI can be an efficient treatment in selected indications. Young patients with anovulatory infertility seem to be the ideal candidates, with a 39% LBR per couple. These data need to be validated in prospective trials, but can be used to council patients on the treatment choice.

Trial registration number: Not applicable.

P-378 In vivo conceived embryos recovered by nonsurgical uterine lavage: Preliminary experience

S. Nakajima[1], S. Najmabadi[2], S. Munné[3], M. Sauer[4], M. Angle[5], C. Nezhat[6], S. Carson[7], J. Buster[8]

[3]*CooperGenomics, Genomics Laboratory, Livingston- NJ, U.S.A.*
[4]*Robert Wood Johnson Medical School, Obstetrics- Gynecology and Reproductive Sciences, New Brunswick- NJ, U.S.A.*
[5]*Laurel Fertility Center, Embryology Laboratory, San Francisco- CA, U.S.A.*
[6]*Center for Special Minimally Invasive and Robotic Surgery, Research Laboratory, Palo Alto- CA, U.S.A.*
[7]*American Congress of Obstetricians and Gynecologists, Education Department, Washington- DC, U.S.A.*
[8]*Warren Alpert Medical School of Brown University, Obstetrics and Gynecology, Providence- RI, U.S.A.*

Study question: After controlled ovarian hyperstimulation (COH) and intrauterine insemination (IUI), can embryos be recovered by uterine lavage using an automated programmable lavage catheter?

Summary answer: In a series of 69 cycles of superovulation followed by IUI, uterine lavage recovered 48 embryos in 25 (36.2%) of cycles.

What is known already: Early work performed by Buster and colleagues in 1983 recovered embryos from the uterus by lavage in natural cycles. Prior attempts performing lavage after COH and IUI failed to recover embryos consistently and resulted in unintended pregnancies in the ovum donors. The current uterine lavage catheter prior to its use in this study underwent extensive bench and in vivo testing for fluid dynamics and the ability to recover known numbers of implanted artificial and human tissue (discarded oocytes and in vitro conceived embryos). Subjects gave their consent for any embryo recovered to be donated to research.

Study design, size, duration: We performed a single site, prospective, feasibility study in 54 women to evaluate the safety and efficacy of a new uterine lavage system (Previvo Genetics, Inc., San Carlos, CA). Subjects gave their written informed consent for the research protocol approved by Western Institutional Review Board. All lavages were performed in Punta Mita, Mexico during August 2017 to January 2018 by a single investigator. Subjects were followed for 30-days post-lavage to monitor for complications.

Participants/materials, setting, methods: 54 women were pretreated with oral contraceptives and stimulated with gonadotropins for 69 COH cycles. Ovulation was triggered with either 5,000 IU of human chorionic gonadotropin (hCG) or leuprolide acetate 4 mg and 2,500 IU of hCG, followed by IUI of donor sperm 36 hours after trigger. Uterine lavage occurred 4-6 days after the IUI. After lavage, uterine curettage performed and a GnRH antagonist injection (0.25 mg/day) was given for 3 days.

Main results and the role of chance: A total of 69 lavages were performed in 54 women with a mean age of 25.7 years (range 19-38) and 44% were nulliparous. Mean subject BMI was 25.4 kg/m^2 (range 17.8-36.7). In the COH cycles, subjects were mildly stimulated an average of 9.2 days of gonadotropins (mean rFSH 733 IU total dose, mean hMG 722 IU total dose). Ovulation trigger was given when there was at least 2 dominant follicles ≥18 mm. After IUI, uterine lavage recovered embryos in 25 (36.2%) cycles (range 0-4/cycle). A total of 48 embryos were recovered: 18 (37%) multi-cell embryos, 7 (15%) morulas and 23 blastocysts (48%). Six (12%) morulas progressed to blastocysts, for a total of 29 blastocysts (60%). Blastocysts were of high quality, 79% (23/29) were 3BB or higher. All embryos regardless of stage were biopsied, vitrified and cryopreserved. All subjects menstruated after the GnRH antagonist injections. Eight cycles (11.6%) had detectable hCG levels (>2 mIU/mL) after their menses, that regressed spontaneously in two, declined after curettage in one and persisted after curettage in five. Persistent hCG levels (highest level 2,652 mIU/mL) were treated with one dose of methotrexate (50 mg/m^2) in 3 cycles and two doses in 2 cycles.

Limitations, reasons for caution: Although sample size is small, there were progressive increases in embryo recovery due to improvements in lavage technique. It is difficult, however, to determine the efficiency of each lavage, because we are unable to verify the number of oocytes ovulated and number of embryos available for recovery.

Wider implications of the findings: Uterine lavage offers a nonsurgical minimally invasive approach to recovering embryos in patients at risk for a multiple gestation after IUI or desire preimplantation genetic screening or diagnosis for genetic conditions without IVF.

Trial registration number: Trial registration number is pending.

P-379 Frozen-thawed embryos generated from a successful fresh IVF cycles have higher potential for favorable outcome than frozen-thawed embryos obtained from unsuccessful fresh cycles

A. Simon, S. Herzberg, A. Ben-Meir, B. Reubinoff, G. Karavani

Hadassah Hebrew University Medical Center, Department of OB/GYN - P.O. Box 12000, Jeruzalem, Israel

Study question: Whether a successful fresh in-vitro fertilization (IVF) cycle correlates with better outcomes of frozen-thawed embryo transfers (FT-ET) from same ovum pick-up.

Summary answer: Frozen-thawed embryos generated from successful fresh embryo transfer cycles have a higher potential to implant when compared to frozen-thawed embryos obtained from unsuccessful fresh cycles.

What is known already: Many variables, including woman's age, embryo quality and endometrial receptivity, influence the success rate of either fresh embryo transfer (ET) or FT-ET cycles. Patients frequently ask whether previous successful fresh IVF attempt is a positive prognostic factor for their FT-ET.

Study design, size, duration: A retrospective cohort study comprised of 2218 patients that underwent IVF treatment in a single IVF unit between 1997 and 2017.

Participants/materials, setting, methods: Patients who underwent fresh ET and at least one consecutive FT-ET cycle at Hadassah Medical center IVF unit were included in the study. Comparison of FT-ET cycles details and outcomes were assessed in relation to the outcome of the preceding fresh ET cycles. Statistical analyses were performed to evaluate the correlation between the outcome of fresh ET attempt and its consecutive FT-ET cycle.

Main results and the role of chance: Six hundred and seven out of 2218 patients achieved clinical pregnancies in their fresh ET (27.4%). No difference was found in the number of retrieved oocytes, maturity rates, fertilization rates and embryo quality distribution between fresh cycles resulting in clinical pregnancy and failed fresh cycles. When the outcome of the consecutive frozen cycles were compared between patients with successful and unsuccessful fresh ET cycles, a significant higher pregnancy rates were observed, for either per patient or per treatment cycle (37.2% vs. 32.1% and 26.6% vs. 21.8%; $p = 0.01$ and $p = 0.026$, respectively). This was substantiated by the McNemar test which showed a significant association between a successful fresh cycle and positive outcome in the consecutive FT-ET cycle ($P<0.001$).

Limitations, reasons for caution: The retrospective design of our study makes it more prone to bias. Assessment is performed for a long period of time where culture condition and laboratory work might be differing between patients and for each particular patient.

Wider implications of the findings: A successful fresh IVF-ET attempt that resulting in a clinical pregnancy can serve as a positive prognostic factor for the subsequent FT-ET cycle. Among other parameters, this finding provides an important information for the clinician when counseling patients before carrying out their frozen thawed ET cycle.

Trial registration number: Not applicable.

P-380 Results from a novel transnational fresh egg donation program based on frozen sperm and embryos shipping

A. La Marca[1], M. Dal Canto[2], M. Valerio[1], R. Fadini[2], S. Brazal[3], R. Vassena[3], A. Rodriguez[3], M. Mignini Renzini[2]

[1]*Clinica Eugin, Clinic, Modena, Italy*
[2]*Biogenesi, Reproductive Medicine Center, Monza, Italy*
[3]*Clinica Eugin, Clinic, Barcelona, Spain*

Study question: To investigate the clinical efficacy of a novel fresh oocyte donation program based on transportation of semen and embryos between two countries.

Summary answer: This novel fresh-egg donation program based on international transportation of frozen embryos is highly effective. When blastocysts are available, the success rate is very high.

What is known already: Despite several advantages of oocyte vitrification in donation cycles, recent large cohort studies suggest that oocyte vitrification may lead to lower live birth rates compared with fresh gametes. On the contrary, increasing evidence suggest comparable outcomes with frozen compared to fresh embryo transfer. Hence, a new strategy could be to treat recipient in countries with limited availability of oocyte donors: the shipping of frozen sperm of the partner to the center where the donor will undergo pick up, insemination of fresh oocytes, the vitrification and shipment of the resulting embryos and to the country of origin.

Study design, size, duration: A retrospective cohort study of donor oocyte IVF cycles with elective vitrified-thawed embryo transfer and shipping from December 2015 to July 2017 between two IVF clinics in different European countries. All donors were stimulated with a GnRH antagonist protocol with GnRH agonist trigger; oocytes were inseminated by ICSI with frozen/thawed semen. Recipients' endometrium was prepared with a standard dose of 6 mg estradiol valerate and 800 mg vaginal progesterone in the last days before the transfer.

Participants/materials, setting, methods: A total of 630 patients were available for statistical analysis. In 11% of cases the semen used was from a donor, in the remaining 89% it was from the male partner and was frozen and transported to the oocyte donation clinic. Resulting embryos were vitrified between with an open system on day +2 or on +5, and shipped back to the original clinic for transfer.

Main results and the role of chance: The main reasons for treatment were female age (40%), reduced ovarian reserve or menopause (25%) and previous IVF failures (21%). The mean (±SD) age of the patients was 42.3 ± 4.2 years. The oocytes were obtained from healthy donors aged 26.2 ± 4.4 years. The number of mature oocytes assigned to each recipient was 6.8 ± 1. The mean number of 2PN and viable frozen embryos per patient was 4.9 ± 1.56 and 4.17 ± 1.5, respectively. For the 630 patients, a total of 1066 embryos were warmed; the survival rate was 98.5% (n = 1051). After the first embryo transfer, the clinical pregnancy rate (CPR) and ongoing pregnancy rate (OPR) were 43 and 31.9% respectively. The embryos were transferred at the cleavage stage (day 2 or 3) in 476 patients (75.5%) and the OPR was 30.6%. The single and twin pregnancy rates were 73 and 27%, respectively. Vitrified blastocysts were available for 154 patients and the CPR and OPR were 44 and 37%, respectively. The median number of days between donor oocyte pick up and the frozen embryo transfer was 63.

Limitations, reasons for caution: Limitations include the retrospective design, sample size and data from a single institution.

Wider implications of the findings: This study reports an oocyte donation program based on transfer of frozen embryos transported between countries. This system eliminates the need to align the timing of donor oocyte retrieval with the embryo transfer to recipients, while using fresh oocytes for treatment.

Trial registration number: Not Applicable.

P-381 The effect of the oocyte donor's and recipient's ages the on cumulative live birth rate: a population-based cohort study

R. Hogan[1], A. Wang[1], Z. Li[1], L. Johnson[2], K. Hammarberg[3], E. Sullivan[1]

[1]*University of Technology Sydney, Faculty of Health, Sydney, Australia*
[2]*Victorian Assisted Reproductive Treatment Authority, Chief Executive Officer, Melbourne, Australia*
[3]*Monash University, School of Public Health and Preventative Medicine, Melbourne, Australia*

Study question: What is the impact of the donor's and recipient's ages on the cumulative live birth rate (CLBR) in oocyte donation cycles?

Summary answer: Recipients using oocytes from donors aged 35 years and older had a significantly lower CLBR compared to recipients using oocytes from donors aged <35 years.

What is known already: Cycle-based statistics show that the donor's age is a major determinant of success in oocyte donation/recipient programmes and that the age of the oocyte recipient has less impact on pregnancy and live birth rates. There is no existing evidence about the impact of the donor's and the recipient's ages on CLBR in oocyte donation cycles.

Study design, size, duration: A population-based retrospective cohort study used data from the Victorian Assisted Reproductive Treatment Authority in Victoria, Australia. This study included 1,490 women commencing assisted reproductive technology using donated oocytes between 2009 and 2016. Demographic characteristics, treatment type and resulting pregnancy and birth outcomes were recorded for the stimulated cycle and associated thaw cycles until 30 June 2016, or until a live birth was achieved, or until all embryos from the stimulated cycle had been used.

Participants/materials, setting, methods: Women using donated oocytes in Victoria, Australia from 2009-2016 were included. The association between the donor's/recipient's ages and CLBR was measured by adjusted hazard ratio (AHR) in multivariate Cox regression. The following covariates were included: cause of infertility, parity and number of embryos transferred (1 or 2). Donor

age was grouped as <30, 30-34, 35–37, 38-40, and 41+ years and recipient age as <35, 35–37, 38–40, 41-42, 43-44 and 45+ years.

Main results and the role of chance: The mean age of the oocyte donors was 33.7 years (range 21 to 45 years) with 64.9% under 35 years. The mean age of the oocyte recipients was 41.4 years (range 19 to 45 years) with 60% of the oocyte recipients aged under 40 years and 25.4% aged 45+ years.

There was a significant relationship between donor's age and CLBR. The CLBR for recipients with donors aged <30 years and 30-34 years was 44.7% and 43.3% respectively. This decreased to 33.6% in donors aged 35-37 years, 22.6% in donors aged 38–40 years and 5.1% in donors aged 41+ years. Compared with recipients with donors aged <30 years, recipients with donors aged 38-40 years had 22.1% less chance to achieve a live birth (AHR 0.60, 95% CI 0.43–0.86) and recipients with donors aged 41+ years had 39.6% less chance to achieve a live birth (AHR 0.14, 0.04–0.44). The multivariate analysis showed no significant differences in the success by recipient's age. Advanced male age was not associated with a decrease in the likelihood of live birth.

Limitations, reasons for caution: The use of data from one state in Australia limits the generalizability of the results. Number of cycles was used as the time variable in Cox regression, which does not account for the time difference between cycles among recipients.

Wider implications of the findings: These estimates can be used when counselling women about their likelihood of having a baby using donated oocytes, and to inform public policy as currently there are no national Australian recommendations on the age of women who donate their oocytes.

Trial registration number: Not applicable.

P-382 Fully automated assay assessment of intra- and inter-cycle variation for Anti-Müllerian hormone during the natural cycle

L. Melado Vidales[1], B. Lawrenz[1], J. Sibal[2], E. Abu[2], A. Navarro[3], H. Mousavi Fatemi[1]

[1]*IVI Middle East Fertility Clinic, Medical department, Abu Dhabi, United Arab Emirates*
[2]*IVI Middle East Fertility Clinic, Laboratory department, Abu Dhabi, United Arab Emirates*
[3]*IVI Foundation., Statistical Department, Valencia, Spain*

Study question: Does Anti-Müllerian Hormone (AMH) have important intra- and inter-cyclic variations during the natural cycle when a fully automated assay is used for the sample analysis?

Summary answer: With the use of a fully automated assay, AMH shows significant intra- and intercycle variations during the natural cycle, not caused by analytical variability.

What is known already: AMH has emerged as one important clinical marker for ovarian reserve. Fully automated assays reduce analytical variability and enables more accurate evaluation of biological variations. The hormone shows strong correlation to the number of antral follicles and provides an important baseline assessment for individualizing of the therapeutic strategy in assisted reproductive techniques (ART). AMH has been considered a reliable test to be measured any day of the cycle without substantial variation. However, recent data have pointed towards important inter- and intra-cycle fluctuations and questioned whether a single AMH measurement is sufficient for decision-making in ART.

Study design, size, duration: Prospective study including 22 volunteers from April to December 2017. Blood samples for AMH, FSH, LH, estradiol, and progesterone were obtained by venous puncture during the natural cycle on day 2/3, day 10, day of LH surge (LH surge was defined as LH concentration rise by 180% above the latest serum value), luteal phase (confirmed by elevated progesterone levels 8 days after LH surge), and day 2/3 of the subsequent bleeding.

Participants/materials, setting, methods: Healthy volunteers between 18–37 years of age were included, with regular menstrual cycles and a BMI between 18-28 kg/m2. Exclusion criteria: Intake of hormonal contraceptives for two previous months, pregnancy, breastfeeding, previous conditions with possible impact on the ovarian reserve (ovarian surgery, chemotherapy, radiation of the pelvis, …). Blood for AMH-evaluation was stored at -20°C. For batch analysis, two kits of Elecsys® AMH automated (Roche for Cobas 601 platform®) were used.

Main results and the role of chance: A total of 99 samples from 22 women with a median age of 30,7 ± 4,11 years and a BMI of 23,2 ± 3,63 were analysed. A substantial longitudinal fluctuation in AMH levels was found, expressed as coefficient of variation (CV) intra-cycle of 0,207, calculated for all individual readings per cycle day. Clinically, AMH value varied 20,7% throughout the cycle from the first serum analysis obtained at the beginning of the cycle with no clear pattern of fluctuation. Serum AMH levels were significantly altered by BMI and age ($p<0,001$), both negative correlated with AMH values. A positive correlation between LH and AMH concentrations was found ($p = 0,01$), but not to other hormones. Absolute intra-individual inter-cyclic variability of AMH (cycle-day 2-3 in two consecutive cycles) was 0,75 ng/mL (range: 0,03 ng/mL – 2,81 ng/mL) and inter-cycle CV was 0,28 (Confidence interval: 0,16-0,39; $p<0,0001$). No differences were found comparing variability of AMH between the assays used. The observed AMH fluctuations across the cycle are noticeably higher than expected from the assay imprecision and therefore seem more likely to be caused by biologic variability.

Limitations, reasons for caution: This study reports limited number of study subjects. However, an average of 4.5 blood-samples study subject were assayed in one run, eliminating inter/intra-assay bias in the normal cyclic women included. Further studies will have to investigate, whether AMH-fluctuations are also present in other subgroups of population.

Wider implications of the findings: The large intercycle and intracycle AMH fluctuations in the same woman during her natural cycle using an automated assay keeps the question open on the best time to measure AMH for decision-making in daily practice. Further RCTs evaluating AMH dynamics and its correlation with treatment outcomes should be conducted.

Trial registration number: This trial has been registered for clinical.trials.gov: NCT03106272.

P-383 Can "patient-friendly" salivary hormone measurements replace serum monitoring of IVF patients? An European multi-center assessment

D. Sakkas[1], L. Atkinson[2], A. Borini[3], E.A. Bosch[2], C. Bryce[4], M. Cattoli[3], A. Finet de Bantel[5], B. French[6], S. Gaitonde[4], J. Gerris[7], S. Granger[4], V. Grzegorczyk-Martin[5], C. Howles[8], S. Somers[7], M. Alper[6]

[2]*IVI-RMA Valencia, Clinic, Valencia, Spain*
[3]*Tecnobios Procreazione S.r.l., Clinic, Bologna, Italy*
[4]*Salimetrics LLC, Research, Carlsbad, U.S.A.*
[5]*Clinique MATHILDE, Laboratoire d'Assistance Médicale à la Procréation, Rouen, France*
[6]*Boston IVF, Clinic, Waltham- MA, U.S.A.*
[7]*Gent University Hospital, Vrouwenkliniek, Gent, Belgium*
[8]*Preglem S.A., Medical Affairs, Geneva, Switzerland*

Study question: Can a saliva based Estradiol (E2) assay replace the use of blood monitoring during a controlled ovarian stimulation (COS) cycle for IVF/ICSI?

Summary answer: Salivary E2 based hormone testing provides an equivalent alternative to serum based assessment and may become the preferred method of COS monitoring in the future.

What is known already: Salivary diagnostic testing is emerging as a less invasive, inexpensive alternative to serum analyte measurements with proven diagnostic accuracy in clinical settings. This study aimed to determine the performance of a salivary hormone competitive immunoassay for monitoring patient E2 levels during monitored cycles for infertility treatment. Such treatments encompass: Undergoing monitored infertility treatment employing controlled ovarian stimulation (COS) with oral agents or gonadotropins for Ovulation induction/ IUI and COS for IVF/ICSI.

Study design, size, duration: The prospective study was performed at 4 different European clinics (Italy, Spain, Belgium, France), between 9/2016-11/2017, whereby at each venipuncture appointment, subjects also collected a saliva sample via passive drool according to the assay specifications. In total 152,

214, 184 and 104 samples were collected from 59, 122, 40 and 40 patients respectively. Between 1 and 6 samples were collected from each individual patient. 122 patients collected ≥3 samples in an individual cycle.

Participants/materials, setting, methods: Saliva samples were coded, de-identified and stored frozen. They were then run blinded in a separate facility. Saliva and serum correlation were calculated using the matched mean saliva and serum assay results for all E2 data points collected. Pearson product moment correlations of the serum and saliva were conducted using the natural log transformed data. Data was assessed per clinic and overall taking into account the different serum E2 testing platforms used per clinic.

Main results and the role of chance: One to six salivary E2 samples were analyzed for each patient. In the four clinics the correlation coefficients of Saliva E2 to serum values were Italy: r = 0.69, p < 0.001; France: r = 0.53, p <0.001; Belgium: r = 0.75, p < 0.001; Spain: r = 0.79, p <0.001. Mean (±SD) serum E2 values (pg/ml) differed between clinics reflecting different demographics and approaches to patient stimulation [Italy: 803 ± 760, France: 862 ± 892; Belgium: 1174 ± 933; Spain: 1276 ± 1026. The respective mean (±SD) saliva values (pg/ml) were 17 ± 9, 26 ± 15, 24 ± 14 and 24 ± 14. When examining individual patients who collected ≥3 samples in one cycle, more than 75% of patients showed an individual within cycle correlation of >0.7 and 62% a correlation of >0.9. Patients with discolored saliva samples generally showed poor correlations, indicating that they failed to collect according to protocol. Patient surveys have also shown that saliva based hormone testing is associated with improved patient satisfaction and decreased stress.

Limitations, reasons for caution: The results could be limited as the study was conducted in an unselected population of all patients performing IVF. A further limitation was that although patients were informed on collection protocols it was evident that some patient saliva samples may have been sub optimally collected which influences the assay outcome.

Wider implications of the findings: Rapid, salivary E2 based hormone testing provides an equivalent alternative to serum based assessment. The ease of saliva sampling allows a reduction in treatment burden, improved patient satisfaction and decreased stress. Saliva based hormone tests may become the preferred method of hormone monitoring for fertility treatments in the future.

Trial registration number: NCT03162809.

P-384 Premature progesterone elevation is associated with decreased uterine artery blood flow and clinical pregnancy rate

C. Kim[1], J.W. Moon[2], H.J. Kim[1], B.M. Kang[1]

[1]*Asan Medical Center- University of Ulsan, Obstetrics Gynecology, Seoul, Korea-South*

[2]*M Fertility Center, Gynecology, Seoul, Korea- South*

Study question: Could premature progesterone elevation (PE) affect the uterine artery (UA) perfusion and IVF outcome?

Summary answer: PE on the day of hCG is associated with decreased UA blood flow and clinical pregnancy rate (CPR) in infertile patients undergoing IVF.

What is known already: Controlled ovarian stimulation (COS) is correlated with premature PE and it is generally believed to have an adverse effect on pregnancy outcome in infertile patients undergoing IVF. Although many possible mechanisms of decreased pregnancy rate by premature PE have been discussed, the causes has not been completely elucidated. Moreover, the study on the effect of premature PE on UA blood perfusion has not been reported.

Study design, size, duration: This retrospective study included 108 infertile patients who had their blood taken for measurement of serum progesterone on the day of hCG in stimulated IVF cycles between February 2015 and January 2017.

Participants/materials, setting, methods: The association of serum progesterone levels (group 1: ≤ 1.5 ng/ml, group 2:1.5-2.0 ng/ml, group 3: > 2.0 ng/ml) measured on the day of hCG with IVF outcome and resistance index (RI) and pulsatility index (PI) of UA on the day of embryo transfer (ET) was evaluated in 108 cycles corresponding to 108 patients who underwent IVF in COS cycles using GnRH antagonist protocol.

Main results and the role of chance: Patients' characteristics were comparable among three groups. Total days of gonadotropins used for COS was significantly longer in group 1 than in group 2 or 3 (*P*=.012 vs group2, *P*=.040 vs group 3, respectively). The number of oocytes retrieved was significantly higher in group 3 than in group 1 (*P*=.029). However, there were no differences among three groups with respect to the numbers of mature oocytes, fertilized oocytes and good quality embryos. RI of UA was significantly higher in group 3 than in group 1 or 2 (*P*<.001, *P*<.001). PI of UA was also significantly higher in group 3 than in group 1 or 2 (*P*<.001, *P*<.001). CPR seemed to be lower in group 3, but this difference did not attain the statistical significance (*P*=.076 between group 1 and 3, *P*=.087 between group 2 and 3). When CPR was compared between the two groups with each progesterone levels ≤ 2.0 ng/ml and > 2.0 ng/ml, CPR was significantly lower in the group with PE (*P*=.034).

Limitations, reasons for caution: This study has a limitation to evaluate the impact of premature PE on UA blood flow and IVF outcome due to a retrospective nature and small number of sample available. The effect of premature PE should be investigated according to the different responders to COS in a bigger patient pool.

Wider implications of the findings: Premature PE (especially > 2.0 ng/ml) can result in a decrease of UA blood flow and it can be one of contributing factors of decreased CPR by premature PE in IVF cycles.

Trial registration number: None.

P-385 Does the effect of body mass index on in vitro fertilization with GnRH-antagonist protocol in polycycstic ovary syndrome vary with the level of androgen?

W. Yang, R. Yang, J. Zhang, T. Pang, F. Deng, Y. Wang, J. Qiao

Peking University Third Hospital, Center for Reproductive Medicine- Department of Obstetrics and Gynecology, beijing, China

Study question: Does the effect of body mass index on in vitro fertilization with GnRH-antagonist protocol in polycycstic ovary syndrome vary with the level of androgen?

Summary answer: Economic benefits were achieved in hyperandrogenism-PCOS patients with less cost and more available embryos. Overweight and hyperandrogenism both have significantly negative effects on pregnancy outcomes.

What is known already: Endocrine disturbances are complicated in polycycstic ovary syndrome (PCOS) patients. hyperandrogenism (HA), and obesity interact with each other and promote PCOS progression. However, few studies to date have investigated body mass index (BMI) and androgen level together. Moreover, there are limited literatures that investigate the clinical phenotype of PCOS patients that can benefit most from the GnRH-antagonist protocol during in vitro fertilization (IVF). Therefore, the present study was designed to evaluate whether the effect of BMI in PCOS varies with the level of androgen on IVF with GnRH-antagonist protocol.

Study design, size, duration: A total of 583 infertile women between 20 and 35 years of age who underwent IVF using the conventional GnRH antagonist protocol at a single center between January 1, 2013, and December 31, 2015, were included in this retrospective cohort study.

Participants/materials, setting, methods: Patients were divided into 4 groups: BMI<25 kg/m^2 with normal androgen level (group 1, n = 218), BMI<25 kg/m^2 with hyperandrogenism (group 2, n = 152), BMI≥25 kg/m^2 with normal androgen level (group 3, n = 117), BMI≥25 kg/m^2 with hyperandrogenism (group 4, n = 96).

Main results and the role of chance: Number of retrieved oocytes was significantly higher in lean PCOS patients compared with overweight PCOS patients. Available embryos were significantly higher whereas Gn stimulation days and total Gn dosage were significantly lower in the HA PCOS group, compared with non-HA PCOS patients. Clinical pregnancy rate was of no significant difference among four groups. Live birth rates in overweight PCOS groups were significantly lower when compared with group 1 (23.9%, 28.4% vs. 42.5%, P<*0.05*). Abortion rate in group 4 was significantly higher than group 1 (45.2% vs. 14.5%, P<*0.05*). Logistic regression analysis revealed that BMI and androgen level both acted as significant influence factors for abortion rate.

Limitations, reasons for caution: One major limitation of our study is the retrospective design. hyperandrogenism, obesity, and hyperinsulinemia are the mainly endocrine disturbances in PCOS patients. Prospective studies should

investigate the effects of hyperinsulinemia and BMIs on IVF outcomes in patients undergoing the GnRH-antagonist protocol to determine their impact on HA.

Wider implications of the findings: Economic benefits were achieved in HA-PCOS patients with less cost and more available embryos. Due to the high abortion rate and low live birth rate, a freeze-all approach might be a preferable option for HA-PCOS patients so as to create a buffer for reducing androgen levels before transferring freeze-thawed embryos.

Trial registration number: None.

P-386 Excessive intrauterine interventions negatively affect in vitro fertilization (IVF) outcomes in women with repeated IVF failure

E. Usoltseva[1], L.K. Dzhemlikhanova[2], D.A. Niauri[3], I.Y. Kogan[4], A.M. Gzgzyan[4]

[1]D.O.Ott Research Institute of Obstetrics and Gynecology RAMS, Assisted Reproductive Technologies Department, Saint Petersburg, Russia C.I.S.
[2]Saint-Petersburg State University, Department of Obstetrics- Gynecology and Reproductology, Saint Petersburg, Russia C.I.S.
[3]Saint-Petersburg State University, Department of Obstetrics- Gynecology and Reproductology, Saint-Petersburg, Russia C.I.S.
[4]D.O.Ott Research Institute of Obstetrics- Gynecology and Reproductology, Assisted Reproductive Technologies Department, Saint Petersburg, Russia C.I.S.

Study question: Does the number of performed intrauterine interventions have an impact on IVF outcomes in women with repeated IVF failure?

Summary answer: The previous history of an excessive number of intrauterine interventions appears to have an adverse effect on IVF outcomes in women with repeated IVF failure.

What is known already: The necessity for comprehensive assessment of endometrial morphology and function in women with repeated IVF failure along with the lack of the non-invasive assessment methods oblige us to perform an invasive intrauterine procedure to get endometrial samples. However, even the minimally invasive intrauterine procedures carry a slight risk of infection and can cause destruction of the endometrium right through to its basal layer. The damaged endometrial basal layer can be responsible for residual fertility impairing changes. However, there is still a lack of systematic analysis to assess the number of intrauterine interventions as a risk factor for IVF outcomes.

Study design, size, duration: A retrospective observational cohort study includes 131 women with previously repeated IVF failure undergoing fresh IVF or cryo cycle in a single University-affiliated infertility clinic. The study was conducted from September 2011 to February 2014.

Participants/materials, setting, methods: The female patients with repeated implantation failure (after at least two previous attempts of embryo transfer) under the age of 40 years with two or more high-quality embryos were enrolled for the study. The history of previously performed intrauterine interventions (both diagnostic and curative, not only a uterine curettage but also minimally invasive procedures) was taken into account.

Main results and the role of chance: On average each woman included in the study had 5,32 ± 0,23 intrauterine interventions (1,85 ± 0,10 uterine curettage procedures and 4,29 ± 0,21 minimally invasive procedures). The number of performed uterine curettage procedures didn't correlate to the IVF outcome (R = 0,031, p = 0,76), while there was a moderate, but significant negative correlation between the number of minimally invasive intrauterine procedures and the implantation rate (R=−0,21, p = 0,013). A logistic regression analysis demonstrated that more than three previously performed intrauterine procedures in women with repeated IVF failure were associated with subsequent implantation failure (OR 2,20; 95%CI 1,06-4,56).

Limitations, reasons for caution: In the retrospective study not all pertinent risk factors could be identified and subsequently recorded. So only association, and not causation, can be inferred from the results. These data for the risk factor analysis were received just from one center. It should be validated using the dataset from other centers.

Wider implications of the findings: These data may provide information for the development of an effective strategy of preconceiving care in women with repeated implantation failure with reasonable rejection of excessive uninformative ineffective intrauterine procedures. The data also could be considered for explanatory and prognostic purposes.

Trial registration number: Not applicable.

P-387 The correlation between oocyte diameter and blastocyst quality

R. Bassil[1], J. Haas[1], Z. Eran[1], M. Chaula[1], C. Robert[2]

[1]University of Toronto- Trio fertility center, ObGyn, Toronto, Canada
[2]University of Toronto- Trio fertility center- Lunenfeld Research Institute, ObGyn-Physiology, Toronto, Canada

Study question: Is there an association between the diameter of the oocyte and the quality of its corresponding blastocyst?

Summary answer: When comparing the ratios of oocyte diameters, the lower the ratio the higher the chance of developing to better quality blastocyst.

What is known already: The reproductive capacity of females decreases significantly in the fourth decade which is directly correlated to an age-related decrease in oocyte quality and quantity. The fact that the live birth rates from oocyte donation in older women is consistent suggests that oocyte quality is the major factor responsible for infertility. Decreased substrate for ATP production and increased mitochondrial deoxynucleic acid (mtDNA) mutations might be involved in increased loss and decreased quality of ovarian follicles in older women. An association between low mitochondrial DNA copy and the ability of the oocyte to become fertilized has been described.

Study design, size, duration: It is a retrospective study conducted at Trio Fertility Center in Toronto, Ontario, Canada affiliated with University of Toronto. We collected all the data from the IVF cycles conducted in 2015 in which an embryoscope was used to visualize the progression of the embryos.

Participants/materials, setting, methods: We retrospectively analyzed the cycles of 470 women where the embryoscope was used which gave us a total of 1914 embryos. The embryoscope's diameter function was used to measure the mature oocytes' (M IIs) diameter at the stage where the first polar body is visible. Two measurements were taken for each oocyte and the average diameter as well as the ratio were calculated.

Main results and the role of chance: We didn't find any correlation between the diameter of the oocyte and the development to a top quality embryo. The diameter of oocytes that developed to a top quality blastocyst compared to the diameter of the oocytes that did not develop to the blastocyst stage was similar (112.3 vs. 112.5 micro)

We did find a correlation between the ratio of the oocytes' two diameters and the development to a top quality blastocyst. The oocytes with a ratio below 1.1 had higher probability to develop to a top quality blastocyst compared to oocytes with ratio above 1.2 (15% vs 5% p <0.001).The probability of oocytes to arrest prior to the blastocyst stage was increased in the group of oocytes with a ratio above 1.2 compared to the oocytes with the ratio below 1.1 (80% vs. 66% p< 0.01)

Limitations, reasons for caution: None.

Wider implications of the findings: The study shows that as the ratio of the oocyte diameters increases, the chances of it developing to a good quality embryo decreases. In other words, the lower the ratio, meaning the more spherical the shape of the oocyte the more likely it will develop to a good quality blast.

Trial registration number: Not applicable.

P-388 Age stratified Anti-Müllerian Hormone (AMH) reference range evaluation in polycystic ovary syndrome women at reproductive age using an automated AMH assay

L. Sun[1], S. Retka[1], C. Lejeune[2], D. Broyles[3]

[1]Beckman Coulter- Inc., Product Management, Chaska, U.S.A.
[2]Beckman Coulter- Inc., Research & Development, Marseille, France
[3]Beckman Coulter- Inc., Clinical Affairs, Carlsbad, U.S.A.

Study question: Do AMH levels differ significantly between age groups in PCOS women?

Summary answer: The AMH levels in PCOS women are substantially higher compared to age-matched healthy controls and decrease significantly with increased age.

What is known already: AMH has been proposed as a surrogate test for follicular count in the diagnosis of PCOS. Although there has been interest to define a universally agreed threshold of serum AMH in PCOS women, studies have shown AMH levels and age have a negative correlation in PCOS women. The age stratified AMH reference ranges for PCOS women at reproductive age has not been determined using the automated AMH assays.

Study design, size, duration: This study was a multi-center, prospective, cross-sectional study of 146 PCOS women enrolled from March 2016 to August 2016. The study used four geographically diverse sites in the United States.

Participants/materials, setting, methods: The study included PCOS women aged 18–45 years who met the Rotterdam criteria. The age stratified AMH reference ranges were established, and the difference of AMH distributions between age groups were further analyzed using the Kruskal-Wallis test. A comparison of PCOS reference ranges was made to age-matched healthy adult females. Serum samples were measured at a separate, single site using the Beckman Coulter Access 2 immunoassay system and the Access AMH assay.

Main results and the role of chance: Age stratified AMH reference ranges were established in 146 PCOS women with AMH levels ranging from 0.03 to 34.6 ng/mL. Age was categorized as 18-25 (n = 16), 26-30 (n = 51), 31-35 (n-41), 36-40 (n = 23), and 41-45 (n = 15) years. Median AMH levels categorized by age for PCOS women demonstrated a decreasing trend (7.11, 7.35, 6.77, 3.95 and 1.63 ng/mL, respectively) with increased age, but were statistically significantly higher than apparently healthy age-matched adult women. Overall, median AMH level for PCOS women was 3 times higher than apparently healthy adult women with a statistical significance (6.02 vs. 1.83 ng/mL, respectively, p-value<0.0001). Kruskal-Wallis test showed substantial difference in AMH distributions between the age groups (p-value = 0.0022) in PCOS women, and the Pearson's correlation analysis confirmed a negative relationship between AMH levels and age (r=-0.229, 95%CI=-0.379 – -0.069, p-value = 0.0054).

Limitations, reasons for caution: The small sample size represents a limitation.

Wider implications of the findings: To our knowledge, this is the first study that established the age stratified AMH reference ranges using the automated AMH assay in PCOS women. AMH distributions in PCOS women differ significantly between age groups, questioning the use of one universal AMH threshold for PCOS women at all ages.

Trial registration number: Not Applicable.

P-389 Mitochondrial DNA copy number in peripheral blood: a potential non invasive biomarker for female subfertility

A. Busnelli[1], D. Lattuada[2], A. Paffoni[3], E. Somigliana[1]

[1]*IRCCS Ospedale Maggiore Policlinico Regina Elena, Obstet-Gynecol, Milano, Italy*
[2]*Fondazione IRCCS Ca' Granda- Ospedale Maggiore, Department of Obstetrics and Gynaecology-, Milan, Italy*
[3]*Fondazione IRCCS Ca' Granda- Ospedale Maggiore, Department of Obstetrics and Gynaecology, Milan, Italy*

Study question: Does the mitochondrial DNA copy number (mtDNAcn) in peripheral blood have the potential to serve as a non invasive biomarker for female subfertility?

Summary answer: A mtDNA peripheral blood level below 105 mtDNAcn resulted associated with a five-folds increased risk of subfertility, providing a possible way of predicting this condition.

What is known already: Low mtDNA content in oocytes and in cumulus cells is a significant indicator of poor oocyte quality and may prevent the oocyte from completing the process of fertilization and embryo development. Furthermore, and of utmost relevance, is the recent evidence showing a correlation between mtDNA content in cumulus cells and mtDNAcn in peripheral blood cells.

Study design, size, duration: This is a nested case-control study drawn from a prospective cohort of pregnant women referred for routine first trimester screening for aneuploidies (from 11+0 to 12+6 weeks of gestation) between January 2012 and March 2013 at the "Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico" of Milan, Italy.

Participants/materials, setting, methods: Cases were subfertile women who attempted to become pregnant for 12–24 months. Controls were the two subsequently age-matched women who became pregnant in less than one year. Blood samples were obtained from all participating women. MtDNA was quantified using real time PCR and normalized to nuclear DNA.

Main results and the role of chance: One hundred and four subfertile women and 208 matched fertile controls were selected. The median (interquartile range) mtDNAcn was 95 (73-124) and 145 (106-198), respectively (p<0.001). The area under the receiver operating characteristic (ROC) curve was 0.73 (95% Confidence Interval-CI: 0.67-0.79) (p<0.001). The Youden index was 105 mtDNAcn. The crude odds ratio for subfertility in women with mtDNAcn below this threshold was 5.72 (95%CI: 3.43-9.55). We repeated these analyses in different age groups: the accuracy of mtDNAcn assessment in peripheral blood resulted higher in younger women and progressively decreased with increasing age.

Limitations, reasons for caution: We did not perform an infertility diagnostic work-up of the couples and we are thus unable to rule out other potential causes of subfertility. However, severe concomitant causes of infertility can be confidently ruled out since all women conceived within two years.

Wider implications of the findings: MtDNAcn assessment in peripheral blood appears to have all the features of the much sought non-invasive biomarker of female fertility. Noteworthy its performance resulted very good in young women. Our results may thus have future clinical applications. However, further independent studies including non-pregnant women undergoing high throughput screening are warranted.

Trial registration number: Not applicable.

P-390 Prognostic of IUI depends of the number of motile spermatozoa inseminated and patient age, however high concentrations are always detrimental: an analysis of 9618 cycles

C. Grysole[1], S. Phillips[1,2], M.P. Velez[3], R. Antaki[1,2], F. Bissonnette[1,2], I.J. Kadoch[1,2]

[1]*Faculty of Medicine- University of Montreal, Obstetrics and Gynecology, Montreal, Canada*
[2]*OVO Clinic, OVO Fertility, Montreal, Canada*
[3]*Queen's University, Obstetrics and Gynecology, Kingstone, Canada*

Study question: What is the impact of the number of motile spermatozoa inseminated (NMSI) on clinical pregnancy rates (CPR) in intrauterine insemination (IUI) according to patient age?

Summary answer: The NMSI positively influences the CPR of IUI for women between 30 and 40 years, while not for women under 30, or older than 40.

What is known already: Many authors have studied the effects of the NMSI on the success of IUI, but a real consensus has not yet been achieved. A minimum of 1 M (million) motile spermatozoa inseminated is often quoted as required to optimize IUI but several authors question this threshold. Some studies have shown that the pregnancy rates were higher if the NMSI exceeds 2 M or 5 M. However, according to a recent study, female age is the only variable significantly correlated with IUI success rates. NMSI and female age have rarely been studied together.

Study design, size, duration: This is a retrospective cohort study, in which 4394 couples completed 9618 IUI cycles with partner sperm, between January 2011 and December 2015, at a University-affiliated private ART clinic in Montreal.

Participants/materials, setting, methods: All couples had been trying to conceive without success for at least 1 year. Indications for IUI included moderate male factor, dysovulation and unexplained infertility. IUI was performed after a natural cycle (n = 180) or an ovarian stimulation by clomiphene citrate or letrozole (n = 7611) or gonadotropins alone (n = 218) or in addition to letrozole (n = 1609). The outcome measure was clinical pregnancy rates defined by an intrauterine gestational sac with heartbeat visible with ultrasonography at 7 weeks.

Main results and the role of chance: The 9618 cycles were divided into four groups based on the NMSI as follows: group 1, <1 M; group 2, 1 to 4 M; group 3, 5 to 10 M; group 4, ≥10 M. In women younger than 30 years (n = 1814 cycles), CPR between the four groups were not significantly different (6.4%, 14.8%, 13.7% and 14.1%, respectively; p = 0.20). Nevertheless, the CPR appeared clinically lower in group 1. In women 30 to 34 (n = 3499 cycles), CPR were significantly different between groups (2.9%, 10.2%, 15.6%, and 15.0%, respectively; p<0.001). In women 35 to 39 (n = 3083 cycles), CPR were also different between the groups (5.5%, 10.5%, 8.0%, 14.2%, respectively; p = 0.001). Thus, better results are observed if the NMSI is ≥5 M between 30 and 34 years, and if the NMSI is ≥10 M between 35 and 39 years. For patients ≥ 40 years (n = 1222 cycles), CPR were not different by groups of NMSI (4.7%, 5.4%, 6.3%, 9.7%, respectively; p = 0.21), although the CPR seemed to double between groups 1 and 4. Less pregnancies in the older age group could explain the lack of significance. Interestingly, we noted that an NMSI ≥150 M had a detrimental effect on CPR any age combined (10.0%, p<0.001).

Limitations, reasons for caution: Our population was heterogeneous; all indications of inseminations combined. Ovulation stimulation treatments varied and the therapeutic strategy was physician-dependent. However, the very high number of cycles adds strong value to our study and the NMSI is a standardized data.

Wider implications of the findings: The only study analyzing the NMSI by age category reported no difference in CPR in women older than 25, possibly due to a lack of statistical power. Our study suggests that in women 30-39 years with NMSI<5 M, IUI results in lower CPR, thus IVF should be considered a first option.

Trial registration number: Not applicable.

P-391 The effect of weight intervention on obstetric and neonatal outcome in obese women scheduled for IVF treatment

S. Einarsson[1], B. Christina[2], L. Kluge[2], A. Thurin-Kjellberg[2]

[1]*Livio Reykjavik, Reproductive medicine, Reykjavik, Iceland*
[2]*University of Gothenburg, Reproductive Medicine, Gothenburg, Sweden*

Study question: What is the effect of a low calorie diet weight intervention in obese women prior to IVF on maternal and neonatal outcome?

Summary answer: No differences in maternal and neonatal outcomes between the study groups were found and most pregnancies were successful with healthy children and few maternal complications.

What is known already: Fertility, obstetric and neonatal outcome are negatively affected in obese women. A recent Dutch randomized trial of infertile women and lifestyle weight intervention with a weight loss of 3,3 kg, found no difference in live birth rate, obstetric or neonatal outcomes. In previously published data from our trial no effect on live birth rates were found despite large weight loss (9,44 kg). A difference was found in spontaneous pregnancies leading to live birth and was in favor of the weight intervention, 10,5% (16/152) versus 2,6% (4/153) in the control group.

Study design, size, duration: This is a secondary analysis of a prospective, multicenter, randomized controlled trial that was performed between 2010 and 2016 in the Nordic countries. 305 women were randomized to one of two groups; weight reduction intervention followed by IVF-treatment or IVF-treatment only. The weight reduction included 12 weeks of a low-calorie liquid formula diet (LCD), of 880 kcal per day followed by two to five weeks of diet re-introduction and weight stabilization before IVF treatment started.

Participants/materials, setting, methods: Nine infertility clinics in Sweden, Denmark and Iceland participated. Women under 38 years of age planning for IVF, and having a body mass index (BMI) ≥30 and <35 kg/m^2 were randomized to two groups: an intervention group (152 patients) with weight reduction before IVF, starting with 12 weeks of a low calorie liquid formula diet of 880 kcal/day and thereafter weight stabilization for 2-5 weeks, or a control group (153 patients) with IVF only.

Main results and the role of chance: There were 87 live births; 45 singletons in the intervention group and 41 singletons and one twin birth in the control group. The characteristics of the women having a live birth were comparable in the two groups. The mean age and infertility length were 31,4 years and 35,3 months in the intervention group and 30,7 years and 36,6 months in the control group. The infertility diagnoses were comparable. None of the maternal and neonatal outcomes differed significantly between the intervention and the control group: cesaerean section 28,9% vs. 24,4%, OR: 1.14 (CI: 0.45; 2.94); preeclampsia 11,1% vs. 9,8%, OR: 1.19 (CI: 0.30; 4.76); gestational diabetes 2.2% vs. 4.9%, OR: 0.45 (CI: 0.04; 5.21); postpartum hemorrhage >1000 ml 4.4% vs. 12.2%, OR: 0.34 (CI: 0.06; 1.88); preterm birth <37 weeks 4.4% vs. 2.4%, OR: 1.95 (CI: 0.17; 22.36); low birth weight <2500 g 4.4% vs. 2.4%, OR: 1.95 (0.17; 22.36). No children within the study were treated in a neonatal intensive care unit or had a major malformation observed within the first week of life. When comparing the women who achieved a live birth through a spontaneous pregnancy in the different randomization groups no significant differences were found for any variables.

Limitations, reasons for caution: The study was not designed or powered to detect differences in maternal or neonatal outcome nor was it blinded for patients or physician. Further, the intervention group had longer time to achieve a spontaneous pregnancy, but was slightly older than the control group at IVF.

Wider implications of the findings: Maternal and neonatal outcomes were satisfactory in both groups. Although estimates of absolute values and OR indicated no differences between groups in any outcomes, the 95% CI were generally wide meaning that clinical important differences may exist.

Trial registration number: ClinicalTrials.gov number, NCT01566929

P-392 The predictive value of pulsatility index for pregnancy after assisted conception: a systematic review

M. Eyo[1], P. Smith[2], J. Chu[3], A. Coomarasamy[4]

[1]*Tommy's National Centre for Miscarriage Research Institute of Metabolism and Systems Research -, Academic Department - Third Floor - Birmingham Women's Hospital NHS Foundation Trust University of Birmingham- Metchley Park Road - Edgbaston- Birmingham-,*
[2]*Tommy's National Centre for Miscarriage Research - Institute of Metabolism and Systems Research - University of Birmingham -, Academic Department - Third Floor - Birmingham Women's Hospital NHS Foundation Trust - Metchley Park Road - Edgbaston- B15 2TG,*
[3]*Tommy's National Centre for Miscarriage Research - Institute of Metabolism and Systems Research - University of Birmingham -, Academic Department - Third Floor - Birmingham Women's Hospital NHS Foundation Trust - Metchley Park Road - Edgbaston- Birming,*
[4]*Tommy's National Centre for Miscarriage Research - Institute of Metabolism and Systems Research - University of Birmingham - Academic Department - Third Floor - Birmingham Women's Hospital NHS Foundation Trust - Metchley Park Road - Edgbaston- Birmingh*

Study question: Is there a difference between the uterine vascularity of women who get pregnant and the uterine vascularity of women who do not become pregnant after assisted conception.

Summary answer: The pregnant group had a significantly lower uterine pulsatility index when compared with the non-pregnant group [WMD -0.14; 95% confidence interval (CI): -0.22,-0.06; p = 0.000].

What is known already: Angiogenesis is critical for the development of the endometrium to enable successful embryo implantation. Pulsatility index is a marker of resistance to blood flow which can be used to quantify and compare downstream blood flow to tissues. Our study is the first systematic review to investigate whether the vascularity of the endometrium correlates with assisted conception outcomes.

Study design, size, duration: The electronic databases EMBASE and MEDLINE Were systematically searched, up to October 2017, for publications that studied the differences in pulsatility index measurements between women who became pregnant and women who did not become pregnant after assisted conception. Twenty-nine papers met the inclusion criteria, which included 4022 participants in total.

Participants/materials, setting, methods: Participants included infertile women who were undergoing either IVF, frozen embryo transfer or intrauterine insemination. 1292 became pregnant and 2730 did not become pregnant

after assisted conception. Causes of infertility included a range of male and female factors. The studies were performed in the fertility clinic setting. Pulsatility index measurements were taken using transvaginal ultrasound at various points prior to embryo transfer.

Main results and the role of chance: The search produced a total of 758 studies which were all retrieved. A total of 29 cohort studies were included in the review. A raised mean PI (>3) was present in 1 study within the group of pregnant women and present in three studies within the group of non-pregnant women. Overall the pregnant group had a significantly lower uterine pulsatility index when compared with the non-pregnant group [WMD -0.14; 95% confidence interval (CI): -0.22,-0.06; p = 0.000; 29 studies]. Pulsatility index measurements taken within a day of embryo transfer most reliably correlated with the primary outcome after assisted conception [WMD -0.18, 95% CI 0.26, -0.10); p = 0.065; 10 studies), however this could be due to chance. There was a high degree of heterogeneity (I^2 = 44%).

Limitations, reasons for caution: There was significant heterogeneity between studies, with variation in population characteristics and the treatment protocols given to participants. Using the Newcastle-Ottawa scale for assessing quality, the included studies were considered "satisfactory".

Wider implications of the findings: This review suggests that women with a lower uterine pulsatility index are more likely to achieve pregnancy, after assisted conception. Further research is required to determine whether there is a cut-off pulsatility index above which pregnancy is not possible and to determine the most reliable test of endometrial vascularity.

Trial registration number: CRD42017059529

P-393 Comparison of Cap-Score™, TUNEL, and semen analysis in couples undergoing timed intercourse and IUI

P. Xie[1], A. Parrella[1], A. Travis[2], D. Keating[1], Z. Rosenwaks[1], G. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.
[2]Cornell University, College of Veterinary Medicine, Ithaca, U.S.A.

Study question: What relationships exist among Cap-Score™ (test of sperm capacitation), TUNEL (test of DNA fragmentation) and traditional semen analysis parameters?

Summary answer: Cap-Score™ didn't correlate with semen analysis or TUNEL. However, TUNEL had a strong negative correlation with motility, making determination of cause of fertilization failure difficult.

What is known already: High sperm DNA fragmentation and diminished capacitation response may impair conception with timed intercourse or intrauterine insemination (IUI). Terminal deoxynucleotidyl transferase dUTP Nick End Labeling (TUNEL) is widely used to assess breaks within sperm DNA. CapScoreÔ measures the proportion of sperm that respond to capacitation stimuli by assessing localization changes in GM1, a key regulator of capacitation and acrosome exocytosis. One prior study showed no relationship between Cap-Score™ and semen analysis, whereas multiple conflicting reports exist on the relationship of TUNEL and semen analysis. No one has previously assessed the potential correlation of Cap-Score™ and TUNEL.

Study design, size, duration: In the past 3 months, ejaculates were obtained from 41 consenting men for infertility screening. Preliminary pregnancy outcomes were also collected. Statistical relationships among semen analysis, TUNEL and Cap-Score™ were assessed. Potential linear associations between Cap-Score™ or TUNEL and traditional semen parameters were assessed by Pearson's Product-Moment Correlation. Any potential relationship between TUNEL and Cap-Score™ was evaluated similarly, and "normal vs abnormal" Cap-Score™ and TUNEL were examined by Chi-Square.

Participants/materials, setting, methods: To control for female confounding factors, inclusion criteria consisted of couples with female partners ≤ 35 years old with normal uterine cavity and patent fallopian tubes. Semen samples were processed by density gradient centrifugation according to WHO 2010 criteria. Post-wash specimens were sent to Androvia LifeSciences for Cap-Score™ assessment. Cap-Scores™ ≥27.6% were considered "normal". DNA strand breaks were assessed by TUNEL on at least 500 spermatozoa under fluorescent microscopy. TUNEL scores £15% were considered "normal".

Main results and the role of chance: Cap-Score™ was independent of ejaculate volume (r = 0.075; p = 0.571), concentration (r=-0.032; p = 0.810), percentage of motile sperm (r = 0.005; p = 0.967) and percentage of sperm having strict normal morphology (r = 0.010; p = 0.942). No relationship was observed between Cap-Score™ and TUNEL, either linearly (r=-0.091; p = 0.571), or when grouped into normal or abnormal bins and evaluated by Chi-Square (p = 0.524). Conversely, a very strong negative relationship was observed between TUNEL and the percentage of motile sperm (r=-0.930; p<0.001), meaning that as DNA fragmentation increased, motility decreased. Of the 41 men, TUNEL was abnormal in 11 (26.8%) and Cap-Score was abnormal in 19 (46.3%). In the 11 patients with abnormal TUNEL (mean = 24.1), no natural conceptions were yet reported, nor in the 2 cycles of IUI for which outcomes are known. Of the 30 having normal TUNEL, there were 3 natural conceptions and 5 conceptions out of 9 cycles of IUI for which outcomes are known. In the 22 men having normal Cap-Scores™, 3 natural conceptions occurred, whereas none occurred in the 19 men with low Cap-Scores™. In couples pursuing IUI with normal Cap-Scores™, there were 3 pregnancies out of 6 cycles for which outcomes are known; 2 of 5 cycles with a low result achieved pregnancy with IUI.

Limitations, reasons for caution: These data clearly indicate that the ability of the sperm to capacitate does not correlate with sperm DNA strand breaks. Clinical outcomes represent preliminary data from a limited number of couples. More clinical outcomes data are needed to determine the efficacy of either test at predicting conception by different means.

Wider implications of the findings: This is the first report showing that Cap-Score™ and DNA fragmentation are not related. As assessed by TUNEL, high DNA fragmentation correlated with decreasing motility. To better test and inform infertile couples, the addition of proven biomarkers to the standard semen analysis would help to identify those who can conceive.

Trial registration number: N/A.

P-394 A novel maternal age and blastocyst cohort size-based prediction model estimating the probability of obtaining at least one euploid blastocyst for transfer in IVF/ICSI cycles

S. Esteves[1], J.F. Carvalho[2], C. Martinhago[3], A.M. Dias[3], P. Humaidan[4], C. Alviggi[5], A. Conforti[5], F. Ubaldi[6], R. Fischer[7], K. Bühler[8], C.Y. Andersen[9]

[3]Chromosome, Center for Genomic Medicine, São Paulo, Brazil
[4]Faculty of Health- Aarhus University, Fertility Clinic Skive- Skive Regional Hospital, Skive, Denmark
[5]University of Naples Federico II, Department of Neuroscience- Reproductive Science and Odontostomatology, Naples, Italy
[6]GENERA, Center for Reproductive Medicine, Rome, Italy
[7]Fertility Center, Hamburg, Hamburg, Germany
[8]Center for Gynecology- Endocrinology, and Reproductive Medicine, Stuttgart, Germany
[9]University Hospital of Copenhagen- Faculty of Health and Medical Sciences, Laboratory of Reproductive Biology, Copenhagen, Denmark

Study question: Can a statistical prediction model estimate the probability of achieving at least one euploid blastocyst as a function of female age and embryo cohort size?

Summary answer: Our novel predictive model estimates the minimum blastocyst cohort size needed to achieve at least one euploid blastocyst for transfer given a specified probability.

What is known already: Array comparative genomic hybridization data indicate a negative correlation between female age and embryo euploidy. Aneuploidy rates do not differ significantly by cohort size in women of same age, and the proportion of women with at least one euploid blastocyst is increased when more embryos are available. An individualized estimate of the couple's probability of having a euploid blastocyst and the number of blastocysts needed to achieve this goal before treatment can be used for counseling and treatment planning. Also, estimation of this

probability after the embryos are generated may aid doctors to set patient expectations.

Study design, size, duration: Retrospective analysis of 1,220 trophectoderm biopsy results from 436 infertile couples undergoing assisted reproductive technology (ART) cycles and preimplantation genetic testing for aneuploidy (PGT-A) between 2016 and 2017. PGT-A was used for reasons of advanced maternal age, severe male factor infertility, recurrent miscarriage, repeated implantation failure, as well as patients who were concerned about the euploidy status of their embryos.

Participants/materials, setting, methods: Biopsied trophectoderm cells were subjected to next-generation sequencing (NGS) analysis using the Ion PGM™ platform. Logistic regression was fit to the dataset, with female age as the predictor and the status of the embryos (euploid or aneuploid) as the response. The best model was chosen and validated by randomly splitting two portions of the data, 80% for training and the remaining 20% for testing. Computations were carried out using JMP 13 (www.jmp.com).

Main results and the role of chance: Given a blastocyst cohort, the number of euploid blastocysts (M) is a random variable with a binomial distribution. The quadratic model on female age was significant (Prob>ChiSquare = 0.028). A model-independent verification by aggregating the data in age bins revealed that the estimated probability distribution was verified in the validation dataset. The model was not biased as there was linearity in the relationship between the fitted probabilities and empirical data. The minimum number of blastocysts needed for obtaining at least one euploid blastocyst for transfer can be computed for different probabilities. At the age of 28 years, the model estimates that a total of three blastocysts is required to obtain at least one euploid blastocyst with 90% probability, whereas it is 4, 5, 6, 9, 16 and 29 for ages 35, 37, 39, 41, 43, and 45, respectively. Furthermore, an embryo cohort size of 2, 3, 5, 7, and 11 are required to obtain at least one euploid blastocyst with 80% probability for ages 28, 35, 39, 41, and 43, respectively.

Limitations, reasons for caution: External validation is currently being performed. Other covariates that could affect embryo genetic status were not analyzed. Furthermore, the model is not intended to be generalized to IVF patients undergoing cleavage-stage embryo transfer and should not be used for making decisions about whether or not patients should undergo treatment.

Wider implications of the findings: This novel resource will aid clinicians counsel and plan treatment of couples regarding the embryo cohort size needed to obtain at least one euploid blastocyst for transfer.

Trial registration number: Not applicable.

P-395 Women with polycystic ovary syndrome are at increased risk of postnatal depression

M. Davies, W. March, M. Whitrow, R. Fernandez, V. Moore

The University of Adelaide, The Robinson Institute, Adelaide, Australia

Study question: Are women with polycystic ovary syndrome (PCOS) at elevated risk for postnatal depression (PND)?

Summary answer: For women with PCOS, a history of miscarriage and assisted conception interacted ($p = 0.06$ and $p < 0.05$, respectively), with 56% having PND.

What is known already: Maternal depression associated with pregnancy and childbirth, known as postnatal depression (PND), is a debilitating condition that can have a significant impact on the health and wellbeing of the woman, her child and her wider family. PND is likely to be under-diagnosed but is estimated to affect 10-20% of mothers in western countries.

Women with PCOS have increased susceptibility to depression and anxiety, which is an identified risk factor for PND. The potential for a link between PCOS and PND has not previously been published.

Study design, size, duration: The Lucina study is a community based retrospective birth cohort of female births from 1973-75 at a single maternity hospital in Adelaide, South Australia. Participants were traced and enrolled at age 30-31, with n = 566 providing data for the current study.

Participants/materials, setting, methods: Details of reproductive history, pregnancy, birth, and PND were obtained through structured face to face interview with study participants. PCOS was diagnosed using the Rotterdam criteria. Comparisons were made between women with and without PCOS using logistic regression analysis including the investigation of interactions.

Main results and the role of chance: Compared to their counterparts, women with PCOS were substantially more likely to have difficulty conceiving (OR = 5.2, 95% CI 2.9-9.4), to have conceived with medical assistance (OR = 11.6, 95% CI 5.5-24.4), and to have pregnancy complications (gestational diabetes, pregnancy-induced hypertension, or pre-eclampsia, OR = 2.0, 95% CI 1.1-3.5). A positive but statistically non-significant association was observed between PCOS and PND (OR = 1.6, 95% CI 0.9-2.9) for the overall group. However, where women with PCOS had a history of miscarriage or conceived with medical assistance, the combination interacted ($p = 0.06$ and $p < 0.05$, respectively), with 56% of these women having PND.

Limitations, reasons for caution: Susceptibility to PND for women with PCOS could be due to either their perturbed hormonal and metabolic profiles, or to distress created by PCOS symptoms and their management. Due to limitations in power, the study was not able to calculate risks for specific PCOS sub-phenotypes or treatments received.

Wider implications of the findings: As the first study to investigate postnatal depression (PND) in women with polycystic ovary syndrome, findings point to vulnerability inherent in PCOS being amplified, or by specific fertility treatment regimens. This highlights a potential need for targeted postnatal follow-up of women with PCOS.

Trial registration number: Not applicable.

P-396 Comparison of the treatment outcomes in women with unicornuate uterus undergoing ART versus controls with normal uterine anatomy: a nested case-control retrospective analysis

Y. Chen[1], V. Nisenblat[2], C. Ma[2]

[1]*Peking University Third Hospital, 49 North Garden Rd.-Haidian District Beijing -P.R. China, Beijing, China*

[2]*Peking University Third Hospital, Center of Reproductive Medicine- Department Obstetrics and Gynecology, Beijing, China*

Study question: Are the ART outcomes different in women with unicornuate compared to normal uterus and whether culture to blastocyst improves the outcomes in unicornuate uterus group?

Summary answer: In unicornuate uterus implantation rate following fresh embryo transfer and cumulative live-birth rate are lower than in normal uterus. Blastocyst transfer significantly improved clinical outcomes.

What is known already: Unicornuate uterus have been associated with a decreased risk of obstetrics complications with lower birth rate, mainly due to an increased risk of miscarriage and very preterm birth. It remains unclear, whether women with unicornuate uterus who undergo IVF-ICSI have different response to ovarian stimulation and whether implantation and pregnancy rates in these women are different from those in women with normal uterus.

Study design, size, duration: A retrospective nested case-control study was conducted at the Reproductive Medical Center of Peking University Third Hospital. The participants were recruited from the cohort of women who underwent IVF-ICSI cycles between 2012 and 2016, identified by using centralized computer database. Consecutive women diagnosed with unicornuate uterus and randomly selected controls with normal uterus were included. The controls were matched 1:3 by age, cause of infertility and number of embryos transferred.

Participants/materials, setting, methods: The study population comprised 342 women with unicornuate uterus (study group) and 1026 patients with normal uterus (control group). Demographic and clinical information was retrieved from the electronic records. Cumulative live birth rate upon one complete IVF cycle, including all resulting embryos was considered as a primary outcome measure. Other outcomes included number of oocytes retrieved, endometrial thickness, implantation rate, number of embryos obtained, clinical pregnancy, multifetal gestation, miscarriage rate.

Main results and the role of chance: The demographic characteristics, duration and causes of infertility were comparable between the groups. There was higher rate of primary infertility in unicornuate uterus group. Unicornuate uterus was associated with significantly lower endometrial thickness on day of hCG ($p<0.001$) and lower number of oocytes retrieved ($p = 0.016$), although

peak E2 levels did not differ between the groups. The number of embryos transferred per cycle, day-3 or blastocysts was similar between the study and control groups. Transfer of day-3 embryos in fresh cycle was associated with lower implantation rate (23.7% vs. 32.5%, p<0.001) and lower live-birth rate (26.9% vs. 34.4%, p = 0.031) per transfer. On contrast, frozen embryo transfer (FET) of day-3 embryos did not result in different implantation and live birth rate between the groups (p = 0.288 and p = 0.686, respectively). Blastocyst transfer led to comparable rates of implantation and live birth between the two groups in either fresh and frozen cycles. The cumulative live birth rate following one complete IVF-ICSI cycle including all the resulting FET was 42.4% in women with unicornuate uterus vs. 52.8%; p = 0.001 in controls. Subgroup analysis revealed that blastocyst transfer in women with unicornuate uterus led to significantly higher live birth rate than cleavage transfer (40% vs. 53%, p = 0.045).

Limitations, reasons for caution: Retrospective nature and no information on the obstetrics and neonatal outcomes are the main limitations of this study. Not all women treated in 2016 utilized their available embryos from the index stimulation cycle and were not included in estimation of cumulative live birth rate.

Wider implications of the findings: Lower implantation and pregnancy rates following fresh but not frozen cleavage embryo transfers and significantly improved outcomes with blastocyst culture were observed in unicornuate compared to normal uterus. This suggests considering blastocyst transfer or freeze all policy in women with unicornuate uterus, which warrants evaluation in prospective randomized setting.

Trial registration number: not applicable.

P-397 Should couples with low sperm count in the first intrauterine insemination (IUI) cycle continue IUI treatment?

S. Huang[1], R. Wang[2], R. Li[3], H. Wang[4], B.W.J. Mol[5], J. Qiao[6]

[1]*Center of Reproductive Medicine- the Third Hospital of Peking University, Department of Obstetrics and Gynecology, Beijing, China*
[2]*Robinson Research Institute, Department of Obstetrics and Gynaecology, Adelaide, Australia*
[3]*Centre of Reproductive Medicine- Peking University Third Hospital-, - Department of Obstetrics and Gynaecology-, Beijing, China*
[4]*Centre of Reproductive Medicine- Peking University Third Hospital-, Department of Obstetrics and Gynaecology, Beijing, China*
[5]*Monash Medical Centre- Monash Health and Monash University, Department of Obstetrics and Gynaecology, Clayton, Australia*
[6]*Centre of Reproductive Medicine- Peking University Third Hospital, Department of Obstetrics and Gynaecology, Beijing, China*

Study question: Should couples with low post-wash total motile count (TMC) in the first intrauterine insemination (IUI) cycle continue IUI treatment?

Summary answer: Couples with low post-wash TMC in the first IUI cycles can continue IUI treatment without compromising their fertility outcomes.

What is known already: IUI is the treatment of first choice for couples with unexplained or mild male infertility. The post-wash TMC in the first IUI cycle can be used to predict pregnancy, and at present many couples switch to IVF after a first poor post-wash semen analysis. However, it is unknown if a poor post-wash TMC in the first IUI cycle is predictive for future IUI outcomes. To study the association between post-wash TMC and outcomes of future IUI cycles, we compared live birth rates in women undergoing IUI in relation to their post-wash semen analysis.

Study design, size, duration: We performed a retrospective cohort study in the Reproductive Medicine Centre of Peking University Third Hospital.

Participants/materials, setting, methods: We included couples with unexplained or mild male infertility treated with IUI in two consecutive cycles with similar protocols. Women with polycystic ovary syndrome were not included. We compared live birth rates in the second cycle according to different groups in post-wash TMC in the first cycle.We also compared the baseline characteristics and clinical pregnancy between groups with different post-wash TMC. ANOVA and Chi square analysis were conducted in SPSS 19.0.

Main results and the role of chance: We studied 4,496 IUI cycles in 2,248 couples, of which 2,732 were unstimulated cycles and 1,764 were cycles stimulated with CC, letrozole or gonadotropins. We sorted data according to their post-wash TMC in the first cycle in ascending order and then divided all patients into eight equal groups. Medians of sperm count were 0.6, 1.3, 2, 3, 4, 5, 7, and 13. Live birth rates in the second cycle were 6.1%, 6.4%, 7.5%, 8.9%, 6.1%, 7.8%, 6.1%, and 7.5%, respectively. Likelihood ratios for various categories of the post wash TMC varied between 0.68 and 1.41, with most likelihood ratios being close to 1, indicating no predictive performance of the post-wash TMC in the first cycle for subsequent pregnancies.

Limitations, reasons for caution: Our study was retrospective, and we included only cycles in which the insemination was performed.

Wider implications of the findings: Our study shows that in couples treated with IUI, the post-wash semen analysis should not be used to select women who should continue IUI or switch to IVF.

Trial registration number: Not applicable.

P-398 Prediction models for IUI success incorporating male age are more accurate among older women

K. Shlush[1], J. Julia[2], S. Moskovtsev[2], L. CliffordLibrach[2]

[1]*Rabin Medical Center Petah Tikva- Israel., OBGYN, Herzliy, Israel*
[2]*CReATe Fertility Centre, IVF unit, Downtown Toronto, Canada*

Study question: What factors are important to predict who will not benefit from IUI and who should be recommended for IVF directly.

Summary answer: We identified clinical and laboratory parameters that predicted a low probability for pregnancy with IUI. These are patients who should be move directly to IVF.

What is known already: The decision of which assisted reproductive technology (ART) method is most suitable for specific subfertile couples is complicated. Intrauterine insemination (IUI) with or without ovulation induction is commonly offered to subfertile couples without bilateral mechanical factor or severe male factor. On average after three to six IUI cycles without pregnancy, couples will be recommended to undergo IVF. IUI success rate predictors have been suggested to be moderately accurate in the past, however older studies did not include ovarian reserve parameters and modern male factor parameters.

Study design, size, duration: In the current study we evaluated the predictive capacity of different parameters in predicting IUI success, and constructed a generalized linear regression model (LRM). A total of 467 patients (1342 IUI cycles) were studied retrospectively.

Participants/materials, setting, methods: Clinical and laboratory parameters significantly different between patients with clinical pregnancy and without clinical pregnancy were identified. The following parameters were significantly different: male age, duration of infertility, AMH, antral follicle count (AFC), DNA fragmentation index (DFI), number of follicles and E2 levels at HCG trigger, and total motile sperm count (TMC). These parameters were used to construct a two-step predictive model.

Main results and the role of chance: Our prediction model was able to identify couples with low probability for pregnancy upfront (less than 5% chance) that should be referred directly to IVF without any IUI cycle. This prediction could have saved going through failed IUI for 20.5% of patients. Later after the first IUI cycle a second predictive score was calculated and identified couples with low pregnancy probability who should be referred to IVF after one IUI cycle (26% of patients). Our predictive model was most accurate for females older than 40 years old (AUC = 0.775), with number of follicles before HCG trigger, male age, and DFI being the most important factors.

Limitations, reasons for caution: This is a single center retrospective study that should be validated prospectively.

Wider implications of the findings: Altogether, based on these results we conclude that after the first IUI cycle a predictive score can be calculated. Couples with a low score (pregnancy probability <5%) should be referred to IVF.

Trial registration number: REB #20120043-E.

P-399 Fresh or vitrified: comparing the number of oocytes necessary to achieve reproductive success in egg donation programme

H. Visnova, R. Huttelova

IVF CUBE, Reproductive Medicine, Prague 6, Czech Republic

Study question: Does egg banking provide comparable outcome to fresh egg donation cycles, what are the oocyte-to-blastocyst and oocyte-to-baby rates per fresh and vitrified oocyte?

Summary answer: Compared to vitrified, fresh oocytes gain more available blastocysts, higher implantation rates and more babies born, higher number of surplus blastocysts increases cumulative success rate.

What is known already: Vitrification of oocytes represents an effective method resulting in pregnancy rates per embryotransfer similar to usage of fresh oocytes. Vitrification and banking of oocytes offers an advantage for both clinics and recipients in terms of management, timing and lesser treatment cancelations. However, due to losses during warming and fertilization failures, the number of available blastocysts declines. Metric methods calculating success rates per oocyte provide more accurate picture of the biological efficiency than standard pregnancy rate per embryotransfer. According to available data, the live birth rate per fresh donated oocytes, even with the best-prognosis group of young donors, is only 7.3%.

Study design, size, duration: A retrospective comparative analysis of 266 fresh egg donation cycles and 63 cycles using vitrified donor oocytes performed from January 2016 to December 2016.

Comparison parameters included age of oocyte donors, age of recipients, total gonadotrophin dose and average duration of stimulation. Total oocyte number and number of metaphase II oocytes, survival rate, fertilization rate, blastocyst rate, implantation rate and ongoing pregnancy rates per ET and per oocyte were calculated.

Participants/materials, setting, methods: All donors underwent gonadotrophin stimulation in antagonist protocol. Antagonist administration was initiated from day 6 of stimulation. GnRH-a (triptorelin 0.2) was used as a trigger and egg collection was performed 35–36 hours later. Oocytes were vitrified using Sage media and closed system. Both fresh and warmed oocytes were inseminated using ICSI. Both groups of fertilized oocytes underwent identical culture and handling conditions.

Main results and the role of chance: There was no statistically significant difference noted for age of donors, body weight or BMI, nor total gonadotrophin dose, duration of stimulation, no difference in age of recipients between both groups. There was no difference observed in terms of fresh oocytes and vitrified oocytes per recipient's treatment cycle (10,89 ± 2,00 vs 11,36 ± 3,14, p = 0,14).

Fertilization rate of fresh oocytes was higher (84,81% vs 72,97%, p<0,001), we have achieved significantly higher oocyte-to-blastocyst rate (32,11% vs 13,36%, p<0,001), Significantly higher numbers of fresh oocytes (6,11% vs 5,07%, p<0,001) increased implantation and live birth rate, oocyte-to-baby rate for fresh oocytes was 5,81% compared to 3,76%, p<0,001.

Average number of blastocyst per embryotransfer was 1,56 ± 0,56 for fresh oocytes and 0,81 ± 0,79 for vitrified ones, p<0,001. Pregnancy rate of 68,05% was significantly higher for fresh oocytes in comparison to 42,86% pregnancy rate for cycles using vitrified eggs (p<0,001).

Significantly higher number of surplus blastocysts per treatment cycle (1,93 ± 1,82 vs 0,60 ± 1,19, p<0,001) favors fresh vs frozen oocytes. Cumulative chance of reproductive success was estimated. If all available surplus blastocyst were used in the future and resulted to similar pregnancy rates, hypothetical cumulative oocyte-to-baby rate for fresh eggs would be 13,06% vs 6,87% for vitrified, p<0,001

Limitations, reasons for caution: Our results might be biased by legally enforced usage of close system for vitrification as majority of studies have included open vitrification systems. Contrary to published results, we have not confirmed the number of 8–10 vitrified eggs per ongoing pregnancy. Cumulative chance of success was based only on hypothetical estimation.

Wider implications of the findings: We assert that oocyte-to-blastocyst and oocyte-to-baby rates offer more equal methods for evaluating fresh and frozen egg donation programmes. Such data are easily interpreted to patients and help to understand better the efficacy of egg banking compared to fresh donation programmes from perspective of providers and patients.

Trial registration number: not applicable.

P-400 Odds and predictors for achieving successful pregnancy at two years follow-up in a cohort of treated and untreated subfertile couples in a secondary care hospital

S. Owen[1], P. Dube[2], S. Amer[2], B. Shah[2], K. Jayaprakasan[1,2]

[1]*University of Nottingham, School of Medicine, Nottingham, United Kingdom*
[2]*Royal Derby Hospital, Derby Fertility, Derby, United Kingdom*

Study question: To estimate the chances of achieving live birth/ongoing pregnancy beyond twenty weeks for couples within two years and determine predictive factors for a successful pregnancy.

Summary answer: 60% in treated and 35% in the untreated cohorts achieved successful pregnancy in two years. Age and duration of subfertility were the most significant predictors.

What is known already: With fertility declining globally, more couples are seeking fertility treatment. Initial clinic investigation is key to determine the cause and future treatment regimen. A large cohort study across all UK in-vitro fertilisation (IVF) clinics identified key factors predicting success in assisted reproductive technology were younger maternal age and shorter duration of subfertility, with younger women being 66% more likely to achieve success. Reduced ovarian reserve, the primary measure of which is age, causes significantly decreased rates of treatment success. National statistics state that live birth rates following IVF and IUI treatment for women under 35 is 32% and 13% respectively.

Study design, size, duration: This observational cohort study evaluated all newly referred patients to a secondary care hospital Fertility Clinic of the UK between January 2013 and December 2015. These patients were followed up for 2 years using electronic records. This included 1257 couples, 1142 of which matched inclusion criteria and 1136 of whom were suitable for analysis.

Participants/materials, setting, methods: Inclusion criteria were heterosexual couples, with no prior fertility treatment. 677 patients were offered treatment based on the National Health Service (NHS) funding criteria. Data collected from electronic records was collated onto an excel database. Statistical analysis was carried out using IBM SPSS, reporting the median (IQR) as the data were skewed. Mann Whitney U Test or Chi Square Test and logistic regression analysis were done as appropriate.

Main results and the role of chance: The overall success rate was 50% among women who were referred. Patients offered treatment (N = 677) achieved 60% success, compared to 35% in untreated patients (N = 459). Across treated patients, those successful were younger (Median (IQR) = 31 (28-34) vs 32 (29-36), P<0.05), had higher rates of primary infertility (86.8% vs 80.6%, P<0.05) and shorter duration of subfertility (P = 0.001). Univariate regression analysis (OR, 95% CI) showed that younger patients (0.95, 0.92-0.98) with a reduced duration of subfertility (0.82, 0.75-0.91), and suffering from primary infertility (1.58, 1.04-2.40) were most successful. Anti-Mullerian Hormone (AMH) and Follicle Stimulating Hormone (FSH) levels were not predictive of successful outcome. Multivariate analysis (OR, 95% CI) showed that age (0.95, 0.90-0.99), duration of subfertility (0.85, 0.75-0.95) and primary infertility (2.03, 1.10-3.72) were still significant factors after adjusting for confounders. The most common cause was unexplained (44%), the least common was uterine factors (1.4%). The best success rates were with ovulatory cause (58%), the worst was uterine factors (25%). While 49% of successful outcomes were following IVF, ovulation induction, intrauterine insemination and spontaneous conception contributed to the success by 24%, 19% and 7.8% respectively.

Limitations, reasons for caution: While data of the treated patients were robust, some of the untreated patients may have been followed up for treatment elsewhere. Although difficult to quantify, this number is assumed to be low because of adherence to local patient referral pathways.

Wider implications of the findings: This study provides realistic chances of success for subfertile couples within two years and demonstrates that age and duration of subfertility are the most significant baseline predictors in achieving live birth/ongoing pregnancy at two years. These results are useful to explain success rates and counselling couples seeking fertility treatment.

Trial registration number: Not Applicable.

P-401 Oocytes quality in women with thalassaemia major

Study question: Is the quality of the oocytes affected in women with thalassaemia major undergoing IVF-ICSI cycles?

Summary answer: The quality of oocytes obtained from women with thalassaemia major is not affected.

What is known already: Women with thalassaemia major commonly face reproductive disorders. The iron overload that is consequent to the lifelong transfusional therapy typically produces a toxic effect on the anterior pituitary, leading to hypogonadotropic hypogonadism, a condition that can be overcome with exogenous gonadotropins. However, recent studies showed that affected women have also reduced levels of AMH and AFC, suggesting that ovarian reserve may be damaged. Moreover, the elevated peripheral levels of free iron may directly harm the quality of primordial follicles and could perturb folliculogenesis. Evidence to support a detrimental effect on oocytes quality is however lacking.

Study design, size, duration: A retrospective case-control study was conducted in women with thalassaemia major referred to our infertility unit between January 2008 and December 2017 and undergoing at least one IVF or ICSI cycle. Controls were matched to cases in a 5:1 ratio by age and study period. Both cases and controls were included only for the first treatment cycle.

Participants/materials, setting, methods: Thirty-five infertile women with thalassaemia major were referred during the study period, of whom 21 (60%) underwent IVF-ICSI. These 21 cases were matched to 105 controls. Participants underwent IVF-ICSI according the local standardized protocols. Compared to controls, cases also received LH in a 1:2 ratio compared to FSH. The primary outcome was the proportion of top quality embryos per oocytes used.

Main results and the role of chance: The baseline clinical characteristics of the two study groups did not significantly differ, with the exception of serum AMH and AFC which were significantly lower among women affected. The medians (Interquartile-IQR) in cases and controls were 0.6 (0.2-1.8) and 1.5 (0.7-3.5) ng/ml ($p = 0.05$) and 4 (1-7.5) and 11 (5.5-16) ($p<0.001$), respectively.

Considering the IVF-ICSI cycle, despite the expected longer duration of stimulation and higher total doses of gonadotropins used for cases, the number of developed follicles and oocytes retrieved did not differ. Live births were 4 (19%) and 34 (32%), respectively ($p = 0.30$). Fertilization rate and cleavage rate were even higher in women with thalassaemia major. The medians (IQR) in cases and controls were 100% (76-100%) and 75% (50-100%) ($p = 0.03$) and 75% (39-100%) and 50% (29-64%) ($p = 0.04$), respectively. In contrast, the rate of top quality embryos (the main outcome of the study) did not differ. The median (IQR) was 20% (0-76%) and 25% (5-50%), respectively ($p = 0.98$). Finally, we correlated serum ferritin and the duration of transfusional therapy with the rate of top quality embryos but failed to detect any significant correlation.

Limitations, reasons for caution: Thalassaemia major is a rare condition and the sample size is inevitably small: a type II error cannot be excluded for some outcomes. Moreover, the primary outcome chosen is a surrogate marker of oocytes quality. Live birth rate would be more informative but would require a significantly larger sample size.

Wider implications of the findings: Fertility preservation in young age is not justified in affected women since the quality of the oocytes does not appear to be compromised. This conclusion is also strengthened by the recent progresses of iron chelation therapies that can reduce the injury to the pituitary, thus potentially consenting natural conception.

Trial registration number: Not applicable.

P-402 Freeze-all versus conventional approach in normal responders: comparison of cumulative live birth in a multicenter cohort study

C. Zaca'[1], A. Bazzocchi[2], G. Coticchio[3], M.A. Bonu[3], A. Borini[4]

[1]Tecnobios Procreazione, IVF laboratory unit, Bologna, Italy
[2]9-Baby Family and fertility center, Reproductive medicine IVF, Bologna, Italy
[3]9.baby Family and fertility center, IVF laboratory unit, Bologna, Italy
[4]9.Baby Family and fertility center, Reproductive Medicine IVF, Bologna, Italy

Study question: Does freeze-all assure a better outcome in terms of cumulative live birth rate (CLBR) in normal responder patients?

Summary answer: In the present analysis, freeze-all is not superior to the conventional strategy in terms of CLBR.

What is known already: To date some studies have suggested that cryopreservation of the entire embryonic cohort derived from a single cycle is associated with a higher live birth rate in selected patient categories, such as women at risk of developing ovarian hyperstimulation syndrome (OHSS), patients awaiting results of genetic tests or in cycles with supra-physiological levels of estrogen and progesterone. Since the experience with freeze-all has been limited to selected typologies of patients, this approach should be tested in a wider context in order to evaluate whether it can be proposed as the gold standard for IVF treatments.

Study design, size, duration: This is a retrospective matched cohort study involving completed IVF cycles conducted between 2012 and 2016, in 5 fertility centres. Cycle data were analyzed according to approach (fresh cycle or freeze-all) and then stratified according to the number of oocytes retrieved, age and embryo transfer day.

Participants/materials, setting, methods: This study analysed 564 completed IVF cycles in which 12-18 oocytes were retrieved[1]. In 435 cycles the conventional strategy was applied, involving first transfer of fresh embryo(s) and afterwards use of cryopreserved embryos; in 129 cycles the freeze all approach was performed, with elective cryopreservation of all viable embryos. Only patients who had transferred all available embryos and/or achieved a live birth, were included.

Main results and the role of chance: Our analysis showed a higher CLBR, but not statistically significant, in the freeze-all group (53.5% vs 45.5%, $p = 0.11$). Data stratification on the basis of age and number of oocytes retrieved suggested a trend towards a higher CLBR in the freeze-all group, although again in the absence statistical significance. In the sub-analysis focusing on the day of embryo transfer, no difference was found in the cleavage stage data segment, whereas in cycles where embryo transfer was carried out at the blastocyst stage the CLBR was significantly higher in the freeze-all group ($p<0.05$).

Limitations, reasons for caution: Since this is a retrospective study, the information obtained is based on previously recorded data. Consequently, certain parameters that could influence the outcome, such as BMI, markers of ovarian reserve and others, were not included in the analysis.

Wider implications of the findings: Our analysis ofCLBRshows that the freeze-all approach is not superior to the conventional strategy.However,its performance appears at least as competitive as the conventional modality of use of fresh and cryopreserved embryos.The statistically significant difference in CLBRin treatments where embryo transfer was carried out at the blastocyst stage warrants further investigation.

Trial registration number: Not applicable.

P-403 Atosiban Infusion (Oxytocin Receptor Antagonist) is effective in improving the pregnancy outcome of Blastocyst Transfer cycle in a Younger population (<35 yrs)

R. Angik[1], A. Chimote[2], N. Chimote[3], N. Chimote[3]

[1]*Vaunshdhara Fertility Centre Pvt. Ltd., OBGYN, Nagpur, India*
[2]*Vaunshdhara Fertility Centre Pvt. Ltd., Obgy, Nagpur, India*
[3]*Vaunshdhara Fertility Centre Pvt. Ltd., Clinical Embryology, Nagpur, India*

Study question: Is Atosiban Effective in reducing myometrial contraction during Blastocyst transfer and improving pregnancy rate in a general population? (18-45 yrs)

Summary answer: Atosiban is more effective in younger population of women undergoing ART cycle (age<35 yrs)

What is known already: Implantation and pregnancy rates are inversely correlated with the frequency of uterine contractions. Supraphysiological concentration of oestradiol following ovarian stimulation has been shown to increase uterine contractility. Atosiban infusion prior to embryo transfer is known to reduce the uterine contraction but its effectiveness in a particular subset of age group is not known.

Study design, size, duration: This prospective non randomised study of infertile women (n = 150) undergoing Blastocyst transfer divided into two group A (Atosiban infusion) & B (no Atosiban) and further divided into subgroups of i (<35 yrs.) ii (>35 yrs.). Both groups received similar quality of blastocyst & were evaluated for myometrial contraction and clinical pregnancy rates by Transvaginal Ultrasound (TVS). Study was conducted between December 2016 and December 2017 at our private ART clinic.

Participants/materials, setting, methods: Group A(n = 75) received total dose of 22.5 mg atosiban in (100 ml Normal saline) @ 32 drops per min half hour before Blastocyst transfer while Group B(n = 75) received no Atosiban infusion. Group A evaluated for myometrial contraction (contraction /2 min) before transfer and after infusion and group B evaluated before transfer. Clinical pregnancy determined by presence of Foetal cardiac activity on TVS in both the groups and subgroups.

Main results and the role of chance: women undergoing Blastocyst transfer in group A and group B were subjected to student T test to determine the pregnancy rates, a significant difference was noted student t test p value 0.0013 between the two groups. A significantly higher rate of pregnancy was noted in subgroup i, student t test p value 0.0211. While there was no significant difference in group ii student t test p Value 0.780 in. There was an extremely significant decrease in the myometrial contraction in group A as compared to group B (p value <0.0001). Contingency analysis for group i (< 35 yrs) Fischer exact test p value was 0.048(significant), odds ratio 2.33, 95 % CI 1.001 to 5.7 sensitivity 21.8 %, specificity 89.2 %, Positive predictive value (PPV) 70 %, Negative predictive value (NPV) 50%, LR 2.04 while for group ii, Fischer exact test p value was > 0.999(non-Significant), odds ratio 1, 95 % CI 0.4002 – 2.499, Sensitivity 10.7%, specificity 89.2 %, PPV 50%, NPV 50% likely hood ratio of 1.

Limitations, reasons for caution: This prospective non randomized study has a small sample size which may cause bias in the Atosiban group hence a multicentre randomized control trial with a large sample size with follow up till delivery is to be done to determine the live birth rate and effectiveness of Atosiban.

Wider implications of the findings: Atosiban used at the time of blastocyst transfer in young age group(<35 yrs.) gives a favourable outcome in an ART cycle as compared to older age group patients in terms of decreased myometrial contraction and higher clinical pregnancy rates.

Trial registration number: not applicable.

P-404 Application of seminal plasma to female genital tract prior to embryo transfer in assisted reproductive technology cycles (IVF, ICSI and frozen embryo transfer)

B. Ata[1], A. Abou Setta[2], A. Seyhan[3], W. Buckett[4]

[1]*Koc University, Obstetrics & Gynecology, Istanbul, Turkey*
[2]*University of Manitoba, Knowledge Synthesis Platform- George and Fay Yee Centre for Healthcare Innovation-, Winnipeg, Canada*
[3]*American Hospital of Istanbul, Assisted Reproduction Unit, Istanbul, Turkey*
[4]*McGill University, Obstetrics and Gynecology, Montreal, Canada*

Study question: Does application of seminal plasma (SP) to the female genital tract prior to embryo transfer improve ART cycle outcome?

Summary answer: We found low quality evidence that SP application may increase clinical pregnancy rate. There was insufficient evidence for live birth or ongoing pregnancy rates.

What is known already: The female genital tract is not exposed to SP during standard assisted reproductive technology cycles. However, it is thought that the inflammatory reaction triggered by SP may be beneficial by inducing maternal tolerance to paternal antigens expressed by the products of conception, and may increase the chance of successful implantation and live birth. Studies have revealed inconsistent results.

Study design, size, duration: Systematic review and meta-analysis of randomised controlled trials (RCTs) comparing SP application versus no SP exposure were identified from Cochrane Gynaecology and Fertility Group Specialised Register of Controlled Trials, Cochrane Central Register of Studies Online, MEDLINE, Embase, CINAHL and PsycINFO, trial registers for ongoing trials, Web of Knowledge, OpenGrey, LILACS, PubMed, Google Scholar and the reference lists of relevant articles.

Participants/materials, setting, methods: Eleven RCTs (3215 women) were included.

Main results and the role of chance: SP may increase clinical pregnancy rates (RR 1.15, 95% CI 1.01 to 1.31; participants = 2768; studies = 10; I2 = 0%). If clinical pregnancy rate following standard ART is 22.0% it will be between 22.2% and 28.8% with SP application.

SP application makes little or no difference in live birth rates (RR 1.10, 95% CI 0.86 to 1.43; participants = 948; studies = 3; I2 = 0%). If the live birth rate following standard ART is 19% it will be between 16% and 27% with SP application.

SP application makes little or no difference in live birth or ongoing pregnancy rates (RR 1.19, 95% CI 0.95 to 1.49; participants = 1178; studies = 4; I2 = 4%). If the live birth or ongoing pregnancy rate following standard ART is 19.5% it will be between 18.5% and 29% with SP application.

There was insufficient evidence to determine whether there was a difference in miscarriage rate between the groups (RR 1.01, 95% CI 0.57 to 1.79; participants = 1209; studies = 4; I2 = 0%). If the miscarriage rate following standard ART is 3.7%, the miscarriage rate following SP application will be between 2.1% and 6.6%.

Limitations, reasons for caution: The quality of the evidence ranged from very low to low. The main limitations were risk of bias (associated with poor reporting of allocation concealment and other methods) and imprecision for the primary outcome of live birth rate.

Wider implications of the findings: We conclude that seminal plasma application is worth further investigation, focusing on live birth and miscarriage rates.

Trial registration number: N/A.

P-405 Reproductive strategy in young women with critical ovarian reserve

G. Damiano[1], E. Porcu[1], L. Cipriani[1], S. Rossi[1], F. Fabbri[1], F. Sacilotto[1], G.M. Cillo[1], L. Notarangelo[1], P.M. Ciotti[1], N. Calza[1], L. Vaccarella[2]

[1]*University of Bologna, Human Reproductive Medicine unit, Bologna, Italy*
[2]*University of Luigi Vanvitelli Naples, Human Repdroductive Medicine unit, Naples, Italy*

Study question: Is Assisted Reproductive Technology (ART) indicated in young women aged ≤34 years old when ovarian reserve is critical?

Summary answer: After ART, the pregnancy rate in young patients with critical ovarian reserve (29.4%) is comparable to ≥35 years old women (30.7%) with normal ovarian reserve.

What is known already: The ovarian reserve reflects the oocyte quality and number. Anti-Müllerian hormone (AMH) and antral follicle count (AFC) are the

best predictive markers of the ovarian reserve and constantly decrease with age. AMH levels play a key role in the proper counselling of the infertile patients and allow the clinician to elect a personalized controlled ovarian stimulation (COS) protocol. AMH and AFC are the most important factor predicting ovarian stimulation response based on retrieved oocytes number. Pregnancy rate also depends on oocyte quality which is strictly related to age.

Study design, size, duration: Retrospective study: 2289 patients undergoing a COS cycle at the University of Bologna infertility and IVF center, from 2011 to 2017. Two groups were considered: Group A with 833 women aged ≤34, and group B with 1465 women aged ≥35. Both groups were divided based on AMH levels into Critical Ovarian Reserve (COR) AMH ≤ 0.5 ng/ml, Diminished Ovarian Reserve (DOR) AMH 0.5–1 ng/ml and Normal Ovarian Reserve (NOR) AMH ≥ 1 ng/ml.

Participants/materials, setting, methods: In group A there were 208 (25%) patients with COR, 51(6.16%) patients with DOR and 574(68.9%) patients with NOR. In group B there were 379(25.9%) patients with COR, 189 (12.9%) patients with DOR and 897(61.2%) patients with NOR. 3227 cycles of COS were performed. Duration of stimulation, total amount of gonadotropins used, number of retrieved oocytes, percentage of cycle cancellation and pregnancy rate were considered.

Main results and the role of chance: Patients of group A-COR compared to group A-NOR had a longer stimulation (11.4 ± 3.4 days vs 10.7 ± 2.8 days, p<0.0001) and a higher dose of gonadotropins used (2721 ± 1021 U.I. vs 1799 ± 927 U.I., p<0.0001). The number of retrieved oocytes decreases with the reduction of AMH level (3.4 ± 2.2 A-COR vs 5.3 ± 3.6 A-DOR vs 7.8 ± 4.6 A-NOR, p<0.0001), whereas the percentage of cycle cancellation was higher in group A-COR compared to group A-NOR (12.2% vs 0.5%, p<0.0001). The pregnancy rate in group A-COR was lower than in group A-NOR (29.4% vs 42,3%, p<0.0001).

Pregnancy rate of group A-COR was higher than that of group B-COR (29.4% vs 20,6% p<0.0001) but similar to that of group B-NOR (29.4% vs 30.7%, p=n.s.)

Limitations, reasons for caution: The scientific community has not determined a standardized cut off to define normal, diminished or critical ovarian reserve. There is not a recognized method to dose AMH level, therefore is not possible to compare values measured with different techniques. The cut-off used in this study are based on literature review.

Wider implications of the findings: Despite critical ovarian reserve, young patients seem to compensate the low number of oocytes with good quality gametes resulting in a satisfactory pregnancy rate.

Trial registration number: \

P-406 Oocyte accumulation as a strategy to optimize clinical outcomes in infertile poor ovarian responders meeting the Bologna criteria: A real-life non-randomized prospective study

C. Herbemont[1], S. Sarandi[1], M. Comtet[2], A. Seroka[2], C. Vinolas[2], J. Calvo[2], B. Dagher-Hayeck[2], J. Boujenah[3], I. Cedrin-Durnerin[2], M. Grynberg[2], C. Sifer[1]

[3]Hôpital Jean Verdier, Gynécologie-Obstétrique, Bondy, France

Study question: Does oocyte accumulation offer reasonable chances of pregnancy in infertile poor ovarian responders (PORs)?

Summary answer: Oocyte accumulation in PORs appears as a successful strategy for both treating their infertility as well as while preserving their fertility potential through embryo cryopreservation.

What is known already: In Assisted Reproductive Technology (ART), chances of live birth are highly correlated to the number of retrieved oocytes. PORs are particularly affected by this issue, since recent studies have set a threshold of 3 oocytes as a predictive factor of live birth. Moreover, repeating ART cycles in such patients represents a high risk of repeated failure, associated to an elevated drop-out rate. Hence, the management of PORs remains quite challenging, and the strategy of oocyte accumulation might constitute an interesting option to optimize clinical outcomes in these patients. However, data on this topic are still scarce.

Study design, size, duration: This single-center, prospective study has been in progress since January 2014. A total of 40 infertile couples have been enrolled in an oocyte accumulation program when female partner was diagnosed as POR according to Bologna criteria (2 out of the 3 following criteria: <4 oocytes in a previous cycle, abnormal markers of ovarian reserve, age >40 years) associated to any other infertility cause (male, female or both).

Participants/materials, setting, methods: Enrollment in the program required patients' written informed consent. Metaphase-2 (M2) oocytes were accumulated by vitrification during ≥1 controlled ovarian hyperstimulation cycle (s) (n = 85 cycles). Then, all vitrified oocytes were warmed and inseminated using ICSI simultaneously with fresh M2-oocytes retrieved during a last cycle of ovarian stimulation. Twenty-four couples underwent the whole procedure (oocyte-vitrification cycles, followed by oocyte warming +/- simultaneous fresh ICSI cycles). Biological and clinical outcomes of these cycles were analyzed.

Main results and the role of chance: Briefly, median patients' age was 36.0 years [28-42]. Their median serum AMH and FSH levels as well as antral follicle count were 1.2 ng/mL [0.2-2.8], 7.6 IU/L [3.2-15], and 6 follicles [3-14], respectively. Each couple underwent an average of 2.6 previous IVF/ICSI attempts before entering our program of oocyte accumulation. During the oocyte accumulation period, a mean of 2.3 cycles/couple (in total, 55 cycles) were performed, leading to the vitrification of 6.2 M2-oocytes/couple (standard deviation (SD) = 3.0). A total of 149 M2 oocytes were warmed (survival rate = 81.2%), and 121 M2-oocytes were micro-injected simultaneously with 81 fresh M2-oocytes (8.4 M2-oocytes injected/couple; SD = 4.6). Number of oocytes retrieved, maturation, fertilization rates and embryo quality were comparable between oocyte accumulation and fresh cycles. So far, oocyte accumulation strategy resulted in 23 embryo transfers (ET) (mean number of transferred embryos = 2.4): 10 ET arose from warmed oocytes only (43.5%), 4 from fresh oocytes (17.4%) and 9 from both warmed and fresh oocytes (39.1%). Furthermore, supernumerary embryos were cryopreserved for 10 couples (41.7%). Finally, clinical pregnancy rate (CPR) of 33.3%/cycle (8/24), and cumulative CPR of 37.5%/cycle (9/24) were achieved. Interestingly, surplus embryo cryopreservation was performed for 55.5% of pregnant patients and only 33.3% of non-pregnant ones.

Limitations, reasons for caution: This preliminary study lacks statistical power, and further investigations are required to confirm the efficiency of oocyte accumulation in the management of infertile PORs. Then, cost-effectiveness issues will have to be considered.

Wider implications of the findings: This study highlighted acceptable CPR for poor-prognosis patients. Thus, enrollment of infertile PORs in oocyte accumulation programs might optimize their success rates. Moreover, this strategy could offer an opportunity of fertility preservation for women whose ovarian reserve is inexorably decreasing, and enhance their chances of achieving a subsequent pregnancy.

Trial registration number: Not applicable.

P-407 Physical activity and sedentary time before and during in vitro fertilization: a longitudinal study exploring the associations with infertility treatment outcomes

D. Sõritsa[1,3], S. Läänelaid[2], E. Lätt[4], N. Margit[5], M. Jarek[4], J.H. Migueles[6], A. Ehrenberg[5], A. Sekavin[5], A. Sõritsa[3], A. Salumets[1,7], F.B. Ortega[8,9], S. Altmäe[9,10]

[10]University of Granada, Department of Biochemistry and Molecular Biology, Granada, Spain

Study question: Do physical activity (PA) and sedentary lifestyle influence controlled ovarian stimulation (COS) and embryo implantation and pregnancy outcomes in in vitro fertilization (IVF) treatment?

Summary answer: Physically more active women obtained higher number of oocytes and embryos after COS, while PA and inactivity levels did not influence embryo implantation in IVF.

What is known already: Regular PA has positive effects on human health and several epidemiologic studies indicate an association between self-reported PA and fertility. There are studies demonstrating that physically more active women during IVF have higher probability of pregnancy, while others, on the contrary, report negative impact of PA on IVF. All these studies have assessed PA using self-reported questionnaires, which give only a rough estimate of PA. Only one published study has measured objectively PA, with accelerometry, in infertile women after embryo transfer, where no effect of PA was detected. We still are lacking objective recommendations of PA for women undergoing IVF.

Study design, size, duration: This longitudinal study was carried out among 108 infertile women receiving fresh embryo transfer (ET) in their first IVF cycle. The study was carried out at the Reproductive Unit at the University Hospital between 2013 and 2016.

Participants/materials, setting, methods: Each woman provided three objective measurements of PA using accelerometry (ActiGraph GT2X+) of 2 weeks: 1) the baseline PA level, 1-6 months before IVF; 2) embryo implantation period, from the day embryo was transferred; 3) early pregnancy establishment period, from the day of pregnancy test. Lifestyle questionnaire, body composition and IVF treatment outcomes were recorded for each patient.

Main results and the role of chance: In general, the group of infertile women undergoing IVF treatment significantly reduced their PA levels and increased sedentary time. Physically more active and less inactive women obtained significantly higher number of oocytes and embryos after COS, while PA and sedentary lifestyle did not seem to have any effect on embryo implantation and early pregnancy establishment in IVF. Further, we found that those women with a high screen time during the weekends (>3 h per day) have 4.7 oocytes and 2.8 embryos less after COS than women with low screen time. Furthermore, isotemporal analysis demonstrated that if a woman would increase her daily light PA for 1.5 h and thus by reducing their daily sedentary time for 1.5 h, she would obtain 2 more oocytes and 1 more embryo after COS.

Limitations, reasons for caution: Regardless of the clear results of PA effects on ovarian stimulation, bigger sample size would increase the power of the study.

Wider implications of the findings: We can suggest recommendations for infertile women undergoing IVF indicating that light and moderate PA is beneficial for ovarian stimulation outcomes, while sedentary lifestyle clearly is not. Additionally, IVF patients could continue with their normal lifestyle and there is no need to reduce PA levels after embryo transfer procedure.

Trial registration number: Not applicable.

P-408 Euploidy rates in donor egg cycles are significantly influenced by the number of accumulated ovarian stimulations

I. Jurado[1], M. Enciso[1], J. Sarasa[1], C. Real[2], B. Rodriguez Estrada[1], I. Vilella[1], J. Luna Romero[1], S. Rogel[2], J. Aizpurua[2]

[1]Integrated Genetic Lab Services SL, Genetic, Alicante, Spain
[2]IVF-SPAIN, Ginecology, Alicante, Spain

Study question: Could ovarian stimulation protocols influence oocyte quality, embryo developmental potential and the euploidy status?

Summary answer: The total number of previous ovarian stimulations in donor egg cycles positively correlates with embryo aneuploidy rates.

What is known already: The presence of chromosome aneuploidy is one of the most significant causes of embryo loss. Studies performed in the last two decades reveal these abnormalities affect a remarkable number of ART produced human embryos (over 50%). Although the majority of aneuploidies are known to be maternal age related, this phenomenon has also been observed in young patients and donors at a considerable and wide ranged frequency (20-60%). Apparently, range dependent from center and/or doctors involved suggesting stimulation and/or culture conditions as possible explanations. To date, no detailed analysis of such factors has been performed.

Study design, size, duration: This observational retrospective study includes data from 102 donor-oocyte cycles undergoing Preimplantation Genetic Testing for Aneuploidy (PGT-A) between January 2017 and January 2018. A total of 2850 oocytes and 569 embryos were studied. Only cycles from couples who showed no clear male factor infertility (normozoospermic sperm according to WHO) were selected. The influence of donor characteristics, ovarian stimulation protocol, dose and number on oocyte count and quality and on embryo competence and ploidy was assessed.

Participants/materials, setting, methods: 67 donors aged 18-34 (24.86 ± 3.87) participated in the study. Donors followed a protocol for ovarian stimulation with rFSH (Puregon®, Merck) with variable doses (AMH, folliculometry and weight dependant). Oocytes collected were in-vitro fertilised, embryos cultured to blastocyst stage (equal conditions), biopsied and PGT-A tested by NGS (VeriSeq protocol, Illumina). Oocyte count and quality, fertilization rate, blastocyst formation rate, embryo quality and chromosome status depending on donor age, BMI, stimulation dose and number were statistically explored.

Main results and the role of chance: A significant positive correlation was found between donor age and the number of oocytes retrieved (Pearson correlation, R=-0.294 p = 0.008). Young donors ≤27 tend to produce significantly higher number of oocytes compared to older (>27) donors (28.74%±1.46 vs 22.35%±1.83, Student´s t-test, p = 0.011). No such age influence was found in embryo competence neither in terms of blastocyst formation rate, good quality blastocyst rate or euploidy rate. No correlation between oocyte count and BMI, stimulation dose or number of ovarian stimulation cycles was identified.

Interestingly, embryonic aneuploidy rates in the donor egg cycles studied were associated with the number of stimulation cycles performed by the donor. The number of previous stimulations negatively influenced embryonic euploidy rates (Spearman correlation, R=-0.222, p = 0.036). A significant increase in the proportion of embryos presenting chromosome abnormalities was found in donors that had undergone more than 5 stimulation cycles compared to donors experiencing 5 or less stimulation cycles (31.93%±3.64 vs 24.40%±2.78, U-Mann Whitney, p = 0.037). Neither age, BMI or r-FSH stimulation dose or hormone levels showed such an impact on embryo ploidy.

Limitations, reasons for caution: The retrospective and unicentric design of this study may be a reason of caution. The number of donors and donor egg cycles was limited; this should be increased to confirm the results ob-tained. Further prospective studies are needed to validate our results.

Wider implications of the findings: Our results show a strong association between the number of previous stimulation cycles and embryo aneuploidy in oocyte donors. These data indicate that other factors like age, previous stimulations or ovarian damages of oocyte maturation and genetic competence, may influence chromosome abnormalities in IVF embryos.

Trial registration number: not applicable.

P-409 Nodal deletion increases susceptibility to inflammation-induced preterm birth in mice and human

T. Ayash

Mcgill, Expreimental medicine, Montral, Canada

Study question: How does inflammation combined with reduced Nodal gene expression increase susceptibility to Preterm Birth in mice and humans.

Summary answer: Nodal heterozygous mice are senstive to LPS which causes preterm birth. In humans,Nodal revealed that Nodal SNPs correlate with increased susceptibility to inflammation-induced preterm birth.

What is known already: Potential risk factors prior to conception, during pregnancy genetic predisposition have been identified to correlate with increase susceptibility to preterm birth. Our lab has been studying the role of Nodal signaling during pregnancy. Nodal is belonging to the Transforming Growth Factor-beta superfamily. Previously we have demonstrated that Nodal signaling is active in uterus during early pregnancy and required both for embryo implantation and for the timing of parturition. We have a uterine specific deletion using

a progesterone receptor-Cre system and observed a 75% reduction in pregnancy, 25% of Nodal mutant gave birth two days prior to term.

Study design, size, duration: In mouse we have injected a low dose of LPS (1.4 mg/kg) which resulted in 50% of pregnant *Nodal* heterozygous mice to give birth preterm. Furthermore, we have also verified the protein and RNA levels of several pro-inflammatory cytokines using immunofluorescence and real time PCR. In the human study, 613 women (189 preterm and 424 term) from the Montreal Prematurty Study were genotyped for *NODAL* polymorphisms and assessed for bacterial vaginosis and placental inflammation.

Participants/materials, setting, methods: We are using an RT^2 Profiler PCR Array, we examined the expression of 84 genes involved in innate and adaptive immunity. Critical cytokines in the parturition cascade were significantly up-regulated in maternal decidua tissue of *Nodal* heterozygous mice at day 16.5 of pregnancy. We have also used different antibodies to look to different immune cells in placental tissue in our mouse model.

Main results and the role of chance: Our mouse study demonstrated that absence of one allele of *Nodal* leads to increased susceptibility to preterm birth in response to low doses of LPS. We also provide evidence that NODAL may regulate the immune system during late pregnancy and labor. We suggest that the *Nodal* heterozygous knockout mouse is a suitable model to study gene-environment interactions in human preterm birth. Future experiments will address the mechanism of how NODAL affects the immune system.

In human, we identified 12 known SNPs in the *NODAL* gene of participants in the study population. Of these, four had VAF > 1%, three of the *NODAL* polymorphisms were not associated with preterm birth.in more details, the rs2231947 variant allele was associated with increased risk for preterm birth among women with bacterial vaginosis. Among women without placental inflammation, the rs1904589 variant allele was associated with increased risk of preterm birth. Among women with placental inflammation, the rs10999338 variant allele was associated with reduced risk of preterm birth.

Limitations, reasons for caution: Experiments were performed on a mouse model and the implication of the Nodal signaling pathway in humans is still unclear.

Wider implications of the findings: As Nodal appears to be involved in the timing of parturition, manipulation of its activity or of its downstream signaling components may lead to effective treatments in the prevention of preterm birth.

Trial registration number: Funded by March of Dimes Grant, Toronto Dominion Bank Post-Doctoral Fellowship for Child Health Research Excellence and The Ministry of Higher Education of Saudi Arabia.

P-410 BMI adversely affect embryo quality and morphokinetics

G. Shrem[1], M. Michaeli[2], D. Poltov[2], N. Asliha[2], N. Rotfarb[2], E. Shoshan-Karchovsky[2], O. Ruzov[2], Y. Atzmon[2], E. Shalom-Paz[3]

[1]Hillel - Yaffe medical center, IVF unit, Hadera, Israel
[2]Hillel Yaffe Medical Center, IVF unit, Hadera, Israel
[3]Hillel Yaffe Medical Center, IVF unit, Hadera, Iceland

Study question: What is the effect of BMI on embryo's morphokinetics as reflected by timelaps scores with regard to treatment protocol IVF cycle outcome.

Summary answer: Obesity has adverse effect on IVF treatment represented by less TOP quality embryo and a trend of lower pregnancy rate.

What is known already: It is well established that there is a strong correlation between obesity and reproductive pathology including anovulation, infertility and obstetrical complication.

Study design, size, duration: A retrospective cohort study.

179 infertile women, total of 2280 oocytes.
January 2016 to December 2017

Participants/materials, setting, methods: Records of all fresh cycles that their embryos were cultured in a time-laps incubator were evaluated. Embryos were scored by EmbryoScope™ and correlated with patients BMI and clinical pregnancy rates.

Main results and the role of chance: 179 infertile women, total of 2280 oocytes were divided according to their BMI into 3 groups: BMI < 25, BMI 25-29, and BMI ≥30. The duration of treatment was significantly longer for the BMI≥30 (10.2 ± 1.6 days vs. 9.3 ± 2.2 days, respectively). The endometrium was significantly thicker in the BMI≥30 group (10.2 ± 1.6 vs. 9.8 ± 2.4). The Estradiol level on ovulation induction day, the number of oocyte retrieved, the number of oocytes at the M2 phase and the number of the normal fertilization oocyte were significantly higher at the BMI<25 group. We found significantly more TOP quality embryos in the BMI< 25 compared with the other groups (58% vs 52%). Pregnancy and clinical pregnancy rate demonstrated a trend towards higher pregnancy in the BMI<25 group vs. the BMI≥30 group (49% vs 32%, NS and 46% vs 32%, NS; rspectively).

Limitations, reasons for caution: Since it is a retrospective cohort study, the results shoud be interprated with cuation.

Wider implications of the findings: Understanding the adverse effects of obesity, may contribute to infertility couples education and may contribute to the understanding of adverse effect of obesity on oocyte developement.

Trial registration number: N/A.

P-411 Association of weight change since age 18 years and probability of live birth among women undergoing assisted reproduction

[5]Harvard T.H. Chan School of Public Health and Brigham and Women's Hospital and Harvard Medical School, Nutrition- Epidemiology- Channing Laboratory, Boston, U.S.A.
[6]Brigham and Women's Hospital and Harvard Medical School- Harvard T.H. Chan School of Public Health, Nutrition and Channing Laboratory, Boston, U.S.A.

Study question: What is the association between female weight change from young adulthood (age 18) to time of ART and the probability of live birth?

Summary answer: Greater weight gain in adulthood was associated with lower probability of live birth following ART, particularly among women who were ≥22.5 kg/m^2 at age 18.

What is known already: Pre-pregnancy overweight and obesity in adulthood has been associated with lower natural fertility and lower success rates in ART. While short-term weight loss trials have not demonstrated improved live birth rates among obese women undergoing ART, the impact of longer-term weight change on ART outcomes, particularly throughout early adulthood has yet to be studied.

Study design, size, duration: Our analysis included 448 women (767 ART cycles) enrolled in the Environment and Reproductive Health (EARTH) study -a prospective cohort study- recruited between 2005-2016 at the Massachusetts General Hospital Fertility Center.

Participants/materials, setting, methods: At study entry, women were asked to recall their weight at age 18 and trained research nurses measured women's current height and weight. ART outcomes were abstracted from medical records. We used multivariate generalized linear mixed models with random intercepts to account for repeated observations adjusted for age, smoking status, race, height, and BMI at age 18.

Main results and the role of chance: At time of study entry, 62% of women had gained > 5 kg since age 18 and 33% were overweight or obese. The

adjusted percentage of initiated ART cycles resulting in live birth (95% CI) among women who gained 0-5 kg, 5-9.9 kg, 10-14.9 kg, and ≥15 kg since age 18 was 57.2% (49.8%, 64.2%), 58.9% (51.4%, 66%), 54.6% (45.2%, 63.7%), and 48.1% (40.5%, 55.9%), respectively (p-trend = 0.08). There was no difference in the probability of live birth between women who lost weight versus those who remained relatively weight stable (gained 0-5 kg). The inverse association between adult weight gain and probability of live birth was more pronounced among women who were ≥22.5 kg/m^2 at age 18 (p-interaction = 0.09). Specifically, among women who were ≥22.5 kg/m^2 at age 18 the adjusted difference in percentage of initiated ART cycles resulting in live birth was 17.6% (95% CI 2.9%, 28.0%) comparing women who remained weight stable versus those who gained ≥15 kg in adulthood. This similar comparison in women <22.5 kg/m^2 at age 18 was 6.6% (95% CI -2.5%, 14.6%).

Limitations, reasons for caution: Weight at age 18 was self-reported by participants, which may lead to misclassification. There were very few women who lost weight since young adulthood which limited the statistical power of those comparison. Despite our adjustment for a variety of confounders, residual confounding is possible.

Wider implications of the findings: Women who gained ≥15 kg in adulthood have lower probability of live birth per initiated ART cycle, particularly among women who were heavier at age 18. These results add to the growing literature supporting the benefits of minimizing weight gain in adulthood on female fertility.

Trial registration number: None.

P-412 Predictive models for pregnancy outcomes with non-IVF treatments reveal that protocol choice, not patient-specific factors, are the primary risk for multiple gestations

K. Hunter Cohn[1], C. Wellock[1], B.T. Miller[2], M. Hinckley[3], J.N. Gutmann[4], C. Benadiva[5], J.C. Nulsen[5], G. Letterie[6], J. Hirshfeld-Cytron[7], A.B. Copperman[8], P. Yurttas Beim[1]

[7]Fertility Centers of Illinois, Reproductive Endocrinology, Highland Park, U.S.A.
[8]Reproductive Medicine Associates of New York, Icahn School of Medicine at Mount Sinai, New York, U.S.A.

Study question: Which factors are predictive of ongoing pregnancy and risk of multiple gestation with non–*in vitro* fertilization (non-IVF) treatment?

Summary answer: Personalized predictive models for OPR (ongoing pregnancy rate) and MGR (multiple gestation rate) highlight an increased risk of multiple gestation with non-IVF treatment using gonadotropins.

What is known already: Non-IVF treatments with OI using oral medications (clomiphene citrate or letrozole) or injectable gonadotropins with IUI or timed intercourse (TI) are frequently used as first-line fertility treatment due to the lower physical and financial burden. Treatments vary in pregnancy rate as well as MGR, and thus in associated maternal and fetal risks. Although previous studies have looked for factors predictive of pregnancy, they did not analyze the multiple gestation rate. Patient-specific predictions for both pregnancy and risk of multiples across treatment options and cumulatively over multiple cycle attempts can help with patient counseling and allow for informed treatment decisions.

Study design, size, duration: Predictive models were built using retrospective data collected from 173,916 cycles from 69,003 patients at 13 fertility centers in the United States between 2002 and 2017. We included cycles that received the OI medications clomiphene citrate or letrozole (Orals) and/or injectable FSH or hMG (Gnd) with or without IUI. We excluded cycles that utilized donor sperm.

Participants/materials, setting, methods: Outcomes evaluated were OPR (presence of fetal heartbeat upon discharge to obstetrical care) and MGR (presence of multiple fetal heartbeats relative to ongoing pregnancy). Patient data were divided into a training set (2/3) and a validation set (1/3). The OPR and MGR models were logistic regression models and used inverse probability-of-censoring weighting to compensate for informative censoring. Continuous patient factors were evaluated for nonlinear spline terms.

Main results and the role of chance: In a multivariate model for OPR, significant nonlinear patient factors included age, anti-Müllerian hormone, body mass index, basal antral follicle count, and day 3 FSH, estradiol, and luteinizing hormone. In addition, endometriosis (odds ratio [OR] 0.48), tubal factor (OR 0.57), and sperm total motile count <10 million (OR 0.55) and morphology <4% Kruger (OR 0.82) (p<0.001 for all) had a negative impact on OPR. Notably, we found that inclusion of Gnd or IUI in the protocol led to increased OPR (OR: Gnd+IUI, 2.80; Gnd+Orals+IUI, 2.13; Orals+IUI, 1.40; Gnd+TI, 2.04; Gnd+Orals+TI, 1.37; Orals+TI, 1.0). Modeling OPR over multiple cycles, we observed that the incremental probability with each additional cycle varied by treatment protocol, with a greater decrease for cycles including Gnd.

Additionally, a multivariate model for MGR showed that risk primarily depended on protocol choice, with Gnd inclusion significantly increasing risk of multiple gestation (OR: Gnd+IUI, 3.34; Gnd+TI, 3.09; Gnd+Orals+IUI, 1.86; Gnd+Orals+TI, 1.45; Orals+IUI, 1.23; Orals+TI, 1.0; p<0.001). The MGR was independent of cycle attempt number.

Evaluating the OPR model against a holdout validation dataset, we observed an AUC of 0.65 and a Brier score of 0.091. The MGR model had an AUC of 0.65 and a Brier score of 0.079.

Limitations, reasons for caution: The described predictive models were built and validated on retrospective data and should be independently validated using a prospective dataset. In addition, differences in clinic treatment and monitoring protocols may influence both OPR and MGR.

Wider implications of the findings: Personalized probabilities for both OPR and the associated MPR are important for helping patients make treatment choices to maximize their likelihood of a healthy outcome. The >3-fold increase in MGR with Gnd compared to oral medications highlights the importance of balancing this significant risk with the incremental increase in OPR.

Trial registration number: N/A.

P-413 Comparative study of the Poseidon subgroups 1a and 1b low responder IVF cycles

N. Massiah, P. Fedorcsak

Oslo University Hospital, Reproduction Medicine, Oslo, Norway

Study question: What are the comparative trends of the Poseidon group 1a and group 1b low responder IVF cycles?

Summary answer: Low responder cycles increased with time and age with group 1a carrying a significantly higher no embryo transfer rate and lower clinical pregnancy rate.

What is known already: The 4 group Poseidon stratification of low responders was introduced in 2016. Unexpected poor or suboptimal responders, 34 years and younger with a normal ovarian reserve are classified as Poseidon group 1. Subgroups 1a and 1b are based on the number of oocytes retrieved after standard ovarian stimulation. Low responders with fewer than 4 oocytes are classified as subgroup 1a. Those with 4-9 oocytes are classified as subgroup 1b. Since this is a new classification, there is a need for fertility centres to apply it to their own population of women to enable the development of reproducible and comparable research.

Study design, size, duration: Retrospective comparative study of 777 IVF cycles of Poseidon subgroups 1a and 1b low responders. The IVF cycles were undertaken between Jan 2007 to Dec 2017.

Participants/materials, setting, methods: First IVF cycle low responders, 34 years and younger with normal ovarian reserve parameters (AFC >5, AMH>1.2 ng/ml). This group was divided into subgroups 1a and 1b. Subgroup 1a were low responders with fewer than 4 retrieved oocytes. Subgroup 1b were low responders with 4-9 retrieved oocytes. The data was extracted from an electronic register of IVF cycles that were undertaken at a university hospital fertility centre. Chi square test for statistical analysis. Significance: p <0.05.

Main results and the role of chance: There was a 4-fold and 7-fold increase in Poseidon subgroup 1a and subgroup 1b first IVF cycles respectively. Poseidon subgroup 1a consisted of 114 women (14.6%) and subgroup 1b consisted of 663 women (85.4%). An upward trend with age was found in both subgroups. The mean (SD) number of oocytes retrieved per cycle was 2.2 ± 0.8 in subgroup 1a, and 6.7 ± 1.7 in subgroup 1b. The mean (SD) number of embryos transferred per cycle was 1.1 ± 0.5 in subgroup 1a and 1.1 ± 0.6 in subgroup 1b.

Embryo transfer was not achieved in 111 women. The no embryo transfer rate was significantly higher in subgroup 1a (29.8% v/s 11.6%, p<0.05). Of the 111 women, 18 (16.2%) undertook further IVF treatment. Of these 18 women, there was a cumulative pregnancy rate of 44.4% over three cycles.

The clinical pregnancy rate of subgroup 1b was significantly greater than subgroup 1a (41.8% v/s 22.8%, p<0.05). A sub-analysis of single embryo transfers found that the clinical pregnancy rate of subgroup 1a was lower than subgroup 1b (30.1% v/s 47.1%, p<0.05). For double embryo transfers, the clinical pregnancy rate in subgroup 1a was significantly higher than subgroup 1b (57.1% v/s 40.0%, p<0.05).

Limitations, reasons for caution: This was a retrospective study which is historically known for its limitations. However, there was no missing data in this study.

Wider implications of the findings: Research is warranted to determine parameters that can identify Poseidon type 1 women prior to ovarian stimulation. This will enable optimisation of treatment and reproductive outcomes. Double ET can be considered for group 1a women based on low oocyte numbers, difficulty creating embryos and low pregnancy rates with single ET.

Trial registration number: Not applicable.

P-414 Antibodies to chlamydial heat shock protein 60 kDa in sera and follicular fluid of women undergoing IVF

V. Muller[1], I. Kogan[2], A. Savicheva[3], A. Gzgzyan[2]

[3]*D.O.Ott Research Institute of Obstetrics- Gynecology and Reproductology, Microbiology, Sankt-Petersburg, Russia C.I.S.*

Study question: To determine whether past or persistent chlamydial infection is associated with the results of infertility treatment with *in vitro* fertilization (IVF)

Summary answer: No relation between antibody positivity to chlamydial heat shock protein 60 kDa (cHSP60) and IVF outcome was found.

What is known already: Recent studies have shown that serum antichlamydial antibodies are found in almost every second woman seeking treatment for tubal infertility with IVF. However, seropositivity of follicular fluid to chlamydial antigens and its diagnostic value is described only in several publications. Even more limited is the knowledge on the prevalence of persistent infection with *Chlamydia trachomatis*, defined by anti-cHSP60 antibody positivity, in women undergoing infertility treatment.

Study design, size, duration: A prospective comparative cohort study of 242 women with tubal factor of infertility was conducted at the IVF department of a state institution between January 2012 – January 2016.

Participants/materials, setting, methods: Serum (obtained at the first day of stimulation) and follicular fluid (aspirated at the day of oocyte pick-up) samples were analyzed using enzyme-linked immunosorbent assay for immunoglobulins (Ig) to major chlamydial antigens (IgG, IgA) and for anti-cHSP60 IgG. Study participants were divided to 2 groups according to the results of serum anti-*C.trachomatis* IgG test: 122 seropositive (main) and 120 seronegative subjects (comparison). Primary study outcome was clinical pregnancy rate.

Main results and the role of chance: Prevalence of anti-*C.trachomatis* IgG, IgA and anti-cHSP60 IgG was 50.4%, 10.7% and 5.8% in sera; 37.1%, 4.6% and 5.6% – in follicular fluid. Major stimulation and in vitro stage parameters did not differ between the study groups. 'Poor response' to ovarian stimulation was found to be 2 times more frequent in the main group (22.9% vs. 13.3%, p = 0.039), however was not associated with anti-cHSP60 antibody detection both in sera (OR: 2.56, 95%CI 0.87-3.34) and follicular fluid (OR: 1.93, 95%CI 0.99-3.87). Seropositive and seronegative women demonstrated similar clinical pregnancy (20.5% vs. 25.0%) and life birth rates (13.1% vs. 20.0%). Incidence of missed abortion after IVF was higher in the main group (28.0% vs 3.3%, p = 0.018) and showed no relation with anti-cHSP60 antibody positivity.

Limitations, reasons for caution: Despite the relatively sufficient initial size of the study, the subpopulation of anti-cHSP60 positive women appeared to be rather small. In addition, only women with tubal factor of infertility were assayed during the trial. All of this expectedly limits the generalizability of the obtained results.

Wider implications of the findings: The possibility of *Chlamydia trachomatis* persistence in women with tubal factor of infertility should be investigated with the employment of additional microbiological methods. Further trials may estimate the diagnostic and prognostic value of antichlamydial antibody testing for women undergoing IVF.

Trial registration number: Not applicable.

P-415 Acquisition of a next baby using a frozen sibling embryo(s): a proposal for advanced aged infertility couples to build a desired family

R. Uekusa[1], H. Ando[1], T. Shimaya[1], M. Kawai[2]

[1]*Toyohasi Municipal Hospital, Center for Reproductive Medicine and Surgery, Toyohashi, Japan*
[2]*Toyohasi Municipal Hospital, Department of Obstetrics and Gynecology, Toyohashi, Japan*

Study question: To evaluate the predictability of the acquisition of a next baby using a frozen sibling embryo(s) from the successful single embryo transfer (SET) cycle.

Summary answer: Our data indicate that 38.8% couples that keep at least one sibling embryo for the next baby may have another success without additional oocyte retrieval.

What is known already: The essential aim of ART is the birth of one single healthy child. SET has been introduced to avoid multiple pregnancy that is a major complication of ART. However, in advanced ages, usually from the latter half of 30's, pregnancy rate is gradually decreasing, and miscarriage rate is markedly increasing. Thus, it is difficult for advanced aged subfertility couples to build a desired family using high potential embryos with safety. Improvement of cryopreservation of embryos may contribute to maintain the reproductive results at the age of the embryo freezing.

Study design, size, duration: This is a retrospective clinical study in our institute from 2007 to 2017. We included 121 patients who gave birth to a baby through a timelapse-confirmed embryo transfer, keeping a sibling frozen embryo(s) and used the frozen embryo(s) for another baby.

Participants/materials, setting, methods: Patients were divided into acquisition and non-acquisition group (AG and non-AG) according to the final results of the new baby acquisition through the sibling embryo transfer(s). Main outcome was the ratio of AG. Furthermore, we newly defined the original embryo score based on the quality of the embryo at any developmental stage. The total score of the frozen embryos at the time of cryopreservation (F score) was evaluated.

Main results and the role of chance: The number of AG and non-AG were 47 (38.8%) and 74 (61.2%), respectively. There was one monozygotic twining in AG. No sibling embryo was remained in non-AG. Female age (32.3 ± 2.8 *vs.* 32.3 ± 3.5; *P* = 0.85) and body mass index (21.3 ± 2.2 *vs.* 21.4 ± 4.2; *P* = 0.15) were similar between the two groups. Common etiological factors of subfertility were also similar between the groups. The number of retrieved oocytes (15.9 ± 7.4 *vs.* 13.4 ± 7.4; *P* = 0.03), that of MII oocytes (12.5 ± 5.9 *vs.* 9.8 ± 5.2; *P* = 0.006), that of fertilized oocytes (10.4 ± 4.7 *vs.* 8.0 ± 4.4; *P* = 0.002), that of frozen embryos (6.4 ± 4.1 *vs.* 4.2 ± 3.3; *P* = 0.0003), F score (9.9 ± 6.5 *vs.* 5.6 ± 4.1; *P* < 0.0001) were higher in AG. The total amount of administrated FSH/HMG and the peak estradiol concentration of each group (AG *vs.* non-AG) were 2,210 ± 1,007 IU *vs.* 1,965 ± 915 IU (*P* = 0.06) and 3,680 ± 2,262 pg/ml *vs.* 2,956 ± 2,627 pg/ml (*P* = 0.009), respectively.

Limitations, reasons for caution: Limitations of this study include the smaller sample size and the retrospective study from a single institute. Consideration for the next baby was not given into the stimulation protocol in this study.

Wider implications of the findings: This study indicate that much higher acquisition rate for the next baby may be expected if we utilize information on the number of children of couple's desire, and if more precise developmental prognosis of each embryo is available in the near future.

Trial registration number: Not applicale.

P-416 Does starting day of progesterone intake really matter in frozen blastocyst transfer cycles?

S. Cavkaytar[1], N. Fındıklı[2], M. Gultomruk[3], G. Karlıkaya[4], M. Kavrut[4], R. Abalı[4], B. Erzik[4], K. Boynukalın[4], M. Bahceci[4]

[1]*Bahceci Umut IVF Center, Infertility Clinic, İstanbul, Turkey*
[2]*Bahceci Fulya IVF Centre, IVF Laboratory, İstanbul, Turkey*
[3]*Bahceci Fulya IVF Centre, R&D Laboratory, İstanbul, Turkey*
[4]*Bahceci Fulya IVF Centre, Infertility Clinic, İstanbul, Turkey*

Study question: This study aims to evaluate whether a 1-day delay in the starting day of progesterone intake can change the clinical outcome in frozen blastocyst transfers.

Summary answer: Both P+0 and P+1 can be taken as the starting day of progesterone supplementation resulting in similar clinical outcome in frozen blastocyst transfers.

What is known already: Due to recent improvements in human embryo cryopreservation, deferred embryo transfer strategies involving frozen cleavage and blastocyst-stage embryos are increasingly adopted in IVF clinics worldwide. On the other hand, this continuous increase in the number of frozen embryo transfer (FET) cycles also necessitates successful endometrial preparation. Although encouraging clinical outcomes have been reported in the literature, optimal timing of progesterone intake during FET cycles still need to be established. Since serum progesterone levels start to rise before ovulation, it can be argued that progesterone administration before FET should also start earlier.

Study design, size, duration: This retrospective study consisted of 1407 consecutive FET cycles involving single blastocysts performed between September 2013 - August 2017. In all cycles, same endometrial preparation strategy was used except the starting day of progesterone which was either P+0 or P+1 depending on the clinician's preference. All embryos were warmed in the morning of embryo transfer day and FET was performed in the afternoon.

Participants/materials, setting, methods: In 749 FET cycles, progesterone intake was found to be started as P+0 (Group I) and in 658 cycles, it was commenced as P+1 (Group II). During the study period, embryo culture media as well as vitrification/warming media were purchased and used from the same producer (Irvine Scientific). FETs were performed either on the fifth or sixth day of progesterone supplementation, which was given either from vaginal or intramuscular route.

Main results and the role of chance: In both groups, general patient- and cycle-related demographics and distributions such as female age, BMI, number of previous ART trials, reason of infertility as well as quality scores and distribution of transferred embryos scores were found to be similar (p>0.05). Comparison analysis also displayed high but similar biochemical pregnancy (74.2% vs. 69.6%) and clinical pregnancy rates (68.6% vs. 65.3%; p>0.05). Twenty-eight percent of these pregnancies have already resulted in live birth in Group I and 30.2% in Group II respectively.

Limitations, reasons for caution: The main limitation of our study was its retrospective design. Also, patients were not blinded about the exact duration of progesterone supplementation.

Wider implications of the findings: Our study shows that setting of starting time of progesterone intake either as P+0 or p+1 does not create any significant difference in clinical outcomes in frozen single blastocyst transfer cycles. Further randomized studies involving single euploid blastocysts with a single progesterone supplementation route are needed to confirm these results.

Trial registration number: Not applicable.

P-417 Impact of Body Mass Index on outcome of the first pregnancy after referral among women with recurrent pregnancy loss

M. El Issaoui[1], M.C. Krog[1], O.B. Christiansen[2], A. Kolte[1], H.S. Nielsen[1]

[1]*Copenhagen University Hospital- Rigshospitalet, Recurrent Pregnancy Loss Unit, Copenhagen, Denmark*
[2]*Aalborg University Hospital, Gynecology and Obstetrics, Aalborg, Denmark*

Study question: Does Body Mass Index (BMI) impact outcome of the first pregnancy after referral among women with recurrent pregnancy loss (RPL) referred to a tertiary center?

Summary answer: BMI is not a prognostic factor for the chance of live birth among women with RPL referred for evaluation and treatment in tertiary center.

What is known already: Obesity has been reported to affect the chance of a live birth in women with RPL. One study reported that BMI, maternal age, number of previous losses, and ethnicity were associated with pregnancy outcome. They found an increased risk of another pregnancy loss in in obese women with unexplained RPL but not in overweight women. We have previously reported that BMI is not a significant prognostic factor for live birth in women with RPL and a normal menstrual cycle. As concluded in the new ESHRE guideline the impact of BMI on the prognosis of live birth has not been determined.

Study design, size, duration: A retrospective cohort study including 1068 Danish women with RPL, defined as three consecutive pregnancy losses, referred for evaluation and treatment at the National Danish RPL Unit between 2000-2010

Participants/materials, setting, methods: Anonymized data on age, number of pregnancy losses prior to referral, outcome of first pregnancy after referral, BMI and menstrual cycle (normal vs. oligomenorrhea) were retrieved from the Danish National RPL database. Chi-square testing and logistic regression analysis were performed. A p-value of <0,05 was considered significant. Women, whose first pregnancy outcome after referral were ectopic pregnancy or induced abortion, were excluded from the analysis.

Main results and the role of chance: Normal weight women with BMI between 18.5–24.9 kg/m^2 constituted the largest group (n = 623, 59.4%) followed by overweight women with BMI between 25.0-29.9 kg/m^2 (n = 242, 23.1%), obese women with BMI ≥30 kg/m^2 (n = 165, 15.7%), and the smallest group being underweight women with BMI <18.5 kg/m^2 (n = 18, 1.7%). Live birth rates in the BMI groups were 60.3% (n = 356); 58.6% (n = 136); 55.3% (n = 89); 64.7% (n = 11), respectively. There was no impact of BMI on chance of a live birth, neither as a grouped variable (<18.5; 18.5-24.9; 25-29.9; ≥30), OR 0.93 (CI 0.79-1.09), $p = 0.37$, nor as a continuous variable OR 0.992 (CI 0.97-1.02), $p = 0.56$ adjusted for menstrual cycle (normal vs. oligomenorrhea), maternal age, and number of previous pregnancy losses. We did not find a poorer prognosis for live birth among obese women compared with non-obese women (% live birth 55.3 vs. 60.2, $p = 0.26$). Maternal age ranged from 20 to 45 years (mean age 33 years). Increasing maternal age reduced the chance of a live birth, OR 0.97 (95% CI 0.94-1.00) $p = 0.05$, as did number of prior losses (OR 0.80 95% CI 0.69-0.92), $p = 0.002$.

Limitations, reasons for caution: We did not adjust for ethnicity, karyotype, autoimmune and endocrine diseases. Especially karyotyping of prior losses could change our results as a higher number of euploid losses are found when BMI >25 kg/m^2, suggesting that high BMI or associated conditions could be the cause in overweight and obese women.

Wider implications of the findings: Our study in women with RPL cannot confirm that high BMI is a negative prognostic factor for birth in the first pregnancy after referral. We confirm that maternal age and number of losses are important prognostic factors. These findings merit further scrutiny and additional studies are needed.

Trial registration number: N/A.

P-418 The influence of subfertility, type of counsellor and educational level on women' choices regarding first trimester prenatal screening

S. Al-Nasiry

azM, Obstetrics & Gynecology, Maastricht, The Netherlands

Study question: Does subfertilit, type of counsellor and education level influence the choice for first trimester prenatal screening?

Summary answer: subfertility and type of counsellor have limited impact on the choice of women for prenatal screening, while education level does.

What is known already: Prenatal screening is performed between 11 and 14 weeks of gestation and provides a risk assessment concerning congenital abnormalities. Since 2017 a non-invasive prenatal test is accessible to all pregnant women, screening for trisomy 13, 21 and 18. In case of an increased risk for congenital abnormalities, termination of pregnancy is permitted till 24 weeks of gestation.

In the Netherlands parental counselling is practiced by both midwives and gynaecologists. Women with healthy pregnancies, defined as a low-risk pregnancy without co-morbidities, are counselled by a midwife. Women with high-risk pregnancies (i.a. previous preeclampsia) are counselled by a gynaecologist.

Study design, size, duration: For a period of 10 months, a questionnaire regarding prenatal screening was given to all women with a new pregnancy, by midwives and gynaecologist in Maastricht, the Netherlands. Prior to the questionnaire, women were informed about the prenatal screening, impact of outcomes). Survey questions focused on social and medical maternal characteristics, socioeconomic. status and choice and motivation for prenatal screening. A total of 82 questionnaires were completed and returned.

Participants/materials, setting, methods: The questionnaire consisted of three parts. The first part focused on the choice of first trimester screening, the second part on screening at 20 weeks of gestation (ultrasound) and the third part on paternal influence regarding (shared)decision making. Questions were formatted into statements and provided with an answer scale from 0 till 4 (0 = no influence, 4 = highly influential). Data on maternal, obstetric and socioeconomic status were recorded in an electronic database.

Main results and the role of chance: In total 258 women returned a completed questionnaire The average age was 31 ± 4 years and 56% of all women were multiparous. Subfertile were 10%. Neither subfertility itself, nor factors related to it (type, cause, duration) affected the choices women made regarding prenatal screening, there was a non-significant trend among subfertile women to more towards NIPT 4% vs 1%, and less towards combined test 43% vs 59%, and invasive tests (0% vs 5%), compared to control women. The type of counsellor did not affect the choice for FTS, 68.6% in the midwife-counselled group vs 69.2% in the gynaecologist-counselled group ($p = 0.66$). Education level was defined as "low educated" (completed primary school), "secondary trained" (completed any secondary education) and "high educated" (bachelor' or masters' degree) according to the Dutch Statistic Registry. The percentage of women that declined versus those that choose FTS were 5% vs 9%, 64% vs 25% and 32% vs 66%, respectively. A significant difference was found between the "low educated" and "high educated" group with a p-value of 0.006.

Limitations, reasons for caution: The educational level of the subjects does not match the Dutch society, more low educated people compared to this study. Furthermore, counselling was not performed in a controlled setting.

Wider implications of the findings: These results show that subfertility and type of counsellor have limited impact on the choice of women for prenatal screening, while education level does Further research should focus on the reason for this difference and eventually may lead to more intensive counselling in lower educated women.

Trial registration number: NA.

P-419 RCT of Single versus double intrauterine insemination in ovarian hyperstimulation cycles

A. Jindal[1], R. Singh[2], M. Singh[2]

[1]Bhopal Test Tube Baby Centre, Infertility, Bhopal, India
[2]Bhopal Test-Tube-Baby Centre, Infertility, Bhopal, India

Study question: To find out any difference in sucess rates between single and double IUI groups in Ovarian Hyperstimulation cycles with multi-follicular development?

Summary answer: Double IUI offers no clear benefit in the overall clinical pregnancy rate in Ovarian Hyperstimulation cycles with multi-follicular development.

What is known already: Correct timing of intrauterine insemination (IUI) might optimize the success rate in infertile couples.

Nonetheless, timing of ovulation varies and might depend on the ovarian stimulation protocol used.

Away to bypass this problem in IUI cycles is to increase the frequencyof IUI in the same treatment cycle.

Early randomized trials revealed higher clinical pregnancy rates during double IUI treatmentcycles. IUI is an evidence-based, first-step approach for the management of patients with unexplained infertility (Verhulst et al., 2006), and it is a generally preferred treatment for mild male factor infertility, ovulatory dysfunction,cervical factor infertility and endometriosis (Duran et al., 2002).

Study design, size, duration: 426 women who underwent IUI from 2015 to 2017.under age of 40 yrs.

Women were randomly assigned to single (n = 213) or double (n = 213) IUI groups.

Women in the single group underwent IUI performed 36-38 hours after human chorionic gonadotropin (HCG) administration.

Women in the double group underwent two IUIs performed 18–20 and 40-42 hours after HCG administration. The main outcome was clinical pregnancy Rate by evidence of fetal cardiac activity.

Participants/materials, setting, methods: 426 women who underwent IUI from 2015 to 2017.under age of 40 yrs. Women were randomly assigned to single (n = 213) or double (n = 213) IUI groups. Women in the single group underwent IUI performed 36-38 hours after human chorionic gonadotropin (HCG) administration. Women in the double group underwent two IUIs performed 18–20 and 40-42 hours after HCG administration.

The main outcome was clinical pregnancy Rate.

Data were analyzed by SPSS software.

Main results and the role of chance: Pregnancy rate was 10.2% in the single IUI group and 11.4 % in the double IUI group. difference between the two groups was not statistically significant.

There were no significant difference between the groups regarding women's age, their husbands' age, women's BMI,duration of infertility, causes and types of infertility, the level of AMH, FSH and LH, the number of dominate follicles, endometrial thickness, endometrial pattern, and the sperm character ($P > 0.05$)

Limitations, reasons for caution: Despite the 36th hour being the preferred timing for IUI, there was no difference regarding pregnancy rates between single and double inseminations.

Wider implications of the findings: There is consensus that controlled ovarian hyperstimulation(COH) combined with an IUI is a much more effective treatment for infertility than single applications of IUI or COH. Limited data exist on the optimal timing of an IUI and the number of inseminations needed to improve pregnancy rates.

Trial registration number: Not applicable.

P-420 The clinical potential of "random start" ovarian stimulation of fertility preservation for Japanese breast cancer patients

K. Nakamura, S. Takae, Y. Suzuki, S. Sawada, H. Iwahata, Y. Sugishita, Y. Horage, N. Suzuki

St. Marianna University School of Medicine, Obstetrics and Gynecology, 2-16-1 Sugao- Miyamae-ku- Kawasaki- Kanagawa 216-8511, Japan

Study question: Is "Random start" ovarian stimulation for Japanese breast cancer patients effective?

Summary answer: The "Random start" ovarian stimulation protocol is effective method for breast cancer patients who need to start their cancer treatment immediately.

What is known already: The traditional approach of ovarian stimulation as fertility preservation depends on their menstrual cycle. As a result, some of the patients may give up fertility preservation, because there are the possibilities of a significant delay of cancer treatment and increasing psychologic stress for the

patients. For that reason, to prevent any delay in cancer treatment, the "Random start" ovarian stimulation has been reported as effective for cryopreservation at any point during the menstrual cycle in 2013.

Study design, size, duration: Data were retrospectively obtained from the clinical records of 44 breast cancer patients who were referred to the Oncofertility Unit at the Center for Reproductive Medicine of St. Marianna University Hospital from March 2014 to December 2017.

Participants/materials, setting, methods: The breast cancer patients who hope to preserve own fertility were received controlled ovarian hyperstimulation regardless menstruation cycle for oocyte or embryo cryopreservation. We checked back the clinical records of patients and figured out their backgrounds, the way of stimulation, the phase of menstruation (follicular, periovulatory, luteal), and the level of serum anti-Müllerian hormone (AMH), the number of oocytes per cycle and the mature oocytes rates.

Main results and the role of chance: Mean age of 44 participants was 34.9 (±3.8) years-old, and 18 of them were unmarried. They had normal menstrual cycles prior to treatment and their average level of serum AMH was 5.1 (±2.8) ng/ml. The period from consultation to the first visit to our hospital was 7.4 (±5.1) days. And the surplus period, which was period for fertility preservation from visiting our hospital to starting the cancer therapy, was around 1.4 (±0.6) months. Nineteen of them used GnRH antagonist for ovarian stimulation, 24 of them were stimulated with short protocol. In addition, 33 of them used aromatase-inhibitor combined FSH agents. Altogether 8.9 (±6.8) oocytes per cycle were retrieved, the mature oocytes rate was 0.86(±0.2), which outcomes were comparable to previous reports. The phase of menstruation did not affect either the number of oocytes extracted ($p = 0.34$) or maturation oocytes ($p = 0.10$). Also, no complications (e.g. OHSS, infection,etc.) resulted from the procedure.

Limitations, reasons for caution: This study was only data which are the numbers of oocytes per cycle and the mature oocytes rates, but the fertilization rates, pregnancy rates are not evaluated enough, because we have few embryo transfer cases. Therefore, they are needed to evaluate, intend for verification the efficacy of "Random start" method.

Wider implications of the findings: Present research outcome which is consistent with published data may promote "Random start" ovarian stimulation for fertility preservation in Asian countries, too.

Trial registration number: This study received Institutional Review Board approval from St. Marianna University of Medicine. (approval No. 1588 2873 3464 3486)

P-421 Asymptomatic bacterial colonization during embryo transfer and its impact on ICSI pregnancy rate

M. Braham[1], M. Hamdoun[2], K. Kacem[3], A. Fadhlaoui[1], S. Mnallah[3], M. Bouyahia[1], M. Ben Meftah[1], G. Merdassi[3], H. Hannachi[2], O. Bahri[2], A. Zhioua[3], F. Zhioua[1]

[1]University of Medicine Of Tunis. Aziza Othmana Hospital, Gynecology- obstetrics and Reproductive Medicine, Tunis, Tunisia
[2]University of Medicine of Tunis. Aziza Othmana Hospital, biochemistry laboratory, Tunis, Tunisia
[3]University of Medicine of Tunis. Aziza Othmana Hospital, Reproductive Medicine Laboratory, Tunis, Tunisia

Study question: What's the effect of bacterial contamination of the embryo transfer catheter and the vagina on ICSI outcomes.

Summary answer: This study shows that the contamination of the embryo transfer catheter by cervical-vaginal bacteria is associated with significantly decreased pregnancy rates during ICSI.

What is known already: As the procedure of ICSI involves the replacement of embryos into the uterine cavity using a catheter that passes through the cervix, bacterial contamination during embryo transfer is possible. Studies have demonstrated a 50% reduction in pregnancy rate when a contamination of the embryo catheter tip occured. Furthermore, a decreased live birth rate has been reported in patients in whom pathogenic bacteria were isolated from the embryo transfer catheter tip. Dominant microorganisms involved were B and D groups *Streptococci, E.coli* and *Enterococcus.*

Study design, size, duration: A prospective, longitudinal and analytical study during eight months (from February 1st to October 31st, 2017)

Participants/materials, setting, methods: The study included patients who attended the ART center for embryo transfer and who matched the following criteria: age ≤ 40, normal uterine ultrasound and hysteroscopy, first or second attempt of ICSI, use of fresh semen and transfer of at least one good quality embryo. At the time of embryo transfer, three samples were done for microbiological analysis: a vaginal swab, a cervical mucus sample and the tip of the transfer catheter.

Main results and the role of chance: The study included 40 patients. The overall pregnancy rate was 52.5%. Catheter contamination occurred in nine cases (22.5%). The most frequently isolated bacteria were Streptococcus anginosus (37%), Gardnerella vaginalis (27%) and Streptococcus agalactiae (18%). In all cases of contamination, the same isolated bacteria were also found at in the vagina and in the cervical mucus. In cases of contamination with Gardnerella vaginalis, the study of vaginal flora based on the calculation of the Nugent score showed bacterial vaginosis. No cases of pregnancy have been obtained when a contamination of the transfer catheter occurred. However, in the absence of contamination, the success rate was 61.2% ($\rho = 0.001$). Patients' characteristics, stimulation protocols, embryology, number and quality of embryos transferred and partners sperm parameters did not vary significantly between the two groups (patients with catheter contamination and patients without catheter contamination). We can then speculate that the presence of these bacteria on the cervix at the time of embryo transfer could affect the pregnancy rate during ICSI.

Limitations, reasons for caution: Even if the results of this study were statistically significant, they need to be confirmed on large scale since the population size was relatively small.

Wider implications of the findings: If the negative effects of bacterial contamination during embryo transfer are confirmed on larger population, systematic antibiotic prophylaxis may be effective to limit this impact. After the inclusion of additional subjects, we could study the cervical vaginal flora before and after antibiotic administration.

Trial registration number: not applicable.

P-422 Embryo development, aneuploidy and clinical outcome in different isolated female infertility indications: Do our expectations meet the reality?

M. Gultomruk[1], N. Findikli[2], F.K. Boynukalin[3], M. Kavrut[3], E. Oral[4], M. Bahceci[3]

[1]Bahceci Fulya IVF Centre, R&D Laboratory, Istanbul, Turkey
[2]Bahceci Fulya IVF Centre, IVF Laboratory, Istanbul, Turkey
[3]Bahceci Fulya IVF Centre, Infertility Clinic, Istanbul, Turkey
[4]Istanbul University Cerrahpasa Faculty fo Medicine, Obstetrics & Gyneocology, Istanbul, Turkey

Study question: This study aims to evaluate the realistic contribution of female infertility on embryonic development, aneuploidy and clinical outcome in non-male infertility couples undergoing PGD-A cycles.

Summary answer: Our results show that embryonic development, aneuploidy and clinical outcome are all variably affected by the nature of female infertility diagnosis.

What is known already: It is nowadays well-known that female age and the severity of male infertility are one of the biggest and direct contributors of human embryonic aneuploidy leading to poor clinical outcome. Although selection and uterine replacement of euploid embryos by preimplantation genetic diagnosis (PGD-A) greatly contributes in successful clinical outcome, recent studies show that its efficiency and possible benefits in IVF are usually hindered by biological and technical limitations related to the complex nature of infertility diagnosis, making it very difficult to predict or assess the true impact and success of the approach.

Study design, size, duration: This retrospective study includes 668 patients undergoing 755 PGD-A and 348 subsequent euploid frozen embryo transfer (FET) cycles performed between January 2016 - August 2017. All PGD-A cycles involved trophectoderm biopsy of developing blastocysts on day 5 or day 6 and subsequent vitrification. Embryonic aneuploidy was analyzed by next generation sequencing (NGS). All embryo transfers were performed as FET.

Participants/materials, setting, methods: Only cycles with a single female infertility diagnosis and non-male infertility were included in the study and grouped as follows: Group I consist of cases with diminished ovarian reserve (DOR; 257 patients/311 cycles), Group II includes cases with endometriosis (55 patients/61 cycles); Group III includes cases with PCOS (66 patients/69 cycles). Group IV consists of unexplained infertility cases (UEI; 290 patients/314 cycles). Laboratory and clinical outcome were compared among groups.

Main results and the role of chance: Female age, laboratory parameters such as mean number of oocytes collected, fertilized and mean number of embryos biopsied in Group I was significantly lower than the others ($p<0.01$). Although blastocyst development rate was found to be comparable among groups (50.9%, 53.4%, 46.9% and 40.6%), the rate of embryo euploidy was found to be significantly lower in Group I than the others (34.0%, 52.4%, 57.4% and 52.2% respectively; $P<0.01$). Cases in Group III and IV had the lowest cycle cancellations compared to Group I and II (13.0%, 29.9%, 58.8% and 36.1% respectively). Once an euploid embryo was found and transferred in the uterine environment, Group I, III and IV resulted in comparable clinical pregnancy rates (64.1%, 61.9% and 67.2% respectively). Although the highest clinical pregnancy rate (90.9%) and lowest miscarriage rate (6.9%) were observed in cycles involving endometriosis (Group II), the differences were not found to be statistically significant ($p>0.05$).

Limitations, reasons for caution: The main limitations in our study were the number of cases included and its retrospective design. Prospective studies with higher number of cases included are needed in order to validate these findings.

Wider implications of the findings: Our results first show that transfer of a euploid embryo results in successful clinical outcome in all non-male infertility groups evaluated in the study. However, quantitatively poor laboratory outcome prior to embryo biopsy is found to be the major determinant which leads in high cycle cancellations (>50%) in DOR cases.

Trial registration number: None.

POSTER VIEWING

Implantation and early pregnancy

P-423 Oxidative stress induced autophagy dysfunction in human decidual cells: a novel mechanism involved in early pregnancy loss

T. Yu[1], L. Jin[1], H. Huang[1,2]

[1]*International Peace Maternal and Child Health Hospital, Shanghai Jiao Tong University, School of Medicine*

[2]*Institute of Embryo-Fetal Original Adult Diseases, School of Medicine, Shanghai Jiao Tong University*

Study question: To examine whether autophagy is associated with the pathogenesis of early pregnancy loss(EPL)?

Summary answer: We found in EPL decidual cells, endoplasmic reticulum stress-induced(ER stress) autophagy through increasing Ca^{2+} release and activating of CaMKKβ-AMPK signaling pathway.

What is known already: Our previous study first reported that ER stress existed in maternal-fetal interface, and sustained ER stress could cause decidual cells apoptosis. Autophagy as an essential, conserved lysosomal degradation pathway, is involved in pathological processes including neurodegenerative diseases, infection and cancer. Many studies have demonstrated that ER stress triggers autophagy. And the possible mechanism of ER stress induced autophagy might be the release of Ca^{2+} from the ER into the cytosol, which can subsequently activate various kinases and proteases involved in autophagy signaling.

Study design, size, duration: Normal and EPL decidual tissues were collected from patients with normal pregnancies undergoing elective termination of gestation, and from patients with EPL, respectively.

Participants/materials, setting, methods: From January 2015 to may 2016, 15 pregnant women with a diagnosis of EPL and 30 age-matched women with normal pregnancy were selected in the international peace maternity and child health hospital, school of medicine, shanghai Jiao tong university. The technology of western blot, immunohistochemical and transmission electron microscopic were performed on deciduas from women with EPL, and then ER stress markers, autophagy associated protein and autophagic features were analyzed in decidual cells (DCs).

Main results and the role of chance: This present study found that EPL deciduas were characterized by up-expression of microtubule-associated protein (MAP) 1 light chain 3II(LC3II), extensive dilation of ER, and morphological features of autophagosome. To explore the function and regulation mechanism of autophagy in the pathogenesis of EPL, we developed a cell model of oxidative stress(OS) using hydrogen peroxide(H_2O_2) administrated normal decidual cells. In normal decidual cells, we found that H_2O_2-induced ER stress could lead to autophagy through increasing Ca^{2+} release and activation of CaMKKβ-AMPK signaling pathway. However, vitamin E could reverse the concentration of cytosolic Ca^{2+} and the expression of LC3II. These findings indicated the occurrence of ER stress-induced autophagy in EPL decidual cells, which might play an important role in the development of EPL.

Limitations, reasons for caution: This study focused on the function of LC3II in EPL, however, numerous other autophagy related proteins may also be responsible for the pathogenesis of EPL. Therefore, further studies are required to elucidate the mechanism in EPL.

Wider implications of the findings: Our findings indicate that autophagy may contribute to the development of EPL, and the inhibition or disruption of autophagy may be a potential therapeutic target to prevent EPL in the future.

Trial registration number: no.

P-424 A systematic review and meta-analysis of chronic endometritis and recurrent miscarriage

M. Rimmer, K. Fishwick, J. Brosens, S. Quenby

University of Warwick, Reproductive Health, WARWICK, United Kingdom

Study question: Is their an association between chronic endometritis (CE) and recurrent miscarriage (RM)? Does CE predict miscarriage? Do antibiotics reduce CE and prevent miscarriage?

Summary answer: Despite a high prevalence of CE in RM, there is insufficient evidence to recommend screening for and treating CE in recurrent miscarriage.

What is known already: Chronic Endometritis (CE) is defined as long-term inflammation of the endometrium and possibly driven by infection. The diagnosis is based on the identification of plasma cells within the endometrium by morphology with Haematoxylin and Eosin or mere recently using immunohistochmestry to CD138 or hysteroscopy. CE has been associated with potential pathogenic organisms, bacterial dysbiosis. Numerous studies have reported a high prevalence of CE in the recurrent reproductive failure population and antibiotics have been used to reduce CE and prevent miscarriage. A systematic review of these studies is needed to provide clarity as to the status of the current evidence.

Study design, size, duration: Search terms were identified and searches were run in the MEDLINE, EMBASE, Web of Science, CINAHL and Cochrane databases. Studies were excluded if large potential bias existed. Two independent reviewers selected 17 studies, which met predefined criteria. Manuscript quality and analysis of bias were assessed using the Critical Appraisal Skills Programme.

Participants/materials, setting, methods: Studies were included if they included women with RM and/or; investigated a link between CE and RM, investigated CE prevalence in women with and without RM, compared treatment of women with RM with antibiotics or no antibiotics, looked for an outcome of live birth rate, tested for CE using endometrial biopsy or hysteroscopy. There were no language restrictions. 173 studies were identified of which 17 met the inclusion criteria.

Main results and the role of chance: Several studies reported a high incidence of CE in recurrent miscarriage, up to 57%. However, there were no studies with adequate controls to establish the prevalence in the general population.

Two studies found a higher live birth rate in women with RM and CE than without CE (OR 3.34 (1.67, 6.87) N = 159).

Based on assessment of a repeat endometrial biopsy, a single course of Doxycycline was reported to "cure" CE defined histologically in 92%, 94%, 75% and 70% of patients (4 studies). Although no randomised controlled trials were identified, non-randomised observational studies found that:

- Published comparisons of livebirth rate in women with untreated CE compared to treated CE were small OR 1.12 (0.27,4.67) N = 71
- An increase in livebirth rate in CE patients who responded to antibiotic treatment compared to those who did not. OR 12.40 (6.74, 22.81) N = 244
- A comparable livebirth rate in women with CE who were actively treated with antibiotics compared to subjects without CE OR 1.48 (0.83, 2.65) N = 540.

Limitations, reasons for caution: The incidence of CE in the normal population was not published. No randomised control trials were identified assessing the efficacy of antibiotics in the prevention of miscarriage for women with CE and RM.

Wider implications of the findings: This review has found insufficient evidence to recommend screening for and treating CE in recurrent miscarriage at the present time. However, the data do suggest that CE may be a treatable cause of recurrent miscarriage. Randomised, controlled trials are urgently needed.

Trial registration number: NA.

P-425 Lipidomic profile as a non-invasive tool to predict endometrial receptivity in freeze-all cycles

D.P.A.F. Braga[1], E. Borges Jr.[2], A.T. Godoy[3], G.P. Oliveira[3], M.N. Eberlin[3], D.A. Montani[4], A.S. Setti[5], B.F. Zanetti[5], E. Ono[5], E.G. Lo Turco[4]

[1]Fertility Medical Group, Scientific Department, Sao Paulo, Brazil
[2]Fertility Medical Group, Clinical Department, Sao Paulo, Brazil
[3]Universidade de Campinas, Laboratorio ThoMSon de Espectrometria de Massas, Campinas, Brazil
[4]Universidade Federal de Sao Paulo, Departamento de Cirurgia, Sao Paulo, Brazil
[5]Instituto Sapíentiae - Centro de Estudos em Reprodução Assistida, Scientific Department, Sao Paulo, Brazil

Study question: Is the endometrial fluid lipidomic an useful approach to predict endometrial receptivity in freeze-all cycles?

Summary answer: The endometrial fluid lipidomic is a valuable tool to predict endometrial receptivity in freeze-all cycles.

What is known already: The embryo implantation depends on the proper embryo development and the acquisition of a receptive endometrium. The embryo is unable to adhere to it through most of the menstrual cycle, except during a short, self-limited period, the window of implantation (WOI). Inadequate uterine receptivity has been estimated to contribute to one third of implantation failures, whereas the embryo itself is responsible for two thirds of them. Predictors of the uterine receptive are needed to better understand the causes of endometrial-based infertility, and help women with recurrent implantation failure (RIF) due to possible dyssynchrony, between embryo and endometrium, to achieve pregnancy.

Study design, size, duration: For this prospective cohort study, endometrial fluid samples, were collected immediately before embryo transfer, using a soft catheter, attached to a 5mL-syringe, with which a slight suction was made to bring the fluid into the catheter. Samples (n = 41) collected between Jan/2015 and Dez/2016 were split into two groups depending on the pregnancy outcome: Positive-Group (n = 24) and Negative-Group (n = 17). The study included exclusively freeze-all cycles in which one or two top quality blastocysts were transferred.

Participants/materials, setting, methods: Collections were performed in university-Affiliated IVF-center. Lipid extraction was performed according with the Bligh and Dyer method and spectra were acquired in the positive mode by MALDI-TOF mass spectrometer method. The principal component analysis (PCA) and Partial Least square discriminant Analysis (PLS-DA) were applied to the dataset. A list of potential ions ratios biomarker was obtained, the values were used to build a ROC curve to predict pregnancy success, and the lipid categories were identified.

Main results and the role of chance: Patient's and cycle's characteristics did not differ among the groups. The raw data was processed and 265 ions were used for statistical analysis. Twenty ions ratios were established according with their correlations and those variables were used for the further analysis. The fold-change analysis detected 13 ratios with two-fold increased representation in the Positive and 84 in the Negative-Group. According with the t-test, 16 ratios were differentially represented among the groups ($p<0.05$), and the volcano plot analysis detected five ratios two-fold differentially represented among groups with statistical significance. The PCA analysis showed a tendency of separation between the studied groups, while the PLS-DA was able to clearly distinguish the groups. Fifteen ratios (13 hyper-represented in the Negative and two in the Positive-Group) were selected considering their importance for the model prediction. These ratios were used to build the ROC curve, which presented an area under the curve of 81.8% (CI 95%: 62.7–94.7%, $p = 0.009$). Ions identified by the lipidmaps database were: phosphoethanolamine, phosphatidic-acid, diacylglycerol, triacylglycerol, glycosyl diacylglycerol, phosphatidylcholin, neutral-sphingolipidium, lysophosphatidylglycerol. Functional enrichment analysis revealed that increased triacylglycerol and phospholipids ratio leads to low density lipoproteins remodeling, which may be associated with changed steroid syntheses, and therefore, WOI displacement.

Limitations, reasons for caution: The model was not validated because the MS/MS experiment was not yet performed.

Wider implications of the findings: Our findings demonstrated that endometrial fluid lipidomics may be a powerful approach to define the exact time of the WOI. This would be extremely important for determination of the right time for embryo transfer and, consequently, diminish the incidence of RIF, a substation challenge in assisted reproduction.

Trial registration number: None.

P-426 Endometrial thickness and oocyte quality affect perinatal outcomes in intracytoplasmic sperm injection cycles

A. Iaconelli Jr.[1], B.F. Zanetti[2], D.P.A.F. Braga[3], A.S. Setti[2], R.C.S. Figueira[4], E. Borges Jr.[1]

[1]Fertility Medical Group, Clinical Department, São Paulo, Brazil
[2]Instituto Sapientiae - Centro de Estudos em Reprodução Assistida, Scientific Department, Sao Paulo, Brazil
[3]Fertility Medical Group, Scietific Department, São Paulo, Brazil
[4]Fertility Medical Group, IVF Laboratory, São Paulo, Brazil

Study question: Which factors affect perinatal outcomes in intracytoplasmic sperm injection (ICSI) cycles?

Summary answer: Perinatal outcomes are positively affected by embryo quality and endometrium thickness and negatively affected by the presence of oocyte polar body fragmentation.

What is known already: Pregnancies derived from assisted reproduction techniques (ART) cycles have been correlated with worse perinatal outcomes, such as preterm birth, low birth weight, small size for gestational age, and perinatal mortality. Although these complications are commonly attributed to the higher rate of multiple births with ART, assisted singleton pregnancies had also worse perinatal results than natural ones. Nevertheless, the role of ART itself on poorer obstetric and perinatal outcomes has not been demonstrated convincingly and is still to be determined which aspects of ART pose greater risks of perinatal complications and how these risks can be minimized.

Study design, size, duration: This cohort study included 402 babies born to 307 patients undergoing ICSI cycles from January/2014 to December/2015. The number of gestational weeks (GW), baby weight (BW) and length (BL) at birth were correlated with: number of follicles and retrieved oocytes, mature and immature oocytes, fertilization rate, number of high-quality embryos, transference stage and endometrial thickness using linear regression models. In single embryo transfer (SET) cycles, oocyte dysmorphisms and embryo quality were also evaluated.

Participants/materials, setting, methods: The study was performed in a private university-affiliated in vitro fertilization center. After childbirth, the GW, BW, BL, baby sex, and presence of malformations at birth were recorded by the patient gynecologist and a written reported. All analysis were adjusted for

mother's age, body mass index (BMI), number of transferred embryos, gestational sacs, and born infants.

Main results and the role of chance: The endometrial thickness was positively correlated with GW (95%CI OR: 0.069; 0.327 p = 0.003) and BW (95% CI OR: 0.770; 55.932 p = 0.044). Blastocyst transference was negatively correlated with the GW in comparison to cleavage-stage embryo transfer (95%CI OR: -1.899; -0.057 p = 0.037). The number of follicles (95%CI OR: -0.127; -0.012 p = 0.018), that of mature oocytes (95%CI OR: -0.175; -0.001 p = 0.050), and that of immature oocytes (95%CI OR: -0.668; -0.141 p = 0.003) were negatively correlated with BL. In SET cycles, the transfer of embryos classified as high-quality was positively correlated with the number of GW (95%CI OR: 0.633; 5.685 p = 0.014) and BW (95%CI OR: 56.394; 720.323 p = 0.022). The only oocyte dysmorphism that negatively impacted all the perinatal outcomes was the presence of polar body fragmentation. Babies born from oocytes with this dysmorphism were characterized by a lower GW (95%CI OR: -2.907;-0.083 p = 0.038), a lower BW (95%CI OR: -814.697; -85.140 p = 0.016), and a smaller BL (95%CI OR: -5.801; -2.346 p<0.001).

Limitations, reasons for caution: Although the analysis was adjusted for a number of important confounders, the dataset included no information on education level, ethnicity, and medical history of the women before and during pregnancy to allow for additional adjustments. Moreover the small samples size may limit the relevance of the study.

Wider implications of the findings: Ovarian stimulation, oocyte and embryo quality may impact perinatal outcomes. Better perinatal outcomes may be achieved through the transfer of high-quality embryos to a proper endometrium. The presence of polar body fragmentation highly impacts the perinatal outcomes, suggesting that the fertilization of oocytes with this dysmorphism must be further evaluated.

Trial registration number: None.

P-427 Embryo transfer medium containing granulocyte macrophage colony-stimulating factor improved implantation and ongoing pregnancy rates in patients who have experienced miscarriage

H. Tomari, K. Kunitake, K. Uchimura, N. Aramaki, S. Kuhara, K. Nishimura, N. Hidaka, K. Honjo, Y. Nagata

IVF NAGATA Clinic, ART Lab, Fukuoka, Japan

Study question: How does embryo transfer medium containing granulocyte macrophage colony-stimulating factor (GM-CSF) affect clinical outcomes in vitrified-warmed embryo transfer cycles in patients who have experienced miscarriage?

Summary answer: Embryo transfer medium containing GM-CSF produced high implantation and ongoing pregnancy rates in vitrified-warmed embryo transfers in patients who had experienced miscarriage.

What is known already: Human embryonic development and implantation *in vivo* is regulated precisely by various cytokines including growth factors. Granulocyte macrophage colony-stimulating factor (GM-CSF) is a cytokine that plays an important role in reproductive function. Previous studies have reported that GM-CSF is increased in normal pregnancy and is very low during pregnancy before abortion. It suggests that increasing the concentration of GM-CSF in implantation environment may be beneficial for previous miscarriage patient. However, the effect of GM-CSF on the cleavage stage in vitrified-warmed embryo transfer in patients who have experienced at least one miscarriage remains unclear.

Study design, size, duration: A prospective quasi-randomized controlled study was performed in a single *in vitro* fertilization (IVF) center between January 2015 and December 2017. This study included patients with nulliparity who had experienced at least one miscarriage. All study participants provided informed consent, and the study design was approved by the ethics committee of IVF Nagata Clinic, Fukuoka, Japan.

Participants/materials, setting, methods: We examined 243 cycles of vitrified-warmed embryo transfer. Embryos were vitrified at the 4-cell stage (day 2). Warmed embryos were cultured for 24 hours and transferred on day 3. Patients were allocated at random to two groups. Embryos were cultured and transferred to control medium containing no GM-CSF (Global; Lifeglobal) (control group) or to test medium containing 2 ng/ml GM-CSF (EmbryoGen; ORIGIO) (test group). Embryo transfer was performed at hormone replacement therapy cycle.

Main results and the role of chance: Clinical pregnancy, implantation, miscarriage and ongoing pregnancy rates after embryo transfer were compared between the two groups. The mean patient age was 38.8 ± 4.1 years (± SD; range 23–45). There were no significant differences in patient characteristics (age, endometrial thickness, number of miscarriages, and number of embryos transferred) between the two groups. Among the 243 vitrified-warmed embryo transfer cycles, 120 were allocated to the control group and 123 to the test group. The clinical pregnancy rate in the test group was higher than that in the control group (p = 0.10, 30.9% vs. 21.7%). The implantation rate in the test group was higher than that in the control group (p = 0.09, 20.3% vs. 13.9%). The miscarriage rate in the test group was lower than that in the control group (p = 0.269, 28.9% vs. 42.3%). The ongoing pregnancy rate in the test group was higher than that in the control group (p = 0.05, 22.0% vs. 12.5%).

Limitations, reasons for caution: The study was limited by the study size and lack of data about live birth rates after embryo transfer. In addition, the mechanism of action of GM-CSF on implantation is unknown. Further functional studies are needed to explain the molecular mechanism of GM-CSF.

Wider implications of the findings: Our findings indicate that medium containing GM-CSF improves implantation and ongoing pregnancy rates. The results suggest that the use of embryo transfer medium containing GM-CSF may be effective as a treatment strategy not only for patients who have experienced miscarriage but also for patients with repeated implantation failure.

Trial registration number: Not applicable.

P-428 Lipidomic analysis reveals increased TXA2 presence in non-receptive endometrium of recurrent miscarriage and repeated implantation failure patients

E. Bastu[1], I. Demiral[2], E. Ulgen[3], M.B. Erkan[4], S.E. Celik[5], Y. Aydin[4], A.N. Onem[5], B. Yuksel Ozgor[2], M. Dogan[2], R. Apak[5], U. Sezerman[3], F. Buyru[2]

[1]Acibadem University Faculty of Medicine, Department of Obstetrics and Gynecology, Istanbul, Turkey
[2]Istanbul University School of Medicine, Department of Obstetrics and Gynecology, Istanbul, Turkey
[3]Acibadem University, Department of Biostatistics and Medical Informatics, Istanbul, Turkey
[4]Istanbul University Faculty of Science, Department of Biology, Istanbul, Turkey
[5]Istanbul University Faculty of Engineering, Department of Chemistry, Istanbul, Turkey

Study question: Would the endometrial prostanoids profile of unexplained infertility, recurrent miscarriage (RM) and repeated implantation failure (RIF) patients differ from fertile controls?

Summary answer: We have identified the increased endometrial presence of TXA2 in RM and RIF patients; TXA2 is a prostanoid linked with platelet aggregation and vessel contraction.

What is known already: The endometrium is a dynamic tissue that undergoes growth, differentiation, and regression periods throughout the menstrual cycle in response to hormonal regulation to prepare the uterus for embryo implantation. In recent years, several studies in animal models have shown the importance of lipids at the time of embryo implantation. Lipidomics studies have enabled the identification and characterization of these lipids at the time of endometrial receptivity. Lipid molecules such as prostaglandins are some of the most widely studied mediators of embryo implantation. Prostaglandins modulate the activity of endometrium and their functional role can be appreciated through tissue concentration of prostanoids.

Study design, size, duration: In this prospective cohort study, endometrial samples were collected from 18 unexplained infertility patients, 16 RM patients, 15 RIF patients and 23 fertile controls during the window of implantation (LH +7 to LH+10) at gynecology and infertility clinics of Istanbul University School of Medicine. Tissue samples were homogenized and extracted. Then lipidomic analysis of prostanoids were carried out by LC-ESI-MS/MS in the analytical chemistry laboratory of the Istanbul University.

Participants/materials, setting, methods: 18 prostanoids were identified according to literature: 6-keto 6-keto PGF1α, PGF3α, TXB2, PGE3, PGD3, PGF1α, PGF2α, PGE2, PGE1, 13,14-dihydro-PGF2α, PGD1, PGD2, 13,14-dihydro-PGF1α, 13,14-dihydro PGE1, 13,14-dihydro-15-keto PGF2α, 13,14-dihydro-15-keto PGE2, 13,14-dihydro-15-keto-PGE1, 15-deoxy-Δ 12,14 PGJ2. Unexplained infertility was defined as normal hormone panel, hysteroscopic findings and sperm parameters. RM was defined as at least 2 miscarriages at 20 weeks or less. RIF was defined the failure to conceive after at least 2 cycles of IVF.

Main results and the role of chance: When prostanoid concentration in endometrium samples of unexplained infertility patients were compared with fertile controls, there was no statistically significant differences (p>0.05). When prostanoid concentration in endometrium samples of RM patients was compared with fertile controls TXA2 (measured as TXB2 in line with literature due to the unstable nature of TXA2) was significantly higher (p<0.001). Similarly, TXB2 was higher in endometrium samples of RIF patients again in comparison to fertile controls (p<0.001). Median values of TXB2 are as follows: in fertile controls 133.5 pg/mg; in RM patients 858.7 pg/mg; in RIF patients 843.1 pg/mg. When TXB2 was further compared between samples of RM and RIF patients, there was no statistically significant difference (p>0.05).

Limitations, reasons for caution: Recent studies have used lipidomic analyses to study pregnancy outcome, but receptive versus non-receptive endometrium in humans were not analyzed. For the first time in literature, we attempted to compare receptive versus non-receptive endometrium using lipidomic approach via 18 chosen prostanoids. However, a comprehensive map of prostaglandin expression is lacking.

Wider implications of the findings: Using lipidomic analysis we have identified the increased endometrial presence of TXA2 in RM and RIF patients, while no such presence in unexplained infertility patients. Interestingly, TXA2 has well-recognized platelet aggregating and vessel-contracting activities. This is clinically relevant because it may shed light on events leading to successful embryo implantation.

Trial registration number: not applicable.

P-429 Ectopic pregnancy and endometrial thickness in assisted reproduction cycles: is there a link?

S. Mattar[1,2], L. Lapensée[1,2], C. Sylvestre[1,2], A. Eberle[3], S. Phillips[1,2], R. Antaki[1,2]

[1]Université de Montréal, Obstetrics & Gynecology- division of Reproductive Endocrinology & Infertility, Montreal, Canada
[2]Ovo Clinic, Ovo Fertility, Montreal, Canada
[3]Université de Montréal, Faculty of Medicine, Montreal, Canada

Study question: Can a thick endometrial lining measured prior to embryo transfer be considered a protective factor against ectopic pregnancy (EP)?

Summary answer: An endometrial thickness (ET) of > 12 mm is associated with a 68% decreased chance of EP in assisted reproduction technology (ART) cycles.

What is known already: EP is more common in pregnancies resulting from ART compared to those from spontaneous conception, with some peculiar risk factors like number and day of embryos transferred, volume and depth of transferred material, among others. However only one study so far assessed the link between ET and EP.

Study design, size, duration: This is a retrospective case-control study comparing all cases (n = 45) of EP (study group) to 119 cases of documented viable intra-uterine pregnancies (control group) between August 2009 and December 2016 at a private fertility clinic (OVO clinic, Montreal, Canada). Pregnancies resulting from both fresh embryo transfer and frozen embryo transfer (FET) were included.

Participants/materials, setting, methods: The study group consisted of 29 EP in the fresh cycles and 16 in the FET cycles. The control group cases were selected based on a random number generator model on a year-to-year basis. Bivariate analysis was conducted to assess the effect of all collected variables on EP. A multivariate analysis was then used to calculate the odds ratio (OR) for EP with an ET > 12 mm, adjusted for known confounders.

Main results and the role of chance: The two groups did not differ significantly in factors traditionally associated with EP (previous EP, endometriosis, tubal disease, history of pelvic infection, and abdominal surgery). Patients with EP were more likely to have a thinner endometrium (9.7 vs 10.2 mm, p = 0.009), had day 3 rather than a day 5 transfer (p <0.001), had double rather than a single embryo transfer (p <0.001), and finally were more likely to have had a difficult transfer (p = 0.002).

When analyzed separately, the association between a small ET and EP was preserved in FET cycles (8.9 vs 9.8 mm, p = 0.015) but not in fresh cycles (10.0 vs 10.4 mm, p = 0.116).

In multivariate analysis, ET > 12 mm was found to be a significant protective factor against EP with an OR of 0.32 (95% CI 0.12-0.84). However, difficult transfer and day 3 embryo transfer remained as statistically significant independent risk factors for EP with OR's of 18.04 (95% CI 2.36-137.62) and 7.07 (95% CI 2.62-19.07) respectively.

Limitations, reasons for caution: The retrospective nature of the study and the inter-observer variability in the measurement of the ET might weaken the conclusion. It is also possible that some other confounders have not been accounted for.

Wider implications of the findings: It is the first study to show that a higher ET could have a risk-reducing effect on EP, which if confirmed by future prospective observations, can act as a counseling cornerstone by providing reassurance for patients at risk undergoing ART.

Trial registration number: Not applicable.

P-430 Danaparoid is effective and safe for patients with obstetric antiphospholipid syndrome

H. Yoshihara, M. Sugiura-Ogasawara, C. Bannno, T. Kitaori, Y. Ozaki, K. Katano, N. Suzumori

Nagoya City University -Gradeate School of Medical Science, Obstetrics and Gynecology, Nagoya, Japan

Study question: It was unclear whether danaparoid sodium (Orgaran[R]) is effective in improving the live birth rate in patients with obstetric antiphospholipid syndrome (oAPS).

Summary answer: The live birth rate in patients who received danaparoid was similar to that in patients who received unfractionated heparin.

What is known already: Unfractionated heparin and low-dose aspirin (LDA) is known to improve the live birth rate in patients with oAPS. Alternatively, anticoagulation with danaparoid was reported to be effective and safe in 83 patients with a history of thrombophilia and/or intra-uterine growth retardation complicated by HIT or intolerance or resistance to low molecular weight heparins.

Study design, size, duration: A case-control study was conducted between 2006 and 2017. It examined 86 pregnancies in 62 patients with oAPS diagnosed according to criteria of the International Congress on APS. Patients who suffered two miscarriages were included based on ESHRE recurrent pregnancy loss guidelines.

Participants/materials, setting, methods: APS was diagnosed by measuring lupus anticoagulant (LA), by the activated partial thromboplastin time and Russell's viper venom time and/or the presence of b2glycoprotein I dependent anticardiolipin antibodies. Live birth rates, and adverse pregnancy and perinatal outcomes were compared among patients given danaparoid and LDA (danaparoid group), unfractionated heparin and LDA (heparin group) and LDA and/or prednisolone (LDA group).

Main results and the role of chance: Live birth rates were 63.6 % (14/22) for the danaparoid group, 79.5 % (31/39) for the heparin group and 56.0 % (14/25) for the LDA group. After excluding 11 miscarriages with abnormal embryonic chromosomes and one ectopic pregnancy, live birth rates were 87.5 % (14/16) for the danaparoid group, 86.1% (31/36) for the heparin group and 63.6 % (14/22) for the LDA group. Frequencies of abnormal embryonic karyotypes were 75.0% (6/8), 25.0% (2/8), 33.3% (3/9), respectively, because the mean (SD) age of the danaparoid group tended to be higher (p = 0.014). The live birth rate of patients given danaparoid and unfractionated heparin was similar and tended to be higher than that of patients given LDA (OR 4.0, 95%

confidence interval 0.72-22.2 and 3.5, 0.98-12.8). One patient given unfractionated heparin developed HIT and this case resulted in stillbirth.

Limitations, reasons for caution: This study was not a randomized control trial (RCT). The sample size of patients with danaparoid was relatively small because Japanese medical insurance could cover only treatment with unfractionated heparin. Further RCTs are necessary to confirm these results.

Wider implications of the findings: Danaparoid is safe and effective in improving the live birth rate in patients with oAPS.

Trial registration number: UMIN000031012

P-431 Serum 17-alpha-hydroxyprogesterone (Sr. 17-α-OHP): a precocious early indicator of implantation and gestational status in double embryo-transfer fresh IVF cycles

B.N. Chimote[1], N. Chimote[2]

[1]*Vaunshdhara Clinic & Assisted Conception Centre, Embryology- Endocrinology, Nagpur, India*
[2]*Vaunshdhara Clinic and Assisted Conception Centre, Endocrinology- Embryology, Nagpur, India*

Study question: To evaluate if serum level of 17-alpha-hydroxyprogesterone (17-α-OHP) in the peri-/post-implantation period may be early indicator of gestational status in double embryo-transfer fresh IVF cycles.

Summary answer: Ratio of Day of Embryo-transfer(dET):d7ET serum 17-α-OHP and its pattern of rise/fall post-ET is a robust marker of implantation and gestational status in IVF cycles.

What is known already: The complications of maternal morbidity and neonatal care associated with high-risk multiple-gestations that often occur in IVF cycles due to transfer of supernumery embryos has prompted the practice of single embryo-transfer. However, several countries, with no IVF funding/insurance cover, continue to transfer ≥2 embryos on day3/day5 to enhance pregnancy rates in minimal number of cycles and to complete family structure (one boy/one girl) in single cycle. Under such circumstances, it is imperative and advantageous to know gestational status well in advance so that necessary care and precautions may be taken. Currently, no such early indicator of gestational status is available.

Study design, size, duration: Prospective cohort study of IVF cycles (n = 780) carried out from July 2014 to March 2017 in consenting women undergoing antagonist stimulation protocol followed by double embryo-transfer on either day3 or day5 in a suitably prepared endometrium. Similar luteal phase support was provided to all women. Serum 17- α-OHP level was measured on dET and subsequently on days 7,11,14,19,23 post-ET. Serum estradiol, β-hCG and progesterone levels were also measured on all these days using diagnostic kits.

Participants/materials, setting, methods: β-hCG measurement on d7ET was considered indicator of pregnancy. Implantation was main outcome measure with singletons (n = 131), twins (n = 43), miscarriages (n = 18), ectopic pregnancy (n = 9) and biochemical pregnancy (n = 70) as offshoot measures of implantation. Ratio of 17-α-OHP levels on dET:d7ET in no-implantation cycles (n = 509) were compared with those in different categories of implantation. Statistical analysis involved Student's-t test, Chi-square test, Correlation, One-Way ANOVA/Post-test, ROC analysis, as applicable, using Graph-pad Prism VI software.

Main results and the role of chance: The ratio dET: d7ET serum 17-α-OHP levels differed significantly between no-implantation (3.2 ± 0.16) versus singletons (1.18 ± 0.05;p<0.0001,), twins (0.67 ± 0.05;p<0.0001), early miscarriages (1.23 ± 0.1;p = 0.02), ectopic pregnancy (0.82 ± 0.1;p = 0.04) and biochemical pregnancy (1.87 ± 0.1;p = 0.002).

Day7 serum 17-α-OHP levels strongly correlated with implantation (Spearman r = 0.63,p<0.0001, 95%CI 0.58-0.67). The likelihood for all kinds of pregnancies increased above the D7 17-α-OHP median value of 3.2 ng/ml; whereas likelihood of singletons and twins was high above the 75th percentile value of 5.4 ng/ml and 95th percentile value of 9.98 ng/ml respectively. Post-test for linear trend in 17-α-OHP levels serially every 4 days from day7 to day23 post-ET showed a linear rise in singleton and twins cycles (Slope 0.77, p<0.0001 and 2.3, p = 0.0002 respectively); displayed non-significant steep rise in ectopic cycles (slope 4.97,p = 0.33) whereas declined in biochemical pregnancies (Slope -0.06, p = 0.45). Indication for IVF, day of ET (Day3/Day5), endometrial thickness and echo-pattern on ultrasonography, all remained non-significantly comparable throughout the study population.

Thus, transition from dET to d7ET and thereafter maintenance of linear rise in 17-α-OHP levels decides the fate of implantation/gestational-status. Minimum sample size of 108 was required for 17-α-OHP to have >85% predictive power for no-implantation versus 5 different types of implantation/gestational status. The power of our study (n = 780) is therefore very strong and predictive.

Limitations, reasons for caution: Not exactly a limitation but although the sample size of this study is sufficiently large with robust results and strong predictive power; a multi-centric Randomized Controlled trial is warranted for establishing serum 17-α-OHP as an early indicator and a gold standard for implantation/ gestational status in multiple embryo-transfer IVF cycles.

Wider implications of the findings: This study assumes immense significance especially in Asian sub-continent where multiple-embryo-transfer is done for various reasons. Risks associated with multiple-gestations/ectopics are well documented and it is often too late to take necessary steps. An early indicator can facilitate timely clinical management and help circumvent the complications to a large extent.

Trial registration number: Not Applicable.

P-432 Endometrial transcriptomic pathways analysis in recurrent miscarriages and unexplained infertility

I. Demiral[1], E. Gumusoglu[2], E. Ulgen[3], M. Hosseini[2], B. Yuksel Ozgor[1], M. Dogan[4], A. Nehir Aytan[1], U. Sezerman[3], T. Gunel[2], E. Bastu[4]

[1]*Istanbul University School of Medicine, Obstetrics and Gynecology, Istanbul, Turkey*
[2]*Istanbul University, Molecular Biology and Genetics, Istanbul, Turkey*
[3]*Acibadem University School of Medicine, Biostatistics and Medical Informatics, Istanbul, Turkey*
[4]*Acibadem University School of Medicine, Obstetrics and Gynecology, Istanbul, Turkey*

Study question: Would endometrial genes and their transcriptomic pathways in patients with recurrent miscarriage (RM) and unexplained infertility (UI) differ from fertile controls?

Summary answer: In RM and IU, respectively 8 and 20 pathways based on 730 and 2171 differentially expressed genes are significantly altered when compared to fertile controls.

What is known already: The endometrium is a complex structure undergoing significant transcriptomic transformations during menstrual cycle. This constantly changing feature support the adherence, then invasion and growth of an embryo. Any disturbance in this fragile system results with infertility or negative pregnancy outcomes. Beginning with Carson's paper in 2002, genomic analysis have been broadly used in different subgroups of infertility. RM and UI have been studied in many papers using microarray analysis in order to find 'target' genes responsible of the disease. Despite the high number of microarray studies, a consistency between results is still lacking, making this topic still interesting for researchers.

Study design, size, duration: This prospective cohort study involved 24 patients in each group: RM, UI and control. Recruited between August 2014-August 2015, all patients were <35 years old. RM was defined as ≥2 consecutives pregnancy losses in women with normal RM workup (hormon profile at Day 3, hysterosalpingogram, spermiogram, karyotype, antiphospholipid syndrome antibodies, inherited trombophilias). Women with no evident reason for infertility were in UI group. Women with ≥1 live birth(s) and no other comorbidities were controls.

Participants/materials, setting, methods: Endometrial samples were taken in Istanbul University School of Medicine, during the window of implantation (LH+7 to LH+10). They were put in RNAlater for one night at +4°C, and then snap frozen in liquid nitrogen. In our molecular biology and genetics laboratory, RNA extraction and hybridization with microarray slides were performed. Slides were scanned and hybridization signals were extracted using a sotfware program. R[10] package limma and PANOGA were used for statistical analysis.

Main results and the role of chance: Analysis for RM compared to controls revealed 730 differentially-expressed genes (DEGs) clustered in 8 representative pathways: pathways in cancer (p value = 3.11E-12), regulation of actin cytoskeleton ($p = 2.81E-09$), NF-kappa B signaling pathway ($p = 5.89E-11$), adherens junction ($p = 9.99E-09$), complement and coagulation cascades ($p = 6.23E-09$), SNARE interactions in vesicular transport ($p = 5.60E-06$), citrate cycle (TCA cycle) ($p = 2.98E-07$) and sulfur relay system ($p = 1.90E-06$).

Analysis for UI compared to controls revealed 2171 DEGs clustered in 20 representative pathways: complement and coagulation cascades ($p = 1.22E-19$), morphine addiction ($p = 6.49E-19$), PI3K-Akt signaling pathway ($p = 3.25E-14$), SNARE interactions in vesicular transport ($p = 2.33E-13$), adherens junction ($p = 4.43E-11$), p53 signaling pathway ($p = 6.15E-11$), spliceosome ($p = 3.02E-10$), endocytosis ($p = 3.02E-10$), TGF-beta signaling pathway ($p = 3.15E-10$), amyotrophic lateral sclerosis (ALS) ($p = 2.30E-09$), notch signaling pathway ($p = 5.36E-09$), viral myocarditis ($p = 1.76E-08$), renin-angiotensin system ($p = 2.64E-08$), maturity onset diabetes of the young ($p = 4.40E-08$), proteasome ($p = 4.97E-06$), dilated cardiomyopathy ($p = 1.08E-05$), non-homologous end-joining ($p = 3.28E-05$), basal transcription factors ($p = 3.83E-05$), folate biosynthesis ($p = 5.74E-05$) and amoebiasis ($p = 6.03E-05$).

Limitations, reasons for caution: Some limitations should be addressed: endometrial samples were not taken on the exact same menstrual day for all patients, the commercially available microarray slides used in our study can have differences from other brands, and complete disclosure of genes in others studies is lacking making a fair literature comparison difficult.

Wider implications of the findings: Instead of being limited to one gene or a group of genes, pathways analysis provides us a better understanding of the ethiology beneath RM and UI. Different genes may impact one common pathway: this could be the reason why a consistency can not be achieved across microarray studies.

Trial registration number: not applicable.

P-433 Prostaglandin E2 receptor 3 (EP3) signaling is induced in placentas of patients with unexplained recurrent pregnancy losses (uRPL)

Y. Ye[1], A. Vattai[1], N. Ditsch[1], C. Kuhn[1], M. Rahmeh[1], S. Mahner[1], M. Ripphahn[2], R. Immler[2], M. Sperandio[2], U. Jeschke[1], V. Von Schönfeldt[1]

[1]Ludwig-Maximilians-University of Munich- Germany, Department of Obstetrics and Gynecology, Munich, Germany

[2]Ludwig-Maximilians-University of Munich- Germany, Department of Cardiovascular Physiology and Pathophysiology, Munich, Germany

Study question: Is prostaglandin E_2 receptor 3 (EP3) signaling involved in the mechanism of unexplained recurrent pregnancy losses (uRPL)?

Summary answer: Elevated expression of EP3 signaling in first trimester placentas plays an important role in the fetal-maternal interface of patients with uRPL.

What is known already: An inflammatory microenvironment is required for successful implantation, however an inflammatory overreaction is one of the main causes for uRPL. Prostaglandin E_2 (PGE_2) plays a pivotal role in regulating immune balance and angiogenesis during early pregnancy and it is able to stimulate inflammatory reactions via EP3.

Study design, size, duration: A total of 19 women with uRPL and 19 healthy pregnancies were included. For *in vitro* studies, JEG-3 and HTR-8/SVneo cells were used and stimulated by PGE_2, sulprostone (an EP1/EP3 agonist) and L-798,106 (an EP3 antagonist) with different concentrations.

Participants/materials, setting, methods: We analysed the expression of cyclooxygenase-2 (COX-2), EP3 and G protein alpha inhibitor 1 (G_{i1}) in first trimester placentas of women with uRPL and healthy pregnancies via immunohistochemistry and double immunofluorescence. The production of β-hCG, progesterone and plasminogen activator inhibitor type 1 (PAI-1) in JEG-3 and HTR-8/SVneo cells was examined by enzyme-linked immunosorbent assay (ELISA). The expression of EP3 and G_{i1} of JEG-3 and HTR-8/SVneo cells was evaluated by western blotting.

Main results and the role of chance: The expression of COX-2, EP3 and G_{i1} was upregulated in the placenta of women with uRPL in comparison to healthy controls. Sulprostone inhibited the secretion of β-hCG and progesterone in JEG-3 cells and the secretion of β-hCG in HTR-8/SVneo cells, while it stimulated the expression of PAI-1 in JEG-3 cells *in vitro*. In addition, PGE_2/sulprostone was able to induce the expression of G_{i1} in JEG-3 and HTR-8/SVneo cells, respectively. L-798,106 (an EP3 specific antagonist) suppressed EP3 expression in both trophoblast cell lines.

Limitations, reasons for caution: Further studies are required to understand the role of the additional membrane receptors of PGE_2 (EP1, 2 and 4) and other members of the G_i family (G_{i2} and G_{i3}) in the placenta of uRPL patients.

Wider implications of the findings: These mechanisms give a better understanding of how PGE_2 may regulate placental inflammatory status in uRPL patients. As an EP3 antagonist, L-798,106 might quantify a 'potential therapeutic candidate' for the treatment of uRPL.

Trial registration number: NA.

P-435 Utilization of dydrogesterone in programmed FET cycles allows the determination of serum progesterone of exclusively trophoblastic origin in pregnancy- an update on the luteoplacental shift

K. Neumann, M. Depenbusch, A. Schultze-Mosgau, T. Osterholz-Zaleski, G. Griesinger

Universitäre Kinderwunschzentren Lübeck/Manhagen, Department of Gynecological Endocrinology and Reproductive Medicine, Lübeck, Germany

Study question: What are the precise kinetics of placental progesterone production in early pregnancy and how do these relate with the type and course of pregnancy?

Summary answer: Progesterone remains virtually undetectable until the +16-22 days (d) after embryo transfer. The increase is nonlinear, depends on the type of pregnancy and predicts miscarriage.

What is known already: The onset of placental progesterone production is termed the luteo-placental shift (LPS). Previous studies on pregnancies after oocyte donation in ovarian failure patients map the LPS to around the 5th (Devroey et al. 1990) or 9th gestational week (GW) (Scott et al. 1991), whereas the classical oophorectomy studies of Csapo *et al.* report the LPS between the 8th and 9th GW. Dydrogesterone does not cross-react with antibodies in ELISAs. The utilization of dydrogesterone in a programmed frozen-thawed embryo transfer cycle (in which no corpus luteum is present) therefore allows the determination of serum progesterone of exclusively trophoblastic origin in pregnancy.

Study design, size, duration: Prospective analysis of pregnancies resulting from programed FET cycles with oral E2 (6 mg/d for minimal intake 13 days) followed by E2 (6 mg/d) and 30 mg/d oral dydrogesterone up to the 12th GW. The sample collection started in 7/2015 and is currently ongoing. Progesterone levels are expressed in µg/l (±standard deviation).

Participants/materials, setting, methods: All patients were transferred one (singletons) or two embryos. Patients were divided into groups by pregnancy type (singletons, n = 17; dichorionic twins, n = 7; triplets, n = 1, abortion, n = 20). The type of pregnancy was determined by ultrasound starting +16-22d following embryo transfer (ET). Progesterone, E2 and hCG was measured in serum samples by the Roche Elecsys ELISA before dydrogesterone intake on day 13-15 (to confirm absence of ovulation) and weekly in early pregnancy up to +65-71d following ET.

Main results and the role of chance: Endogenous progesterone was not increased in all groups on first blood analysis on day 9-15 days following ET compared to baseline levels on day 13-15 (singletons after eSET: 0.25 ± 0.20; n = 16; twins: 0.25 ± 0.15; n = 6, triplet: 0.33; n = 1) and increased only marginally up to +16-22d post ET independently from the type of pregnancy (singleton: 0.33 ± 0.11; n = 13; twins: 0.51 ± 0.27; n = 6, triplet: 0.33). Progesterone levels started to rise above 1.0 µg/l within 23-29d post ET (singleton: 1.43 ± 0.89; n = 16; twins: 1.96 ± 0.83; n = 6, triplet: 3.44). From

+30-36d on the twin group and the triplet pregnancy (n = 1) showed an elevated progesterone increase versus singleton pregnancies (singleton: 3.67 ± 1.53; n = 14; linear slope: y = 2.8465× - 6.912; twins: 6.45 ± 2.29; linear slope: y = 4.6047× - 10.821; n = 6, triplet: 11.9; linear slope: y = 6.5007× - 15.602) which was aggravated even further on following analysis and resulted in markedly enhanced progesterone levels on last analysis during +65-71d (singleton: 23.33 ± 7.51; n = 11; twins: 36.57 ± 6.57, n = 4; triplet: 60.9;) in parallel with estradiol levels. While hCG plateaus around +37-43d, placental progesterone production steadily increases throughout the first trimester. Miscarriage was reliably predicted by progesterone levels measured +23-29d after embryo transfer (ROC analysis AUC = 0.85, 95% CI: 0.69–1.00, p = 0.004).

Limitations, reasons for caution: Minimal cross-reaction of the antibodies used in the Roche ELISA between endogenous progesterone and dydrogesterone may have slightly distorted the values. The sample size is too small to reliably establish the predictive performance of endogenous progesterone values for miscarriage or adverse events related to abnormal early placental development.

Wider implications of the findings: For the first time in human reproduction, early pregnancy trophoblastic progesterone production was assessed without the background "noise" caused by either a corpus luteum graviditate or exogenous progesterone supplementation. The findings fire new studies on the LPS, prediction of pregnancy viability, placental activity/pathology with wide implications (fetal growth etc.).

Trial registration number: n.a.

P-436 Local Endometrial injury before frozen-thawed embryo transfer (FTET) cycles? A review and meta-analysis

E. Theodorou, J. Ben Nagi, O. Ozturk, P. Serhal

The Centre for Reproductive and Genetic Health CRGH, Reproductive Medicine, London, United Kingdom

Study question: Does endometrial injury before a frozen-thawed embryo transfer (FTET) cycle increases chances of pregnancy or live birth?

Summary answer: Currently there is limited evidence to recommend endometrial injury before FTET cycles.

What is known already: Randomised studies and meta-analysis suggest that local endometrial injury (LEI) in the cycle preceding IVF treatment appears to increase pregnancy rate particularly in women with recurrent implantation failure. A further meta-analysis concluded that while results must be interpreted with caution due to low quality evidence, endometrial injury before intrauterine insemination or when trying for a natural conception could be associated with higher live birth rate. It is not known whether the same benefit could be observed after endometrial injury for FTET cycles.

Study design, size, duration: We searched the MEDLINE, EMBASE and the Cochrane Central Register of Controlled Trials (CENTRAL), as well as reference lists of relevant reviews and included studies. We performed the search from inception to January 2018. We included randomised controlled trials (RCTs) that evaluated any kind of intentional endometrial injury in women planning to undergo a FTET compared to no intervention or a mock intervention. The risk of bias was judged according to Cochrane Handbook's recommendations.

Participants/materials, setting, methods: We identified 4 RCTs that included in total 476 FTET cycles; three studied patients who had FTET with hormone replacement treatment (HRT) and one patients during a natural cycle. In all studies the intervention group had endometrial injury with an endometrial biopsy catheter (Pipelle, Pipette or an Endocyte® sampler) while the control group in one of the three studies had endocervical manipulation and in the remaining three no uterine manipulation.

Main results and the role of chance: Meta-analysis of two RCTs that evaluated LEI in women undergoing FTET showed no significant difference in pregnancy rate between the LEI and control group (OR 0.89; 95% CI 0.41-1.94; p = 0.77).

Studies that investigated FTET during natural and HRT cycles were pooled due to evidence suggesting the outcome is similar and also due to the small number of studies.

Four RCTs evaluated the role of LEI in women undergoing FTET (1 with natural cycles and 3 studies with HRT) showed no difference rate in clinical pregnancy rate and ongoing/live birth rate versus the control group (OR 1.17; CI 0.68-2.01; p = 0.57 and OR 1.40; CI 0.63-3.11; p = 0.40, respectively).

A subgroup analysis of two RCTs including unselected women for FTET and two RCTs including women with at least 2-4 failed embryo transfers didn't suggest a higher LBR for women having EI for either of the two subgroups (OR 0.95; CI 0.54-1.66; p = 0.85 and OR 2.61; CI 0.44-15.51; p = 0.29, respectively).

Limitations, reasons for caution: This is the first attempt to systematically review the evidence for endometrial injury before FTET. However, this was based on a small number of RCTs, which did not allow for the analysis of subgroups such us natural vs HRT or number of previous failed embryo transfers for all outcomes.

Wider implications of the findings: While there is evidence to suggest that endometrial injury could increase the success rate for women having fresh IVF treatment, IUI or when trying to conceive naturally, there is currently limited evidence to indicate that LEI could improve FTET outcome.

Trial registration number: Not applicable.

P-437 Identification of the human uterine acetylome

M. Taggart[1], M. Karolczak-Bayatti[2], R. Watson[1], A. Treumann[3], G.N. Europe-Finner[1], P. Palmowski[1]

[1]*Newcastle University, Institute of Genetic Medicine, Newcastle upon Tyne, United Kingdom*
[2]*Manchester University, School of Health Sciences, Manchester, United Kingdom*
[3]*Newcastle University, Newcastle Proteome and Protein Analysis, Newcastle upon Tyne, United Kingdom*

Study question: Can we identify the breadth of lysine residues modified by acetylation in the human uterine proteome?

Summary answer: Almost 2,000 lysine residues were acetylated in the human myometrium proteome. >300 were potentially modulated by treatment with a lysine deacetylase inhibitor TSA.

What is known already: There are many possibilities for post-translationally modifying proteins and regulating uterine cell function during menstruation, early and established pregnancy - e.g, acetylation of lysine residues, regulated by acetyltransferases (KATs) and deacetylases (KDACs), plays a prominent role in cellular biology via modification of histones and non-nuclear proteins. We have previously shown that protein acetylation is important for regulating human uterine contractility. Treatment of ex vivo biopsies with KDAC inhibitors changed the acetylation of selected proteins – e.g. the cytoskeletal protein HSPB6 - and altered contractility. These observations suggest protein acetylation to be a potential mechanism for initiation/regulation of uterine function.

Study design, size, duration: Uterine biopsies were obtained, following written informed consent, from pregnant women undergoing elective Caesarean section (38 subjects in total). 20 samples were treated with TSA and 18 were used as controls. To reach the required amount of material per replicate, samples were randomly pooled into 5 treated and 6 control pools.

Participants/materials, setting, methods: The collected tissues were immediately treated with 3.3uM TSA for 6 hours and stored frozen. Tissues were homogenized, digested to peptides with tripsin/endolyse C and subjected to immunoprecipitation with anti-Acetyl Lysine Antibody. The eluates, containing enriched acetylated peptides, were analysed using LC-MS based approach (Thermo Q-Exactive). The individual peptides and acetylated residues were identified and quantified using MaxQuant 1.5.3.8 comparisons to a Uniprot–derived human proteome database.

Main results and the role of chance: We identified (with FDR<0.01) 1951 acetylation sites (localization probability >0.75) related to 821 protein groups. 342 acetylation sites were uniquely identified in TSA-treated samples. Acetylation of 1254 sites was quantifiable between experimental conditions, of which 127 differed significantly (t-test, FDR<0.05) and 45 were increased by TSA treatment. A combination of quantitative (t-test and clustering) and interrogative analysis allowed us to identify that many of the acetylated proteins were involved in cellular processes related to energy utilisation (TCA cycle and

oxidative phosphorylation), cell motility (MYH9, MYH10, ACTB, TPM4) and adhesion (COL6, ZYX, VCL) and chromatin structure (histones).

Limitations, reasons for caution: The process of immunoprecipitation targeted for acetylated lysine residue-containing peptides enriches a small pool of total digested peptide and cautions the interpretation of subsequent quantifications.

Wider implications of the findings: This study provides a platform of identification of almost 2,000 protein lysine acetylation sites in human uterine tissue. Future experiments designed to expand the breadth of acetylated protein identification (the acetylome) will facilitate the examination of the regulatory influences of protein acetylation on human uterine function.

(Supported by MRC grant MR/L0009560/1)

Trial registration number: not applicable.

P-438 Is Endometrial Receptivity Array (ERA) screening relevant to increase pregnancy rates in patients with failed IVF cycles?

G. Teles[1], R. Lacordia[2], T. Bonetti[3], A.R. Lorenzon-Ojea[4], E. Motta[5]

[1]*Huntington Medicina Reprodutiva, Clinical Medicine Department, São Paulo, Brazil*
[2]*Huntington Medicina Reprodutiva, Clinical Medicine Department, São Paulo- SP, Brazil*
[3]*Federal University of São Paulo, Gynecology Department, São Paulo- SP, Brazil*
[4]*Huntington Medicina Reprodutiva, Scientific Coordination, São Paulo- SP, Brazil*
[5]*Huntington Medicina Reprodutiva/Federal University of São Paulo, Clinical Medicine Department/Gynecology Department, São Paulo- SP, Brazil*

Study question: Is Endometrial Receptivity Array (ERA) screening relevant to increase pregnancy rates in patients with previous negative IVF results?

Summary answer: There is no difference in pregnancy rates for patients with previous fails followed by personalized ERA embryo transfer if compared to controls with standard preparation.

What is known already: Onset of pregnancy is given when a proper embryo has the ability to attach in a receptive tissue. Endometrial receptivity is accomplished on day 19-21 in normal cycle, also known as window of implantation (WOI). Usually, endometrial thickness and progesterone serum levels are parameters considered to evaluate the endometrium receptivity, but it remains a lack of accurate methods. The endometrial receptivity array (ERA) is a transcriptomic signature test aiming to provide profiles of biopsied tissue in pre/post non-receptive or receptive endometrium. According to this profile, an adjustment in endometrial stimulation protocol could be performed to better synchronize an embryo transfer.

Study design, size, duration: A retrospective study, including 418 patients divided into two groups: 209 had at least 1 previous IVF fail, followed by an ERA biopsy, proceeded to a frozen embryo transfer (FET) where the endometrial stimulation was adjusted according to the ERA result in a later cycle (personalized embryo transfer, pFET), named ERA group, and 209 age-matched controls, at the same time, not-biopsied for ERA with a FET with a standard endometrial preparation, named non-ERA group.

Participants/materials, setting, methods: Endometrial biopsies samples were obtained after 120 hours of progesterone introduction and classified into Receptive, Pre-Receptive, Post-Receptive or Non-Receptive by ERA. In both groups, transfers were performed on blastocyst stage (embryo day 5-6). Patients from pFET and FET groups (38 ± 5.26 years old) were also subdivided into 2 subgroups: those with euploid biopsied embryos (ERA/PGD and Non-ERA/PGD, n = 92 each, CGH or NGS) and those with no biopsied embryos transferred (ERA/non-PGD and non-ERA/non-PGD, n = 117 each).

Main results and the role of chance: The majority of patients, with at least one IVF fail and submitted to an ERA test, were found to displace a receptive endometrium (n = 137, 65.55%) followed by pre-receptive (n = 53, 25.35%), non-receptive (n = 11, 5.26%) or post-receptive (n = 8, 3.82%). The average pregnancy rates were similar comparing both groups (51.67% vs 47.85%, p = 0.4935; ET number 1.75 ± 0.62 vs 1.56 ± 0.52, p = 0.0011). Either in euploid biopsied embryos or not biopsied embryos subgroup: ERA/PGD vs Non-ERA/PGD (48.91% vs 43.47% p = 0.5561; ET number: 1.60 ± 0.50 vs 1.43 ± 0.57, p = 0.02), ERA/No PDG vs Non-ERA/No PGD (55.55% vs 51.28% p = 0.6002; ET number: 1.88 ± 0.72 vs 1.65 ± 0.51 p = 0.009). Receptive and pre-receptive endometrium showed similar pregnancy rates (54.01% vs 49.05%, p = 0.6274, ET number: 1.77 ± 0.68 vs 1.72 ± 0.49, p = 0.8607). Non-receptive and post-receptive patients were in low numbers for relevant purpose (n = 11 and 8 respectively). For statistical analysis, paired T-test or Fisher´s test was applied as appropriated.

Limitations, reasons for caution: In the cases where ERA result was pre, post or non-receptive, adjusted endometrial stimulation protocol was applied in a later cycle as suggested, but the array was not repeated to confirm the adjusted receptivity. Male factor and primary infertility reason were not considered in this study.

Wider implications of the findings: Using ERA adjustment indiscriminately, is not relevant to increase patient's pregnancy rates when compared to standard endometrial stimulation protocol. However, ERA should be considered for patients with specific cause of infertility, such as repeated implantation failure.

Trial registration number: Not applicable.

P-439 The inflammatory response during the implantation period: association with the Reticular Stress and the Unfolded Protein Response

R.E. Ramhorst[1], E. Grasso[1], S. Gori[1], E. Soczewski[2], L. Fernánez[2], L. Gallino[2], T. Lobo[3], S. Daher[3], M. Irigoyen[4], G. Martínez[4], C. Ruhlmann[4], C. Pérez Leirós[2]

[1]*CONICET- UNIVERSIDAD DE BUENOS AIRES, Laboratorio de Inmunobilogía de la Reproducción, Buenos Aires, Argentina*
[2]*CONICET- Uinversidad de Buenos AIres, Laboratorio de Inmunobilogía de la Reproducción, Buenos Aires, Argentina*
[3]*Universidade Federal de São Paulo- São Paulo- Brazil, Department of Obstetrics-, Sao Pablo, Brazil*
[4]*Instituto Feritilidad San isidro, Instituto Feritilidad San isidro, Buenos Aires, Argentina*

Study question: Could the decidualization program of endometrial cells induce a sterile inflammatory response through the induction of reticular stress (RS) and unfolded protein response (UPR)?

Summary answer: Decidualized cells display a physiological RS and UPR that induce the inflammasome activation generating a sterile inflammatory response with production of IL-1b.

What is known already: Embryo implantation in humans requires the generation of a sterile inflammatory response for blastocyst invasion; however, it is still unclear how it could be induced. During decidualization, endometrial stromal cells suffer RS and trigger UPR, allowing the expansion of the endoplasmic reticulum and the production of immunomodulators. The physiological RS generates the activation of sensing proteins, which induces kinase/Rnase-TXNIP expression, activating the inflammasome. This multiprotein system allows caspase-1 activation, which catalyzes the cleavage of inactive pro-form IL-1b to secretory mature IL-1b. This pro-implantaoty cytokine is associated with an inflammatory response that should be control in favor of a tolerogenic microenvironment.

Study design, size, duration: Human endometrial stromal cell line (HESC) was decidualized or not with medroxiprogesterone+dbcAMP during 8 days, and was used to evaluate RS and UPR. An *in vitro* implantation model based on co-culture of blastocyst-like spheroids (BLS) from Swan-71 trophoblast cells line over decidualized-HESC cells was used to evaluate decidual functionality. Finally, we evaluated the UPR-inflammatory pathway in endometrial biopsies obtained from fertile women, with recurrent spontaneous abortions (RSA) or with *in vitro* fertilization failures (RIF).

Participants/materials, setting, methods: RS sensors (IRE1a, ATF6 and PERK) and UPR markers (sXBP1 and CHOP) were evaluated by RT-qPCR. Inflammasome activation was measured by TXNIP and NLRP3 expression. Caspase-1 activity was evaluated by the fluorescent inhibitor probe FAM-Flica and IL-1b production by FACS analysis, ELISA and Western Blot. Assays were performed also in the absence/presence ofSTF083010 (an Ire1α inhibitor) and Thapsigargin, Tg (RS-inducer). These pahtways were evaluated in endometrial samples from RSA, RIF and fertile women by RT-qPCR.

Main results and the role of chance: The decidualized cells (Dec) increased the expression of RS-sensors (ATF6, PERK and IRE1a) and UPR markers (sXBP1 and CHOP) in comparison with non-Dec cells. Tg-treated non-Dec cells were used as RS +control. Then, we evaluated the UPR inflammatory

pathway, which activates the inflammasome. Interestingly, while TXNIP expression remains unchanged, we oberved an increased NLRP3 expression in Dec cells compared with non-Dec cells, while STF083010 prevented this increase. Downstream, we detected increased levels of active caspase-1 on Dec cells compared with non-Dec uding the fluorescent inhibitor probe-FAM-Flica Caspase-1, suggesting the NLRP3 inflammasome activation. According to this, decidualized cells significantly increased IL-1b protein expression compared with non dec cells. This multiprotein complex increases IL-1b production in Dec cells. In fact, the inhibition of IRE1α-UPR by STF083010 treatment prevented IL-1b increase in Dec cells and decreased the invasion index evaluated in the *in vitro* model of implantation, suggesting that the induction of IL-1b is partially dependent of a RS-UPR process. Finally, the present results were validated using endometrial samples. We found an increase expression of IRE1α, sXBP1, TXNIP, NLRP3 and IL-1b on RSA-endometrial biopsies in comparison with fertile women; while biopsies from RIF patients showed a significantly lower expression than fertile women.

Limitations, reasons for caution: The present results were obtained using immortalized cell lines and *in vitro* decidualization and implantation models. Even the results were validated in endometrial samples from fertile women, recurrent spontaneous abortions and in recurrent in vitro fertilization failures, further studies are necessary to elucidate whether these mechanisms operate similarly *in vivo*.

Wider implications of the findings: The present results suggest that human decidualization process is accompained by a physiological RS/UPR, which induces a physiological and sterile inflammatory response associated with an increase of IL-1b production. These processes were differentially affected in RSA and RIF patients in comparison with fertile women, suggesting their relevance on reproductive pathologies.

Trial registration number: n/A.

P-440 HLA-C haplotypes distribution among gametes donors in our population

D. Alecsandru[1], C. Iglesias[1], A. Pacheco[2], A. Barrio[1], N. Garrido[3], J.A. García-Velasco[4]

[1]IVI Madrid, Department of inmunology and department of reproductive endocrinology and infertility, Madrid, Spain
[2]IVI Madrid, Andrology department, Madrid, Spain
[3]IVI Foundation Director, Research administration and innovation, Valencia, Spain
[4]IVI Madrid. Rey Juan Carlos University. Hospital Universitario La Paz- Madrid., Department of inmunology and department of reproductive endocrinology and infertility, Madrid, Spain

Study question: HLA-C haplotypes distribution among gametes donors in Caucasian population.

Summary answer: Among oocyte donors, 37.5% have an HLA-C1C1 haplotype, and very similar among sperm donors 32%.

What is known already: Increased risk of recurrent miscarriage (RM), preeclampsia and fetal growth restriction has been described in mothers KIR AA when the fetus has more HLA-C2 genes than the mother with a higher incidence in oocyte donation pregnancies compared to spontaneous conception or IVF pregnancies. In oocyte donation, the oocyte HLA-C behaves as the paternal HLA-C increasing the number of non-self-antigens presented to the mother´s uterine immune cells. This KIR-HLA-C combination is still not considered nowadays in the process of donor selection. KIR AA patients have lower live birth rates (LBR) after double embryo transfer (DET) oocyte-donation, especially with HLA-C2 partner.

Study design, size, duration: Between April 2015 and October 2017, we performed a prospective study that included 783 gametes donors matched for couples with recurrent miscarriage or recurrent implantation failure of unknown etiology. We performed HLA-C typing for 683 oocytes donors and for 100 sperm donors.

Participants/materials, setting, methods: All the donors were selected from IVIRMA Clinics, and showed a normal karyotype, negative serology and fulfilled our standards for gamete donation. We did genetic typing for HLA-C after obtaining signed informed consent. HLA-C haplotype distribution among oocytes and sperm donors in our Caucasian Spanish population was analyzed.

Main results and the role of chance: In our cohort of 683 oocytes donors, we observed a 37.5% HLA-C1C1 haplotype (N = 256), 47.7% HLA-C1C2 and 14.8% HLA-C2C2. Among the sperm donor cohort, HLA-C haplotype distribution was 32% for HLA-C1C1, 50% for HLA-C1C2 and 18% for HLA-C2C2.

Knowing the HLA-C distribution in our gametes donors might be helpful as LBR is lower when women KIR AA received a C2 donor, especially when they have a HLA-C2 partner and the embryo has more HLA-C2 antigens than the mother. This first study, observed a 32-37% of HLA-C1C1 frequency among gametes donors in our population. Those KIR-HLA-C mismatched couples affected by recurrent miscarriage or recurrent implantation failure may benefit from this approach.

Limitations, reasons for caution: The study's objective was to describe the HLA-C distribution among our donors cohort and the frequency of what we may consider the "best" haplotype, HLA-C1C1. This is the first study observing the HLA-C distribution among gametes donors and represent useful data.

Wider implications of the findings: It's believed that completing a normal pregnancy is possible only for KIR AA mothers who carry a baby with a least one non—self HLAC1. During oocyte donation, the KIR-HLA-C mismatch increases compared to own oocytes. Therefore, selecting HLA-C1 among donors could be more efficient and safer, for specific couples.

Trial registration number: not applicable.

P-441 In-cycle prediction of the outcome after fresh embryo transfer in IVF/ICSI: a molecular analysis of follicular endometrial biopsies

S. Mackens[1], S. Santos-Ribeiro[1], C. Blockeel[1], A. Racca[1], A. Koch[2], W. Essahib[1], A. Aberkane[1], I. Van Riet[3], C. Bourgain[1], W. Verpoest[1], J. Brosens[4], H. Tournaye[1], Y.H. Lee[5], H. Van de Velde[1]

[1]UZ Brussel, Centre for Reproductive Medicine, Jette- Brussels, Belgium
[2]Maastricht University Medical Center, Pathology, Maastricht, The Netherlands
[3]UZ Brussel, Blood transfusion/Immunology/stem cells, Jette- Brussels, Belgium
[4]University of Warwick, Division of Biomedical Sciences- Clinical Science Research Laboratories, Warwick, United Kingdom
[5]KK Research Centre, Department of Reproductive Medicine, Singapore, Singapore Rep. of

Study question: Can molecular analysis of an endometrial biopsy harvested during ovarian stimulation (OS) predict the outcome of fresh embryo transfer (ET) in that cycle?

Summary answer: Early follicular phase endometrium harvested during OS is significantly different in patients having a live birth compared to an implantation failure after fresh ET.

What is known already: The endometrium adapts from cycle to cycle thanks to tissue renewal and decidualization. Endometrial biopsies taken during OS have been shown not to harm the chances of implantation in case of fresh ET. At the molecular level, differential gene expression (DGE) has been reported between women that achieve pregnancy versus those who do not. In luteal phase endometrial biopsies, a transcriptional signature predictive for repeated implantation failure (RIF) was shown to be associated with reduced cell proliferation, an essential function of the proliferative phase. Furthermore, a disordered endometrial stromal cell (EnSC) secretome has been linked to failed implantation.

Study design, size, duration: This study was part of a RCT investigating the effect of scratching during OS on clinical pregnancy rates after IVF/ICSI. Patients in the intervention arm underwent an endometrial biopsy in the early follicular phase of OS. Of the 85 biopsies available for this study, after matching to minimize the risk of potential confounding, 18 (9 versus 9) were used for transcriptome analysis and 9 (5 versus 4) for EnSC isolation and in vitro decidualization (IVD).

Participants/materials, setting, methods: RNA-sequencing was performed for individual endometrial biopsies on an Illumina HiSeq1500 machine (BrightCore, Brussels). DGE was analyzed using 3 software systems (DESeq2 in R, EdgeR, Wilcoxon rank-sum test) and gene set enrichment analysis (GSEA) was performed using the GOrilla tool.

EnSC isolation and IVD (for 2 and 4 days) was performed, after which media from undifferentiated and decidualized cultures were harvested, stored at

-80°C and later assayed using a multiplex suspension bead immunoassay (Ebioscience, Singapore).

Main results and the role of chance: After correction for multiple hypothesis testing, DGE analysis of whole tissues revealed no differences between patients having a live birth and patients having an implantation failure after fresh ET (lowest adjusted p-value = 0.15). However, after GSEA (false discovery rate < 0.05) several enriched ontologies were identified, the most affected biological process being protein targeting to the endoplasmic reticulum and the cell membrane.

Secretome analysis after EnSC isolation and culture, analyzed by partial least squares regression modelling, showed 2 distinct clusters that corresponded to the two clinical groups. Increased secretion of MCP-1, LIF and eotaxin in undifferentiated EnSC was associated with implantation failure. Upon IVD, the secretome profile clearly shifted from that of undifferentiated cells, although it remained different between the 2 groups. VEGF-A was highly secreted in the live birth group whereas a preponderance of IL-8 secretion characterized the implantation failure group. The differences in secretomes between the groups became muted upon prolonged IVD, suggesting convergence of cytokine profiles upon full differentiation.

Limitations, reasons for caution: Caution is warranted because of the limited sample size of the study and the in vitro nature of the second part of the experiment.

Wider implications of the findings: If confirmed on a larger scale, an in-cycle predictive test could be developed to guide clinical decision-making between a fresh ET immediately after OS or a freeze-all approach with a frozen ET in a subsequent cycle, possibly linked to higher success rate in case of a sub-optimal test result.

Trial registration number: This study was part of a clinical RCT: the REFRESH trial, NCT02061228.

P-442 Serum vitamin D and calcium levels in ectopic pregnancies

P. Yalcin bahat[1], B. Yuksel ozgor[2], B. Aslan cetin[1], N. Koroglu[1], N. Arslan[1]

[1]*Istanbul Kanuni Sultan Suleyman Training and Research Hospital, obstetric and gynecology, istanbul, Turkey*
[2]*istanbul university medical faculty, obstetric and gynecology, istanbul, Turkey*

Study question: what is the place of vitamins and calcium metabolism in ectopic pregnancy?

Summary answer: this is the first study that reports the decreased serum levels of vitamin D, calcium and magnesium in patients with ectopic pregnancy.

What is known already: According to recent evidences, vitamin D was found to have important roles in female reproductive system, both in physiological and also pathological mechanisms. Since vitamin D is tightly related with calcium metabolism, both molecules were reported to be associated with some pregnancy complications including preeclampsia, gestational diabetes, low birth weight, preterm delivery, and cesarean section. The aim of the present study was to evaluate the vitamin D levels in ectopic pregnancies, which may have clinical importance in the etiology of this disorder.

Study design, size, duration: Between October 2015 and June 2017,50 women with ectopic pregnancy and 61 women with normal 1st trimester pregnancy were included. Blood samples were taken for biochemical analyses including vitamin D, calcium, magnesium, parathormone, thyroid stimulating hormone (TSH), T3, T4, hemoglobin, hematocrite, thrombocyte, C-reactive protein, beta-human chorionic gonadotropin, and procalcitonin. Study groups were compared for these biochemical markers.

Participants/materials, setting, methods: In the study, 50 women with ectopic pregnancy and 61 women with normal 1st trimester pregnancy were included. Blood samples were taken for biochemical analyses including vitamin D, calcium, magnesium, parathormone, thyroid stimulating hormone (TSH), T3, T4, hemoglobin, hematocrit, thrombocyte, C-reactive protein, beta-human chorionic gonadotropin, and procalcitonin. Study groups were compared for these biochemical markers.

Main results and the role of chance: The distribution of the serum levels of vitamin D, calcium, thyroid hormones, magnesium, and hemoglobin are presented in Table 1. Accordingly, vitamin D (p = 0.006), Ca^{++} (p<0.001), T3 (p = 0.003), magnesium (p = 0.001), and hemoglobin (p = 0.040) levels were significantly lower in the ectopic pregnancy group than those in the normal pregnancy group. On the other hand, TSH (p = 0.029) and thrombocyte (p = 0.018) levels were significantly lower in the normal pregnancy group than those in the ectopic pregnancy group.

Limitations, reasons for caution: study was conducted in a single center and with low number of participants. Te number should be extended for the future studies.

Wider implications of the findings: This study reports the decreased serum levels of vitamin D, calcium and magnesium in patients with ectopic pregnancy. The molecular interactions at ultrastructural level, altered tubal fluid content, or an inflammatory process that affects ciliary motility might all play a role in the etiology of tubal implantation of the fetus.

Trial registration number: 'not applicable.

P-443 Chemokines in relation to human Choriogonadotropin (hCG) after four weeks of gestation are significantly altered in women with miscarriage

A. Freis[1], J. Schlegel[1], D. Volker[2], J. Jauckus[1], T. Strowitzki[1], A. Germeyer[1]

[1]*Universitäts-Frauenklinik, Department of Gynecologic Endocrinology and Fertility Disorders, Heidelberg, Germany*
[2]*Transplantation-Immunology, Institute of Immunology- University Hospital Heidelberg-, Heidelberg, Germany*

Study question: Are chemokine levels at the time of pregnancy testing relative to human Choriogonadotropin (hCG) altered in patients who will experience a miscarriage in this pregnancy?

Summary answer: Chemokines in relation to hCG after four weeks of gestation are significantly altered in women with miscarriage, promising potential as a prognostic biomarker.

What is known already: Miscarriage is one of the most common complications in early pregnancy and affects 10-20% of all pregnancies. A predictive test to identify women who will experience a miscarriage even before first symptoms occur is not established. Activation of maternal immunological tolerance seems to be essential for early fetal development and various cytokines have been described in different stages of pregnancy. However, none of these cytokines alone has been described as a useful biomarker in asymptomatic women. To screen for promising biomarkers, we tent to enhance the possible predictive effect for later abortion by examining a chemokines/hCG correlation in maternal plasma.

Study design, size, duration: The prospective pilot study was approved by Heidelberg University Ethical Committee (protocol S-243/2015). Blood samples were obtained at the time of pregnancy testing after informed consent from women who underwent ovarian hyperstimulation to perform in vitro fertilization by IVF or ICSI during the period 05/15-05/16 at the University Hospital in Heidelberg, Germany. Exclusion criteria were autoimmune diseases, essential hypertonia, diabetes mellitus or the intake of confounding medication.

Participants/materials, setting, methods: We obtained blood samples from n = 39 women. Dependent on the follow-up, patients with a positive pregnancy test were subsequently divided in two groups: ongoing pregnancy (n = 22, group 1) and 1st trimester miscarriage (n = 17, group 2) in this pregnancy. Immunological and endocrine profiling of maternal blood was performed using Multiplex and ELISA assays. Statistical analysis using student's t-test was performed with SPSS® Version 24, IBM, Armonk, USA. $p \leq 0.05$ was considered to be significant.

Main results and the role of chance: There was no significant difference in age (33.64 ± 6.49 years vs. 33.94 ± 4.4 years), body mass index with 23.81 ± 4.29 kg/m^2 in group 1 vs. 26.48 ± 5.27 kg/m^2 in group 2 or transfer day. hCG levels, despite normal overall levels, were significantly decreased in patients with abortion compared to those with ongoing pregnancy (151.75 ± 25.29 IU/l vs. 351.27 ± 111.02 IU/l, p<0.05) whereas levels of IL-1ra (655.80 ± 78.80 pg/ml vs. 398.69 ± 32.73 pg/ml, p<0.01), MIP-1a (73.74 ± 9.91 pg/ml vs. 34.20 ± 8.25 pg/ml, p<0.01) and TNF-alpha (5.11 ± 0.40 pg/ml vs. 4.00 ± 0.26 pg/ml, p<0.05) were significantly increased. GCSF/ IL-1ra-ratio was 1.66-fold increased in patients with ongoing pregnancy. TGF-beta /MIP1a-ratio was

significantly 3,45-times higher in patients with miscarriages. Comparing patients with ongoing pregnancy to patients experiencing a miscarriage, we could demonstrate significant alterations of the ratios MIP1a/hCG (0.16 ± 0.04 pg/mIU vs. 1.02 ± 0.38 pg/mIU, p<0.05), IL-1ra/hCG (2.22 ± 0.72 pg/mIU vs. 7.83 ± 2.30 pg/mIU, p<0.05), TNFalpha/hCG (0.02 ± 0.01 pg/mIU vs. 0.07 ± 0.02 pg/mIU, p<0.05), MCP1/hCG (0.50 ± 0.16 pg/mIU vs. 1.44 ± 0.40 pg/mIU, p<0.05), IL-6/hCG (0.0681 ± 0.002 pg/mIU vs 0.016 ± 0.003 pg/mIU, p<0.05), TPO/hCG (2.50 ± 0.70 pg/mIU vs 5.47 ± 1.31 pg/mIU, p<0.05) and TGF-beta1/hCG (68.04 ± 22.37 pg/mIU vs. 149.35 ± 33.89 pg/mIU, p<0.05). The strongest effects were seen for the ratio MIP1a/hCG, IL-1ra/hCG and TNFalpha/hCG.

Limitations, reasons for caution: The limitations of this study are its small sample size and the fact, that we only detected protein in maternal plasma with no further validation technique.

Wider implications of the findings: Biomarkers screening for an upcoming miscarriage in asymptomatic women of the first trimester can be a helpful instrument to reassure patients with expected normal pregnancy outcome. We think that these established ratios are better predictors for pregnancy outcome than cytokine levels alone.

Trial registration number: na.

P-444 Impact of resveratrol supplementation on implantation and early pregnancy during embryo transfer cycles: a cross-sectional study

K. Kuroda[1,2], A. Ochiai[2], Y. Ikemoto[2], A. Matsumoto[2], K. Nakagawa[1], S. Nojiri[3,4], R. Sugiyama[1]

[1]Sugiyama Clinic Shinjuku, Division of Reproductive Medicine, Tokyo, Japan
[2]Juntendo University Faculty of Medicine, Department of Obstetrics and Gynaecology, Tokyo, Japan
[3]Juntendo University, Medical Technology Innovation Center-, Tokyo, Japan
[4]Juntendo University Hospital, Clinical Research and Trial Center, Tokyo, Japan

Study question: To determine whether resveratrol supplementation impacts on implantation and early pregnancy following transfer of morphologically competent embryos.

Summary answer: Resveratrol supplementation during the luteal phase was associated with lower implantation and clinical pregnancy rates and higher miscarriage rate following embryo transfer.

What is known already: Resveratrol is a polyphenolic compound and natural activator of SIRT1. Based on animal experiments, resveratrol has been mooted as a potentially therapeutic agent preventing infertility associated with ovarian aging due to its inhibition of senescence. Recent reports have shown a relationship between decidualization of human endometrial cells and cell senescence. Furthermore, inhibition of decidual senescence had also been reported to suppress decidual changes in the endometrium. However, clinical trials involving resveratrol supplementation for infertility treatment have not been performed in humans.

Study design, size, duration: The present study was approved by the local ethics committee. This single-centre, cross-sectional retrospective study (2012 to 2014) was designed to compare the outcomes of ET between women receiving resveratrol supplementation (200 mg/d) during the luteal phase (RES group) and a control group (non-RES).

Participants/materials, setting, methods: Of 8,686 ET cycles, we excluded 1,097 cycles with poor prognostic factors, including those from women ≥44 years old and those with poor-quality embryos (Veeck grade 4–5 or Gardner grade CC). The RES group (205 cycles, 102 women) was then compared with the non-RES group (7,382 cycles, 3024 women). Odds ratios (OR) and 95% confidence intervals (CIs) were calculated using multivariate logistic regression after controlling for potential confounders; patient age, embryo grade and cleavage speed.

Main results and the role of chance: After adjusting for age and embryo quality, statistical analysis showed a lower hCG positivity rate (OR = 0.68; 95% CI: 0.46–1.00), lower clinical pregnancy rate (OR = 0.51; 95% CI: 0.32–0.80) and higher miscarriage rate (OR = 2.68; 95% CI: 1.11–6.51) in the RES group compared to the non-RES group.

Limitations, reasons for caution: We focused on ET cycles with morphologically competent embryos. However, resveratrol supplementation may have a positive impact on the development of follicles and production of high-quality embryos.

Wider implications of the findings: In line with the adverse effects of senescence inhibitors on endometrial decidualization *in vitro*, resveratrol supplementation during the luteal phase appears to be detrimental for pregnancy outcomes during IVF treatment. Nonetheless, analysis of the supplementation period and additional studies are required.

Trial registration number: None.

P-445 Mid-luteal serum progesterone levels determine the reproductive outcome following controlled ovarian stimulation. A prospective study of 602 IVF/ICSI cycles

L. Thomsen[1], U.S. Kesmodel[2], K. Erb[3], P. Humaidan[1]

[1]Department of Clinical Medicine- Aarhus University- Denmark., The fertility Clinic- Skive Regional Hospital- Denmark., Skive, Denmark
[2]Department of Clinical Medicine- University of Copenhagen- Denmark., The fertility Clinic- Herlev Hospital- Denmark., Herlev, Denmark
[3]Odense University Hospital- Denmark., The Fertility Clinic. Odense University Hospital- Denmark., Odense, Denmark

Study question: Is the chance of on-going pregnancy following IVF treatment and fresh embryo transfer affected by early and mid-luteal serum progesterone (P_4) levels?

Summary answer: Low as well as high s-P_4 levels during the early and mid-luteal phase reduce the chance of on-going pregnancy following IVF-treatment and fresh embryo transfer.

What is known already: Data from non-human studies and studies of frozen/thawed embryo transfer cycles indicate that low as well as high P_4-levels during the early/mid-luteal phase decrease the chance of pregnancy. A suboptimal P_4-level may disrupt the endometrial maturation and lead to asynchrony between embryonic development and the endometrial receptivity, thereby compromising implantation and early pregnancy development.

Study design, size, duration: Prospective multicenter cohort study of 602 women undergoing IVF treatment. Patients were recruited from four Danish public Fertility Centers from May 2014 to June 2017. The study population was unselected, thus representing a normal everyday Danish patient cohort. Patients were treated in a long GnRH-agonist protocol or a GnRH-antagonist protocol and triggered for final oocyte maturation with either hCG or a GnRH-agonist. The same vaginal luteal support regime was applied in all patients.

Participants/materials, setting, methods: Serum P_4 levels on luteal day 2/3 or luteal day 5 were correlated to the rate of positive hCG and to on-going pregnancy rates (> gestational week 10). Patients were divided into four P_4-groups based on raw data of P_4-concentrations and reproductive outcome on luteal days 2/3 (P_4<60 nmol/l, P_4 60-100 nmol/l, P_4 101-400 nmol/l and P_4>400 nmol/l) and luteal day 5 (P_4<150 nmol/l, P_4 150-250 nmol/l, P_4 251-400nmol/l and P_4>400 nmol/l).

Main results and the role of chance: The optimal chance of pregnancy was achieved with s-P_4 levels 60-100 nmol/l on luteal day 2/3 whereas the optimal P_4-level on day 5 was 150-250 nmol/l. Below, but most distinctly above these levels, the chance of pregnancy was consistently reduced. Following cleavage-stage embryo transfer and an early luteal P_4-level of 60-100 nmol/l, the chance of a positive hCG- test was 65%, CI [51; 77%]. In contrast, with a cleavage-stage embryo transfer and a P_4-level > 400 nmol/l, the chance of a positive hCG-test was significantly reduced to 34%, CI [17; 56%], thus, a reduction of -31%, CI [-54;-10%]. A similar negative association between early luteal P_4 and on-going pregnancy rate was found, although it did not reach statistical significance. Following blastocyst transfer and a mid-luteal P_4 level of 150-250 nmol/l, the chance of on-going pregnancy was 57%, CI [41;73%] compared to 38%, CI [20;59%] with a P_4-level > 400 nmol/l, thus, a reduction in chance of -19%, CI [-40;2%], p = 0.078. With blastocyst transfer and P_4 < 150 nmol/l, the chance of an on-going pregnancy was reduced to 41%, CI [43;59%]. All estimates were adjusted for maternal age, BMI, smoking, final follicle count and late follicular P_4 levels.

Limitations, reasons for caution: This study is the first to explore a threshold and ceiling level for luteal P_4 following IVF treatment and fresh embryo transfer, and the optimal P_4-ranges found in this study must be corroborated in future clinical trials.

Wider implications of the findings: Future studies need to be performed to establish whether additional exogenous luteal P_4-supplementation in the low P_4 -group could increase the chance of on-going pregnancy following fresh embryo transfer and whether patients with luteal P_4-levels > 400 nmol/l would benefit from segmentation followed by subsequent transfer in frozen/thawed cycles.

Trial registration number: NCT02129998 (Clinicaltrials.gov).

P-446 The role of sub-chorionic blood flow measured by 3D power Doppler ultrasonography in the prediction of pregnancy outcome: a preliminary study

J. Huang[1,2], W. Cheung[2], X. Chen[2], Y. Liu[2], S. Saravelos[2,3], T.C. Li[2]

[1]The First Affiliated Hospital of Chongqing Medical University, Obstetrics and Gynaecology, Chongqing, China
[2]The Chinese University of Hong Kong, Obstetrics and Gynaecology, Hong Kong, Hong Kong
[3]Hammersmith Hospital- Imperial College Healthcare NHS Trust, IVF Unit, London, United Kingdom

Study question: Does sub-chorionic blood flow at 6 weeks of gestation analyzed by 3D power Doppler ultrasonography predict pregnancy outcome?

Summary answer: The sub-chorionic blood flows at 6 weeks of gestation analyzed by 3D power Doppler ultrasonography have the potential of predicting miscarriage.

What is known already: Transvaginal ultrasound has been considered as a reliable technique to monitor early pregnancy. Present ultrasonography features at the time of 6-8 weeks of gestation have been applied as a diagnostic tool of early pregnancy; while the predictive role of pregnancy outcomes were seldom developed.

Study design, size, duration: This is a prospective cross sectional preliminary study in a setting of assisted reproductive technology (ART) center. So far, 37 cases were recruited, in which 4 lost follow up of pregnancy outcome, 5 excluded from this study for twin pregnancy, and 2 excluded for biochemical pregnancy loss. Therefore, in total, there were 21 term live birth and 5 miscarriages (miscarried during 7-12 weeks of gestation) included in the analysis.

Participants/materials, setting, methods: After embryo transfer and positive hCG test, transvaginal ultrasound scan was scheduled for confirmation of clinical pregnancy for patients recruited for this study on the day of 6 weeks of gestation. After the routine confirmation of clinical pregnancy by 2D ultrasound, a 3D power Doppler dataset were taken and stored for VOCAL® (Virtual Organ Computer-Aided Analysis) histogram analysis to measure the gestational sac volume and indices of sub-chorionic blood flows.

Main results and the role of chance: There seems no difference in the comparison of the miscarriage and term live birth group in demographic information and general pregnant conditions, including patient age, body mass index, embryo quality, hormone levels (hCG and P4). It is also not significant different in the comparison of 2D ultrasound parameters between the two groups, including crown-rump length, diameters of gestational sac, yolk sac and presentation of heart beat. For 3D power Doppler VOCAL analysis, vascularization index (VI), and vascularization flow index (VFI) were likely higher in the live birth group compared with those of the miscarriage group (3.02 ± 1.03 vs 0.74 ± 0.58, $p = 0.08$; 1.26 ± 0.23 vs 0.23 ± 0.10, $p = 0.07$, respectively); whilst flow index (FI) might be not different between the two groups (32.92 ± 2.14 vs 28.60 ± 2.41, $p = 0.14$).

Limitations, reasons for caution: This is a preliminary prospective study with a current small group of patients. As our clinical routine monitoring of patients conceived by ART were scheduled in 6 weeks of gestation, we are recruiting more cases in this cohort for a more robust interpretation of the 3D parameters.

Wider implications of the findings: VI is considered to indicate the vascularity in the sub-chorionic area; FI indicating the average intensity of blood flow; while VFI is a combination of vascularity and flow intensity. Our preliminary data suggested that miscarriage may have some angiogenesis abnormalities early on, before the miscarriage occur.

Trial registration number: None.

P-447 Reference intervals of gestational sac, yolk sac, embryonic length, embryonic heart rate at 6-10 weeks after in vitro fertilization-embryo transfer

Y. Ouyang, X. Li, Y. Wen

Reproductive and Genetic Hospital of Citic-Xiangya, Imaging department, Changsha, China

Study question: What are the ultrasound reference intervals of early pregnancies after in vitro fertilization-embryo transfer (IVF-ET)?

Summary answer: Reference intervals and centile charts for early pregnancy biometry after IVF-ET have been established in this study.

What is known already: To accurately determine the normal range of early pregnancy biometry was the basis for predicting adverse pregnancy outcomes. Some studies have constructed such kind of reference intervals, mostly, depending on natural conceptions. However, the ovulation day were changeable even in regular menstrual cycle, which makes the uncertainty of the accuracy for reference intervals in natural pregnancies. While during the IVF-ET procedure, the days of oocytes retrieval and ET were certain, and thus, the gestational age (GA) was accurate. Then, we speculate the reference intervals deriving from IVF-ET data would be more accurate than natural conceptions.

Study design, size, duration: The data of 3763 singleton pregnancies, including embryonic length (or crown-rump length, CRL), embryonic heart rate (HR), gestational sac diameter (GSD) and yolk sac diameter (YSD) at 6–10 gestational weeks from January 2014 to December 2015 after IVF-ET were retrospectively analyzed. The ultrasound measurements conformed to uniform standards by experienced sonographers. The GA was calculated by subtracting the date of embryo transfer from the date of birth and the addition of 17 days.

Participants/materials, setting, methods: This study was conducted at the Reproductive and Genetic Hospital of CITIC-Xiangya (Changsha, China). All included patients conceived singleton pregnancies via IVF-ET and resulted in phenotypically normal live neonates after 36 complete gestational weeks, with birth weight above the 5th centile for GA. All patients had full records of early ultrasound measurements of CRL, HR, GSD and YSD. Regression analysis was used to establish normal ranges of CRL, HR, GSD and YSD with gestation.

Main results and the role of chance: At 6–10 weeks, there were significant quadratic associations between CRL, HR, GSD, YSD and GA. The corresponding quadratic models were $CRL = -0.445 - 0.559GA + 0.015GA^2$ ($R^2 = 0.986$, $F = 128300.664$, $P < 0.001$); $HR = -382.279 + 16.623GA - 0.123GA^2$, ($R^2 = 0.927$, $F = 23740.394$, $P < 0.001$); $GSD = -26.547 + 0.991GA + 0.001GA^2$, ($R^2 = 0.851$, $F = 10768.859$, $P < 0.001$); $YSD = 1.709 + 0.079GA + 0.000GA^2$, ($R^2 = 0.986$, $F = 128300.664$, $P < 0.001$). The normal ranges of CRL, HR, GSD and YSD were successfully derived from these models.

Limitations, reasons for caution: This study was confined to a reproductive center, territorial limitation may exist. A future study with multi-center samples are necessary to establish a nationwide or worldwide reference interval. In addition, whether the references coming from IVF population are suitable for natural conceptions needs further elucidation.

Wider implications of the findings: The normal ranges of early pregnancy biometry provide clinicians a reliable reference to analyze the development of early embryos after IVF-ET and also give a possibility for predicting pregnancy outcomes at an early stage.

Trial registration number: None.

P-448 Virtual screening and molecular dynamics of FDA drugs into the beta-2-glycoprotein I's fifth domain for treatment of pregnancy complications with antiphospholipid antibody syndrome

S. Mahdian[1], M. Movahedi[1], M. Zarrabi[2], M. Shahhoseini[3], A. Moini[4]

[1]Faculty of life Sciences- Islamic Azad University- Tehran North Branch, Department of Cellular and Molecular Biology, Tehran, Iran
[2]biological faculty- alzahra university, Department of biotechnology, Tehran, Iran
[3]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- Academic Center for Education Culture and Research, Department of Genetics, Tehran, Iran

[4]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- Academic Center for Education Culture and Research, Department of Endocrinology and Female Infertility, Tehran, Iran

Study question: What drugs can be used for treatment of pregnancy complications with antiphospholipid antibody syndrome?

Summary answer: Some drugs prescribed for recurrent miscarriage, RIF and preeclampsia and some FDA drugs might be useful candidates for pregnancy complications with antiphospholipid antibody syndrome.

What is known already: Antiphospholipid antibody syndrome (APS or APLS), is an autoimmune disease, caused by antiphospholipid antibodies. APS is associated with pregnancy complications, including preeclampsia, thrombosis, fetal growth restriction, fetal loss and recurrent implantation failure. B2GPI is the major antigen for APL antibodies and associated with thrombosis. B2GPI exists in different conformations, an open J-shaped conformation, a circular conformation and a S-shape conformation. B2GPI is a glycoprotein by a single polypeptide chain of 326 amino acids with five repeated domains. B2GPI's fifth domain is highly effective in binding to negative charge phospholipids and binding to oxidized LDL in inflammatory and blood clotting reactions.

Study design, size, duration: In this study calculation of binding free-energy change (ΔG) of drugs that are prescribed during pregnancy, and especially recurrent miscarriage, RIF, preeclampsia and all of the FDA drugs, were evaluated using virtual screening to b2GPI's fifth domain. The starting coordinates of b2GPI were obtained from PDB (PDB code: 1C1Z). The next step were Molecular dynamics simulation studies of protein and drugs/ protein complex using gromacs software in the Linux environment.

Participants/materials, setting, methods: Bioinformatics software, such as, auto dock vina, molegro virtual docker, pyrx 0.8, linux, gromacs software and online resources like NCBI, RCSB and Drug bank were used in this study. The best drugs were chosen based on binding free energy value and hydrogen bonding interaction. Regarding the mechanism of action for vorapaxar and antrafenine, as well as the optimal ΔG for these two drugs, vorapaxar and antrafenine were selected for more accurate studies using molecular dynamics.

Main results and the role of chance: In this study calculation of binding free-energy change (ΔG) of drugs that are prescribed during pregnancy, and especially recurrent miscarriage, RIF and preeclampsia, were evaluated using the Auto Dock Tools method on b2GPI's fifth domain. Heparin, folate and warfarin have highest ΔG. Also in the present study, the molecular docking and MD simulations were performed to explore the possible binding mode of beta-2-glycoprotein I's fifth domain with FDA drugs. The best drugs were chosen based on binding free energy value and hydrogen bonding interaction. The conclusion drawn from the docking analysis was that eight FDA drugs had the highest binding affinity with b2GPI. Vorapaxar and antrafenine are anti-platelet and anti-inflammatory drugs. Regarding the mechanism of action for vorapaxar and antrafenine, as well as the optimal ΔG for these two drugs, vorapaxar and antrafenine were selected for more accurate studies using molecular dynamics. B2GPI exists in different conformations, an open J-shaped conformation, a circular conformation and a S-shape conformation. In this study using molecular dynamics for protein, it was shown that the J-shaped was transformed into a s-shaped during the 10 ns. RMSD, RMSF, and H-bond results reveal that two complexes were stable.

Limitations, reasons for caution: Findings of this study is based on in silico method. Studies in vitro and in vivo can help us complete this study.

Wider implications of the findings: This study for the first time evaluated the effect of FDA Drugs on antiphospholipid antibody syndrome (APLS) based on in silico method. Vorapaxar and antrafenine might be useful candidates for antiphospholipid antibody syndrome and pregnancy complications with APLS.

Trial registration number: This investigation is based on in silico method.

P-449 Novel insights into 3D endometrial tissue and cellular architecture during preimplantation, in women with recurrent miscarriage

J. Pearson-Farr[1], R. Lewis[2], Y. Cheong[1]

[1]University of Southampton, Obstetrics & Gynaecology, Southampton, United Kingdom
[2]University of Southampton, Institute of Developmental Sciences, Southampton, United Kingdom

Study question: Can whole-mount confocal microscopy be used to analyse three-dimensional spatial relationships between multiple endometrial cell types, providing a platform to individualise reproductive health diagnostics?

Summary answer: 3D endometrial tissue provides informative insight on the interaction between cell populations and tissue architecture in women with recurrent miscarriage versus controls.

What is known already: The endometrium forms the first point of contact for a conceptus during implantation, acting as the barrier between the uterine tissue and uterine cavity milieu. Immunohistochemistry is widely used to study the role endometrial cell types with respect to reproductive health. However, the 2D nature of these samples means that much of the information about the relationships between these cells is lost.

Study design, size, duration: An observational study comparing three main patient groups; (1) egg donor controls, (2) recurrent miscarriage patients with ≤ 4 consecutive miscarriages and (3) ≥ 4 consecutive miscarriages.

Participants/materials, setting, methods: Endometrial biopsy samples were collected at mid-luteal phase (LH +7-10). Patients were excluded if they were on hormonal contraceptives, had a history of subfertility or uterine pathology. Multi-marker whole mount immunohistochemistry was carried out for all endometrial samples, including markers for uterine natural killer cells (CD56), macrophages ($CD163^+$), and endometrial fibroblasts (anti-vimentin). Quantification methods were developed to investigate inter and intra-cellular relationships.

Main results and the role of chance: An informative approach to imaging the endometrium in 3D has been developed. Uterine natural killer cells (CD56), macrophages ($CD163^+$) and fibroblasts were imaged simultaneously in 3D endometrium, and the relationship between these cells identified at the mid-luteal phase. Tissue and cellular morphology was quantified in relation to uterine glandular structures and the luminal epithelial surface. With regard to patient groups, results are indicative of differences in morphological spatial relationships.

Limitations, reasons for caution: This is an observational study with a small sample size, larger studies are required. Further, 3D analysis of endometrial samples is currently time consuming in comparison to traditional 2D immunohistochemistry, thus more applicable for research studies.

Wider implications of the findings: This 3D approach can be later applied to answer questions in reproductive health and implantation.

Trial registration number: not applicable REC ref: 08/H0502/162

P-450 Interaction among embryos in blastocyst double embryo transfer: better alone than in bad company

C. Jacobs[1], M. Piccolimini[1], D. Garcia[2], R. Vassena[2], E. Motta[3,4], T. Bonetti[4,5]

[1]Huntington Medicina Reprodutiva, Embriology, Sao Paulo, Brazil
[2]Clinica EUGIN, Scientific, Barcelona, Spain
[3]Huntington Medicina Reprodutiva, Clinical Director, Sao Paulo, Brazil
[4]Universidade Federal de São Paulo – Escola Paulista de Medicina UNIFESP-EPM, Gynecology, Sao Paulo, Brazil
[5]Huntington Medicina Reprodutiva, Scientific, Sao Paulo, Brazil

Study question: How does the quality of an additional blastocyst transferred with a top-quality one affect pregnancy rates?

Summary answer: The addition of a good-quality blastocyst to a one top-quality blastocyst transfer does not increase substantially pregnancy rates, while increasing twin gestations.

What is known already: It is well stablished that increasing the number of transferred embryos increases pregnancy rate; this is however associated with a substantial rise in multiple pregnancies. The morphology of transferred embryos is linked to IVF success and, combined with extended culture to blastocyst stage, it has been considered effective in selecting top-quality (TQ) blastocysts for transfer. Double embryo transfer (DET) is commonly used as a strategy to increase pregnancy rates. On the other hand, it is not clear how the morphological scores of any additional embryo affects the implantation and pregnancy rates of each embryo transfer.

Study design, size, duration: Retrospective cohort study of 1149 fresh IVF-cycles with single (SET) or double embryo transfer (DET) between 2014-2016. Cycles with donated oocytes and PGS cycles were excluded. Blastocysts were classified as good-quality (GQ; B and C scores according to Gardner) or top-quality (TQ; at least one A score). Patients received one TQ blastocyst (1-TQ, n = 62), one GQ (1-GQ, n = 158), two TQ (2-TQ, n = 235), two GQ (2-GQ, n = 488) or one TQ and one good blastocysts (1-TQ+1-GQ, n = 206).

Participants/materials, setting, methods: Ovarian stimulation, oocyte pickup and embryo culture followed routine protocols. Fresh blastocyst transfers were done at day 5 following routine protocols, and clinical pregnancy (CP) was confirmed by the presence of gestational sac with fetal heart-beat. Student's t-test and Chi-square were used as appropriate. Multivariate analysis was performed to evaluate the effect of transferring additional embryo, of same or different quality, on clinical pregnancy, adjusted for women age. Differences were considered significant if $p<0.05$.

Main results and the role of chance: The groups were comparable in women age (1-TQ:34.0 ± 3.6, 1-GQ:36.0 ± 4.2, 2-TQ:33.6 ± 3.9, 2-GQ:34.5 ± 4.0, 1TQ+1GQ:33.7 ± 3.8; $p<0.001$), number of MII oocytes recovered (1-TQ:7.1 ± 4.7, 1-GQ:5.2 ± 3.4, 2-TQ:10.2 ± 4.2, 2-GQ:8.3 ± 3.8, 1TQ +1GQ:8.1 ± 3.9; $p<0.001$), and of blastocysts available for transfer (1-TQ:2.6 ± 2.8, 1-GQ:1.3 ± 1.1, 2-TQ:5.3 ± 2.4, 2-GQ:2.9 ± 1.6, 1TQ+1GQ:3.5 ± 2.0; $p<0.001$). Both CP (1-TQ: 41.9%, 1-GQ: 18.4%, 2-TQ: 61.3%, 2-GQ: 43.9, 1TQ+1GQ: 51.5%; $p<0.001$) and multiple pregnancy rate (1-TQ: 3.8%, 1-GQ: 0.0%, 2-TQ: 40.3%, 2-GQ: 20.6%, 1TQ+1GQ: 26.4%; $p<0.001$) were much higher when two TQ blastocysts were transferred compared to all other categories. When 1TQ+1GQ were transferred, the CP was still satisfactory and multiple pregnancy rate was approximately half of that observed in 2-TQ. Multivariate analysis adjusted for woman age was performed to evaluate the interaction between different quality embryos and its effect on CP. Compared to a SET of 1-GQ embryo (OR = 1.0), having a SET of a TQ embryo increases the CP threefold (OR = 3.0). A second TQ embryo would give an OR = 6.3 and a second GQ embryo an OR = 3.96; this difference is due to the lower quality and the moderate negative interaction of the GQ embryo, meaning that when transferring 1-TQ, the addition of 1-GQ embryo only improve CP 4%. Since multiple PR is still high, SET of 1-TQ should be preferred.

Limitations, reasons for caution: The main limitations of this study reside in the fact that most SET were not elective, and in the small size of the 1-TQ group. Nevertheless, the multivariate and interaction analysis allows for generalizable results.

Wider implications of the findings: The higher clinical pregnancy rate was observed in the 2-TQ group, as did multiple pregnancy. However, the presence of a second GQ blastocyst didn't significantly improve the clinical pregnancy, but significantly increased multiple gestations. When at least one TQ-blastocyst is available, SET should be considered.

Trial registration number: not applicable.

P-451 Non-classical progesterone signaling may be sufficient to induce decidualization in Human Endometrial Stromal Cells (ESC)

S. Salsano[1], A. Quiñonero[1], S. Pérez[1], R. Gonzalez[1], C. Simón[2], F. Domínguez[3]

[1]IVI Foundation-RMA Global, Research, Valencia, Spain
[2]Igenomix Academy, Research, Valencia, Spain
[3]IVI Foundation-RMA Global- INCLIVA Biomedical Research Institute- Valencia- Spain, Research, Valencia, Spain

Study question: Is it progesterone (P4) entry into the human endometrial stromal cells (ESC) necessary to produce a correct decidualization?

Summary answer: P4 entry in ESC is not necessary to induce in vitro decidualization as long as PGRMC1 is inhibited by AG205.

What is known already: PGRMC1 is a membrane receptor that mediates non-genomic action of P4.It has been implicated in a diversity of biological events,including apoptosis and folliculogenesis(1,2).PGRMC1 mediates non-classical P4 signaling in endometrium but its mechanism of action is still unknown.PGRMC1 protein is down-regulated in receptive endometrium but its expression is higher in stromal compartment compared to epithelial cells(3). We previously published that it localizes in membrane, cytosol and nucleus of non-decidualized ESC,but accumulates in the nucleus of decidualized ESC (dESC).Its overexpression inhibits in vitro decidualization,co-localizing with SERPINE 1 mRNA binding protein(SERBP1) throughout the menstrual cycle and in the cytosol of non-decidualized and decidualized ESC(4).

Study design, size, duration: Endometrial biopsies were obtained from donors (n = 7) and ESC were isolated. In vitro decidualization was induced by a long protocol using P4/E2 (Estradiol) (8 days) and a short protocol using cyclic adenosine monophosphate/Medroxyprogesterone (cAMP/MPA) (4 days). To activate only membrane progesterone receptors we used a membrane-impermeable P4 (P4-BSA) that avoids P4 entry in the cell. Also, we employed AG205, a PGRMC1 antagonist that blocks PGRMC1 activation.

Participants/materials, setting, methods: We induced in vitro decidualization by long protocol with P4(1uM)/E2 (10 nM) or P4-BSA(1uM)/E2 in combination with AG205 (50uM) (PGRMC1 antagonist), and by short protocol with MPA/cAMP or P4-BSA/cAMP+AG205. Decidualization was checked by IGFBP1 and Prolactin (PRL) secretion by ELISA and F-actin staining with phalloidin in each condition (n = 7). Classic progesterone receptor (PRAB) and PGRMC1 localization was performed in non-decidualized ESC (ndESC) and decidualized ESC (dESC) of both protocols by immunofluorescence (n = 4).

Main results and the role of chance: PRL secretion significantly decreased in the presence of P4-BSA/E2 compared to dESC P4/E2 group ($p<0.05$). Nevertheless, PRL levels were significantly increased in the presence of P4-BSA/E2+AG205 compared to ndESC and dESC P4-BSA/E2 group ($p<0.05$). However, when we use the short protocol, all groups were able to secrete high levels of PRL included the P4-BSA/cAMP and P4-BSA/cAMP+AG205 groups. F-actin staining showed a lack of cytoskeleton reshaping in P4-BSA dESC group compared to the typical polygonal shape observed in decidualized controls. The F-actin filaments disposition of a dESC were restored in P4-BSA group in the presence of AG205. Again, dESC of all groups showed a correct F-actin structure when we induced decidualization with the short protocol, also in the P4-BSA/cAMP and P4-BSA/cAMP +AG205 groups. Immunocytofluorescence assay revealed a clear PGRMC1 perinuclear and nuclear sublocalization in P4/E2 and P4/E2+AG205 dESC groups, while it persisted at the membrane and cytosol in P4-BSA/E2 and P4-BSA/E2+AG205 dESC groups. Surprisingly, PRAB, continued translocating to the nucleus in P4-BSA/E2 dESC group as in the control (P4/E2). However, PRAB signal strongly decreased in P4-BSA/E2 +AG205 dESC group. Finally, immunocytofluorescence of PR receptors using the short protocol did not show localization differences between all the groups in both receptors.

Limitations, reasons for caution: Due to the variability between human endometrial samples and the low number of experiments performed, results should be taken with caution.

Wider implications of the findings: According to our results, we demonstrated that in absence of the P4 entry into the stromal cell, the activation of P4 membrane receptors in concomitance with PGRMC1 inhibition, is sufficient to achieve in vitro decidualization. Further molecular experiments are needed to understand the underlying mechanisms.

Trial registration number: Not applicable.

Supported by IVI Foundation (1405-FIVI-024-FD),the Spanish Ministry of Economy, and Competitivenessthrough the Miguel Servet programme (CP013/0450)(F.D.)co-founded by FEDER and by aSantiago Grisolia (S.S.) grant.

P-452 Sufficient vitamin D supplementation regulates maternal T-helper cytokine production in women suffering from infertility

S. Yamashita[1,2], Y. Ikemoto[1], A. Ochiai[1], K. Nakagawa[3], K. Murakami[1], R. Ozaki[1], K. Nakao[3], A. Matsumoto[1], K. Kuroda[1,3], R. Sugiyama[3]

[1]Juntendo University Faculty of Medicine, Obstetrics and Gynecology, Tokyo, Japan
[2]Oita University Faculty of Medicine, Obstetrics and Gynecology, Oita, Japan

[3]Sugiyama Clinic Shinjuku, Obstetrics and Gynecology, Tokyo, Japan

Study question: To determine the impact of vitamin D (VD) supplementation on maternal immune tolerance in vivo, as well as decidualisation of human endometrial stromal cells (HESCs) in vitro.

Summary answer: VD supplementation suppressed T-helper (Th)1 cell levels in vivo and secretion of interferon (IFN)-γ in decidual HESCs in vitro.

What is known already: Maternal immune tolerance during pregnancy has been associated with the balance between Th1 (IFN-γ production) and Th2 (IL-4 production) cells in favour of the latter. An imbalance in the Th1/Th2 cell ratio has been associated with reproductive failure, such as implantation failure and miscarriage. VD plays a significant role in regulating the immune system, including Th and other cells. However, the impact of VD on successful pregnancy and optimal preconception levels of VD have not been clearly understood.

Study design, size, duration: The present study was approved by the local ethics committee. This prospective intervention study was designed to determine the impact of VD supplementation on Th cell immune response. Various Th cell tests before and after VD supplementation (vitamin D3 1,000 IU/day) for 3 months were compared. In primary culture, HESCs were decidualised using 8-bromo-cAMP and progesterone with or without 1,25(OH)2VD for 4 days. Molecular analysis was then used to examine the cells and condition media.

Participants/materials, setting, methods: Out of 28 patients aged 40 or below suffering from infertility and low 25(OH)VD levels (<30 ng/ml), five were excluded (one was lost to follow-up and four had received immunosuppressive drugs for post-liver transplantation or collagen disease). Twenty-three women suffering from infertility underwent various Th cell tests before and after VD supplementation. We then examined the effects of VD on HESC decidualisation using real-time quantitative PCR, ELISA and immunohistochemical staining.

Main results and the role of chance: Among the 23 patients, 22 (95.7%) had increased 25(OH)VD ($p < 0.0001$). Moreover, VD supplementation significantly decreased the Th1/Th2 cell ratio (14.8% ± 4.0% to 13.1% ± 4.1%, $p = 0.015$). Sufficient VD levels [25(OH)VD level ≥30 ng/ml] had been found in 11 patients (47.8%), among whom significantly decreased Th1 cell levels and Th1/Th2 cell ratios had been observed ($p = 0.032$ and 0.010). However, no significant differences in Th cell levels had been observed in patients who did not reach sufficient VD levels after supplementation. No complications or adverse effects were identified in all patients.

Basic research has suggested that co-treatment of decidualising cultures with 1,25(OH)2VD increased the expression of vitamin D receptor (VDR) in decidual cells, leading to the upregulation of IGFBP1 expression, a marker of decidualisation. Moreover, 1,25(OH)2VD treatment of decidual cells in parallel cultures showed nuclear accumulation of VDR, unlike cells not treated with 1,25(OH)2VD. In a cytokine assay of decidualised HESCs in culture media with or without 1,25(OH)2VD, IFN-γ levels were significantly lower in cells treated with 1,25(OH)2VD compared to those without 1,25(OH)2VD ($p = 0.008$), but not IL-4.

Limitations, reasons for caution: Considering that VD levels can be affected by exposure to sunlight and diet, supplementation may not be the only factor affecting VD levels. We recognise that significant seasonal changes had not been observed in the present study.

Wider implications of the findings: Optimal Th1/Th2 cell balance is important during implantation and maintenance of pregnancy. Aberrantly high population of Th1 cells has been associated with embryonic rejection, leading to repeated reproductive failure and complications during pregnancy. Sufficient preconception VD levels may prevent maternal immune rejection of the embryo, leading to a successful pregnancy.

Trial registration number: None.

P-453 The effect of maternal BMI on the development of human fetal kidney

S. Banh[1], J. Mulhern[1], N. Walker[1], M. Bellingham[2], P.J. O'Shaughnessy[2], H.M. Wilson[1], P. Filis[1], P. Brown[3], P.A. Fowler[1]

[1]University of Aberdeen, Institute of Medical Sciences, Aberdeen, United Kingdom
[2]University of Glasgow, Institute of Biodiversity- Animal Health and Comparative Medicine, Glasgow, United Kingdom
[3]Aberdeen Royal Infirmirary, Department of Pathology, Aberdeen, United Kingdom

Study question: How does maternal BMI affect development of the human fetal kidney?

Summary answer: High maternal BMI affects fetal kidney development and dysregulates development of the renin-angiotensin system.

What is known already: The obesity epidemic worldwide currently affects one-third of women in reproductive age, giving rise to higher prevalence of obesity in pregnancy. Children born to overweight or obese mothers (BMI ≥25) are at an increased risk of developing childhood obesity and type 2 diabetes, which in turn predisposes individuals to chronic kidney disease (CKD). Although clear associations have been demonstrated between maternal obesity and long-term consequences on offspring health, the mechanisms underlying the effects remain largely unknown.

Study design, size, duration: We aimed to characterize and identify phenotypic and molecular changes to the human fetal kidney in relation to maternal BMI status. A total of 112 human fetal kidneys were collected from elective terminations of normally-progressing pregnancies (7-20 weeks of gestation, Scottish Advanced Fetal Research Study, REC 15/NS/0123). 53 from mothers of BMI <25 and 59 from overweight or obese mothers of BMI ≥25.

Participants/materials, setting, methods: All 112 kidneys were weighed before sample processing. Whole kidney extracts were prepared from 58 fetuses. 23 transcripts of key renal developmental genes, renin-angiotensin system (RAS), and kidney injury markers were quantified by qPCR. 27 whole kidneys were processed for histomorphological analysis to assess gross phenotype and podocyte density. Statistical analysis was done by ANOVA, linear regression and non-parametric tests as appropriate.

Main results and the role of chance: High maternal BMI significantly increases the relative ratio of kidney weight to total fetal body weight in male fetuses ($p < 0.02$), but maternal BMI has no significant association with overall podocyte density in fetuses.

Expression of 11/23 transcripts (5 renal developmental genes, 4 components of RAS, 1 kidney injury marker and 1 hypoxic marker) significantly increased with fetal age, while the erythropoietin (*EPO*) transcript was undetectable in all groups. The renal renin encoding gene, *REN*, involved in blood pressure and fluid balance control was significantly increased in fetal male kidneys if maternal BMI was ≥25 ($p < 0.04$).

These findings are suggestive of altered kidney development, particularly the renin-angiotensin system in male fetuses carried by women with high maternal BMI. This study is currently being expanded by analysis of the RAS and kidney damage markers in fetal human plasma.

Limitations, reasons for caution: Human nephrogenesis begins from 4 weeks of gestation and continues into the late fetal period (gestation week 34-35). Our population sample includes fetuses up to 20 weeks of gestation, hence the final stages of podocyte development cannot be quantified in our study.

Wider implications of the findings: Disturbance of the fetal renal renin-angiotensin system is a major contributor to the development of hypertension and kidney diseases in later life. Insight into mechanisms underlying effects of maternal BMI on fetal kidney development may provide key data to prevent progression of kidney damage and reduce CKD complications in adulthood.

Trial registration number: Not applicable.

P-454 Clusterin, CXCL1 and MUC1 may play important roles in improving endometrial receptivity with local injury of endometrium in unexplained recurrent implantation failure patients

K. Huang[1], Q. Mai[1], Y. Luo[2]

[1]The First Affiliated Hospital of Sum Yat-sen University, Reproductive Medical Center, Guangzhou, China
[2]The First Municipal Hospital of Foshan, Reproductive Medical Center, Foshan, China

Study question: How endometrial scratch improves endometrium receptivity in unexplained recurrent implantation failure (RIF) patients.

Summary answer: Endometrial scratch might be related to the up-regulation of the expression of CLU and MUC1 and the down-regulation of CXCL13 after the scratch.

What is known already: The effectiveness of endometrial scratch on improving endometrial receptivity in unexplained RIF patients has been reported in multiple clinical studies, but the molecular and genetic mechanism of this appearance remain unclear.

Study design, size, duration: It was a self-contrast designed study, 27 patients diagnosed as unexplained RIF were included. Patients diagnosed with intrauterine adhesions, poor ovarian response, autoimmune disease were excluded. Expression of 14 genes regulating the process of the response to wounding and 8 gene reported to be related to endometrial receptivity were analyzed in the endometrium sample before and after scratching. The immunohistochemistry tests were performed to further testify expression and distribution of deferential expression genes.

Participants/materials, setting, methods: Included RIF patients were monitoring by ultrasonic and endometrium samples were obtained on the fifth day after ovulation as control group. Scratches were performed on day 5 of following menstrual cycle with biopsy catheters and endometrium sample were taken on the fifth day after ovulation as test group. The expression levels of targeted genes were assessed by RT-qPCR tests, then immunohistochemistry (IHC) tests were performed to analyze the expression status of the significantly regulated genes.

Main results and the role of chance: We select 14 genes that have been reported as genes regulating the process of the response to wounding, including C4BPA, HPSE, FGB, SCYE1, CXCL14, THBD, CXCL13, BCL6, SERPING1, CLU, CFD, C3, PROS1 and AOX1. Meanwhile, 8 gene symbols reported to be related to endometrial receptivity were also tested, including TP53, COX2, CPLA2, MUC1, SGK1, LIF, ITGAV, and ITGB3. Our RT-PCR data demonstrate that there are no significant changes of the expression levels of most detected genes except for CXCL13 (fold change: 0.91), MUC1 (fold change: 1.42) and CLU (fold change: 2.19). Immunostaining endometrium were observed and analyzed with average positive staining method. The CXCL13 positive cells area percentage (PCA%) is 4.89% vs 2.78% ($p = 0.10$), showing reduction after the scratch but without statistical significance. On the other hand, MUC1 was specifically stained in the cytoplasm of endometrial glandular epithelial cells before and after the scratch, and the PCA% is significantly higher after the scratch (15.18% vs 33.20, $p = 0.01$). Unlike MUC1, CLU stained mostly in the cytoplasm of endometrial stromal cells, and the PCA% also elevated after the scratch but the difference is no statistical significance (15.51% vs 19.43%, $p = 0.37$).

Limitations, reasons for caution: This is an observation study and the regulating mechanism of MUC1 on human endometrium receptivity should be further evaluated by gene knock-out model.

Wider implications of the findings: Endometrial receptivity defect is a major factor that's hampering the embryo implanting and endometrial scratch is one of the most applied procedure in clinical practice on RIF. With the revealing of its detail, we are aiming for more targeted examination and therapy to improve endometrial receptivity for unexplained RIF patients.

Trial registration number: not applicable.

P-455 Pregnancy loss rates (PLR) in IVF patients as an overlooked topic

M. Murtinger[1], B. Wirleitner[2], P. Vanderzwalmen[3], M. Schuff[2]

[1]IVF-Centers Prof. Zech Endocrinology- IVF Centers Prof. Zech, Bregenz, Austria
[2]IVF-Centers Prof. Zech, Bregenz, Bregenz, Austria
[3]Centre Hospitalier Inter Régional Edith Cavell CHIREC, Braine-l'alleud, Bruxelles, Belgium

Study question: Are IVF patients of increased risk for pregnancy loss compared to natural conception and is there a benefit of pre-implantation genetic screening (PGS)?

Summary answer: Interestingly, PLR were not increased in sub-fertile IVF-patients compared to spontaneous conception. No significant improve with PGS questions aneuploidy as major early PL factor.

What is known already: Human reproduction is characterized by a high embryo-wastage. The majority of embryos are already lost before implantation with chromosomal imbalance suggested as the most important cause for this phenomenon. Major concern in IVF was turned on implantation failure, including the implementation of PGS. Less interest was drawn on PL after successful implantation of the embryo. While several studies focused on PL in natural conception, e.g. the pioneering work of Wilcox *et al.*,1988, PL in IVF-patients and especially in PGS remains under-investigated.

Study design, size, duration: A retrospective study single center study was conducted including 1.383 vitrified/warmed blastocyst transfers between 01/2010 and 12/2016 to insure a standardized optimal endometrial preparation. Clinical data were extracted by using the DynaMed® software; statistics were performed using SPSS statistics.

Participants/materials, setting, methods: All patients with a positive pregnancy test after blastocyst transfer in the test period were included. Mean female age at the time-point of cryopreservation was 35 years. In PGS-cycles trophectoderm biopsy was performed with aCGH or NGS analysis. We compared outcomes of single or double blastocyst transfers with or without PGS by analyzing implantation rate (IR), pregnancy loss rate (PLR) and birth rate (BR). Obtained data were compared with data published on natural conceptions.

Main results and the role of chance: After positive hCG-test a PLR before detection of embryonic heart-beat of 22.8% was observed in IVF-cycles, no statistically significant difference between conventional and PGS cycles was seen (22.6% vs. 30.0%, respectively). Thirteen pregnancy losses (0.94%) occurred due to ectopic implantation. Distinctly higher IRs were found in single blastocyst transfer (SBT) compared to double BT (DBT) in both, conventional and PGS cycles (SBT 79.7% and 70.8% vs. DBT: 50.0% and 33.3%, respectively). SBTs resulted in a 1.5% monozygotic twin rate; DBTs in 28.8% twin pregnancies. PLR after implantation and detection of embryonic heart-beat was 13.7% after frozen/warmed BT in conventional IVF-cycles and 9.5% in PGS-cycles with not statistically significant difference. These observed PRL in sub-fertile IVF patients were close to natural embryo loss after detection of fetal heart beat (assumed 6-12%). No statistically significant difference was detected between singleton and twin pregnancies. In this line, similar BRs/BT were detected in both groups: 66.7% in conventional vs. 63.3 % in PGS cycles.

Limitations, reasons for caution: Only vitrified/warmed BT were included, thus results might be not applicable for fresh BT. Further limitations are the small data set of PGS BTs. Larger data analysis are needed to further confirm our data.

Wider implications of the findings: Our data show increased risk of non-implantation for embryos in DBT. However, PLR after embryonic heart-beat in both, conventional IVF and natural conception are similar, potentially due to the benefit of an optimal luteal phase support. The benefit of PGS in PRL remains to be proven.

Trial registration number: 'not applicable'

P-456 Human chorionic gonadotropin improves endometrial receptivity by increasing the expression and enhancing phosphorylation of HOXA10

M. Zhu, S. Yi, X. Huang, J. Meng, Y. Cai, W. Shen, H. Sun, J. Zhou

Nanjing University Medical School, Reproductive Medicine Center- Drum Tower Hospital, Nanjing, China

Study question: Does hCG affect endometrial receptivity by regulating the expression of homeobox A10 (HOXA10)?

Summary answer: hCG activates endometrial decidualization by reducing expression and concomitant DNA methylation of HOXA10 and enhancing phosphorylation of HOXA10.

What is known already: HOXA10 has emerged as an important molecular marker of endometrial receptivity. Recent evidence suggested that hCG may influence the endometrial milieu thereby enhancing receptivity and implantation success, but the exact underlying mechanism of this phenomenon remained elusive.

Study design, size, duration: Endometrial samples were collected from normal cycling women during the mid-secretory phase for endometrial stromal cells (ESCs) isolation used to investigate the molecular mechanisms in vitro. Blastocyst-like spheroid(BLS) implantation models were performed to examine the roles of hCG during embryo expansion on hESCs. This is an experiment study lasted nine months.

Participants/materials, setting, methods: Endometrial stromal cells (ESCs) and JAR cells were used as study models. Western blotting, real-time

RT-PCR and BLS expansion assay were used to determine the mechanism of endometrial receptivity changes induced by hCG. All experiments were conducted using at least three different cell culture preparations in triplicate.

Main results and the role of chance: Western Blot analysis revealed that addition of 0.2IU/mL hCG to ESCs induced the increase of HOXA10 and decrease of DNA methyltransferases 1 (DNMT1) at 48 h (both $p<0.01$ versus control). Increase of mammalian sterile20-like kinase1(MST1) in ESCs treated with 0.2IU/mL hCG at 20 min ($p = 0.043$ versus control). HOXA10 mRNA levels were significantly increased by hCG 0.2IU/mL treatment for 48 h ($p<0.01$) and DNMT1 mRNA levels were decreased by hCG 0.2IU/mL treatment for 48 h. hESCs treated with hCG 0.2IU/mL up to 48 h showed a good decidual response, mainly characterized by increased BLS expansion.

Limitations, reasons for caution: This is an in vitro study utilizing hESCs and JAR cells. The changes of DNA methylation of HOXA10 and phosphorylation of MST1 should be further evaluated. Furthermore, the results obtained should be confirmed in mice with hCG intrauterine perfusion treatment in vivo.

Wider implications of the findings: Our results suggest that hCG activates endometrial decidualization not only by reducing expression and concomitant methylation of HOXA10 also enhancing phosphorylation of HOXA10. These finding may subsequently provide novel potential therapeutic regimens for patients with poor decidualization.

Trial registration number: This work was supported by the National Natural Science Foundation of China (81571504).

P-457 Increased NK-cell subsets with inhibitory cytokines and surface receptors in patients with recurrent miscarriage

R.J. Kuon[1], L. Zhu[2], M. Aly[2], K. Vomstein[3], T. Strowitzki[1], B. Toth[3], V. Daniel[2]

[1]*University Hospital, Department of Gynecological Endocrinology and Fertility Disorders, Heidelberg, Germany*
[2]*University of Heidelberg, Department of Transplantation- Immunology, Heidelberg, Germany*
[3]*Medical University Innsbruck, Gynecological Endocrinology and Reproductive Medicine, Innsbruck, Austria*

Study question: How do the counter-regulating inhibitory mechanisms of NK-cell subsets differ in patients with recurrent miscarriage compared to healthy controls?

Summary answer: Patients with recurrent miscarriage show abnormally high NK-, NKT- and T- cells in the blood which express inhibitory cytokines and inhibitory surface receptors.

What is known already: NK-cells are in the focus of debate as potential immunologic markers and targets in recurrent miscarriage. There is increasing evidence for immunoregulatory NK cells that might mediate immune responses by secretion of IL10, IL4, and TGFß. Patients with recurrent miscarriage show upregulated cytotoxic NK cells that are suspected to play a causal role in the pathogenesis. Further elevated NK-cells are associated with decreased uterine blood flow in early pregnancy, possibly leading to hypertension, preeclampsia, and fetal growth restriction.

Study design, size, duration: Prospective cohort study, in total $n = 31$ patients with recurrent miscarriage and $n = 37$ healthy controls were recruited between 01/2016 and 09/2017.

Participants/materials, setting, methods: NK-, NKT- and T-cell subsets were analyzed in the peripheral blood of $n = 31$ patients with idiopathic recurrent miscarriage and $n = 37$ healthy controls using eight-color fluorescence flow cytometry. Patients had a history of 3 and more consecutive miscarriages and were screened for anatomical disorders (vaginal ultrasound and hysteroscopy), endocrine dysfunctions, autoimmune disorders, deficiencies in coagulation factors, inherited haemostatic changes and parental chromosomal abnormalities. All analyses were performed at least 3 months after the last pregnancy.

Main results and the role of chance: Compared with healthy controls, patients with recurrent miscarriage showed significantly higher absolute numbers of CD56+ NK-cells co-expressing the phenotype IFNyR+, IL4+, TGFβ+, IL4+HLADR+, TGFβ+HLADR+, IL4+TGFβ+, IL4+TGFβ-, IFNy+ and/or IL10- IFNy+ (all $p\leq0.01$), more IL17+CD56bright ($p = 0.028$) NK-cells, and more CD56dimCD16+ NK-cells co-expressing IFNyR, IFNy, IL4 and/or TGFβ (all $p\leq0.01$). Further, patients with recurrent miscarriage showed significantly higher absolute numbers of CD158a-CD158e+, CD158a+, CD158b+ (all $p<0.05$), NKG2D+NKG2A+, NKG2D+NKG2A-, NKG2D+ and/or NKG2A + (all $p\leq0.01$) CD56+ NK-cells and higher CD158a+, CD158b+ (all $p<0.05$), NKG2D+ and/or NKG2A+ (all $p<0.01$) CD56dim+CD16+ NK-cells than healthy controls.

Limitations, reasons for caution: This data needs to be confirmed in a larger cohort of patients.

Wider implications of the findings: Compared to healthy controls, patients with recurrent miscarriage have abnormal high circulating NK-cells expressing inhibitory cytokines and inhibitory surface receptors which might contribute to the pathogenesis. This immune profile might be used to identify patients that benefit from therapies that inhibit cytotoxic immune response in clinical trials.

Trial registration number: not applicable.

P-458 Recurrent implantation failure: should we refuse from scanning electron microscopy

I. Gyulmamedova[1], T. Tatarchuk[2], O. Nosenko[3], E. Gyulmamedova[2], P. Bazanov[4], S. Khabarov[5], O. Babenko[6]

[1]*VitroKlinik, IVF, Moscow, Russia C.I.S.*

[4]*VitroKlinik, In vitro fertilisation, Moscow, Russia C.I.S.*
[5]*VitroClinik, Gynecology, Moscow, Russia C.I.S.*
[6]*Medical Center "Mother Child-", gynecology, Kyiv, Ukraine*

Study question: To evaluate clinical outcome of scanning electron microscopy (SEM) usage for Personalized Embryo Transfer (PET) algorithm in women with recurrent implantation failure (RIF).

Summary answer: Determination of the implantation window via SEM helps improve the strategy of PET, as well as pregnancy rate in women with RIF.

What is known already: Recurrent implantation failure is a challenge of modern reproductive medicine. The endometrium acquires the ability to implant a hatched blastocyst only within a specific time termed the receptive phase. Pinopodes have been suggested as the markers of uterine receptivity. Endometrial pinopodes formation can be detected by SEM. Controversial data are published on SEM as an efficient method of endometrial receptivity determination. Implementation of endometrial receptivity array (ERA) test for «Implantation Window» determination (IW) limited SEM usage. However, in recent years interest to SEM has revived, given its availability, reproducibility and informative value.

Study design, size, duration: A prospective study of 66 cycles in patients with recurrent implantation failure was conducted between 2012 and 2016. Patients with RIF who had euploid embryos according to PGD results were included in the study after Informed Consent was obtained. Hysteroscopy was performed for all patients to exclude intrauterine pathology. Patients were divided in two groups. 1.89 ± 0.05 embryos were transferred in the first group and 1.94 ± 0.06 - in the second, ($p> 0.05$).

Participants/materials, setting, methods: Patients were divided in two groups. 1 group - 36 patients - transfer of frozen-thawed euploid embryos on day (P+7) after initiation of progesterone therapy in hormone replacement cycle (HRC). 2 group - 30 patients - Pipelle endometrium sampling was performed on day (P+6) and day (P+8). SEM was performed for pinopodies imaging. Frozen-thawed euploid embryos in this group were transferred depending on the IW according to results of SEM.

Main results and the role of chance: There were no differences in age, BMI, reproductive and gynaecological history, as well as in the number of previous IVF cycles in the groups. Analysis of SEM results on day P+6: lack of pinopodes in 24 (80,00%) patients, sites of scant pinopodes around the uterine gland in 4 (13,33%), plenty of developing pinopodes – in 2 (6,67%). On Day P +8 we found lack of pinopodes in 5 (16,67 %) participants. Scant, moderate and abundant amounts of developing pinopodes - in 8 (26,67%); 6 (20,00%); 4

(13,33%) respectively. The abundance of developing and single developed ones in 4 (13.33%); and scant, moderate and abundant quantity of regressed pinopodes in 1 (3.33%), 1 (3.33%), 1 (3.33%) respectively. Transfer of frozen-thawed embryos was performed according to the IW: on day P+5–1 (3,33%); P+6–6 (20,00%); P+7–5 (16,67%); P+8–10 (33,33%); P+9–6 (20%). In 2 cases was performed double transfer. Endometrial thickness on the day of ET was 9,35 ± 0,31 mm and 9,34 ± 0,3 mm (P>0.05). Pregnancy rate was 4 (11,11 %) in the first group and 18 (60%) in second (P <0.05). Live birth incidence on ET was 3 (8.33%) and 16 (53.33%) (P <0.05).

Limitations, reasons for caution: For the effectiveness of the proposed approach it is necessary to know the exact day of administration of exogenous or secretion of endogenous progesterone. The IW formation is different in women in the natural cycle, in cycle with HRT, and in the cycle with controlled ovarian stimulation.

Wider implications of the findings: Knowledge of IW in patients with RIF helps to obtain pregnancy in this complex category of patients. Along with the modern transcriptomic genetic investigation of IW, SEM remains an informative, reproducible, accessible method.

Trial registration number: Not trial; this prospective study was approved by Ethics Committee.

P-459 Systematic review and meta-analysis of variants in cytokine genes emphasizes their clinical validity with respect to recurrent pregnancy loss

E. Parfitt, C. Clementi, T. Hu-Seliger, B. Burnett, P. Yurttas Beim

Celmatix Inc., Research and Development, New York, U.S.A.

Study question: Is existing evidence sufficient to conclude that testing variants in cytokine genes is not useful in the context of recurrent pregnancy loss (RPL)?

Summary answer: Systematic assessment of all association studies to date, followed by meta-analysis, reveals that 5 variants in 3 cytokine genes are significantly associated with RPL.

What is known already: Although immunological cytokines are involved in establishing and maintaining pregnancy, studies testing the association of variants in cytokine genes with RPL have yielded mixed results. Indeed, the ESHRE Early Pregnancy Guideline Development Group (2017) recommends against testing for cytokine polymorphisms because 'meta-analyses have not been able to find polymorphisms in relevant cytokine genes associated with RPL." However, only one of the studies cited to support this recommendation is a meta-analysis, covering 3 variants in 3 genes (Medica et al., 2009). Moreover, since the publication of this analysis, at least 26 studies of cytokine variants and RPL have been published.

Study design, size, duration: Natural language processing algorithms were used to identify articles in NCBI PubMed pertaining to genetics and RPL. Of the 1,599 articles identified, 684 were found to be true positives after manual evaluation. The evaluation also uncovered articles cited as references that were not identified algorithmically. Reported gene associations were ranked using an adaption of the Clinical Genome (ClinGen) Gene-Disease Clinical Validity Classification Framework. Data was extracted upstream of meta-analysis following PRISMA guidelines.

Participants/materials, setting, methods: Variants in genes that met ClinGen-adapted criteria for 'strong" evidence of clinical association with RPL were statistically validated using random-effects model meta-analyses. Variants were excluded from analysis if there were <2 published studies or evidence of overlapping cohorts, or if an article's presentation of information precluded the determination of the risk allele. p<0.05 was considered statistically significant, equivalent to a false discovery rate cutoff of approximately 0.10.

Main results and the role of chance: We found no genes demonstrating 100% penetrance with RPL over multiple independent studies, which is required for a "definitive" association ranking based on the adapted ClinGen framework. Our analysis revealed that 39 genes, including the cytokines *IFNG*, *IL1B*, *IL6*, *IL10*, *IL18*, and *TNF*, currently satisfy guidelines for strong evidence of association with RPL. This ranking requires at least 2 independent demonstrations of statistically higher prevalence of variants in affected individuals than in controls, as well as supporting experimental data (e.g., from mouse models or human gene expression studies). Of the variants within these genes, 62 had sufficient experimental evidence for inclusion in meta-analysis, including 19 in 6 cytokine genes. Five of these variants were found to be significantly associated with RPL after meta-analysis. Three of these 5 lie within *TNF* and include the c.-488G>A variant (OR = 1.43, 95%CI:1.09-1.76, p = 0.003), previously observed to have no association with RPL after meta-analysis. Notably, the *TNF* variants c.-1211T>C and c.-556G>A have an even higher effect size, with ORs of 2.64 (95%CI:1.77-3.50, p<0.001) and 2.29 (95%CI:1.07-3.51, p = 0.002), respectively, which emphasizes the importance of assessing different variants in the same gene. We observed a similarly high effect for the c.-887T>G variant in *IL18* (OR = 1.92, 95%CI:1.58-2.27, p<0.001).

Limitations, reasons for caution: We only included studies in which patients had experienced ≥2 losses in our analyses. Heterogeneity introduced by other factors, such as age, population stratification, stage of loss, whether or not losses were consecutive, and the wide variety of exclusion criteria, were not adjusted for.

Wider implications of the findings: The association of genetic biomarkers with RPL cannot be discounted without objective, systematic, and standardized analysis. While the significant variants identified here may not be causative by themselves, such markers may enable physicians to distinguish molecular subtypes of RPL, leading to treatment strategies that help mitigate inherent, patient-specific risk factors.

Trial registration number: N/A.

P-460 Which one is more effective on Recurrent Implantation Failure,innate or adaptive immunity?

F. Amjadi[1], Z. Zandieh[1], M. Mehdizadeh[1], S. Aghajanpour[2], R. Aflatoonian[2]

[1]Iran University of Medical Sciences, Department of anatomy, tehran, Iran
[2]Royan Institute for Reproductive Biomedicine- ACECR-, Department of Endocrinology and Female Infertility at Reproductive Biomedicine Research Center-, Tehran, Iran

Study question: *Which one is more effective on Recurrent Implantation Failure, innate or adaptive immunity?*

Summary answer: adaptive immunity play more important role in recurrent implantation failure patient.

What is known already: The immune system is required for maternal immune tolerance, protecting the fetus, and regulating the placentation process. In RIF patients, Many factors may contribute to implantation failure as inappropriate immune responses at the time of embryo introduction is one of the reason for unsuccesful implantation. So, evaluation of innate and addaptive immune syatem in RIF patients seems valued.

Study design, size, duration: This study was a basic genomic analysis of human endometrial biopsies taken from 10 patients with repeated implantation failure and 6 healthy fertile women in the secretory phase. All participants are in reproductive age with normal menstrual cycles.

Participants/materials, setting, methods: Total mRNA were extracted from endometrial tissues of women with repeated implantation failure (on day 3-5 after ovulation, n = 12) and healthy fertile individuals (on day 3-5 after ovulation, n = 10) during luteal phase. The expression profile of 84 genes related to innate and adaptive immunity was investigated using qRT-PCR array. Informed consent was obtained from patients. All measurements were performed in triplicates on independent biological replicates.

Main results and the role of chance: Our data clearly showed that cytokines expressions like IL6, IL-2, IFN gamma, IL17, IL23 and IL13 are higher in RIF group than normal. The innate immunity pathways as, pattern recognition receptors and their pathways like TICAM1, TICAM2, IRAK1, TRAF, MYD88 expression are lower or not significant in RIF than normal group, also the expression of NFKBIA (IκBα, MAD3) as an inhibitor of NFKB1 are higher in RIF group. The adaptive immunity markers like T cell activation,Thelper1 and Thelper17 like CD86, ICAM1, CXCR3, TBX21 and FASLG (TNFSF6) expressions are higher in RIF than normal.

Limitations, reasons for caution: The results need to be confirmed in more cases and in protein level.

Wider implications of the findings: Results showed more proinflammatory environment than anti-inflammatory in RIF. Apparently, the source of inflammatory cytokines production are Tcells not PRR pathways. For example, MYD88, an important factor downstream of PRR was decreased in RIF patients. So, it seems adaptive is more contributing factor than innate immunity in pathophysiology of RIF.

Trial registration number: N/A.

P-461 Patient acceptability and perception of randomisation in a trial of Scratch in Recurrent Miscarriage (SiM trial)

V. Kandavel[1], S. Quenby[2]

[1]*Sub specialty trainee in reproductive medicine and surgery, Complete Fertility centre, southampton, United Kingdom*
[2]*Professor of Obstetrics, UHCW NHS Trust- University of Warwick, coventry, United Kingdom*

Study question: 1. Would women be prepared to be randomised to scratch vs sham examination?

2. Will patients be aware of endometrial biopsy compared to sham procedure?

Summary answer: Women were accepting to the randomisation process within the trial.

Women were not aware whether they had the endometrial biopsy or the sham procedure.

What is known already: The Cochrane meta-analysis of the effects of endometrial scratch in women undergoing assisted reproductive conceptions, suggested that obtaining endometrial biopsy in the luteal phase prior to the treatment improves the clinical pregnancy and live birth rates. This was particularly so in women with previous failed IVF's.

The trials in the review compared endometrial scratch vs endometrial injury by other methods such as hysteroscopy.

In the Endoscratch trial for women prior to their first IVF, women are randomised to scratch vs no examination.

The ESHRE RPL guideline acknowledges the gap in the evaluation of endometrial scratch in women with recurrent miscarriage.

Study design, size, duration: Evidence from trials in recurrent miscarriage (RM) patients suggests good outcomes in the placebo group. The presence of a sham arm was important methodologically, in the trial. However patient acceptability was unknown.

The SiM trial is a pilot randomised controlled trial of endometrial scratch vs sham procedure, in the luteal phase, on the pregnancy outcomes in RM.

109 women were recruited over a 2 year period (2015-2017). Ethics approval was obtained for trial, questionnaire collation.

Participants/materials, setting, methods: Women (age 18-42) were approached in the recurrent miscarriage clinic to participate in the SiM trial. There were given trial explanation and PIS by the research midwife and clinical fellow. The questionnaire was provided in a self addressed envelope at their randomisation visit, to be completed and returned within 4 weeks.

The questionnaire contained objective measures quantifying pain, bleeding, duration- to assess the difference between the groups and free text box for comments and feedback.

Main results and the role of chance: Of the 226 women screened, 150 women were eligible. 133 patients were consented and 109 women were randomised. The acceptance rate was 72.66 %.(10/24 women were excluded as pregnant before randomisation). 109 Questionnaires were given at randomisation. The response rate was 62.38 %(68/109), with similar numbers in both groups-(33 and 35), with most responses within 2 weeks from randomisation (76.5%, 52/68). There were no reported infection following the procedures.

More bleeding was reported in the biopsy group (28/33) compared to the control group (8/35), which was mild in 80% of the women. A significant proportion of women in both the groups experienced pain, but more women in the biopsy group (30/33) reported pain than the control group (20/35). However the pain score was reported as mild by the majority of women in both the groups. Interestingly 7of 20 women who reported pain in the control group described it as moderate pain. 1 in 10 patients experienced severe pain in the biopsy group.30/68 patients had prior analgesia intake. The duration was short lasting (< 10 minutes) in most women.

Women who experienced pain in the sham group thought they had the intervention and those painfree in the biopsy group vice-versa.

Limitations, reasons for caution: The numbers are small as this is a pilot trial. There is a possibility of recall bias especially when the response has been delayed. The influence of the procedure expectations and experience leading upto the randomisation may have contributed to the recall bias.

Wider implications of the findings:

- Women with recurrent miscarriage accepted to randomisation in the trial with a sham group.
- More women experienced bleeding in the biopsy group.
- As some women in both groups experienced pain and others did not during the procedure, they were not aware of the allocation group and so blinding occurred.

Trial registration number: The trial is registered on clinicaltrials.gov.

The trial registration number is NCT02681627

P-462 The effect of uterine cavity irrigation with office hysteroscopy during antagonist cycle 0varian stimulation on IVF outcome

M. Ghasemi[1], A. Aleyasine[2], M. Aghahosseini[2]

[1]*Pregnancy Health Research Center-Zahedan University of Medical Sciences-Zahedan-Iran, obstetric and gynecology -IVF center, Zahedan, Iran*
[2]*Tehran University of Medical Sciences, obestetric and gynecology and Ivf center-Tehran University of Medical Sciences, Tehran, Iran*

Study question: Dose uterine cavity irrigation with office hysteroscopy in the day 5-7 during antagonist cycle ovarian stimulation in the IVF cycle improve the endometrial receptivity and ivf outcome.

Summary answer: hysteroscopy could not improve the IVF outcome in the same cycle but could enhance the cumulative pregnancy rate.

What is known already: Although many studies were done about the effect of routine hysteroscopy prior to the first IVF cycle, there is still no agreement about the effect of hysteroscopy on IVF outcomes.

Study design, size, duration: This prospective randomized clinical trial was conducted in the shariati hospital infertility ward, Tehran university of medical sciences from June 2015 to June 2016.

250 women who were less than 40 years, with primary infertility and without the history of prior hysteroscopy examination in the first IVF cycle, and also with normal transvaginal sonography and hysterosalpingography were entered to the study.

Randomization was done with web-based concealed allocation and patients were randomly entered to each group.

Participants/materials, setting, methods: Controlled ovarian hyperstimulation was done by using antagonist regimen with r-FSH in two groups.

Hysteroscopy was performed in the early mid-follicular phase of a stimulation cycle (day 5-7) with a vaginoscopy approach in hysteroscopy group. Embryotransfer was done in the same cycle. The primary outcomes were clinical pregnancy rate and secondary outcome was live birth rate.

also we followed all patients without live births through the second freeze embryo transfer cycle for secondary outcome.

Main results and the role of chance: From June 2015 to June 2016 we randomly assigned 250 women in one of the two groups: hysteroscopy (case group) or without hysteroscopy (control group) and finally 228 patients finished the study. clinical pregnancy rate was 47% in the case group and 40% in the control group. (p-value = 0.396, RRR = 13.8% [-5.9% to 35.9%], NNT = 15 [-16 to 5])

Live birth rate was 41.28% in the hysteroscopic group and 31.9% in the control group (p-value = 0.18, RRR = 22.7% [-9.2% to 45.2%], NNT = 11 [-32 to 5]).

When the patients were followed for 2 months for an additional embryo transfer, LBR was 78% in the hysteroscopic group and 47.5% in the control group (p-value = 0.039, RRR = 26.9% [3-44.9%] and NNT = 8 [4-85]).

Limitations, reasons for caution: conduction in just one center and small sample size were two limitations in this study.

Wider implications of the findings: in order to decide about the generalisability to other populations, more robust RCTs must be coducted.
Trial registration number: IRCT2016011022795N2

P-463 The relationship between angiogenic markers in peri-implantation endometrium and hypertensive disorder in pregnancy in women with reproductive failure

X. Chen, W.C. Cheung, Y. Liu, Y. Zhao, C.C. Wang, T.C. Li

The Chinese University of Hong Kong, Department of Obstetrics and Gynaecology, Hong Kong, China

Study question: Do angiogenic markers in peri-implantation endometrium predict hypertensive disorder in pregnancy in women with reproductive failure?
Summary answer: Micro vessel density (MVD) in the peri-implantation endometrium may have a predictive value for hypertensive disorders in a subsequent pregnancy in women with reproductive failure.
What is known already: Vascular endothelial dysfunction in the placenta bed has an important role in the pathogenesis of gestational hypertension and preeclampsia. Barker hypothesis proposed that early intrauterine events might have a long-term effect on the later on pregnancy or even after birth. We aimed to examine the relationship between angiogenesis at the peri-implantation period and hypertensive disorders in the subsequent pregnancy in this study.
Study design, size, duration: This is a retrospective study including 110 women with a history of reproductive failure, including 58 women with recurrent miscarriage, 38 infertile women and 14 women with recurrent implantation failure.
Participants/materials, setting, methods: Endometrial biopsies were obtained precisely 7 days after luteinization hormone surge in natural cycles. Immunohistochemistry was used to determine expression of VEGF-A, VEGF-C and PLGF and micro blood vessels were identified by von Willebrand factor (vWF). A semi-quantitative analysis was performed by using *H*-score analysis of staining intensity for VEGF-A, VEGF-C and PLGF in the luminal epithelium, glandular epithelium and stroma, separately. The number of vWF-positive endometrial micro vessels were counted by Image J software.
Main results and the role of chance: Nineteen out of the 110 women were diagnosed as gestational hypertensive disorders in the subsequent pregnancy, including 16 women with gestational hypertension and 3 women with preeclampsia. The mean±SD number of micro blood vessels/mm^2 in women with gestational hypertensive disorders ($15.2 \pm 5.1/mm^2$) was found to be significantly ($P = 0.041$) higher than those with normal gestational blood pressure ($9.8 \pm 3.1/mm^2$). However, there was no significant difference in the expression intensity of VEGF-A, VEGF-C and PLGF in any endometrial compartments (luminal epithelium, glandular epithelium and stroma) between women with or without gestational hypertensive disorders.
Limitations, reasons for caution: Immunohistochemistry and H-score analysis for staining intensity are semi-quantitative methods to determine the amount of protein expression. The study could potentially be strengthened by other quantitative measurements.
Wider implications of the findings: Observations of relationship between MVD in peri-implantation endometrium and gestational hypertensive disorders may indicate the long-term effect of peri-implantation events on the later-on pregnancy. Further studies may be considered whether the same conclusion applies to other markers or other pregnancy complications.
Trial registration number: N/A.

P-464 Reduced adrenomedullin expression leads to aberrant macrophage activities in human oviduct: implications for the pathophysiology of tubal ectopic pregnancy

X. Wang[1], C.L. Lee[1,2], M. Vivijian[1], R.H.W. Li[1,2], Y.L. Lee[1], S.B. Liao[1], K.F. Lee[1], W.S.B. Yeung[1], Y. Zhang[3], P.C.N. Chiu[1,2]

[1]*Department of Obstetrics & Gynecology, The University of Hong Kong,*
[2]*Shenzhen Key Laboratory of Fertility Regulation, Department of Obstetrics and Gynecology, The University of Hong Kong-Shenzhen Hospital, Hong Kong*
[3]*Department of Obstetrics and Gynecology, Reproductive Medicine Center, Zhongnan Hospital of Wuhan University*

Study question: Does adrenomedullin (ADM) play a role in the pathogenesis of tubal ectopic pregnancy (tEP) by modulating tubal macrophage activities?
Summary answer: ADM inhibits tubal implantation by suppressing the pro-inflammatory activities of tubal macrophages.
What is known already: tEP accounts for ~2% of all pregnancies in the western world and is the major cause of maternal morbidity and mortality in the first trimester of pregnancy. The most important predisposing condition of tEP is salingitis. ADM is an immune-modulatory molecule with anti-inflammatory activities. Its expression in human oviduct is steroid dependent and peaked in a steroid environment simulating the early luteal phase, a phase when embryo transport occurred. We have demonstrated lower plasma and oviductal ADM levels in patients with tEP than in normal pregnancy. Macrophages is the predominant leukocyte populations in the oviduct with tEP.
Study design, size, duration: Women undergoing salpingectomy due to tEP were recruited as tEP group (n = 19). Non-pregnant women undergoing hystero-salpingectomy for benign diseases were also recruited and divided into control (n = 11) or salpingitis group (n = 19) according to their clinicopathological diagnosis.
Participants/materials, setting, methods: Oviducts were collected from the patients. ADM and implantation-related molecules expressions were determined by RT-qPCR and immunohistochemistry. Tubal macrophages were isolated and cultured with or without ADM treatment. Their conditioned medium (CM) were collected for inflammatory cytokine level determination by cytokine array and ELISA. The effect of CM form macrophages on the implantation-related molecules expressions and implantation capacity of tubal epithelial cells was also studied by RT-qPCR and trophoblastic spheroid attachment model respectively.
Main results and the role of chance: There was a reduced oviductal ADM levels and an elevated implantation-related molecules levels in patients with salpingitis and tEP when compared to the normal patients. Interestingly, ADM treatment significantly suppressed the stimulatory effects of tubal macrophages on the implantation-related molecules expressions and implantation capacity of tubal epithelial cells. These observations were associated with a decreased pro-inflammatory cytokines secretion of tubal macrophages after ADM treatment. Since Implantation is widely accepted to be associated with local inflammatory event, the results indicated that reduced oviductal ADM level in tEP patients may contribute to exacerbating pro-inflammatory activities of tubal macrophages, leading to a permissive environment for the embryo-tubal ectopic implantation.
Limitations, reasons for caution: Our study only focused on the role of ADM on tubal macrophage-derived pro-inflammatory cytokines production. Further studies are required to illustrate whether there are other factors from tubal macrophages can be modulated by ADM and thereby affecting implantation process.
Wider implications of the findings: Our study provides a new insight on the microenvironment change leading to tEP, as well as promote our understanding on the immunopathological mechanism of tEP.
Trial registration number: Not applicable.

P-465 Personal frozen-thawed embryo transfer in unexplained RIF patients according to the blinded histological dating of endometrial biopsies

Li[1], Gan[2], J. Song[2], J.N. Liao[3], G.X. Lu[1], G. Lin[1], F. Gong[1]

[1]*Institute of Reproduction and Stem Cell Engineering- Basic Medicine College- Central South University-Reproductive and Genetic Hospital of CITIC-XIANGYA, China,*
[2]*Reproductive and Genetic Hospital of CITIC-XIANGYA, China,*
[3]*Institute of Reproduction and Stem Cell Engineering- Basic Medicine College- Central South University, China,*

Study question: To determine the clinical effect of blinded endometrial histological dating in RIF patients.

Summary answer: Personal frozen-thawed embryo transfer(pFET) according to more accurate endometrial histologic dating (ovulation monitoring by ultrasound) may improve clinical outcomes in unexplained RIF patients.

What is known already: Many endometrial markers, such as pinopods, immunohistochemical biomarkers, endometrial blood flow, have been used to determine the receptivity. They may interact transiently with the embryo at implantation but appear not to be reliable markers of receptivity as the precision clinical diagnostic tools. The morphological changes observed on histology for each specific day after ovulation were described by Noyes in 1950'. Endometrial biopsy that shows a difference of more than 2 days between the histologic dating and actual day after ovulation is considered to be "out of phase". But such pFET studies according to the Noyes criterion are relatively lacking.

Study design, size, duration: From July 2017 to December 2017, altogether 205 infertility patients were recruited in the prospective intervention study.

Participants/materials, setting, methods: A total of 50 patients in control group and 155 RIF patients underwent endometrial biopsy. In phase I, control group patients with PGD-CCS were recruited before their first FET cycles in luteal phase (postovulatory +3/+5/+7/+9/+11) (ovulation monitoring by ultrasound). Endometrial histological dating were evaluated in control patients who were ongoing pregnancy in next natural FET cycle. In phase II, according to the results of endometrial dating, pFET were performed in the RIF group.

Main results and the role of chance: In the phase I, criteria for endometrial dating according to the Noyes dating criteria was developed in different time (postovulatory +3, postovulatory +5, postovulatory +7, postovulatory +9, postovulatory +11). And all the blinded endometrium dating (n = 205) was evaluated by two experienced pathologists. The agreement between pathologist A and pathologist B was determined to be good (weighted kappa = 0.672; 95% CI 0.606–0.737; P < 0.001). In the phase II, the rate of out of phase in the day of postovulatory +7 was significantly higher (31.61% vs 8.0%, P = 0.015) in RIF group than control group.The ongoing pregnancy rate(OPR) was dramatically high in the pET RIF group (61.70%).

Limitations, reasons for caution: We didn't design randomized controlled study in RIF group which the endometrial dating was out of phase. Because the RIF patients who have experienced multiple IVF failure were mostly reluctant to try routine treatment protocol.

Wider implications of the findings: Provide a new insight for the unexplained RIF patients with individualized treatment.

Trial registration number: NCT03222830

P-466 Usefulness of hysteroscopic intrauterine perfusion in frozen-thawed embryo transfer (FET) cycles

K. Takeuchi, T. Iwakawa, Y. Nagai, K. Hazeyama, C. Uchimura, A. Ogawa, C. Kondo, N. Mori, M. Takeuchi

Takeuchi Ladies Clinic / Infertility Center, Infertility, Aira-shi- Kagoshima-, Japan

Study question: Patients who did not become pregnant after initial FET underwent hysteroscopic intrauterine perfusion. Its usefulness was examined by comparing pregnancy status.

Summary answer: Intrauterine perfusion with 500 ml of saline solution significantly increased the pregnancy rate even in women without macroscopic abnormalities in hysteroscopy.

What is known already: FET is now being performed more often in the world. FET is also what has mainly been performed at our hospital. Although the involvement of endometrial thickness in pregnancy is widely known, there are few reports on the other intrauterine environments.

Study design, size, duration: Between January 2013 and December 2017, the pregnancy rate in FET was 46.3% (1545/3337). Subjects comprised 710 women who did not become pregnant after initial FET. Conditions of embryo transfer limited materials strictly to an endometrial thickness of more than ≧8 mm and good-quality embryos (Veeck's classification for Day 3 embryos ≧6 cell G II, Gardner's classification for blastocysts ≧3BB) in this study.

Participants/materials, setting, methods: Subjects were classified into three groups: Group I (women who underwent FET without hysteroscopy), Group II (women who received treatment for polyps and inflammation detected by hysteroscopy and then underwent FET) and Group III (women who had no macroscopic abnormalities in hysteroscopy and underwent FET immediately after intrauterine perfusion). A comparison of the pregnancy rate was made between the three groups.

Main results and the role of chance: The pregnancy rate was 40.5% (85/210) in Group I, 57.9% (168/290) in Group II and 59.0% (124/210) in Group III, respectively. In terms of pregnancy rate, a more significant increase was recognized in Group II and Group III than in Group I (Group I vs Group II P<0.01, Group I vs Group III, P<0.01). Even in the women without any macroscopic abnormal hysteroscopic findings, the pregnancy rate increased significantly after intrauterine perfusion.

Limitations, reasons for caution: None.

Wider implications of the findings: It is suggested that intrauterine perfusion with saline solution during hysteroscopy might improve conditions for implantation. Further examination is underway to clarify differences in bacteria and endometrial microbiota before and after intrauterine perfusion.

Trial registration number: None.

P-467 Novel binding partners with serine protease A differentially expressed in recurrent pregnancy loss

K.H. Baek[1], C.Z. Pei[1], J.H. Park[1], L.A. Li[1], I.K. Oh[2], B. Choi[2]

[1]CHA University, Department of Biomedical Science, Seongnam, Korea- South
[2]Creative and Love Hospital, Gwangju, Korea- South

Study question: Could the role of serine protease A in regulating its matrix proteins be related to the pathophysiology of recurrent pregnancy loss (RPL)?

Summary answer: We identified novel binding partners of serine protease A and found that the regulation of this protease has an important role in women with RPL.

What is known already: In humans, serine proteases are responsible for various cellular processes including reproduction, immune response, and blood coagulation. In a previous study, a novel serine protease gene was identified to be more expressed in chorionic villi from the normal controls than in those from the RPL patients.

Study design, size, duration: The serine protease A was investigated to identify putative substrates using yeast two-hybrid screening. 22 different genes encoding proteins, which may interact with the novel serine protease A, were identified. The serine protease A and its putative binding proteins may play a role in the occurrence of RPL.

Participants/materials, setting, methods: The full-length serine protease A and human cDNA library were used for yeast two-hybrid Matchmaker GAL4 Two-Hybrid System 3. The novel serine protease A gene was transfected into HeLa cells, and cellular lysates from these cells were separated on SDS-PAGE, and proteins in these lysates were immunoblotted with diverse antibodies. In addition, bioinformatics tools were employed to identify putative substrates of the novel protease A.

Main results and the role of chance: In a previous study, we identified eight differentially expressed genes in chorionic villi between the normal control and RPL groups. Of these, a novel serine protease A gene was less expressed in chorionic villi from RPL patients than in those from controls. By performing yeast two hybrid screening, 22 different genes encoding proteins, which interacted with the novel serine protease A, were identified. In addition, we tried to identify the interaction between the novel serine protease A and known substrates through the bioinformatics tools. Immunoprecipitation assay revealed that putative substrates including immunoglobulin transporter (IGT) and inhibitor of apoptosis (IOA) interacted with the novel serine protease A. Exogenous and endogenous expression levels of substrates were decreased by the novel serine protease A in a dose-dependent manner.

Limitations, reasons for caution: The results of this study can only indicate the limitations of serine protease A function in vitro.

Wider implications of the findings: This is to explain the pathogenesis of RPL from a new perspective, and will be the cornerstone of the development for diagnostic reagents and the treatment of drugs.

Trial registration number: not applicable.

P-468 Effect of intrauterine perfusion of granulocyte colony stimulating factor on endometrial parameters, implantation and pregnancy rate in women undergoing IVF cycles: randomised controlled trial

A. Kriplani[1], S. Jain[2], R. Mahey[2], N. Malhotra[2], N. Singh[2], M. Kalaivani[2]

[1]All India Institute of Medical Sciences- New Delhi- India, Obstetrics Gynaecology, New Delhi, India
[2]All India Institute of Medical Sciences- New Delhi, Obstetrics & Gynaecology, New Delhi, India

Study question: Whether there is any benefit of intrauterine perfusion of Granulocyte- Colony Stimulating factor (G-CSF) on Endometrial parameters, implantation and pregnancy rate in women undergoing IVF-ICSI cycles?

Summary answer: Intrauterine perfusion of G-CSF had no benefit in terms of clinical pregnancy rate and implantation rate in women undergoing fresh IVF-ICSI cycles.

What is known already: Implantation is the rate limiting step in ART cycles. The interaction between a good quality embryo and a receptive endometrium at the time of implantation determines the success of ART cycles. A lot of research has been directed towards studying the factors that influence endometrial receptivity, measures to assess and possibly improve endometrial receptivity. Role of G- CSF is being investigated in increasing endometrial thickness and pregnancy rate in women undergoing ART. Few studies have shown that it increases implantation in women with poor endometrial thickness. Its benefit in women undergoing IVF with normal endometrial thickness is unknown.

Study design, size, duration: A randomised controlled trial was conducted among 150 women undergoing IVF/ICSI treatment at ART Centre after taking approval from Institute Ethics Committee.

According to inclusion/exclusion criteria, 76 patients were randomised to the intervention group (I) and 74 patients were randomised to the control group (II). IVF protocol was decided according to age, BMI hormonal parameters and previous response. Primary outcome was clinical pregnancy rate. Secondary outcome were effect endometrial parameters, implantation rate and ongoing pregnancy rate.

Participants/materials, setting, methods: Patients in the intervention group received intrauterine perfusion of 300μgm (0.5 ml) of G-CSF on the day of ovulation trigger. Control group was administered intrauterine perfusion of 0.5 ml of normal saline. Endometrial thickness, volume and vascularity was assessed by TVS on trigger day and embryo transfer day. The IVF protocol was started according to age, BMI, previous IVF response, ovarian reserve, AMH and FSH levels. Clinician and participants both were blinded about the group allocation.

Main results and the role of chance: Baseline demographic parameters and IVF characteristics were comparable between the two groups. Endometrial thickness on day of ovulation trigger was 9.3 ± 1.6 mm in group I and 9.4 ± 1.6 mm in group II and was comparable (p value 0.660). Endometrial volume on day of trigger was 5.4 ± 1.7 ml in group I and 5.3 ± 1.8 ml in group II and was comparable.Endometrial thickness on day of embryo transfer (ET) was comparable in group I (11.3 ± 2.0 mm) and group II 11.2 ± 1.8 mm (p value 0.697). Endometrial volume was also comparable. Only parameter which showed significant improvement in intervention group was endometrial vascularity on day of embryo transfer (CI 1.67 (1.24, 2.24); p-0.001). Though there were more clinical pregnancies in group I (21/76; 27.6%) as compared to group II (14/74; 18.9%), but the difference was statically significant (CI-1.25 (0.9, 1.74) p value- 0.207). Implantation rate was also comparable between the two groups. Ongoing pregnancy rate (pregnancy beyond 12 weeks) was 20/76 (26.3%) in group I and 12/74 (16.2%) in group II. But the difference was not statically significant (p value 0.131).

Limitations, reasons for caution: Main limitation of this study was small sample size. Further large number data is required to document the role of intrauterine perfusion of G-CSF on clinical pregnancy rate and implantation rate in women undergoing IVF-ICSI cycles with normal endometrial thickness.

Wider implications of the findings: As published previously, our study also did not find any benefit of intrauterine perfusion of G-CSF on clinical pregnancy rate and implantation rate in women undergoing IVF cycles with normal endometrial thickness.

Trial registration number: CTRI/2017/10/010310

P-469 Mutations in the sperm-activating factor PLCZ1 causing fertilization failure after ICSI lead to partial hydatidiform moles

R.R. Guggilla[1], M. Ferrer-Buitrago[1], D. Bonte[1], L. Dhaenens[1], J. Parrington[2], P. De Sutter[1], P. Coucke[3], B. Heindryckx[1]

[1]Ghent University Hospital Ghent Fertility and Stem cell Team, Reproductive Medicine, Gent, Belgium
[2]University of Oxford, Department of Pharmacology, Oxford, United Kingdom
[3]Ghent University Hospital, Center for Medical Genetics, Ghent, Belgium

Study question: Is the occurrence of partial hydatidiform moles (PHMs) related to a sperm-related activation deficiency, caused by mutations in the phospholipase C zeta (PLCZ1) gene?

Summary answer: Mutational screening of the PLCZ1 gene revealed three distinct point mutations in male partners of three women with a previous history of PHMs.

What is known already: PHMs are aberrant pregnancies characterized by trophoblastic proliferation and may contain embryonic tissues. PHMs mostly contain one maternal and two paternal chromosomes, in 90% of cases due to a dispermic fertilization. PLCZ1 is a sperm-related oocyte activating factor which is required to induce normal calcium oscillations after fertilization. Aberrant patterns of Ca^{2+}oscillations caused by sperm of infertile men have been associated with deficient oocyte activation and failed fertilization. Genetic predisposition for PHM in females have been described (e.g. NLRP7), but none are studied in males. We therefore investigated the possible.

new role of PLCZ1 mutations in males causing PHMs.

Study design, size, duration: Three couples with a history of PHMs and failed fertilization after ICSI were enrolled in this study. The mouse oocyte activation test (MOAT) was performed to reveal sperm-related activation deficiencies. Mouse and human oocyte calcium analysis were performed to evaluate the activation capacity of sperm. Male and female partners were screened for mutations in the PLCZ1 and NLRP7 genes respectively. Patients were counseled to undergo assisted oocyte activation (AOA) during ICSI to overcome fertilization failure.

Participants/materials, setting, methods: Mutation screening included all coding exons of the PLCZ1 gene. After PCR amplification, products were sequenced using Illumina MiSeq. Mouse oocyte assays were carried out with piezo-drilled microinjection. Human ICSI was performed following standard procedures. For Ca^{2+} imaging, oocytes were loaded with a Ca^{2+} sensitive dye before ICSI. For ICSI-AOA treatment, a sperm was injected into the oocyte together with 0.1 mol/l $CaCl_2$ followed by a double exposure to ionomycin (10 mM) 30 minutes after ICSI.

Main results and the role of chance: While two patients showed high activation rates after the MOAT, one patient showed a slightly reduced activation rate (78%). Remarkably, all sperm samples induced abnormal Ca^{2+} oscillatory patterns in mouse oocytes. This was even more pronounced when calcium analysis was performed using human oocytes, with most of the oocytes failing to show calcium rises. However, in accordance with the hypothesis of dispermic fertilization causing PHM, when two spermatozoa were injected into human oocytes, an increase in the number of oocytes showing normal calcium oscillations was observed. Sequencing of the three patients revealed three different heterozygous mutations in the PLCZ1 gene which include two missense mutations: D46N and H233L, and a splice mutation: c.136-1 G>C.RT-PCR on the cDNA of the patient sperm revealed that the c.136-1 G>C mutation leads to loss of exon 4, subsequently leading to a truncated protein. No mutations in NLRP7 were found in their female partners, thus excluding its role in these PHM. To overcome fertilization failure after routine ICSI, ICSI-AOA was

successfully employed for two couples, resulting in a total of 5 healthy children. The other couple conceived spontaneously while waiting to start an ICSI-AOA cycle, this pregnancy did develop normally, and a healthy child was born.

Limitations, reasons for caution: More studies confirming this new role of PLCZ1 in causing PHMs are needed. The functional effect of the mutations identified has to be studied by making recombinant protein with these mutations and look at their effect on activation rate, the pattern of Ca^{2+} signals, and embryonic developmental potential.

Wider implications of the findings: This study shows for the first time the involvement of mutations in the sperm-related oocyte activating factor causing PHMs in vivo, instead of an oocyte-related deficiency, as previously thought. PLCZ1 gene screening may contribute to better understanding of the pathophysiological mechanisms in PHM, thus improving clinical management of these cases.

Trial registration number: not applicable.

P-470 A comparison of miscarriage and live birth rates between hormone replacement treatment cycle versus natural cycle for frozen embryo transfer

S. Abdul Mubarak[1], S. Acharyya[2], V. Viardot-Foucault[3], H.H. Tan[3], J.W.L. Phoon[3]

[1]General Hospital Kuala Lumpur - Ministry of Health - Malaysia, Obstetrics and Gynaecology Unit, kuala lumpur, Malaysia
[2]Centre for Quantitative Medicine, Duke-NUS Medical School -The Academia-, Singapore 229899, Singapore Rep. of
[3]KK Women's and Children's Hospital, Department of Reproductive Medicine, Singapore 229899, Singapore Rep. of

Study question: Primary objective is to compare miscarriage rates for frozen embryo transfer cycles, between the hormone replacement treatment (HRT) thaw cycle and the natural thaw cycle.

Summary answer: A significant increase in miscarriage rates in frozen embryo transfer(FET) cycles for patients who underwent the HRT thaw cycles compared to the natural thaw cycle.

What is known already: The FET protocol is easy to perform and can be accomplished in a shorter period of time than repeated in-vitro fertilization or intracytoplasmic sperm injection cycles. FET can result in extra work on weekends for both clinicians and laboratory staff. This is more likely to happen with natural thaw cycles, as the ovulation timing is not predictable.The recent Cochrane database stated that there is no difference in the outcome with the various methods of endometrial preparation used for FET.Thus we embarked on this study to evaluate if it will be worthwhile to continue performing natural thaw cycles at our centre.

Study design, size, duration: Design: Retrospective analysis of hospital records.

Setting: KK Women's and Children's Hospital, Singapore. An Academic Hospital with reproductive care.

Patient(s): Women undergoing frozen embryo transfer cycles either with HRT thaw cycle or the natural thaw cycle from 1st January 2011 till 31st December 2015.

Sample size: We would need 957 subjects in each arm to achieve a power of 90% to detect the difference at 5% statistical significance level in a two-sided chi-squared test after applying continuity correction.

Participants/materials, setting, methods: We had a large sample size of 2752 subjects.To exclude any pelvic pathology, all women included in our study had a recent endometrial cavity assessment within the last 6 months to exclude any pelvic pathology.Patients with regular menstrual cycles were mostly selected for true natural thaw cycle and irregular menstrual cycles were selected for HRT thaw cycle.Statistical analysis was carried out using R version 3.1.1. All tests were done at 5% statistical significance level.

Main results and the role of chance: A total of 2752 FET cycles were included in this retrospective study analysis.A total of 81 (6.6%) and 171 (11.2%) women suffered from miscarriage in the natural and HRT thaw group, respectively (p value 0.004). The live birth rate per transfer was significantly higher in the natural thaw group (22.8%) compared to the HRT thaw group (17.3%) with p value <0.001. Multivariable logistic regression models were used to control for factors that might be potentially associated with the risk of both the miscarriage and live birth rates as well as the choice of FET cycles. We adjusted for the patient's age at which the embryo was cryopreserved, race, BMI, main indication for IVF, number of embryo transferred, the type of embryo transferred and the type of protocol used for the FET cycle (either natural cycle or HRT cycle). The natural thaw group was considered as reference group to estimate the odds ratios. The protocol type used was independently associated with the risk of miscarriage (odds ratio 1.55; 95% confidence interval 1.15 to 2.08; p value 0.004) and live birth rates (odds ratio 0.69; 95% confidence interval 0.56 to 0.84; p value <0.001) after adjusting for potential covariates.

Limitations, reasons for caution: The limitation is that this is a retrospective study and the patients included were those with ovulatory and anovulatory menstrual cycles. Patient allocation to the different type of endometrial preparation based on their menstrual cycle characteristics can pose as a bias as patient characteristics differ in both the groups.

Wider implications of the findings: As the protocol type used for FET cycles was independently associated with miscarriage rates, patients with regular menstrual cycles should be offered natural FET cycles for better outcomes in live birth rates and reducing the miscarriage rates in the future.

Trial registration number: The Centralized Institutional Review Board at SingHealth Services approved this study (CIRB/2014/033/D).

P-471 The effect of low oxygen concentration on gene expression of potassium channels in human secretory endometrium

H. Al-Ahwany, S. Amer, C. Tufarelli, R. Khan

Division of Medical Sciences and Graduate Entry Medicine, School of Medicine, University of Nottingham

Study question: Does changing in vitro partial oxygen pressure affect the molecular expression of potassium ion channels in the human endometrium?

Summary answer: A significant difference was observed on the expression of potassium channels in cells cultured in normal oxygen and low oxygen concentration.

What is known already: There is a known functional significance of intrauterine acute oxygen concentration changes in relation to both gamete viability, embryo implantation and development. Potassium channels have been shown shown to play an important role in implantation but the effect of oxygen concentration on potassium channels is not yet clear.

Study design, size, duration: This is a lab based study investigating the effect of oxygen concentration on potassium channel in normal human secretory endometrium (n = 6) and Recurrent implantation failure (RIF) human secretory endometrium (n = 4).

In each group we are comparing the potassium channels gene expression of KCNK9, KCNK10, KCNK17 and KCNMA1 under 2 different oxygen concentrations (atmospheric and 5% low oxygen concentrations). The experiment were carried out using qPCR and flow cytometry.

Participants/materials, setting, methods: Human endometrial samples are collected after consenting the patients. Samples are washed from blood in HBSS media and cultured in media supplemented with 10% fetal bovine serum (FBS) and incubated for 24 hours, half of sample in atmospheric oxygen incubators and other half in 5% low oxygen tri-gas incubator. After 24 hours, RNA is extracted, cDNA synthetized and qPCR carried out. Also same samples were prepared for flow cytometry.

Main results and the role of chance: Expression of all potassium channels (KCNK9, KCNK10, KCNK17 and KCNMA1) in all samples are tested. After the oxygen tension is modified, two of the channels showed significant altered expression (P<0.05). Translation to protein for the potassium channels was confirmed by flow cytometry.

Limitations, reasons for caution: Larger (n) number of samples is needed in order to apply two oxygen conditions on same patient sample.

The criteria of target group is so precise not allowing a high recruitment flow.

The heterogeneity of the tissue makes it difficult to identify which cell types showed the expression.

Wider implications of the findings: The findings from this study will provide new knowledge on the role of potassium channels contributing to normal and RIF endometrial function and may have future application in improving implantation rates and identifying novel targets for fertility regulation.

Trial registration number: 'not applicable'

P-472 Exosomal profile of the receptive endometrium: a source of non-invasive biomarkers for guiding of a successful embryo implantation

P. Piomboni[1], A. Luddi[1], C. Marrocco[1], A. Capaldo[1], V. Pavone[1], L. Boschi[1], V. De Leo[1], V. Cappelli[1], L.A. Quintero[2], F. Loria[3], N. Zarovni[3]

[1]*Siena University, Molecular and Developmental Medicine, Siena, Italy*
[2]*IMER Valencia, Spain*
[3]*Exosomics Siena, Siena, Italy*

Study question: Is endometrial fluid exosomal profile is a non-invasive source for biomarker for guiding a successful embryo implantation in order to reduce the time to pregnancy?

Summary answer: Exosomes playing key roles during embryo implantation, should be used to drive a single embryo transfer in the proper time with the highest endometrial receptivity.

What is known already: Accurate timing of embryo transfer is a critical clinical need in reproductive medicine. Several factors secreted by the endometrium in uterine fluid control implantation by directly affecting blastocyst development and/or by modulating the expression of key epithelial adhesion molecules and embryo-endometrial cross talk. Some of these molecules may be sorted from cytoplasmic endosomal compartments into secretory exosomes/Ev which selectively interact with specific target cells, delivering their biologically competent cargo of lipids, proteins and RNAs. Hence, Exosomes/Evs act at the same time as effectors of endometrium/embryo cross talk and as indicators of the specific molecular profile distinctive of the implantation window.

Study design, size, duration: Uterine fluid samples were collected from women undergoing hormonal stimulation for assisted reproductive techniques. The uterine flushing was collected at different times after the LH surge, from women volunteers with proven fertility (n = 14). All samples were taken with prior informed consent and exosome isolation and analysis were performed by researchers blinded to the study protocol. The study has been carried out during 12 months.

Participants/materials, setting, methods: Uterine washings, obtained by using a disposable catheter for histerosalpingography, were scheduled in LH +1/LH+3/LH+5/LH+7/LH+9, from women volunteers with proven fertility (n = 14) at the Centre for Couple Sterility, Siena University Hospital. EXs/MV were isolated by ultracentrifugation and precipitation and counted with NTA. Conventional technologies for RNA quantification and analysis have been used, including in-house optimized LNA PCR assays, and TaqMan miRNA arrays.

Main results and the role of chance: Two fractions of the uterine flushes, mucus (M) and supernatant (UF), were analyzed for overall vesicles content by NTA (Nanoparticle Tracking Analysis). Despite very low protein content UF appears rich in particles as measured by NTA and ELISA. Conversely, M, although rich in overall proteins, is very poor in vesicles. This drives us to conclusion that exosomes largely contribute to a proteome of UF while are not contained in its mucous fraction. By confronting the protein content and the particle number we can appreciate that protein equivalent of UF has about 16-fold more particles with respect to M. This is even more striking when we confront total proteins and exosome associated CD9 levels in ELISA, where the fold of exosomal protein enrichment of UF versus M is $>2*10^6$. To trace the portion of endometrial EVs in totals recovered from each sample we have assessed a small set of genes specific of the endometrium. Their assessment in EVs/exosomes recovered from healthy volunteer's raises the possibility that some of these genes, PAEP and PGR, are confined to, or increased in UF fraction, and their expression fluctuates along the phases of the cycle.

Limitations, reasons for caution: All findings have to be validated in a larger cohort. Moreover, Embryo implantation involves a complex crosstalk have to be established between the embryo and human endometrium. Therefore, our data regarding the maternal contribution must be interpreted with caution and integrated with data resulting from embryo derived exosomes.

Wider implications of the findings: Our study allows the identification of the informative biomarker pannel, with the potential to drive a single embryo/blastocyst transfer during the highest endometrial receptivity. This clinical approach would be widely applied not only in ART cycles, but also in treatment of uterine pathology negatively influencing the beginning of the pregnancy.

Trial registration number: None.

P-473 Effect of N-acetyl cysteine on expression of oxidation-reduction genes during implantation window in Recurrent Implantation Failure: a double blinded randomized placebo controlled trial, phase II

B. Salmani[1], E. Teimoorbakhsh[2], M. Shahhoseini[1], A.A. Akhlaghi[3], A. Moeini[4,5], P. Afsharian[1]

Study question: Is N-acetyl cysteine (NAC) effective on the Expression of genes *NRF2*, *GPX3*, *GSTM1*, *GSTM2*, *GSTM5* and *PRDX6* in recurrent implantation failure (RIF)?

Summary answer: our preliminary results have demonstrated no significant differences in expression level of studied genes in comparing pre-treatment NAC-supplementation and placebo administered groups in RIF patients.

What is known already: Assisted reproductive techniques help infertile couples to conceive, however, the implantation rate is one of the limiting factors in assisted reproductive techniques. Endometrial receptivity plays an important role in embryo implantation. NAC as a nutritional supplement is a precursor of glutathione-biosynthesis, therefore, it has been greatly applied as an antioxidant. Since recent studies that showed high expression of genes which involved in oxidation-reduction pathway effect on successful implantation rate, thus we examined the expression of Oxidation-Reduction genes of *NRF2*, *GPX3*, *GSTM1*, *GSTM2*, *GSTM5*, *PRDX6* in NAC supplementation during implantation window in women with Recurrent Implantation Failure.

Study design, size, duration: A single center, double-blinded, placebo controlled, randomized trial was performed over one year with 40 women (age: 22-40 years) with at least two RIF history who were undergoing IVF cycle (long protocol for their ovarian stimulation). Subjects received either NAC or placebo with both effervescent tablets having similar color, size and appearance. Expression of genes *NRF2*, *GPX3*, *GSTM1*, *GSTM2*, *GSTM5*, *PRDX6* were evaluated on the day of Window of Implantation biopsies from the endometrium.

Participants/materials, setting, methods: forty RIF patients were randomized to receive NAC 1200 mg/day or placebo for at-least 6 weeks before starting ovarian stimulation. Their tissue took (Pipelled based biopsy from endometrium) on 19-21 day of their cycle, the day of WOI. Then patients were undergone ovarian stimulation (using NAC) ended to IVF. Total RNA-extraction and cDNA synthesis were performed from samples. Real Time PCR was conducted to evaluate Expression of genes *NRF2*, *GPX3*, *GSTM1*, *GSTM2*, *GSTM5*, *PRDX6*.

Main results and the role of chance: mean (SE) of the fold change of expression *NRF2*, *GPX3*, *GSTM1*, *GSTM2*, *GSTM5*, *PRDX6* were 2.62 (0.69), 14.83 (7.4), 19.82 (9.23), 9.73 (4.5), 7.40 (2.36), 1.74 (0.2) in drug group respectively and were 1.85 (0.3), 8.93 (5.4), 8.38 (3.7), 2.09 (0.7), 3.82(1.7), 1.75(0.3) in placebo group. No statistical significant difference between gene expression two arm were detected.

Limitations, reasons for caution: Owning the strict selection criteria in this late phase trial caused limitation to achieve enough patients participation in limited period of time (one year). Thus, to overcome this issue and also for the purpose of getting more experimental data, a larger number of RIF patients is needed.

Wider implications of the findings: There are no significant differences in expression of evaluated genes in comprising two NAC supplementation (as scavenging free radicals) and placebo groups during IVF protocols for RIF patients.

Trial registration number: Not Applicable.

P-474 Can we increase the Live-Birth predictive value of early beta-hCG level: A simple proposal for clinical practice

P. Arvis[1], A. Guivarch-Leveque[1], M. Bidet[1], F. Jaffre[1], P. Lehert[2]

[1]Clinique La Sagesse, Amp Department, Rennes, France
[2]The University of Melbourne and Melbourne IVF, Faculty of Medicine- Psychiatry Department, East Melbourne VIC, Australia

Study question: Can the Live birth (LB) predictive value from serum concentrations of beta-hCG level (bHCG) in early pregnancy be enhanced in adding other simple predictors?

Summary answer: Early Single bHCG level remains a strong predictor of pregnancy outcome after embryo transfer. However, maternal age significantly increases the precision of prediction.

What is known already: bHCG rapidly increases during normal early pregnancy, however with a high inter-individual variation. bHCG blood level possibly dependent on the volume of distribution in the mother's body, and thus on maternal age and BMI, Eskild and al. (Fertil Steril. 2012) suggested that bHCG were negatively associated with maternal BMI, and Haavaldsen and al. (ACOG, 2014) found the same negative association with maternal age. In parallel, Age and BMI are predictors of live birth (Arvis et al 2012).

Study design, size, duration: In this non-interventional, retrospective, observational, single-centre cohort study, 3,077 live-births (LB) followed 16,105 embryo transfers after IVF or frozen-thawed embryo (FTE) cycles during 2000-2016 period. Intent to treat principle was used, no inclusion or exclusion criteria were applied. Luteal phase was supported by vaginal progesterone only. Serum bHCG were measured on day 14 after oocytes retrieval, or on day 14 embryo in FTE.

Participants/materials, setting, methods: The association between LB and maternal age, BMI and log-transformed bHCG was estimated by a linear mixed model, patient considered as random factor, Log-Transformed (or not) BHCG, BMI and age as fixed covariates. Main effects and Interaction with bHCG were tested. The final model was obtained through a backward strategy based on likelihood ratio.

Main results and the role of chance: The determination coefficient based on Log-transformed BHCG was higher (R2 nagelkerke=.67) than its untransformed value BHCG (R2=.56). The backward process identified a simple model where only log(bHCG) and its interaction with age remained the only significant predictors. Area under the ROC curves with this model reached a value of c = .91 95%CI [.86,.93] compared with the bHCG only (C=.82 95%CI [.79,.86] with a significant difference, p=.015).

Predicting values of this model are illustrated by a curve, providing LB probability according to bHCG level and age.

As a conclusion, although bHCG remains a strong predictor of LB, adding age adds important precision. Neither BMI, nor other predictors, influence significantly this probability. However bHCG exhibit a non-linear variation: the age effect is not constant with bHCG, the difference being the largest for intermediate values of bHCG. For example, for a bHCG level of 50 UI/L, probability of LB is 72% at the age of 20, 55% at 30 and 37% at 40. Above 200, the probability is closed to 100% for youngest patients.

Limitations, reasons for caution: This was a Retrospective uni-center study, needing external validation, and the assessment of other potential predictors of live birth.

Wider implications of the findings: Such result remains simple to used for clinical practice, while significantly increasing the precision of prediction.

Trial registration number: not applicable.

P-475 Mucin1 (MUC1) localization and quantitative study in luminal epithelium during implantation window

F. Wu, Y. Liu, D. Mao, X. Chen, H. Xu, T.C. Li, C.C. Wang

Department of Obstetrics and Gynaecology- The Chinese University of Hong Kong-Shatin Hong Kong, Obstetrics and Gynaecology, HONG KONG, Hong Kong

Study question: Are MUC1 differentially expressed among different develop stage of pinopodes in fertile and recurrent implantation failure (RIF) patients?

Summary answer: MUC1 only expressed on the surface of ciliated cell, and showed no relationship with pinopode. Its expression level was significantly decreased in RIF patients.

What is known already: MUC1 has long been supposed as an anti-adhesion molecule during embryo implantation because of its molecule structure. But its expression level significantly increased in human endometrium during implantation window. The exact function of MUC1 in early development of pregnancy is still unknown. Endometrium is made up by ciliated cell and microvilli cell. During implantation window, microvilli cell lost its microvilli and developed as pinopodes. Animal and in vitro study have showed that pinopodes provided the implant site for embryo. However, the relationship between MUC1 expression concentration and different develop stage of pinopodes have not be studied.

Study design, size, duration: Twenty-five fertile control and 25 RIF patients were recruited in this study. All participants underwent daily urine test from day 9 of the cycle onwards to identify the LH surge, and endometrial biopsy was obtained at LH+7 day.

Participants/materials, setting, methods: Recurrent implantation failure was defined as failure to achieve a clinical pregnancy after at least 4 good-quality embryos have been transferred in 3 or more transfer cycles. Infertile patients who got ongoing pregnant result from a FET cycle were recruited as fertile control, and the endometrial biopsy was conducted just one cycle preceded embryo transfer. Scanning immunoelectron microscope and double immunofluorescence staining have been used to determine MUC1 expression on luminal epithelium.

Main results and the role of chance: MUC1 expressed mainly on the surface of ciliated cell. There was no MUC1 expression on developing, developed and regressing pinopodes. Double immunofluorescence staining showed that ciliated cell counting and MUC1 expression level were significantly decreased in RIF patients ($P < 0.05$).

Limitations, reasons for caution: The main limitation of this study is its only one-time point biopsy study, which cannot demonstrate MUC1 dynamical change as menstrual cycle proceeding. And this is only an observational study, research into the mechanism of MUC1 and pinopodes in embryo implantation is needed.

Wider implications of the findings: This investigation reveals that MUC1 is not expressed on the surface of potential implantation site. Its anti-adhesion function need to be further discussed. And ciliated cells maybe played a role in embryo implantation.

Trial registration number: NO.

P-476 Capturing the physiological characteristics of early pregnancy using wrist worn wearables

M. Shilih[1], B. Goodale[2], L. Falco[2], F. Kuebler[2], F. Dammeier[2], B. Leeners[1]

[1]University Hospital Zurich, Department of Reproductive Endocrinology, Zurich, Switzerland
[2]Ava AG, Research and Development, Zurich, Switzerland

Study question: Could wrist worn wearable sensors capture the physiological changes associated with early pregnancy?

Summary answer: We observed significant differences in heart rate variability, pulse rate, breathing rate, perspiration, temperature, and susceptance (of the wrist skin).

What is known already: The physiological changes associated with the reproductive hormones are well studied and widely reported (e.g., the increase of temperature associated with post-ovulatory progesterone rise). The onset of pregnancy is known to impart significant endocrinological changes. The

hormonal profile of the late luteal phase is therefore significantly different when comparing conceptive cycles to non-conceptive cycles. Consequently, it is plausible that these physiological changes could be captured by wrist worn wearables.

Study design, size, duration: This study is an interventional longitudinal observational study conducted at the University Hospital Zurich. The study is planned to run from the fourth quarter 2016 to the second quarter of 2018, with 430 participants. The participants are requested to measure the specified parameters for 6 months, and if they conceive, to term.

Participants/materials, setting, methods: We included healthy, eumenorrheic women, 20-40 years old, who are trying to conceive. Participants wore Ava bracelet which measures temperature, pulse rate, and heart-rate-variability ratio among other parameters. An LH home-urine test was used to estimate the ovulation day. The late luteal phase was defined as ovulation+7 to the end of the cycle for the non-conceptive cycles, ovulation+10 to ovulation +18 for conceptive cycles. Associations were evaluated using linear-mixed-effects models with random intercepts for each participant.

Main results and the role of chance: We included 49 conceptive cycles and 560 non-conceptive cycles from 253 women in the analysis. In comparison to the late luteal phase of non-conceptive cycles, conceptive cycles were characterized by: an increase in pulse rate^{+}, breathing rate***, perspiration^{+}. In addition, non-conceptive cycles were more likely to have lower wrist skin temperature***, heart rate variability ratio***, and wrist skin susceptance*. Overall, the physiological parameters trends in conceptive cycles had steeper rises and falls, and more pronounced peaks and troughs, compared to non-conceptive cycles. This suggests that the underlying hormonal dynamics (which are responsible for the physiological changes) in conceptive cycles are similarly steeper in rising and falling, and have higher peaks and lower troughs.

Note: $^{+}$p<.10, *p<.05, **p<.01, ***p<.001

Limitations, reasons for caution: The limited number of conceptive cycles limits the generalization of the results and the development for a pregnancy recognition classifier. Pregnancy tests are known to have limited sensitivity at the beginning of the pregnancy, hence, some conceptive cycles could be labeled as non-conceptive.

Wider implications of the findings: Wirst worn wearables are capable of capturing known and novel early-pregnancy associated physiological changes. Wearables represent a useful and non-invasive research tool to monitor women's health, and given sufficient data could allow for the continuous monitoring of early-pregnancy.

Trial registration number: NCT03161873.

P-477 What is the real length of the window of implantation (WOI) in humans?

A. Rincon[1], M. Clemente-Císcar[2], E. Gomez[1], C. Marin[1], D. Valbuena[3], C. Simon[4,5,6,7]

[1]*Igenomix SL, Endometrial Receptivity Department, Valencia, Spain*
[2]*Igenomix SL, Bioinformatics Department, Valencia, Spain*
[3]*Igenomix SL, Medical Department, Valencia, Spain*
[4]*Igenomix SL, Scientific Director, Valencia, Spain*
[5]*University of Valencia / INCLIVA, Department of Obstetrics and Gynecology, Valencia, U.S.A.*
[6]*Stanford University, Department of Obstetrics and Gynecology, California, U.S.A.*
[7]*Baylor College of Medicine, Department of Obstetrics and Gynecology, Texas, U.S.A.*

Study question: How long the human window of implantation (WOI) last?

Summary answer: Using endometrial receptivity analysis (ERA) in paired samples (same patient), the WOI last from 29-36 hours, exceptionally shorter WOI than 24 hours are found.

What is known already: The window of implantation (WOI) is a transient functional state when the endometrium became receptive for the implantation of the blastocyst. The endometrium is a hormonally regulated organ, progesterone (P) induces the acquisition of endometrial receptivity that theoretically last from LH+6 to LH+9 of the menstrual cycle or from P+4 to P+7 in a hormonal replacement therapy (HRT) cycle. Currently, it is possible to determine the molecular diagnosis of the WOI analyzing the transcriptomic signature known. But, the length of the WOI has never been previously determined.

Study design, size, duration: From the paired-biopsy dataset (n = 3,616) from patients who underwent ERA to test their endometrial receptive status, a selection of 2,874 endometrial samples from 1,437 patients were analyzed. The inclusion criteria was that the first biopsy was taken in the time interval of 120 +12 hours (P+5). Samples were collected from the same patient and HRT on P +5 and P+7 (n = 627 pairs) or on consecutives HRT cycles with the second biopsy made at P+6 toP+7 (n = 810 pairs).

Participants/materials, setting, methods: ERA results were reported as 1 day pre-receptive, 12 hours to Receptive, receptive (R), 12 hours late R and 24 hours or more post-receptive.

A cross-tabulation analysis of time between biopsies (10-hours intervals) was performed for each combination of paired-samples. A descriptive analysis of the obtained percentages for each time-interval was used for describing the length of WOI. Average time between paired-biopsies of main stages combinations was studied and a confidence interval was computed.

Main results and the role of chance: In general, we stablished the opening of the WOI at early-receptive stage and the closing at late-receptive stage. The average length of the WOI between these two stages was 32.8 hours (95% IC, [29.2, 36.3] (n = 47 patients).

The average length of the WOI between early-receptive to post-receptive was 48.2 hours (95% IC, [45, 51.4] (n = 94 patients), indicating the WOI was already closed. Although few patients passed from early-receptive to post-receptive stages in less than 24 hours (n = 4 patients), indicating that they have a narrow WOI (<24 hours).

When analysis was performed from previous non-receptive stages to our reference (late-receptive stage), the average time between 1 day pre-receptive and late-receptive was 41.7 hours (95% IC, [39.4, 44], n = 201 patients). However, some patients last less than 30 hours from 1 day pre-receptive to late-receptive (n = 46 patients) or less than 40 hours to post-receptive (n = 13 patients), showing narrow WOI.

Limitations, reasons for caution: This study has been performed using a retrospective descriptive approach. An increase sample size is needed.

Wider implications of the findings: This study suggests that using molecular diagnosis, the WOI length varies from 29 to 36 hours, although exceptionally few cases have shorter WOI.

Trial registration number: not-applicable

P-478 Changes in human chorion gonadotropin as a predictor of live birth outcome among Danish women with recurrent pregnancy loss

S. Landersø[1], A.M. Kolte[2], M.S. Kroman[3], M. El Issaoui[2], H.S. Nielsen[2]

[1]*Rigshospitalet, Fertility Clinic, KØBENHAVN Ø, Denmark*
[2]*Rigshospitalet, Recurrent Pregnancy Loss Unit, Copenhagen, Denmark*
[3]*Rigshospitalet, Fertility Clinic, Copenhagen, Denmark*

Study question: Are changes in serum-human chorion gonadotropin (hCG) levels in early pregnancy a reliable predictor of live birth in women with recurrent pregnancy loss (RPL)?

Summary answer: A daily hCG increase of 20% and 40%, respectively, can predict a 65% and 70% chance of live birth among women with recurrent pregnancy loss.

What is known already: The increase of hCG in early pregnancy is used to clinically differentiate between viable and non-viable early pregnancies (ectopic/biochemical pregnancies and miscarriages). However, the evidence behind this practice is limited. A small study (n = 20) from 1990 showed a doubling time of 2 days for intrauterine pregnancies and this rate is often used in the clinic. Other studies have addressed the change in hCG according to the pregnancy outcome, but often only on symptomatic women (bleeding/pain) or IVF-patients – with inconsistent results.

No studies have evaluated the change in hCG in RPL patients, despite this being a crucial part of RPL care.

Study design, size, duration: This was a large retrospective cohort study at a national tertiary Recurrent Pregnancy Loss Unit.

In total 409 women were included between 2008 and 2016.

Inclusion criteria: ≥3 consecutive pregnancy losses; known outcome of the pregnancy; minimum two hCG samples in early pregnancy.

Exclusion criteria: Extra-uterine pregnancies (due to too small a number for the purpose of the statistics), pregnancies after donation of an ovum, and missing data on pregnancy outcome.

Participants/materials, setting, methods: The first pregnancy after referral to the RPL-Unit was included. Serum-hCG was measured in at least two blood samples few days apart during gestational week 4-7. Logistic regression analyses were used to investigate the change in hCG according to pregnancy outcome. Results were adjusted for maternal age, number of prior losses, and the between-sample interval.

When viability was uncertain, serial hCGs were performed until a final diagnose could be made.

P-values <0.05 was considered significant.

Main results and the role of chance: Pregnancy outcome was: 261 live births; 100 miscarriages; 38 biochemical pregnancies, not counting 10 excluded observations due to missing data/extreme outliers. In the final sample the mean age was 35.0 years (SD = 4.4), mean number of prior pregnancy losses was 3.8 (SD = 1.8), mean time of the first hCG sample was 4^{+4} weeks of gestation (SD = 5.7 days), and hCG samples were on average collected 3.1 days apart (SD = 2.0). The lowest initial hCG that subsequently led to a live birth was 12.

Main results: A 20% daily increase in hCG predicted a 65% chance of a live birth whereas a 40% increase predicted a live birth in 70% of the cases.

The association between change in hCG and live births was weaker for women with more than three losses, and was strongest for age <30years. The probability of a live birth decreased with increasing number of losses.

In summary, a daily increase in hCG between 20 and 40% is a strong indicator of live birth together with low maternal age and a lower number of losses. Increases above 40% did not add significantly to prognostic value.

All abovementioned results are significant at a 5% level. We therefore assess that the findings are not due to chance.

Limitations, reasons for caution: This study is limited by uncertainties regarding e.g. ovulation date, implantation date and the timing of both urine and blood testing depending on patient preferences. However, all measurements are related to the menstrual cycle and the date of last menstrual period was known for all except two women.

Wider implications of the findings: For women with RPL the uncertainty about whether a pregnancy is viable or not causes a lot of psychological distress. By this study clinicians can become better equipped to predict which pregnancies will lead to live births and thereby – hopefully – diminish the amount of distress for these women.

Trial registration number: not applicable.

P-479 Screening for pre-eclampsia: toward the development of a non-invasive repaid clinical mass spectrometry pregnancy urine test

M. Naase[1], S. Butler[1], R. Zmuidinaite[1], S. Keshavarz[1], F. Sharara[2], R. Iles[1]

[1]*MAP Sciences-, Research and Development, Bedford- UK, United Kingdom*
[2]*Virginia Centre for Reproductive Medicine, Embryology, Reston, U.S.A.*

Study question: Can Matrix Assisted Laser Desorption Ionisation Time of Flight (MALDI ToF) Mass Spectrometry of early pregnancy urine be used to predict the likelihood of preeclampsa?

Summary answer: It is possible to use the analysis of data, following MALDI-ToF MS of maternal urine, to generate risk screening algorithms for subsequent development of pre-eclampsia.

What is known already: Identifying pregnant women who will develop pre-eclampsia is one of the last remaining grand challenges in obstetric medicine and pre-eclampsia occurs in around 1 in 50 pregnancies. The ability to do so non-invasively and at low cost in early pregnancy would dramatically impact maternal obstetric care worldwide. Recently proteomic and metabolomic analysis of maternal urine have been proposed as a possible route to an inexpensive and truly non-invasive screening test for Downs Syndrome. Using a similar approach it should be possible to achieve a risk score for preeclampsia.

Study design, size, duration: In this diagnostic test study to determine the analytical process and corrections needed to develop a clinical maternal urine screening test for risk of subsequent pre-eclampsia; we examined the spectral profiling of maternal urine at 15-17 weeks of gestation by MALDI ToF mass spectrometry from pregnant women being monitored for PE.

Participants/materials, setting, methods: A retrospective collection of 40 urine samples at 15-16 weeks of pregnancy 28 women (12 developed pre-eclampsia). Samples were examined by MALDI-ToF mass spectrometry in the mass/charge range between 1000 and 100,000 m/z. The spectral masses between 2000 and 11,000 m/z were specifically examined and a method was developed by mathematical algorithm to normalise spectral data in mass bins of 100 m/z and express as a percentage of the total mass spectra.

Main results and the role of chance: Of the ninety 100 m/z bins, forty-six were identified as m/z bins at which statistically significant spectral differences occurred between those who developed pre-eclampsia and control samples where pre-eclampsia was not subsequently diagnosed. Based on the differences and variance, for values at these bins, weighted scores of the probability of developing pre-eclampsia were assigned. Comparative algorithms consisting of various mass bins were tested for ability to distinguish those who developed pre-eclampsia as the pregnancy progressed. A change in pattern was evident from the raw and normalized spectra of pregnancy urine from women who developed pre-eclampsia and those who did not. Interestingly the changes seen were different to those found previously in screening for Downs syndrome by this same methodology. In this cohort decrease of signal intensity in the profile at 6000 and 7000 m/z were associated with those pregnancies that developed pre-eclampsia. An algorithms based on these changes had a sensitivity of 91.7% and specificity of 85.7%.

Limitations, reasons for caution: This study is limited by cohort size.

Wider implications of the findings: Using a simple, non-invasive screening tool such as MALDI ToF MS of early pregnancy urine could potentially improve pregnancy outcomes. Targeted maternal and fetal monitoring would lead to earlier detection of the clinical signs and, where necessary, intervention planned for those individuals at increased risk.

Trial registration number: not applicable.

P-480 Improved pregnancy rates following endometrial receptivity analysis and personalized embryo transfer in patients with previous failed implantation after euploid embryo transfer

M. Leondires[1], A.L. Akopians[2], T. Stankewicz[3], E. Gomez[4], A. Snider[5], G. Harton[6], D. Valbuena Perilla[7], C. Simon[8,9,10,11]

[4]*Igenomix SL, ERA Department, Paterna- Valencia, Spain*
[5]*Igenomix SL, Genetic Counceling Department, New York, U.S.A.*
[6]*Igenomix SL, Operations Department, New York, U.S.A.*
[7]*Igenomix SL, Medical Department, Paterna- Valencia, Spain*
[8]*Igenomix SL, Scientific Director, Paterna- Valencia, Spain*
[9]*University of Valencia/INCLIVA, Department of Obstetrics and Gynecology, Valencia, Spain*
[10]*Stanford University, Department of Obstetrics and Gynecology, California, U.S.A.*
[11]*Baylor College of Medicine, Department of Obstetrics and Gynecology, Houston, U.S.A.*

Study question: Does Endometrial Receptivity Analysis (ERA) with personalized embryo transfer (pET) of euploid embryos improve the reproductive outcome in patients with previous failed euploid embryo transfer?

Summary answer: Patients who experienced failed euploid embryo transfer had improved reproductive outcome combining pET of euploid embryos guided by ERA.

What is known already: Recurrent implantation failure (RIF) is a frustrating condition for patients and clinicians. The two most likely candidates implicated are embryo chromosomal abnormalities and/or alterations/desynchrony of endometrial receptivity. Preimplantation genetic testing for aneuploidy (PGT-A) identifies euploid embryos for selective ET improving reproductive outcomes in RIF due to embryo abnormalities (Rubio et al., 2013). The Endometrial

Receptivity Analysis (ERA) is based on the transcriptomic signature of 236 genes used to diagnose the receptive status of the endometrium guiding a pET. Increased reproductive outcome following pET guided by ERA has been demonstrated in patients with RIF of endometrial origin (Ruiz et al., 2013).

Study design, size, duration: In this prospective pilot study, fifteen patients with previous failed euploid embryo transfer after PGT-A in a hormone replacement therapy cycle (HRT) underwent ERA to assess the endometrial receptivity status. In a subsequent cycle, a pET guided by ERA with euploid embryo(s) was performed. This study was done in two independent reproductive centers from December 2016 to November 2017.

Participants/materials, setting, methods: Women of reproductive age (34.5+4), who have never achieved clinical pregnancy following at least one failed euploid ET in a HRT cycle were enrolled in this study. An endometrial biopsy for ERA was obtained in a HRT cycle identical to one carried out in the failed euploid ET cycle. Once a receptive result was obtained, the patient underwent a pET with the remaining euploid embryo(s). Pregnancy rates and follow-up data were collected from participating sites.

Main results and the role of chance: Thirteen of the fifteen patients with failed euploid ET were diagnosed with a non-receptive (NR) endometrium (86.7%), from those, four were early-receptive and nine were pre-receptive. The other two patients had receptive result (R). At this time, we have clinical follow-up data from all patients who have undergone pET of remaining euploid embryo(s). All fifteen patients (100%) achieved pregnancy (+hCG) when pET was performed based upon their personalized Window of Implantation (WOI) guided by ERA, one had a biochemical pregnancy (6.7%), three presented clinical miscarriages (20%) and the other eleven are ongoing or have delivered, corresponding to 73.3% ongoing pregnancy rate (OGP). The implantation rate was 87.5%.

Limitations, reasons for caution: The main limitation for this study is the number of patients included due to pilot nature. Further clinical validation in a Randomized Clinical Trial (RCT) is underway.

Wider implications of the findings: Our study demonstrates that patients with previous failed euploid embryo transfer could have WOI displacements in high proportion (86.7%) and it may benefit from ERA testing to guide pET when a displaced WOI is the cause of their failed implantation.

Trial registration number: Not applicable.

P-481 The inhibitory T cell co-receptor molecule B7-H4 (VTCN1) regulates major histocompatibility complex class I expression in a stem cell-derived model of primitive human trophoblast development

J. Zhou[1], R. Karvas[1], L. Schulz[1], T. Ezashi[2], R.M. Roberts[2], D. Schust[3]

[1]*University of Missouri, Obstetrics- Gynecology and Women's Health, Columbia, U.S.A.*
[2]*University of Missouri, Animal Sciences, Columbia, U.S.A.*
[3]*University of Missouri, Obstetrics and Gynecology, Columbia, U.S.A.*

Study question: Could the isolated expression of the inhibitory T cell co-receptor B7-H4 on human trophoblast cells during the first half of pregnancy be important in maternal-fetal immune interactions?

Summary answer: Downregulation of B7-H4 in an in vitro stem cell-derived model of primitive human trophoblast development dramatically increases HLA-A and –B, but not HLA-G protein levels.

What is known already: Downregulation of the classical MHC class I molecules, HLA-A and HLA-B on trophoblast cells in direct contact with maternal immune cells is thought to aid in the escape of the semiallogenic fetus from maternal immune rejection. B7-H4 is a co-receptor in MHC/T cell interactions and decreases T cell activities. Increases in B7-H4 expression correlate directly with cancer invasion and severity and **increases** in MHC class I expression. We have demonstrated that B7-H4 is expressed in first and second trimester placenta and in an in vitro human embryonic stem cell-derived model of early placental development ($hESC_{BAP}$), but not in term placenta.

Study design, size, duration: In vitro *B7-H4* knockdown study of human embryonic stem cell (hESC)-derived trophoblast cells.

Participants/materials, setting, methods: The human embryonic stem cell line, H1, was treated with BMP4, A83-01 and PD173074 (BAP treatment) to create an established in vitro model for peri-implantation trophoblast development. Cells were transfected with silencing *B7-H4 siRNA* or *control siRNA* on day 3 or 4 of differentiation. Proteins were collected on day 6 and expression of B7-H4 and MHC class I proteins compared to that of a housekeeping protein (GAPDH) using western immunoblotting.

Main results and the role of chance: In direct contrast to findings in cancer cell lines, downregulation of B7-H4 expression in cells representing the earliest stages of placental development dramatically increased the expression of HLA-A and HLA-B molecules at the protein level. Interestingly, knockdown of B7-H4 had little effect on the expression of HLA-G, a non-classical MHC class I molecule whose normal tissue expression is restricted to a subset of invasive placental cells called extravillous cytotrophoblast cells.

Experiments were repeated at least three times and after 3 days as well as after 4 days of differentiation. Endpoints were assayed at 48 and 72 hours after knockdown, all with consistent results. Comparison to experiments using a scrambled siRNA control limits the chance that the effects noted are the result of exposure to gene silencing methods. No differences in cell proliferation or cell viability were observed between the B7-H4 knockdown and control cells across the time period studied. This is consistent with equivalent protein expression of the control housekeeping gene, GAPDH.

Mechanism identification using comparisons of RNAseq datasets from knockdown and control cell lines is ongoing.

Limitations, reasons for caution: The cell system used is an in vitro system and may not directly mimic in vivo occurrences. Unfortunately, ethical and logistical factors limit access to human tissues directly post-implantation and before clinical detection of a pregnancy is possible. In vitro surrogates remain our best methods to study early post-implantation events.

Wider implications of the findings: Discrepancies between HLA responses to B7-H4 knockdown in cancer cells and in early trophoblast cells suggest the B7-H4 pathway regulates the unique transplantation antigen expression patterns found in the human placenta. This exposes opportunities to fill the pronounced knowledge gap in our understanding of HLA regulation in the human placenta.

Trial registration number: not applicable.

P-482 The uterine cavity in patients with recurrent pregnancy loss (RPL)

L.H.J. Andersen[1], K.J. Hare[2], H.S. Nielsen[3]

[1]*Hvidovre Hospital- University hospital of Copenhagen- Denmark, Department Of Gynecology and Obstetrics, Copenhagen, Denmark*
[2]*Hvidovre Hospital- University hospital of Copenhagen - Denmark, Department Of Gynecology and Obstetrics, Copenhagen, Denmark*
[3]*Rigshospitalet and University of Copenhagen - Denmark, Consultant Fertility Clinic and Recurrent Pregnancy Loss Unit, Copenhagen, Denmark*

Study question: What is the frequency of uterus pathology and histological analysis in a consecutive cohort of well characterized RPL patients, and is evaluation justified?

Summary answer: We report lower incidence of intrauterine adhesions and chronic endometritis compared to previous reports. However, 14.3% of the patients had intrauterine pathology justifying sensitive investigation.

What is known already: RPL patients have often had several uterine evacuations (medical (with Misoprostol) or D&C), which increases the risk of chronic endometritis (CE) and intrauterine adhesions (IUA). A meta-analysis from 2014 found that 19.7 % of women with one pregnancy loss had IUA, the incidence increases significantly with further pregnancy losses. Other studies evaluating biopsies from the uterine cavity suggests: that CE is as high as 10–30 % in patients with RPL.

We aimed to evaluate the uterine cavity in a well characterized group of RPL, and compare our incidences of CE and IUA to international findings.

Study design, size, duration: The study design is a macroscopic and histological description of the uterine cavity and endometrium in a cohort of women with RPL. We recruited a cohort of 70 women with RPL, over a time period of 19 month from May 2016 to December 2017. Inclusion criteria: three consecutive first- or second trimester miscarriages and no known uterine abnormalities or pathologies.

Participants/materials, setting, methods: All the included patients had a diagnostic office hysteroscopy (OH) with biopsies. The OH was performed by trained gynecologists; fixated biopsies were evaluated by pathologists. We compared the macroscopic description with the histologic diagnoses. The OH was performed during the proliferative phase of the menstruation cycle to standardize biopsies, as the numbers of immune cells change during the menstruation cycle. We confirmed the timing by measuring peripheral Oestrogen- and Progesterone levels at the examination day.

Main results and the role of chance: Seventy patients with RPL had an office hysteroscopy with biopsy during the study period. One patient was excluded due to the formalities. Histological diagnoses: 1/69 had signs of inflammation, with the presence of plasmacells, and was diagnosed with CE. Macroscopic diagnosis: 3/69 had IUA, 3/69 had placenta remnants, 1/69 had a polyp, 1/69 had a septum and 2/69 had intrauterine leiomyomas, macroscopic pathology in total 10/69.

These data diverse from earlier published data. We describe a much lower incidence of IUA (only 4% compared to 19.7 %) and only one patient were diagnosed with CE (1.4 % compared to 10 % - 30 %) in our clinical setting/cohort. Although we do not describe the same incidence of IUA and CE, we describe intrauterine pathology in 14.5 % of the women with RPL. All women were examined with TVUS, none were suspected to have the positive findings subsequently found at OH, despite a high incidence of earlier interventions (Misoprostol or D&C). Hereby we suggest that standard OH is a highly sensitive diagnostic tool for evaluating women with RPL.

Limitations, reasons for caution: This is a descriptive study on a large cohort of well characterized RPL patients. The study is not powered or designed to study the prognostic impact of uterus pathology or histology.

Wider implications of the findings: We describe low incidence of IUA and CE compared to historic data. We hope this confirm a trend towards higher quality in treatment of pregnancy loss. Further, we suggest OH as frontline examination elucidating the uterine cavity; reducing uterine pathology in women may increase the chance of a successful pregnancy.

Trial registration number: NCT02746588

P-483 Global Gene Expression Analysis of Blastocyst Implantation on 2D and 3D Implantation Models: Towards a Comprehensive and Inclusive Research

K. Sarı[1], S. Karahuseyinoglu[2], D. Yucel[3]

[1]*MSc. Student, Graduate School of Health Sciences- Reproductive Biology, ıstanbul, Turkey*
[2]*Koç University, Research for Translational Medicine KUTTAM, Istanbul, Turkey*
[3]*Acıbadem University, School of Medicine- Department of Histology- Embryology, Istanbul, Turkey*

Study question: Does the use of mesenchymal stem cells or endometrial cells on 2D and 3D implantation models enough for demonstrating large scale molecular regulation?

Summary answer: Endometrial and mesenchymal stem cells can be used for constructing implantation models with gel or polymer-based carriers to analyse differential expression of implantation related markers.

What is known already: Implantation is complex series of events; apposition, adhesion and invasion; that happens during a well-defined period with competent embryo and receptive endometrium. Since the process takes place in 3D environment, it is difficult to mimic implantation process in vitro. To examine invasion, human trophoblast cells and embryos have been cultured with human endometrial stromal cells. Endometrial cells cultured in collagen matrices to create a 3D model with different layers of trophoblast spheroids and embryos. The pregnancy is balanced with fetal decidual defense against pathogens therefore; immunomodulatory properties of MSCs could have positive effects on implantation and embryo development.

Study design, size, duration: Effects of 2D and 3D implantation models; designed with gel or polymer-based carriers with endometrial and mesenchymal stem cells; were analysed to reveal differential expression of 24 different implantation related markers; LIF, Hoxa10, Hoxa11, Wnt4, IHH, E-cadherin, Trophinin, Fibronectin, L-selectin, Laminin, Entactin, Integrin, MMP9,TIMP3, HBEGF,ErbB1, ErbB2, HBEGF, Progesteron and Estrogen Receptor and Collagen I,III,IV,V. Comparative analysis at 48 and 96 hours were performed by; IF, WB, qRTPCR and by multiphoton microscopy (for invasion depth) quantitavely.

Participants/materials, setting, methods: Mouse blastocysts were cultured in four groups as: i. routine IVF drop culture, ii.blastocysts on collagen coated biofilm, iii. blastocysts on gel matrices over biofilm decorated with endometrial cells, iv.blastocysts on collagen coated biofilm with human mesenchymal stem cells.Groups were compared in terms of structure, function and invasion by several signalling molecules, including cytokines, growth- transcription factors together with hormone receptors. Live/dead cell assay was also performed. Statistical analysis was performed by student's t-test.

Main results and the role of chance: Two very effective gel and polymer based 3D in-vitro implantation models, supported by either mesenchymal stem cells or endometrial cells,were constructed successfully and efficacy of new systems were compared with control group which is of routine-IVF culture. Both can be used to see the in-vitro development and survival of the blastocyst together with the newly differentiating trophoblasts. Comparative analysis was made between groups and also within groups from 48 to 96 hours. There is increase in LIF, trophinin, entactin, integrin expression of all groups. Additionally; LIF, MMP9 and PR showed significant increase with approximate p-value of 0,02. HOXA10 and HOXA 11 showed increase with tissue remodelling enzymes; MMP9 and TIMP3 in expression on 3D implantation models. E-cadherin and fibronectin expression decreased significantly ($p \leq 0,04$) in 3D models consistent with extracellular matrix remodeling process in vivo and suggest modulation of endometrial stroma during implantation. Among collagen types, collagen V was detected the most increasing type during implantation ($p \leq 0.05$). Endometrial co-cultures supported the blastocyst to invade horizontally under the implantation area as depicted by the increase of dead cells, and human MSC also supported the blastocysts for invasion, implicating that human MSC can be used for generation of 3D endometrial co-cultures.

Limitations, reasons for caution: This study is based on use of mouse endometrial epithelial and stromal cells and human MSCs.The limitation is the inter-species implantation differences between of mouse and human. Human blastocysts were intentionally not used for such trial, since there is a major ethical concern.

Wider implications of the findings: There is a clear need to develop 3D in vitro models to investigate embryo implantation.The methods proposed here are based on mouse blastocyst implantation, they provide information about different implantation models with the effects of human mesenchymal stem cells and endometrial cells to reveal extensive analysis of implatation markers.

Trial registration number: Not applicable.

P-484 Cripto is required for normal uterine remodeling, decidualization and development of placental vasculature

S. Shafiei[1], D. Dufort[2]

[1]*Research Institute of the McGill University Health Center, Experimental Medicine, Montreal, Canada*
[2]*Research Institute of the McGill University Health Center, Obstetrics and Gynecology, Montreal, Canada*

Study question: What is the role of CRIPTO, a member of the TGFβ superfamily, in female reproduction?

Summary answer: Deletion of uterine *Cripto* causes defective uterine remodeling, decidualization and placental development resulting in subfertility, fetal intrauterine growth restriction (IUGR) and fetal loss in mouse.

What is known already: Cripto, a member of the TGFβ superfamily, encodes for a cell surface receptor whose role in embryonic development and stem cell maintenance has been studied. Cripto mRNA and protein have been detected in the human uterus at all stages of the menstrual cycle with moderately higher levels of expression during the secretory phase and its dysregulation has been found in *placenta creta* and *endometriosis* in humans. To date, there is not much known on Cripto's role in female reproduction.

Study design, size, duration: As Cripto null Knockout (KO) is embryonic lethal, we created a conditional KO (cKO) mouse model in which Cripto is deleted only in the reproductive tissues using a Cre-loxP system. We assessed

major reproductive events necessary for the establishment and maintenance of pregnancy (e.g. ovulation, fertilization, implantation, decidualization and placental development) in Cripto cKO versus control mice. For every studied stage, 8 to 10 mice were included in each of cKO and control groups.

Participants/materials, setting, methods: Cripto deletion in cKO mice was confirmed by PCR and insitu hybridization. Pregnancy rate and number of pups/litter were evaluated as general fertility indices. To determine the underlying causes of the observed subfertility, these approaches were used: embryo flushing and retrieval, dissections and histology of uterus and placenta at several time points during pregnancy, measuring blood Progesterone level, size and weight of decidua, placenta and fetus, artificial decidualization, quantitative PCR, immunofluorescence staining and western blot.

Main results and the role of chance: We observed a significant decrease in pregnancy rate (cKO 62% vs Control 100%) and litter size (cKO 7.68 vs Control 9.51 pup/litter) with loss of uterine Cripto. Even though no significant effects were detected in the pre-implantation period, assessment of the post-implantation period showed that 20% of cKO females fail to establish pregnancy and an additional 20% of females undergo full litter loss after implantation (between day 5.5 postcoitum and d8.5). By means of histology (d5.5, d7.5), quantitative PCR (d5.5) for assessing expression of important uterine remodeling and decidualization factors (Wnt4, Bmp2, Hoxa10, components of notch signaling pathway, etc.) and artificial induction of decidualization, we showed this is due to defects in uterine decidualization and remodeling/luminal closure.

During placental development, we observed that decidual area (d10.5) and fetal weight (d16.5) were significantly lowered, while the number of fetal deaths was significantly increased in cKOs. Histological examination of the placenta revealed abnormal labyrinth development; showing increased cellular density. The surface area of fetal vasculature in the labyrinth of the developing placenta on d12.5 was significantly reduced in the cKOs compared to controls. Interestingly, surface area of maternal blood sinuses, however, doesn't show any significant difference. (Where indicated significant: $P<0.05$ or $p<0.01$)

Limitations, reasons for caution: Limitations in *in vivo* research on uterine-embryo interactions in humans has led to relying primarily on animal models. Although there are considerable similarities between reproductive processes in mouse and humans, there are some differences which should be kept in mind when extrapolating data obtained from mouse model studies to humans.

Wider implications of the findings: While the major physiological events associated with female reproduction have been characterized, there are still many molecular pathways that have yet to be uncovered in order to open new windows toward overcoming and managing infertility and pregnancy associated complications which place both mother and fetus's health at risk.

Trial registration number: not applicable.

P-485 The roles of let-7 contained in extracellular vesicles (EV) in embryo implantation in human

W. Liu[1], Z. Niu[2], W. Yeung[2]

[1]*University of HongKong, O&G, HongKong, China*
[2]*University of HongKong, Dept. O&G, HongKong, China*

Study question: human uterine fluid contained plenty of EVs, the precise functions are still not clear.

Summary answer: let-7 contained in EVs decreased embryo implantation potential in human and mouse.

What is known already: embryonic diapause is an evolutionarily conserved phenomenon across mammals. The expression of Let-7 family members was significantly higher in dormant mouse embryos than estradiol-activated embryos. Human ULF contained EV and Let-7 was highly expressed in EV of human endometrial cell line ECC1. To investigate if EVs have regulatory functions in human blastocyst, we collected EV from non-receptive endometrial cell line, HEC-1B, which were transfected with pre-let-7a

Study design, size, duration: firstly, we detected the expression patterns of small RNA in EVs of dormant and activated uterine fluid in mice; secondly, we demonstrated the functions of EV-containing let-7 in embryo implantation and dormancy in mice; finally, we tested the potential roles of EV-containing let-7 in embryo attachment in human.

Participants/materials, setting, methods: morphology of EVs was observed by electron microscopy, identification of EVs was done by western blotting, small RNAs were detected by RNA-seq, targeted miRNAs were validated by Q-PCR

Main results and the role of chance: electron microscopy showed the presence of EV-like structures in the mouse uterine lumen. CD63 immnoreactivities were also localized to the endometrial epithelium during dormancy, on Day 4 of pregnancy and after E2-activation of delayed implanting mice. To determine if blastocysts internalized EV from ULF, scanning electron microscopy showed binding of EV-like particles to the trophectoderm of in vivo isolated blastocysts. RAN-seq and Q-PCR results showed that the expression of let-7 family was significantly increased in EVs of dormant uterine fluids compared to that of activated uterine fluids. EVs-containing let-7 induced blastocysts diapause-like state in mice. Let-7 of dormant embryos was mainly derived from uterine fluids. To investigate if EVs have similar functions in human blastocyst, we collected EV from non-receptive endometrial cell line, HEC-1B, which were transfected with pre-let-7a. EDU incorporation assay showed that DNA synthesis was significantly decreased in blastocysts co-cultured with let-7a-EV for 2 days. To further demonstrate if EVs contained let-7 regulate human blastocyst implantation potential, attachment rates of BAP-EB (surrogate of human embryos) were detected in the presence of let-7-EVs. After 48 h of treatment by let-7-EVs, attachment rates of BAP-EB were significantly decreased compared to Crtl-EV (65% vs 95%)

Limitations, reasons for caution: BAP-EB is not human embryos although spheroids expressed many markers which are similar human embryos and have cavity after 72 h of differentiation.

Wider implications of the findings: small RNAs are differentially expressed in uterine fluid EVs during menstrual cycles. EVs of uterine fluid are used as marker of receptive endometrium.

Trial registration number: embryos were collected from 8 IVF patients.

P-486 Odds and predictors of monozygotic twinning in a multi-centre cohort of 25,794 IVF cycles

G. Woodhead[1], L. Kellam[1], A. Campbell[2], K. Jayaprakasan[1,3]

[1]*CARE Fertility Nottingham, Embryology, Nottingham, United Kingdom*
[2]*CARE Fertility, Embryology, Nottingham, United Kingdom*
[3]*Derby Fertility Unit, Royal Derby Hospital, Derby, United Kingdom*

Study question: To estimate the incidence of monozygotic twinning (MZT) in In-Vitro Fertilisation (IVF) and embryo transfer (ET; Single–SET and double DET) cycles and to determine the predictive factors of MZT.

Summary answer: MZT following SET and DET were 0.47% and 0.16% respectively with its odds being highest with fresh, blastocyst SET and lowest with frozen, cleavage DET.

What is known already: While the single best intervention to decrease multiple pregnancy rate is elective single embryo transfer (SET), the risk is not completely eliminated. The incidence of MZT from SET is up to around 2%, the risks are reported to increase with ICSI insemination, assisted hatching or blastocyst transfers. Some smaller studies reported frozen embryo transfers and advanced age increase the incidence of MZT. The data on MZT with double embryo transfers (DET) are limited.

Study design, size, duration: This observational study involved analysis of prospectively collected data of all consecutive IVF treatment cycles of seven tertiary fertility units in the UK between 2013 and 2017. Out of 26,347 embryo transfer cycles, 25,794 cycles matched inclusion criteria and were suitable for analysis. 16,845 cycles were SET and 8,949 were DET.

Participants/materials, setting, methods: All fresh IVF and intracytoplasmic injection (ICSI) cycles and frozen embryo transfer (FET) resulting in SET and DET were included. As per the unit protocol, all women were advised not to have unprotected intercourse during the treatment cycles. MZT was confirmed if two foetal hearts were detected for SET at the 8 week post

embryo transfer scan and three or more foetal hearts for DET. Data analysed by Chi square tests and logistic regression analysis.

Main results and the role of chance: While the over all risk of MZT was 0.37% (96/25794), the risks following SET and DET were 0.47% (82/16845) and 0.16% (14/8949) respectively. The risk of MZT in all SET cycles was significantly higher with blastocyst transfer compared to cleavage stage embryos (OR; 95% CI: 3.2; 1.01-10.1). But on subgroup analysis the increased risk persisted only with fresh SET cycles (OR 8.4; 1.16-60.9), but not with frozen transfers (OR 0.65; 0.16-2.67). With DET, there was no difference in the risks of MZT between blastocyst transfer and cleavage stage transfer regardless of whether the cycles were fresh or frozen. The risk of MZT was higher with SET than with DET (OR 3.12; 1.77-5.42) with the same effect seen with blastocysts only (OR 3.15; 1.58-6.26), but not with CSE (OR 1.18; 0.28-4.93). Both fresh and frozen SET had significantly higher MZT rates compared with DET (OR 3.15; 1.6-6.2 and OR 2.88; 1.02-8.1 respectively). On regression analysis women's age was not a significant predictor for MZT. There was no difference in MZT risks between IVF and ICSI cycles whether the cycles were fresh, frozen, SET, DET, blastocyst or cleavage stage embryo transfer cycles.

Limitations, reasons for caution: MZT was diagnosed if the number of foetal hearts seen on ultrasound scan were higher than the number of embryos transferred. While the chances of concurrent natural conception from unprotected sexual intercourse during treatment leading to dizygotic and higher order pregnancies with SET and DET respectively, such risk is low.

Wider implications of the findings: The study provides data to counsel couples undergoing IVF/ICSI treatment about the risks of MZT following SET and DET. The study agrees with the previous reports of increased risk of MZT with blastocyst SETs. However, no relationship between age, IVF or ICSI and frozen ET with MZT risks were observed.

Trial registration number: not applicable.

P-487 Effect of embryo morphology on maternal serum β-hCG level in pregnancies resulting from a fresh single cleavage embryo and a fresh single blastocyst

G. Kuspinar[1], I. Kasapoglu[2], S. Saribal[1], G. Uncu[2], B. Avci[1]

[1]*Uludag University Faculty of Medicine, Histology and Embryology, Bursa, Turkey*
[2]*Uludag University Faculty of Medicine, Obstetric and Gynecology, Bursa, Turkey*

Study question: Is there any effect of early embryonic factors on serum β-hCG levels in biochemical pregnancy resulting after a single fresh cleavage embryo or blastocyst transfer?

Summary answer: The day 12 serum β-hCG levels has no association with early embryonic factors and similar between a single fresh cleavage embryo and blastocyst transfer.

What is known already: Results of studies comparing β-hCG levels after the transfer of cleavage stage or day blastocyst stage have been mixed, with some studies reporting higher β-hCG levels after the transfer of blastocysts and others reporting higher levels after the transfer of cleavage-stage embryos. A limited numbers of studies have evaluated relation β-hCG levels with embryo quality parameters resulted with biochemical pregnancy from single fresh cleavage ETs or blastocyst ETs.

Study design, size, duration: In this retrospective cohort study, we reviewed all fresh single ET (sET) cycles performed between September 2011 and December 2016 at the University affiliated Assisted Reproductive Technology Center. Positive serum β-hCG levels (>5mIU/ml 12 days after ET, biochemical pregnancy) resulting from transfer of a fresh cleavage-stage embryo (day 2 or 3 after oocyte retrieval) and those of a fresh blastocyst transfer (day 5 after oocyte retrieval) were compared.

Participants/materials, setting, methods: Four thousand fifty-five fresh single ETs were analyzed, 82 biochemical pregnancies from single blastocyst transfer and 60 biochemical pregnancies from a single cleavage ET were included.

Main results and the role of chance: The median β-hCG levels resulting from a single fresh blastocyst stage transfer was 173.4 (88.8-476.0) IU/L and similar with hCG levels resulting from a cleavage-stage transfer (140.8 [66.5-448.3] IU/L) (p=.70). In the simple correlation analysis, the median β-hCG levels resulting from a cleavage-stage transfer or blastocyst transfer and early embryonic factors had no associations. The threshold value predicting a clinical pregnancy for a cleavage stage-embryo was 127.1 IU/L, and for a blastocyst transfer was 173.5 IU/L. The proposed optimal thresholds predictive for live birth were 129.4 IU/L and 178.5 IU/L for cleavage-stage and blastocyst stage ETs, respectively.

Limitations, reasons for caution: The limitations of our study include its retrospective nature and the ability to include only resulted with biochemical pregnancy from single fresh cleavage ETs or blastocyst ETs for avoiding missinterpretion of early embryonic factors on serum β-hCG levels.

Wider implications of the findings: The threshold value predicting a clinical pregnancy and live birth for a cleavage-stage embryo and blastocyst transfer provides information regarding the outcome of pregnancy.

Trial registration number: This study is retrospective cohort study, not clinical trial.

P-488 RCT depicting favourable IVF outcomes following ATT (anti-tubercular treatment) either on abnormal endoscopy findings or history of contact of tuberculosis

P.C. Jindal[1], R. Singh[2], M. Singh[3]

[1]*Bhopal Test Tube Baby Centre, Infertility, Bhopal, India*
[2]*Bhopal Test- Tube- Baby Centre, Infertility, Bhopal, India*
[3]*Bhopal Test-Tube-Baby Centre, Infertility, Bhopal, India*

Study question: Genital Tuberculosis is a major cause of infertility in India. Does Anti-Tubercular Treatment on the sole basis of abnormal endoscopy findings OR history of contact yield better IVF-Result?

Summary answer: Prior treatment of abnormal Endoscopy findings OR history of contact of Tuberculous Mycobacterial infection cases with no other demonstrable cause improves the ART results.

What is known already: The morbidity and mortality due to tuberculosis (TB) is high worldwide, and the burden of disease among women is significant, especially in developing countries. Mycobacterium Tuberculosis bacilli reach the genitaltract primarily by haematogenous spread and dissemination from foci outside the genitalia with lungs as the common primary focus. Genital TB in females is a chronic disease with low-grade symptoms.

The fallopian tubes are affected in almost all cases of genital TB, and along with endometrial involvement, it causes infertility in patients.

More research is needed on the changing trends in the prevalence and on the appropriate methods for diagnosis and management.

Study design, size, duration: 423 infertile patients below 40 years were evaluated by laparoscopy and hysteroscopy between 2010 to 2017. Out of these, 108 patients having abnormal hysteroscopic findings or history of contacts only, were prospectively randomised into Anti-Tuberculosis treatment and Non-treatment groups by a computer generated list, before undergoing IVF.

History of contact of Tuberculosis and Screening for genital TB needs to be a part of evaluation of infertility and menstrual abnormalities.

Participants/materials, setting, methods: 423 infertile patients below 40 years were evaluated by laparoscopy and hysteroscopy between 2010 to 2017. Out of these, 108 patients having abnormal hysteroscopic findings or history of contact only, were prospectively randomised into Anti-Tuberculosis treatment and Non-treatment groups by a computer generated list, before undergoing IVF.

The primary outcome measured was cumulative pregnancy rate following IVF, and secondary outcome was the miscarriage rate.

Main results and the role of chance: There was a statistically significant difference between the two groups, the cumulative pregnancy rate being higher following IVF in the group who took prior anti tubercular treatment - 34% versus 16%. Although the miscarriage rate was lower in the treatment group, it was not statiscally significant (9% Vesrsus 13%).

Most of the patients present in advanced stage with scarring, severe fibrosis and adhesions and treatment outcomes, especially with regard to infertility, are

poor. Hence, early diagnosis and correct treatment is vital to avoid complications and to restore fertility.

Clinicians need to be aware of this important cause of infertility and menstrual dysfunction in women and major cause of poor IVF results.

Limitations, reasons for caution: Genital TB is a major cause of infertility inwomen, and prevalence is generally under stimated because of the asymptomatic nature of the infection and diagnostic challenges. Large multicentric studies are needed to estimate the magnitude of FGTB and to identify the most sensitive test for diagnosis.

Wider implications of the findings: In resource poor developing countries where IVF cycles are self-funded and difficult to afford, prior treatment of abnormal hysteroscopic findings or history of contact of tuberculous mycobacterial infection cases with no other demonstrable cause improves the ART results. Genital Tuberculosis is a major cause of infertility in developing countries.

Trial registration number: no trial number.

P-489 Bed rest after embryo transfer might affect embryo implantation, clinical pregnancy and spontaneous miscarriage rates: a prospective cohort analysis

H. Asakura, K. Nishio, Y. Nakahara, M. Nagaike

Ohgimachi ART Ladeis' Clinic, Reproductive Medicine, Osaka, Japan

Study question: Bed rest after embryo transfer has been routinely advised without clear clinical evidence and benefit. We investigated whether abolishing the practice would negatively affect the clinical outcomes of ART.

Summary answer: Routine bed rest after embryo transfer appeared detrimental to the clinical outcomes including clinical pregnancy and embryo implantation rates, and spontaneous miscarriage rate after ART.

What is known already: There are several routine measures for embryo transfer to maximize its efficiency since inception of ART. Bed rest after embryo transfer has been historically practiced without clear medical benefit and evidence by meta-analysis (Cochrane Review, 2014: CD006567). Other recent publications suggested bed rest for long duration after embryo transfer might lower implantation as well as ongoing pregnancy rates. Even short 10 minutes' bed rest after embryo transfer using donor oocytes had negative impact on ART delivery rate (Gaikuwad et al. Fertil. Steril, 2013;100:729).

Study design, size, duration: A prospective non-randomized cohort study: clinical outcomes of frozen embryo transfers were compared before (86 cycles) and after (83 cycles) abandoning routine bed rest in July, 2015. Ethics committee approved the study protocol and consent was obtained from each participant.

Participants/materials, setting, methods: Females under age 43 receiving autologous frozen embryos were recruited for the study at a single private ART institution. The endometrium was prepared using transdermal estradiol and vaginal progesterone was administered until 8 weeks' gestation. The vitrified embryos were thawed at cleavage or blastocyst stage and transferred. Bed rest group spent 30 minutes' in supine or prone position after embryo transfer, and no bed rest group was ambulatory immediately after embryo transfer.

Main results and the role of chance: Between the two groups with and without bed rest, the average female age (38.3 vs. 38.3 y.o.) and the order of transfer (2.8 vs. 2.9) and the number of embryos transferred (1.4 vs. 1.5) were similar. There was tendency of higher clinical pregnancy rate (38.6% vs. 27.9%, OR 1.6 ($p = 0.14$)), implantation rate (27.6% vs. 22.8%, OR1.3 ($p = 0.38$)) and lower miscarriage rate (45.8% vs. 28.1%, OR 0.46 ($p = 0.17$)) for the group without bed rest. These trends were similarly observed despite the stage of thawed embryos (cleavage or blastocyst), and the uterine positions (anterior or posterior). Further analysis with fresh embryo transfer had the same findings though not statistically significant.

Limitations, reasons for caution: Lack of study power due to relatively small sample size, and non-randomized and non-blinded nature of the study design are the major limitations.

Wider implications of the findings: Abolishing routine bed rest after embryo transfer increased pregnancy and implantation rates, and lowered chance of miscarriage. The effects were unrelated to the stage of thawed embryos, or uterine positions. The uterine condition or higher sense of self efficiency with early ambulation after transfer might be related to the findings.

Trial registration number: Not applicable.

P-490 Relationship between gestational age and the observed protein patterns of first trimester maternal urine analysed by maldi-tof mass spectrometry

R. Zmuidinaite[1], F. Sharara[2], S. Butler[3], S. Keshavarz[3], R. Iles[3]

[1]Employee of MAP Sciences, Research and Developement, Mill Hill, United Kingdom
[2]Virginia Centre for Reproductive Medicine, Embryology, Reston, U.S.A.
[3]MAP Sciences Ltd, Research, Bedford, United Kingdom

Study question: Does mass spectral patterns of healthy pregnancy maternal urine analysed by MALDI-ToF MS represent the gradual and directional changes associated with increasing gestational age?

Summary answer: The observed difference in maternal urine of different gestational age show a consistent pattern at selected regions corresponding to protein peak areas.

What is known already: Urinalysis by MALDI-ToF MS has been shown to be a useful tool for identification of pregnancy related diseases including pre-eclampsia screening, downs syndrome screening and assessment of pregnancy viability in case of threatening miscarriage. Furthermore it is also recognised, by both biochemical testing and MALDI-ToF MS technique, that gestational age is a very important factor affecting maternal urine protein levels. Therefore, this is likely to have an effect on any methods which involve the study relative protein in the urine of women during pregnancy.

Study design, size, duration: Retrospective longitudinal study analysing a total of 633 urine samples at an average of 8 weeks of gestation from four USA IVF clinics collected between May 2014 and August 2016. Samples were categorised into five groups for gestational weeks from six to ten (n = 187, 127, 162, 103 and 54). Pregnancy losses were excluded and only MALDI ToF MS profiles from healthy pregnancies were assessed for changes relating to gestational age.

Participants/materials, setting, methods: Subsequent to the mass spectral analysis all data was subject to meticulous pre-processing to render data comparable and the region between 2000 to 12000 m/z was subject to further testing. There were 274 peaks identified to be representative throughout the data and were quantified by summing the ion count in the peak regions. Non-parametric test for trend was applied to medians of five groups for all 274 peaks. Analysis was performed using R.

Main results and the role of chance: Total of 274 peaks were tested for upward or downward trends, each one representing the upregulated or down-regulated proteins present during the ongoing pregnancy. Visual assessment of the 274 peaks by scatter plots and boxplots led to the conclusion that such trends both positive and negative are present in about quarter of the peaks analysed. Twenty (7.3%) of the observed peaks had a strong (>0.8) negative correlation and forty two (15.4%) peaks had a strong positive linear correlation for gestational weeks. These significant peaks were further examined for trends by removing the categories and analysing the raw data by day, giving more certainty to the results and to confirm the existing trends. Furthermore, the increase of human chorionic gonadotropin (hCG) during first weeks of gestation was represented by the increase of ion counts in the mass region of 9425 m/z to 9847 m/z which corresponds to the hCG β subunit core fragment. The consistent presence of this peak provides additional confidence in the reliability of the data. Additionally, this has confirmed the previously observed pattern (unpublished data) for maternal urine in Downs screening data.

Limitations, reasons for caution: Urine samples were not analysed fresh and were subject to at least one freeze – thaw cycle.

Wider implications of the findings: The study furthers the understanding of maternal pregnancy urine analysed by MALDI-ToF MS which has several potential applications for diagnostic testing including pre-eclampsia and aneuploidies screening. This new knowledge will allow improvements to the diagnostic algorithms by adjusting predictive models to particular gestational ages.

Trial registration number: n/a.

P-491 Towards the development of rapid, first trimester, maternal urine maldi-tof ms screening tests for Downs syndrome

S. Keshavarz[1], S. Butler[2], J. Iles[1], R. Zmuidinaite[1], F. Sharara[3], R. Iles[2]

[1]*Employee, Research, Bedford, United Kingdom*
[2]*MAPSciences Director, Research, Bedford, United Kingdom*
[3]*Virginia Centre for Reproductive Medicine, Embryology, Reston, U.S.A.*

Study question: Question - Can the examination of mass spectral data from maternal urine obtained from 12 to 14 week high risk pregnancies predict a risk of Downs syndrome?

Summary answer: Mass spectral examination of maternal urine, in the range of 2,000 to 11,000 m/z, gives rise to gestational age specific testing algorithms for Downs syndrome screening.

What is known already: The established methods of antenatal screening test for Down's syndrome are based on a panel of maternal serum biomarkers measured by immunoassay together with ultrasound markers. Recently, a method based maternal plasma cell free (cf)DNA has begun to be used but it has a number of limitations including excessive turn-around time and cost. We aimed to develop an alternative method based on urinalysis which is simple, affordable and accurate.

Study design, size, duration: A retrospective collection of 20 Down Syndrome and 100 non-aneuploid pregnancy urines collected in 2007-2008 from high risk pregnancy cohorts.

Participants/materials, setting, methods: Samples were thawed and examined by MALDI-ToF mass spectrometry in the mass/charge range between 1000 and 100,000 m/z. The spectral masses between 2000 and 11,000 m/z were specifically examined and a method has been developed by which data was collected and analysed. Normalisation of spectral data was defined using mass bins of 100 m/z expressed as a percentage of the total mass spectra from 2,000 to 11,000 m/z.

Main results and the role of chance: Of the ninety 100 m/z bins, nineteen of them, covering the maximum amount of variation were selected, all demonstrating statistically significant difference between Downs and control/non-aneuploid samples as verified by Mann-Whitney test. Based on the differences and variance, for values at these spectral regions, weighted scores of the probability of being Downs were assigned. Comparative algorithms consisting of various mass peak regions were tested for ability to distinguish Downs syndrome from non-aneuploid pregnancy. Although various algorithms could distinguish Downs from non-aneuploid controls, it was found that gestational age was a confounding factor and that if separated into gestational age matched cohorts the ability to distinguish the groups improved dramatically e.g. whilst an algorithm consisting of nineteen measured bin spectral regions separated a 100% of Downs for non-Downs for 10% false positive in the mixed gestational ages cohort; a two mass peak algorithm distinguished 100% of Downs for 6% false positive rate for a cohort of 12 weeks gestation samples.

Limitations, reasons for caution: This study is limited by the cohort number and samples which have been stored for a considerable time.

Wider implications of the findings: Implementation of simple screening programmes based on rapid analysis of urine from women in early pregnancy would provide an economical alternative to complex screening programmes and costly genetic NIPT. This will be of particular use in countries with large and widespread populations.

Trial registration number: N/A.

P-492 Duration of medicated frozen embryo transfer cycles. Is length of estradiol supplementation having a role in outcomes? A retrospective study

A. Tsironis, S. Priyanka, S. Campbell, G. Nargund

Create Fertility Ltd, St Paul's London, LONDON, United Kingdom

Study question: Is the length of estradiol supplementation affecting outcomes in frozen embryo transfer cycles?

Summary answer: Our data suggest that clinical pregnancies are significantly increased with duration of estradiol supplementation of twelve or more days.

What is known already: According to data presented in the recent ASRM[1], estradiol duration n does not have an impact on pregnancy rates. Other studies suggest that prolonging estradiol supplementation may have negative effects on pregnancy outcomes[2].

1. Sekhon L, Endometrial preparation for FET: Does the duration of estradiol supplementation matter? (2017) ASRM P675

2. Sunkara SK., The impact of the duration of estrogen supplementation on the outcome of medicated frozen-thawed embryo transfer (FET) cycles (2011) Fertil Steril, Vol96, Issue 3, S43

Study design, size, duration: Retrospective analysis of medicated frozen embryo transfer cycles in our unit from January 2016 until December 2017. We reviewed 378 consecutive medicated frozen embryo transfer cycles. Cycles were divided into 2 groups A. those with duration of estradiol supplementation of 11 days or less (duration varied between 5 and 11 days) and B. those with estradiol supplementation of 12 days or more (duration varied between 12 and 28 days)

Participants/materials, setting, methods: Group A consisted of 154 cycles frozen embryo transfer cycles and Group B of 224. Egg recipients were not included in the study. Five PGS cycles were included in the study (1 in Group A and 4 in Group B but their inclusion does not affect the significance of results). Main outcomes off the study were implantation (as defined by positive pregnancy test) and clinical pregnancy rates (presence of heartbeat in the 7th week scan).

Main results and the role of chance: Age and AMH were similar in the 2 groups (p: 0.22 and p: 0.385 respectively). BMI was significantly higher in Group A 23.9 vs 23.2 in Group B (p: 0.039). Endometrial thickness was significantly higher in Group A (8.7 mm vs 8.1 mm, p:0.002). Endometrial morphology was recorded as triple layer endometrial lining in the majority of cycles. Implantation rates were similar in both groups (40.25% vs 43.7%) but clinical pregnancy rates were significantly higher in Group B (30.8% vs 22.7%, p: 0.03). In the subgroup analysis, the increase involves mainly blastocyst transfers with cleavage stage transfers demonstrating similar results in both groups. More specific, for cleavage stage transfers implantation (Group A 35.5% vs Group B 33%) and clinical pregnancy rates (Group A 21% vs Group B 22.3%)were similar in both groups. In blastocyst transfers implantation was higher in Group B (52,9% vs 43.5%) but did not reach significance. Clinical pregnancies were significantly higher in Group B (38% vs 23.9%, p:0.012).

Limitations, reasons for caution: The major limitation of the study is its retrospective design. BMI and endometrial thickness were significantly different in both groups but it is difficult to quantify the effect of these features on the outcomes as in both groups BMI and endometrial thickness are within normal limits.

Wider implications of the findings: Improved endometrial maturity and receptivity are possible key factors implicated in lenght of estradiol supplementation of 12 or more days. Our findings are in contrast with current literature suggesting that length does not have a role or increased length may have a negative impact on outcomes.

Trial registration number: not aplicable.

P-493 Minimally-invasive RNA-Seq profiling of the endometrium during stimulated in vitro fertilization cycles to identify predictive markers of endometrial receptivity

C. Chan[1], T. Li[1], E.J. Shin[1], N. Stickle[2], C. Virtanen[2], N. Winegarden[3], T. Brown[1], E. Greenblatt[1]

[1]*Mt Sinai Hospital, Obstetrics and Gynaecology, Toronto, Canada*
[2]*University Health Network, Bioinformatics and HPC Core, Toronto, Canada*
[3]*Princess Margaret Cancer Centre, Genomics Centre, Toronto, Canada*

Study question: What genes are differentially expressed by the endometrium at the time of embryo transfer in stimulated cycles and how does this compare to natural cycles?

Summary answer: A distinct gene expression signature distinguishes the receptive phase endometrium in stimulated cycles, with 58 genes overlapping with the natural cycle.

What is known already: Several groups, including ours, have characterized the gene expression of the endometrium in natural cycles and identified

transcripts that are differentially expressed during the receptive phase (LH+7) versus the pre-receptive phase (LH+2). Most investigators have used invasive endometrial biopsy to sample the endometrium, which must be performed in a 'mock" cycle as the biopsy may disrupt implantation. Therefore, molecular characterization of the endometrium in stimulated IVF cycles and same-cycle correlation of gene expression to pregnancy outcome are lacking. We previously developed a minimally-invasive technique of uterine fluid aspiration (UFA) that allows for transcriptomic profiling during an active conception cycle.

Study design, size, duration: Healthy women ≤ 40 years of age with regular cycles and normal uterine cavities, undergoing their first or second IVF cycle, were recruited with informed consent. UFA sampling was performed at the time of oocyte retrieval (hCG+2), classified as 'pre-receptive" samples (N = 40). UFA sampling was also performed in the same women at the time of fresh day 5 embryo transfer (hCG+7), classified as 'receptive" samples (N = 26).

Participants/materials, setting, methods: Total RNA was extracted from samples and RNA-Seq analysis was performed. Reads from each sample were mapped to the human reference genome (UCSC hg19) using HISAT2. Transcript assembly and abundance estimation was performed using StringTie, and R statistical software with the Ballgown package was used to determine differentially expressed transcripts between timepoints (fold change ≥ 4, false discovery rate q<0.05). These transcripts were cross-referenced with our previously published data from natural cycles (LH+2 and LH+7).

Main results and the role of chance: Statistical analysis showed 11,152 genes were differentially regulated between hCG+2 and hCG+7 samples. Hierarchical clustering of the samples using these genes revealed a clear segregation of samples into two major sub-groups: the first consisting almost exclusively of hCG+2 samples and the second of hCG+7 samples. The differentially expressed genes between hCG+7 and hCG+2 were then compared to a list of 245 genes showing ≥ 4-fold change from our previous natural cycle data (LH+7 versus LH+2). Of those 245 genes, 58 overlapped with the stimulated cycle data (q<0.05). The RNA-seq data for these genes were then clustered using a divisive analysis clustering method (DIANA) and showed two major sub-groups that correspond to hCG+2 and hCG+7. Of the patients that underwent fresh embryo transfer, 7 conceived. No statistically significant differences were identified between the samples from pregnant vs. non-pregnant patients.

Limitations, reasons for caution: This translational study focused on discovery of candidate biomarkers of endometrial receptivity in stimulated cycles. The main limitation is a small sample size. The gene expression profile requires further validation through prospective clinical trials with more patients to determine the transcripts that may have predictive value for implantation.

Wider implications of the findings: This is the first whole-genome transcriptomic study on the stimulated endometrium, with direct correlation to embryo transfer outcomes. Prospective studies using this signature will allow identification of predictive markers of pregnancy. Overlapping transcripts between stimulated and natural cycles imply conserved pathways involved in endometrial receptivity that are of particular interest.

Trial registration number: Not applicable.

P-494 Clinical pregnancies achieved after embryo transfer date adjustment based on novel endometrium receptivity test

A. Lukaszuk[1], R. Lenckowski[2], W. Sieg[1], G. Jakiel[3,4], W. Kuczynski[5,6], K. Lukaszuk[1,7,8]

[8]*Gdansk Medical University, Department of Nursing, Gdansk, Poland*

Study question: Does the embryo transfer (ET) date adjustment based on the new endometrium receptivity test lead to increased clinical pregnancy rate?

Summary answer: We can report encouraging preliminary results in patients who had their embryo transfer date adjusted based on the results of the simple endometrium receptivity test.

What is known already: Embryo implantation is a crucial step in the in-vitro fertilization. The so called "window of implantation" is a 4-5 days usually between cycle day 20 and 24. This, however, can vary depending on the cycle type and on individual basis. Analysis of the reasons for implantation failure in cases of top quality embryos showed that a common cause is the lack of synchronization of embryonic development with endometrial maturation.

There are commercial and non-commercial tests available that assess endometrial receptivity based on expression levels of genes linked to the status of endometrial receptivity, using RNA sequencing.

Study design, size, duration: This is an ongoing study initiated in April 2017. Study will include 160 patients with 3 previous implantation failures after a transfer of top quality embryos (with a total number of transferred embryos being at least 4), who are planning a frozen embryo transfer (FET). Patients are divided equally into study group that undergoes endometrium receptivity testing and the control group of those patients who do not opt for the test.

Participants/materials, setting, methods: To date 68 patients were qualified and underwent endometrial biopsies. Endometrial biopsies on day 5 and 7 after ovulation or after start of progesterone supplementation, depending on the planned preparation for FET. Endometrial biopsy material was processed with immunohistochemical staining to evaluate presence of the following protein: estrogen receptor (ER), progesterone receptor (PR), BCL-6, interleukin 15 (IL-15), osteopontin, beta-3 integrins, HOXA10.

Main results and the role of chance: 58.2% of patients had a normal result for both biopsy samples - day 5 and day 7. 38.2% had at least one of the results showing endometrium as delayed in development, prematurely developed or showing mixed development. There were 2 non-diagnostic results (due to poor sample quality) where D5 result was Normal and D7 was non-diagnostic.

D5 samples were Normal in 88.1% cases (59 patients), Delayed - 6.0% (4), Premature - 3.0% (2) and Mixed - 3.0% (2). For the day 7 samples the results were as follows: Normal - 64.2% (43), Delayed - 9.0% (6), Premature - 11.9% (8), Mixed - 11.9% (8), Non-diagnostic - 3.0% (2).

It is worth noting that in 11.9% of cases D7 biopsy results showed mixed endometrium development, i.e., party delayed and party premature development. In those cases other mRNA based tests may show misleading results.

24 patients have already undergone an FET. 15 of those had a normal receptivity test result and 9 an abnormal one. In the normal result subgroup there are 4 clinical pregnancies (26.7%). For patients in the abnormal subgroup the FET date was adjusted based on the receptivity test result. In that group there are 5 clinical pregnancies (55.6%)

Limitations, reasons for caution: These are preliminary results and the group of patients that had already underwent the FET is relatively small.

Wider implications of the findings: This test may provide a simple and cost effective method of determining endometrial receptivity. The preliminary results are encouraging. It appears that when endometrial receptivity is determined the be the cause of implantation failure adjustment of transfer date helps in achieving clinical pregnancies.

Trial registration number: Not applicable.

P-495 Frozen Embryo Transfer Protocols: Which one is best?

J. Joy, P. Lowe

CARE Manchester, Reproductive Medicine, Manchester, United Kingdom

Study question: Is there a difference in live birth rates between frozen embryo transfer (FET) protocols?

Summary answer: In under 36 year olds having FET with single vitrified top quality blastocyst, live birth rates are significantly higher after natural cycle compared to medicated.

What is known already: Currently, there is no definitive evidence that there is a superior protocol for frozen embryo transfer. Several studies have compared natural cycle, modified natural cycle and medicated cycles including both with down regulation and with out. Whilst pregnancy rates have been shown to be higher in some groups in some studies, the live birth rates have not shown

any significant differences. Most of these studies have not be carefully selected with heterogeneity and confounding factors affecting reliability.

Study design, size, duration: This was a retrospective study, from July 2011 to Dec 2016. 1933 FET cycles were included.

Participants/materials, setting, methods: Inclusion criteria: ≤36 years, vitrified top quality blastocysts, elective single embryo transfers, own eggs, no assisted hatching, at least 75% recovery of embryos at FET, patients with over two previous failed embryo transfers.

Exclusion criteria: egg recipients, double embryo transfer, age over 36 yrs, embryos cryopreserved by slow freeze.

1933 FET cycles that complied with inclusion criteria during study period were categorised into 3 groups based on treatment protocol and live birth rates were compared.

Main results and the role of chance: 746 had down regulation protocol, 981 had non downregulation protocol and 206 had natural cycle. (There were no significant differences between three protocols (Down regulation protocol (DR), Non downregulation protocol (NonDR) and natural cycles) in positive pregnancy rates (58.7%, 56.7%, 60.2%, $p = 0.54$). The clinical pregnancy rates (44.1%, 43%, 53.9%, $p = 0.16$) and live birth rates (38.5%, 36.7%, 46.1%, $p = 0.008$) were however significantly higher in the NC group. This can be attributed to a significantly lower biochemical pregnancy loss and miscarriage rate in natural cycle group. The number of natural cycle protocols are less than the medicated and so perhaps there is the role of chance which can be confirmed by further prospective analysis.

Limitations, reasons for caution: The main draw back is the retrospective design.

Wider implications of the findings: Natural cycle FETs can be unpredictable and hence may increase workload over weekend. This can be particularly unsuitable for planning clinic timings.

Trial registration number: not applicable.

P-496 CCS-STR analysis as standard of care for loss of pregnancy has advantages over traditional culture and karyotype

K. Bauckman, T. Escudero

CooperGenomics, Laboratory, Livingston, U.S.A.

Study question: Does CCS-STR analysis of pregnancy loss products have advantages over traditional culture and karyotype analysis?

Summary answer: CCS-STR analysis has several advantages over culture and karyotyping as a method to determine cause of early pregnancy loss.

What is known already: Simpson (1990) summarized the results of culture and karyotyping studies of pregnancy loss products.

Study design, size, duration: 516 pregnancy loss products were analyzed over a 5 year period using CCS technology (array-CGH and NGS sequencing) with follow-up STR analysis when appropriate.

Participants/materials, setting, methods: SurePlex whole genome amplification products from dissected pregnancy loss products that were previously performed in a clinical setting were analyzed.

Main results and the role of chance: Unlike traditional karyotyping, CCS-STR analysis is able to confirm the presence of fetal tissue being analyzed due to unique STRs found in the purported fetal tissue compared to the maternal tissue. We found that the proportion of "normal" results in the karyotyping study (51%) was comparable to combining both the normal and maternal contamination results using the CCS-STR method (31.4% diagnosed normal, 23.3% diagnosed as maternal contamination, total 54.7%).

CCS-STR analysis is able to be accurately identify monosomic lines and abnormalities involving 2-3 or more chromosomes. Simpson identified no losses involving both a monosomy and a trisomy or three or more abnormalities, while CCS +STR analysis found 1.2% and 0.2% of losses in those categories, respectively.

In addition, karyotyping involves use of the subcategory "G", when the operator has difficulty differentiating chromosomes 21/22. CCS-STR analysis is able to confidently distinguish even small chromosomes accurately, including 21/22. While culture and karyotype and CCS+STR identified the same proportion of losses involving trisomy 21 (2.1% vs 2.3%), CCS+STR identified almost double the proportion of trisomy 22 losses (5.2% vs 2.3%).

Limitations, reasons for caution: CCS-STR is not able to identify certain forms of polyploidy, including high-order polyploidy and mitotically-derived polyploidy.

Wider implications of the findings: CCS+STR analysis is a highly accurate way to determine cause of pregnancy loss without many of the drawbacks involved in culture and karyotyping. Shifting pregnancy loss testing towards SNP array + STR analysis should maintain the advantages of CCS+STR in addition to being able to identify more types of polyploidy.

Trial registration number: Not applicable.

POSTER VIEWING

Male and female fertility preservation

P-497 Small or large ovarian tissue fragment. Which is the ideal size for fertility preservation?

A. Mikich[1], Á. Dupont[1], E. Sanguinet[1], E.T. Massignam[2], B. Iser[1], M. Ferreira[1], F. Klamt[2], N. Lothhammer[1], N. Frantz[3]

[1]*Federal University of Rio Grande do Sul, Morphological Sciences, Porto Alegre, Brazil*
[2]*Federal University of Rio Grande do Sul, Department of Biochemistry, Porto Alegre, Brazil*
[3]*Nilo Frantz Fertility Center, Assisted Reproduction, Porto Alegre, Brazil*

Study question: Does the size of the ovarian fragment affect stromal and follicular morphology and tissue physiology after vitrification?

Summary answer: Electron microscopy and Gomori´s staining show normal follicular morphology, collagen fibers and fibroblasts in small and large samples and similar lactate dehydrogenase production in culture.

What is known already: Reports describe the use of small and large fragments and slow freezing. Ovarian tissue vitrification is gaining attention, however, effects of the size of the fragment on stroma morphology and tissue physiology were not reported. Larger samples may reduce mechanical damage caused by dissection. Fibroblasts and extracellular matrix present in the stroma play a critical role in folliculogenesis and angiogenesis through microenvironment remodeling and growth factors delivery, two processes involved in successful grafting and prevention of necrosis. Gomori´s staining and electron microscopy reveal details of stromal components and lactate dehydrogenase (LDH) represents a signature of necrotic cells pos-cryopreservation and culture.

Study design, size, duration: Fresh small (S, 1 × 1 × 2 mm) and large (L, 1 × 1 × 5) fragments of bovine ovaries were fixed for light (LM) and electron microscopy (EM) observations, or vitrified. Fresh and rewarmed fragments were cultured for 48hrs. Next, tissues were fixed and processed for LM and EM. LM, sections were stained with Gomori´s trichrome for connective tissue and collagen fibers. Culture media was collected for LDH assay. Experiments were performed in triplicates.

Participants/materials, setting, methods: S and L fragments from 4-6 ovaries were fixed for LM and EM observations or vitrified using 15% DMSO, 15% ethylene glycol and 0,5 M sucrose in human tubal fluid. Fixed S and L tissues were prepared according to standard LM and EM protocols. Morphological analysis included: collagen fibers, fibroblasts, follicle and blood vessel structures. LDH activity was measured by enzymatic colorimetric assay. LDH measurements were compared by ANOVA. *P* value was considered significant when <0.05

Main results and the role of chance: Gomori´s trichome staining of S and L vitrified tissue sections showed that interstitial matrix, collagen fibers and fibroblasts maintain a similar structure to that found in fresh tissues. However, S fragments presented a looser matrix structure, than L samples. Follicles in S and L fragments show no major alteration in relation to findings observed in fresh tissues. These observations were confirmed by EM micrographs, where collagen fibers in vitrified samples appear as continuous structures, with no interstitial gaps between them. In addition, it is possible to observe the normal fusiform morphology of fibroblasts, intact blood vessel wall and endothelium. Ultrastructural

analysis of primordial follicles demonstrated well-preserved integrity of the oocyte and the surrounding follicular cells. No differences in LDH activity were found between fresh and vitrified, S and L fragments after 48 hours culture (P = 0,347).

Limitations, reasons for caution: The main limitation of our study refers to the fact that results were shown for ovarian tissue collected from one species, bovine. Further studies with human ovarian samples are necessary to confirm our findings. Also, EM micrographs show detailed structures within limited areas of tissue, not the whole fragment morphology.

Wider implications of the findings: The present study provides evidence that vitrification does not induce major morphological and physiological changes in the stroma and follicles of S and L ovarian tissue fragments. Thus, it is recommended to use L ovarian fragments for tissue banking.

Trial registration number: Basic animal research.

P-498 Luteal phase stimulation, the future of fertility preservation? Retrospective cohort study of luteal phase stimulation versus follicular phase stimulation

F. Jochum[1], N. Sananes[1], I. Lichtblau[2], M. Teletin[2], C. Rongieres[1], O. Pirrello[1]

[1]*University hospital of Strasbourg, Department of Obstetric and Gynaecology, Strasbourg, France*
[2]*University hospital of Strasbourg, Reproduction laboratory, Strasbourg, France*

Study question: Is luteal phase stimulation capable of improving fertility preservation?

Summary answer: Luteal phase stimulation appears to be a promising alternative to conventional protocols in view of the number of mature oocytes obtained.

What is known already: Ovarian stimulation with cryopreservation of oocytes / embryos is today the most widely used technique for fertility preservation in women. Usually, ovarian stimulation starts early in the follicular phase. However, this method requires, depending on the day of the cycle of the patient on the day of consultation, between 2 and 6 weeks of implementation. This can delay the beginning of cancer treatment. In this context, luteal phase stimulation appears as a solution. It would indeed reduce the time of completion so the cancer treatment can start quickly as possible.

Study design, size, duration: We performed a retrospective cohort study of consecutive ovarian stimulations, during January 2012 and October 2017 in the University Hospital of Strasbourg.

Participants/materials, setting, methods: Were included all patients under 40 who were referred to our centre for fertility preservation. All included patients had regular cycles and normal ovulation. Non-inclusion criteria are a low expected ovarian response defined by AMH<0.75 µg/l, polycystic ovarian syndrome, amenorrhea, history of infertility or hypofertilization treatment. The primary endpoint is the number of mature oocytes (metaphase II) obtained.

Main results and the role of chance: A total of 87 patients were included: 19 in luteal phase and 68 in follicular phase. A larger number of mature oocytes was obtained in luteal phase versus follicular phase (12.4+/-8.8 versus 7.9+/-5.6 with p = 0.046). A greater amount of total (mature and immature) oocytes was obtained in luteal phase versus follicular phase with a significant difference (15.5+/-10.0 versus 10.2+/-6.9 with p = 0.041). No difference was found for the initial and total doses of gonadotropin.

Limitations, reasons for caution: One of the issues of our study was to determine the progesterone level to define the beginning of the luteal phase. In our study, a progesterone level above 2 ng/ml arbitrarily defined the luteal phase, while many studies have used a higher rate.

Wider implications of the findings: Luteal phase stimulation has the advantage of a better flexibility with positives results as to the number of oocytes obtained. It is easy to imagine a future for this new protocol, particularly in the preservation of fertility, where it is essential to reduce the delay in achieving stimulation.

Trial registration number: Not applicable.

P-499 An existing tool in a new concept: Retrieval of immature oocytes during laparoscopy/hysteroscopy followed by in vitro maturation as a strategy for oocyte banking

C. Lu, X.L. Song, X.Y. Zheng, J. Qiao

Center for Reproductive medicine, Department of Obstetrics and Gynecology- Peking University Third Hospital, Beijing, China

Study question: The feasibility of performing transvaginal retrieval of immature oocytes and subsequent in vitro maturation (IVM) in adjunct with gynaecological surgery for women themselves or donation.

Summary answer: IVM-surgery is simple, safe and associated with good results, which allows embryo or oocyte cryopreservation utilised by treated women or donation of spare oocytes.

What is known already: n contrast to conventional in vitro fertilization (IVF), IVM offers several advantages. It may be performed without ovarian stimulation with gonadotrophins, thus avoiding ovarian hyper stimulation syndrome (OHSS), and requires shorter treatment time. IVM also involves less complexity associated with planning and monitoring of the cycle, and incurs lower costs, which is expected to be more acceptable to the patients and to expand access to fertility treatments.

It's common that women undergo non- assisted reproduction technologies (ART) procedures, such as hysteroscopy or laparoscopy prior or during their fertility treatment.

Study design, size, duration: To assess the feasibility and the efficacy of IVM treatment when oocyte retrieval was performed in adjunct with laparoscopy/ hysteroscopy in infertile women. To evaluate the outcomes of the ART cycles with both fresh and vitrified-warmed fertilised IVM oocytes and the efficiency of this technique compared with conventional IVM in our center. In addition, we examined the safety of the technique including ovarian function.

Participants/materials, setting, methods: We included 158 consecutive women with PCOS who underwent laparoscopy or hysteroscopy had concomitant transvaginal oocyte retrieval followed by IVM between June 2014 and May 2016. Matured IVM oocytes were either fertilised (n = 46) or vitrified (n = 112) and then warmed and inseminated (n = 33). Women with PCOS who underwent conventional IVM and women who underwent gynaecological surgery without IVM served as controls. The analysis of outcomes included embryological data, clinical outcomes, and ovarian function 6 months post-procedure.

Main results and the role of chance: The number of oocytes retrieved per patient was 14.5 (9.0, 20.0), the average maturation rate was 47.4% ±16.5%. Fertilisation rate of fresh-inseminated oocytes was 64.6% and of vitrified-warmed oocytes was 50.0% with oocyte survival 83.0%. Vitrified blastocysts were available for 41.3% patients (2.4 ± 1.641). Vitrified-warmed oocytes resulted in high-quality cleavage embryos in 63.6% patients [32.5 (0.0, 50.0)]. Clinical pregnancy and live birth rates per single blastocyst transfer cycle in vitrified blastocyst group were 63.6% and 54.6%, respectively and per single or double day-3 cleavage transfer cycle in vitrified oocyte group were 31.8% and 22.7%, respectively. No adverse neonatal outcomes were recorded in either group.

IVM-surgery resulted in comparable oocyte yield and maturation rate as conventional IVM. The fertilisation rate and high-quality cleavage embryos from fresh-inseminated oocytes were also similar to those of conventional IVM.

IVM-surgery added 30 minutes to operative time, but was not associated with postoperative complications or longer hospital stay and did not seem to affect ovarian function compared with those of surgery alone group.

Limitations, reasons for caution: We included only women with PCOS because PCOS patients have larger follicle pool and were more likely to benefit from IVM cycle.

Sample size limited our ability for meaningful conclusions regarding perinatal outcomes.

The findings need to be confirmed in a larger population and in different phenotypic groups of women.

Wider implications of the findings: Combined IVM-surgery is a simple and safe procedure. It carries minimal risk of OHSS and is associated with acceptable live birth rate. Importantly, this approach provides additional avenue for social fertility preservation in treated women and allows utilising excess vitrified oocytes for oocyte donation program or for research.

Trial registration number: The study was retrospectively registered with the Chinese Clinical Trial Registry on 04.07.2017; clinical trial registration ID ChiCTR-ONC-17011861.

P-500 Effect of letrozole added to gonadotropins in controlled ovarian stimulation protocols for fertility preservation on the yield and maturity of retrieved oocytes

A. Wertheimer[1,2], E. Klochendler[2], O. Sapir[1,2], Y. Shufaro[1,2], G. Oron[1,2], A. Ben-Haroush[1,2]

[1]Helen Schneider Hospital for Women- Rabin Medical Center-Beilinson Hospital-, IVF and Infertility Unit, Petach-Tiqva, Israel
[2]Tel Aviv University, Sackler Faculty of Medicine, Tel Aviv, Israel

Study question: Does the co-administration of letrozole and gonadotropins during ovarian stimulation influence oocyte yield and maturation in breast cancer patients prior to chemotherapy?

Summary answer: In apparently normal responders with breast cancer, the addition of letrozole to gonadotropins does not increase the number of retrieved oocytes or maturation rate.

What is known already: Ovarian stimulation with letrozole and gonadotropins is effective in patients with breast cancer and spares them exposure to high estradiol levels in fertility preservation cycles. Adjunctive letrozole administration in poor-responder patients decreased the rate of cycle cancelation with increased oocyte yield, perhaps due to increased endogenous gonadotropins secretion or increased follicular androgens concentration.

Study design, size, duration: A retrospective cohort design was used comparing oocyte cryopreservation cycles among patients with breast cancer patients with other oncological indications and women undergoing elective oocyte cryopreservation at a single tertiary medical center between 2007 and 2017. All patients were treated with GnRH antagonist protocol using GnRH agonist for final oocyte maturation. The breast cancer group was additionally treated with letrozole (5 mg/day) from the first day of treatment until the day of oocyte retrieval.

Participants/materials, setting, methods: The cohort included 418 patients: 145 breast cancer patients, 168 with other oncological indications, and 105 patients who chose to undergo elective oocyte cryopreservation.

Main results and the role of chance: There were no significant differences among the groups in number of retrieved oocytes (13.1 ± 11.9 vs. 14.4 ± 11.0 vs. 13.6 ± 10.8, respectively, p = 0.593) or proportion of mature oocytes (85 ± 16% vs. 81 ± 22% vs. 80 ± 20%, respectively, p = 0.125). On multivariate linear regression models, co-treatment with letrozole was not a significant factor for the number of retrieved oocytes (p = 0.408) or for oocyte maturation rate (p = 0.127) after controlling for age, body mass index, and FSH dose.

Limitations, reasons for caution: Our study has several limitations, including the fact that the groups were not evenly distributed, age differences, and the BRCA status was not available for all breast cancer patients.

Wider implications of the findings: The suspected biological effect of aromatase inhibitors and increased intrafollicular androgens level reported in poor responders is probably unique to that specific population and was not found in apparently normal responders.

Trial registration number: 0163-16-RMC

P-501 Oocyte vitrification for elective Fertility preservation. An excellent tool for fertility counseling

F. Lorenzo[1], F. Macarena[2], A. Valcarcel[2], T. Caballero[3], V. Taquini[4], E. Young[4]

[1]IFER, Reproduction, Buenes Aires, Argentina
[2]IFER, Embriologyst, Buenos Aires, Argentina
[3]IFER, Reproductive Medicine, Buenos Aires, Argentina
[4]IFER, Reproductive Medicine, Buenos Aires, Argentina

Study question: Is the number of oocytes obtained for vitrification in an elective fertility program a good tool for fertility counseling?

Summary answer: Our results show that vitrification of oocytes for elective fertility preservation is an excellent tool to be use for fertility counseling.

What is known already: Vitrification has superior post-thaw survival and fertilization outcomes compared with oocytes frozen with the slow-freeze technique.Oocyte vitrification is being offered to healthy women to extend their reproductive options,providing similar results to fresh oocytes.Currently, delayed maternity is most motivated by career aspiration, relationship instability, breakdown and late marriage.Age is strongly related to the probability of having a child with better chances when they do younger than 35,and between 10-12 oocytes would be the ideal number to obtain good results in terms of live birth rates and cost effectiveness.Obteining less oocytes than expected make us provide an strict reproductive counseling.

Study design, size, duration: Retrospective study, September 2008 to December 2017

Participants/materials, setting, methods: A total of 280 patients (37.4 ± 2,8 years), in 327 cycles, vitrificated 1584 MII oocytes, All patients had normal values of FSH, AHM and E2. The length of stimulation was 11.2 (10.1 12.3), Mean FSH dose (IU) 1445.85(1408.5-1483.2), E2 on day of hcg (pg/ml) 1636 (1548.3-1725.4).

Main results and the role of chance: A total of 280 patients, vitrificated 1584 MII oocytes, the mean age was 37 ± 2,8, (<35 y: 45(16.07%), 35-37 y: 67 (23.92%), 38-40 y: 122 (43.57%), >40 y: 46(16.42%), E2 on day of hcg (pg/ml) 1636 (1548.3-1725.4) (<35 y 1404 ± 1244, 35-37 y: 1479 ± 1074, 37-40 y:1209 ± 911, >40 y: 905 ± 674, Number of oocyte obtained/patient age: < 3: 87 (< 35 y: 9, 35-37 y:19, 38-40 y: 37, >40: 22), 4-6: 87 (<35 y: 15, 35-37 y: 17, 38-40 y: 43, >40 y: 22), 7-10: 57(<35 y: 11, 35-37 y: 15, 38-40 y: 21, >40: 10), > 11: 49 (<35 y: 10, 35-37 y: 15, 38-40 y: 21, >40 y: 2).This retrospective analysis, shows that the 67.5% of patients were between 35 and 40 years old, even more the 43,57% were between 38 and 40 years old.The 62.14% of patient vitrified 6 oocytes or less, in patients younger than 35 years old 53,3% vitrified 6 or less oocytes (<3:9 patients,4-6:15 patients, 7-10:11 patients, >11:10 patients).The probability of having a baby according to N*of oocytes used is: oocytes/CLBR(95%CI) 5: 14.7 (6.2-23.1), 8: 30.9 (19.1-42.7), 10: 37.9 (24.9-51.0)

Limitations, reasons for caution: This is a retrospective study. Although the size of our sample is small, our data provides useful information regarding convenient reproductive counseling, even more when the amount of oocytes obtained is less than expected.(empty follicles,poor response) with normal values of serum estradiol at the day of HCG.

Wider implications of the findings: Oocyte vitrification is an efficient tool which can be helpful In women who delay child bearing,we should inform women about their specific probabilities according to their age and number of oocytes at vitrification,is important to counsel women that elective oocyte cryopreservation can increase future reproductive chances but cannot guarantee success.

Trial registration number: Not applicable.

P-503 Optimising ovarian stimulation protocol for oncology patients

E. Yasmin[1], E. Parker[1], G. Williams[1], S. Sheth[2]

[1]University College London Hospital, Women's Health, London, United Kingdom
[2]UCLH, Women's Health, London, United Kingdom

Study question: Do timing of start and dose of gonadotrophin stimulation effect oocyte yield in oncology patients.

Summary answer: The timing of the start of stimulation in menstrual cycles does not appear to affect oocyte yield but the starting dose does.

What is known already: Oocyte number is a good predictor of live birth when using cryo-preserved oocytes. Time is of essence in oncology patients as the ovarian stimulation cycle needs to be completed swiftly to enable oncology treatment to commence without delay. This may make conventional early follicular phase stimulations difficult or incur time delay. There is concern about oocyte yield in late follicular or luteal phase stimultion starts as it may affect quality and number of eggs. There is also concern about using high dose of gonadotrophin due to risk of OHSS.

Study design, size, duration: A retrospective analysis was carried out in 78 patients having 78 cycles having ovarian stimulation and oocyte collection for fertility preservation prior to oncological treatment.

The study period was 2014-2017

Participants/materials, setting, methods: An analysis of 78 cycles was performed.

Demographic characteristics like age and BMI were evaluated.

Ovarian reserve was assessed with AMH and AFC.

Oncology diagnosis was taken.

Start time of stimulation, dose pf gonadotrophin used and number of oocytes collefted were evaluated.

Any adverse events like OHSS or haemorrhage was noted.

Duration of treatment to oocyte collection was assessed.

All patients had antagonist cycles with agonist trigger.

The study was perfomed in a tertiary care reproductive medicine unit.

Main results and the role of chance: There were 8 late follicular and luteal phase starts and 70 early follicular starts. An average of 13.75 (9-17) oocytes were collected in the late follicular and luteal phase with an average of 10.25 metaphase 2 eggs. The average oocyte yield in the early follicular phase start was 12.45 (2-31).

AMH of <5pmol/l was associated with a lower egg yield as expected (7.25). AMH of <1 were noted in some of the pill users which did not affect oocyte yield.

An analysis of oocyte yield with AMH>15pmol/l revealed fewer than 10 eggs when start dose of gonadotrophin was 150units. Average oocyte yield was 15 (11-30) with starting dose of 225-300 units in the same group. In an analysis of 12 cases with an oocyte yield of <5neggs, 5 were in young women with AMH >20pmol/l started on 150 units of gonadotrophin. There was no significant difference in oocyte yield between different diagnosis and no significant difference in those patients who came to freeze oocytes after chemotherapy. There were no cases with OHSS. Patients did not have to delay oncological treatment in any case.

The late follicular/luteal phase start group was small and the absence of effect could be due to chance.

Limitations, reasons for caution: The retrospective nature of the study and low numbers are limitations.

Luteal phase starts need more numbers.

Wider implications of the findings: AMH is not lways reliabe as a measure of ovarian reserve prior to fertility preservation.

Conventional stimulation protocols are not always suitable for oncology patients.

Trial registration number: not applicable.

P-504 Long term cumulative rate of use of frozen sperm in cancer patients

M. Reschini[1], S. Ferrari[1], C. Guarneri[1], S. Noli[2], A. Paffoni[3], E. Somigliana[2]

[1]Fondazione Ca' Granda Ospedale Maggiore Policlinico, Infertility Unit, Milano, Italy
[2]Università degli Studi di Milano, Department of Clinical Sciences and Community Health, Milano, Italy
[3]ASST Lariana, Infertility Unit, Cantù, Italy

Study question: What is the long-term cumulative use rate of frozen sperm in men who storage the semen before cancer therapies?

Summary answer: The cumulative usage rate is 11%.

What is known already: Cancer therapies are frequently aggressive and unwanted side effects are common, including threats to fertility. Affected patients should be aware of the risk of permanent infertility and on the possible options for fertility preservation. Currently, the only way to efficiently preserve the reproductive potential in men remains sperm cryopreservation. However, the economical validity of this intervention has been questioned because of the low rate of use. A recent review reported a mean percentage of use of only 8%. Unfortunately, evidence on the long-term cumulative rate of use, which is far more significant than the crude rate, is scanty.

Study design, size, duration: The analysis includes all males cancer patients who cryopreserved semen from 1986 to 2009 at the Infertility Unit of the Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico of Milan. Information were obtained from patients' charts. Moreover, men with incomplete information were actively contacted by phone and interviewed using a standardized questionnaire.

Participants/materials, setting, methods: The analysis focussed on the following information: age at semen preservation, semen parameters at the time of preservation, oncological diagnosis, use of frozen samples and time of use, duration of follow-up, disposal of samples and reasons for their removal.

Main results and the role of chance: We included 1524 cancer patients cryopreserving at least one sperm sample. Most frequent classes of malignancies among patients were testicular cancers (n = 660, 43%) and lymphatic-haematological cancers (n = 651, 43%). Mean age at the time of sperm banking was 30.0 ± 7.5 years (range, 14–66 years) and the median time from storage to use or to the last follow-up was 12 years (range 0–28 years). Out of 1524 patients, 137 (9%) used their cryopreserved sperm sample to perform ART. The cumulative rate of use for the whole cohort at 10 and 20 years follow-up was 9% and 11%, respectively. We then evaluated predictive factors of use. The Cox regression analysis identified two factors that were significantly associated with the chances of use: 1) age at the time of cryostorage (B = 1.033, 95%CI: 1.011-1.056, p = 0.003), and 2) cancer diagnosis (haematological versus testicular tumours B = 1.808, 95%CI: 1.234-2.648, p = 0.002; other diagnoses versus testicular B = 1.675, 95%CI: 0.996-2.818, p = 0.052).

Limitations, reasons for caution: Duration of follow-up is insufficient to draw information regarding young adults. Distribution during the duration of the program is unlikely to be uniform because interest in fertility preservation has grown during the last two decades.

Wider implications of the findings: Using these data, the cumulative rate of men banking and subsequently using their semen is 11%. On this basis, one should claim in depth economical analyses to investigate the economical validity of sperm banking programs in cancer male patients.

Trial registration number: Not applicable.

P-505 Comparison of conventional and random start ovarian stimulation for fertility preservation in oncological patients

N. Jancar, E. Vrtacnik Bokal, I. Virant Klun, M. Stimpfel, L. Bacer Kermavner, V. Salamun

University Medical Center Ljubljana, Department of Human Reproduction- Division of Obstetrics and Gynecology, Ljubljana, Slovenia

Study question: To compare the number of retrieved oocytes in oncological patients, when ovarian stimulation started in early follicular, late follicular or luteal phase of menstrual cycle.

Summary answer: The number of retrieved oocytes was similar when the ovarian stimulation was initiated in early follicular, late follicular or luteal phase of the cycle.

What is known already: Chemotherapy and pelvic irradiation for malignant or autoimmune disease have improved survival of patients but may lead to premature ovarian failure and infertility. Therefore, young oncological patients should be referred to Reproductive medicine subspecialist for counselling and procedures to preserve their chances to be parents with their own genetic material. With the usage of short antagonist protocols the ovarian stimulation requires no important delay in systemic oncologic treatment.

Study design, size, duration: We included all women who were referred to the Department of Human Reproduction of the Division of Obstetrics and Gynecology of the University Medical Centre Ljubljana for fertility preservation before gonadotoxic treatment from January 2013 to the end of December 2017.

Participants/materials, setting, methods: A total of 127 female patients were referred to our Department for counselling in this period. Our Department is the only one offering genetic material preservation for oncological patients in Slovenia. If the time available for stimulation was > 1 month, the ovarian stimulation started in early follicular phase, otherwise it was initiated immediately or ovarian tissue cryopreservation was offered.

Main results and the role of chance: Out of 127 patients, 54 (42.5%) had breast cancer, 36 (28.3%) had lymphoma, 7 (5.5%) had leukaemia, 7 (5.5%) had borderline ovarian tumour, 6 (4.7%) had autoimmune disease, 5 (3.9%) had sarcomas, 3 (2.4%) had colon cancer and 9 (7%) had other rear malignant disease such as brain tumour, disgerminomas and vaginal cancer. The median age of included women was 29 ± 2.3 years (range 3 to 43 years). In 41 (31.5%) patients we did not preserve any material due to variety of reasons. In 67 (52.7%) patients oocytes were vitrified, in 14 (11%) patients embryos were vitrified, in 3 (2.4%) patients oocytes and

embryos were vitrified, in 6 (4.7%) patients ovarian tissue was cryopreserved. When the stimulation started in early follicular phase (N = 58), the mean number of retrieved oocytes was 10 (range 1-31 oocytes); 8.56 oocytes were mature at aspiration. With the start in late follicular phase (N = 11) the mean number of oocytes was 11.3 (range 1-35 oocytes); 10.2 were mature at aspiration. With the start in luteal phase (N = 14) the mean number of oocytes was 12.6 (range 1-30 oocytes); 9.6 oocytes were mature at aspiration.

Limitations, reasons for caution: The majority of patients had breast cancer and time interval to the initiation of systemic treatment was 6 to 8 weeks. Therefore, majority of patients had conventional start of stimulation in early follicular phase. The number of patients in other two groups is quite small, so further studies are needed.

Wider implications of the findings: It has already been published, that random start stimulation can be used in oncological patients with good results. Our study also showed that numbers of retrieved and numbers of mature oocytes were similar when the ovarian stimulation was started in early follicular, late follicular or luteal phase of menstrual cycle.

Trial registration number: not applicable.

P-506 Does oxygen tension influence in vitro maturation of human oocytes in a fertility preservation program? Preliminary results of a prospective auto-controlled study

M. Dahoun[1], C. Herbemont[1], N. Sermondade[1], A. Seroka[2], B. Dagher-Hayeck[2], M. Comtet[2], C. Vinolas[2], I. Cedrin-Durnerin[2], M. Grynberg[2], C. Sifer[1]

[1]Hôpital Jean Verdier, Histologie-Embryologie-Cytogénétique-CECOS, bondy, France
[2]Hôpital Jean Verdier, Médecine de la reproduction, bondy, France

Study question: Are human oocyte (i) maturation rate (MR) and (ii) morphological score enhanced by low oxygen (O_2) tension applied during *in vitro* maturation (IVM) cycles?

Summary answer: Oocyte MR was similar whatever the O_2 tension applied during IVM, whereas morphologic Total Oocyte Score (TOS) was significantly higher under low oxygen tension.

What is known already: O_2 tension within the mammalian female genital tract is low, (2-8%), contrary to culture conditions applied in most of Assisted Reproductive Technology laboratories (20%O_2). Hypoxia might reduce oxidative stress commonly triggered by atmospheric O_2 tension, further allowing a more physiological process. Besides, the latest recommendations state that embryos should be cultured under hypoxia. However, several randomized studies in mammals have reported controversial findings concerning *in vitro* MR and subsequent embryo development when oocytes were matured under either 5% O_2 or atmospheric conditions. To date, no study has ever evaluated the impact of O_2 tension on human oocyte matured *in vitro*.

Study design, size, duration: prospective, observational, monocentric, auto-controlled study on sibling oocytes was performed from November 2016 to July 2017. Fifty-nine patients candidates for fertility preservation (FP) using vitrification of metaphase 2 (M2) oocytes from IVM cycles were included when at least 2 cumulus-oocyte complexes (COCs) were retrieved. Each COC cohort was randomly split into two equal groups: group 1=culture under 20% O_2; and group 2=culture under 5% O_2.

Participants/materials, setting, methods: COCs were incubated for 48 h using an appropriate media, in similar benchtop incubators (G-210, K-Systems®), either under 5 or 20%O_2. After 24 h and 48 h of culture, every oocyte was assessed for maturity and morphology, using 6 parameters (shape, size, ooplasm, perivitelline space, zona pellucida and polar body characteristics) each graded as -1, 0 or +1, giving a TOS ranging from -6 to +6 (Lazzaroni-Tealdi et al., 2015). MR and TOS were compared using paired-sample analysis.

Main results and the role of chance: We analyzed our preliminary data. Briefly, patients' mean age was 30.6 years. Their mean serum AMH levels and antral follicle count were 3.62 ng/mL and 33.2 follicles, respectively. On average, 13.13 COCs per cycle were retrieved, leading to 7.5 M2 oocytes vitrified (global MR = 58.01% (449 M2/774 COCs)). Respectively 383 and 391 COCs were included in groups 1 and 2. In group 1 (20% O_2), MR after 48 h of culture yielded 56.14% of M2 oocytes (215/383), which was comparable to MR achieved in group 2 (5% O_2) (59.85%; 234/391; p = 0.21). Considering M2 oocyte morphology, the mean TOS was significantly higher under low O_2 tension (3.44 per oocyte in group 2 *versus* 3.16 in group 1; p = 0.014). Finally, a subgroup analysis outlined a significantly higher number of high-grade oocytes (TOS ≥ 4) in group 2 than in group 1 (2.24 *versus* 1.64, respectively; p = 0.032).

Limitations, reasons for caution: This study, still in progress, needs to be continued to clarify the impact of O_2 tension on human IVM oocyte and their morphology. Furthermore, analysis of subsequent warming cycles would complete these data, in terms of survival, fertilization rates, embryo quality and clinical outcomes according to IVM culture conditions.

Wider implications of the findings: Although these preliminary results failed to highlight any increase in MR under hypoxia, oocyte morphology has been improved. Therefore, further analysis is needed to investigate whether oocyte maturation under 5% O_2 increases the chances of pregnancy after thawing.

Trial registration number: N° ID RCB: **2017-A02264-49**

P-507 Spermatogonial quantities in untreated prepubertal cancer patients are comparable to normative prepubertal spermatogonial values

I. Masliukaite[1], E. Ntemou[2], M. Van de Wetering[3], A. Meißner[1], L. Kremer[3], S. Repping[1], K. Jahnukainen[4,5], E. Goossens[2], A. Van Pelt[1]

[1]Academic Medical Center AMC, Center for Reproductive Medicine, Amsterdam, The Netherlands
[2]Vrije Universiteit Brussel VUB, Biology of the Testis- Department of Reproduction-Genetics and Regenerative Medicine, Brussels, Belgium
[3]Academic Medical Center AMC, Department of Pediatric Oncology- Emma Children's Hospital, Amsterdam, The Netherlands
[4]Karolinska Institutet and University Hospital, Department of Women's and Children's Health- Pediatric Endocrinology Unit, Stockholm, Sweden
[5]University of Helsinki and Helsinki University Central Hospital, Children´s Hospital, Helsinki, Finland

Study question: Does cancer affect spermatogonial quantity in the the testes of prepubertal boys?

Summary answer: Spermatogonial quantities in prepubertal boys with hematologic, solid cerebral, or solid extra-cerebral cancer were comparable to those in healthy prepubertal boys.

What is known already: The incidence of pretreatment azoospermia in adult men diagnosed with cancer is known to be ten-fold higher compared to the general population, with the highest rates among hematologic and testicular malignancies (9-13% and 10-15%, respectively). It has been hypothesized, that such fertility impairments are caused by disease-related effects on the body, including hormone and metabolic imbalances, and immune response. However, no studies have thus far investigated the effect of different types of cancers on the numbers of germ cells in prepubertal boys. If numbers are reduced, these cancer survivors may face sub-/infertility without the possibility to use fertility preservation treatments.

Study design, size, duration: In this study, we collected data on cancer diagnosis in 83 prepubertal boys, who underwent testicular biopsy for fertility preservation prior to cancer treatment between 2011 and 2017. We classified their diagnoses into three cancer categories (hematologic, solid cerebral and solid extra-cerebral) and examined histology of the testicular biopsies by immunohistochemistry. Patients with the history of testicular torsion or cryptorchidism, able to ejaculate spermatozoa, or with malignancies in the testes were excluded from the study.

Participants/materials, setting, methods: Patient data were identified through records of the Academic Medical Center in Amsterdam, the Netherlands, and included patient age at the time of testicular biopsy and cancer diagnosis. A small part of the testicular biopsies were fixed, paraffin embedded, and labelled for MAGE-A4, a biomarker for human spermatogonia. The amount of spermatogonia per tubular cross-section (S/T) was determined using bright-field microscopy and compared with the normative reference values. Polynomial regression was used for data analysis.

Main results and the role of chance: In the analyzed cohort of 83 prepubertal boys diagnosed with cancer, median age at diagnosis was 9 years (range 0.5-16 y). Altogether, 15.7%, 27.7%, and 56.6% of boys had hematologic, solid cerebral, and solid extra-cerebral malignancy, respectively. The average S/T in the total cohort was 4.4 (SD = 5.29), with 6.59 (SD = 7.34) in hematologic cancer, 3.10 (SD = 4.54) in solid cerebral cancer, and 4.43 (SD = 4.87) in solid extra-cerebral cancer patients. No significant differences or associations between S/T and cancer categories were found. The amount of spermatogonia per tubular cross-section in all three patient groups was within the range of the normative reference values for healthy prepubertal boys.

Limitations, reasons for caution: These results should be interpreted in the context of the small sample size per cancer category, as well as the high variance between patients' general health condition within each group.

Wider implications of the findings: Our data suggest, that in each cancer category the size of the spermatogonial pool in prepubertal boys was comparable to the normative values. Therefore, all pediatric cancer patients who might face high risk of spermatogonial depletion due to gonadotoxic treatment can be referred for fertility preservation.

Trial registration number: Not applicable.

P-508 New miRNAs to evaluate ovarian reserve in patients with breast cancer

S. El Moghrabi[1], C. Decanter[2], P. Pigny[3], D. Haouzi[1], S. Hamamah[4]

[1]*Inserm U1203, Institut de Médecine Régénérative et Biothérapies IRMB- Hôpital Saint Eloi- CHU Montpellier, Montpellier, France*
[2]*Service d'Assistance Médicale à la Procréation et de préservation de la fertilité- Hôpital Jeanne de Flandre- CHRU Lille, EA 4308 Gamétogénèse et qualité du gamète- Centre Hospitalier Universitaire de Lille, Lille, France*
[3]*Laboratoire de Biochimie Hormonologie HMNO- Centre de Biologie Pathologie- CHRU Lille, Inserm- UMR-S 1172, Lille, France*
[4]*Service de Biologie de la Reproduction- Hôpital Arnaud de Villeneuve- CHU Montpellier, ART/PGD Department, Montpellier, France*

Study question: The aim of this study is to identify a new non invasive strategy to evaluate the ovarian reserve in patients with breast cancer.

Summary answer: We found 4 deregulated miRNAs as a potential target for fertility preservation in patients with breast cancer.

What is known already: Anti-Müllerian hormone (AMH) is a reliable quantitative biomarker of the ovarian reserve, but not after chemotherapy treatments. Indeed, young breast cancer patients have significantly lower AMH after chemotherapy than age-matched controls. In addition, AMH solely is not able to determine the quality and the fertilization capacity of oocytes containing in the resting follicles from patients who wish to conceive after breast cancer treatment. Indeed, the necessity to quantify the ovarian reserve in patients after chemotherapy treatment remains a major medical issue.

Study design, size, duration: 21 serum samples were obtained from three breast cancer patients aged between 35 and 37 years old (mean age±SD: 35.7 ± 1.1 years) with chemotherapy treatment. All patients were prospectively recruited before initiation of the chemotherapy.

Participants/materials, setting, methods: Serum miRNAs and AMH quantification were performed at baseline, 15 days after and before the first chemotherapy treatment and every 3 months after the end of chemotherapy until time + 18 months.

We used Serum/Plasma Focus PCR MicroRNA Panel (Exiqon) that allows to study a total of 178 miRNAs.

Main results and the role of chance: Our preliminary results revealed that four miRNAs (miR144-5p, miR186-5p, miR34-5p and miR21-5p) were overexpressed during chemotherapy treatment compared with both before and after the chemotherapy treatment although these differences were not significant. Meanwhile, serum AMH concentration dramatically decreased 6 months after chemotherapy treatment in breast cancer patients compared at baseline measure (3 ± 0.03 *vs* 10.3 ± 3.5 ng/ml), and thus, until 18 months post-treatment. One of these miRNAs, miR 21-5p was suggested to affect follicular development. These four miRNAs could be a potential target for fertility preservation in patients with breast cancer.

Limitations, reasons for caution: This result is issue from few samples and the study is in progress.

Wider implications of the findings: This finding opens new perspectives in the patient care management of patients with breast cancer.

Trial registration number: CHACRY-1501.

P-509 A follow-up survey on the reproductive intentions and experiences of women who underwent "social freezing" or elective oocyte cryopreservation

A. Wafi, J. Nekkebroeck, C. Blockeel, N. De Munck, H. Tournaye, M. De Vos

Universitair Ziekenhuis Brussel- Vrije Universiteit Brussel- Brussel- Belgium., Centre for Reproductive Medicine, Brussel, Belgium

Study question: What are the reproductive attitudes and experiences in women who previously underwent elective oocyte cryopreservation for anticipated gamete exhaustion (AGE)?

Summary answer: Women who previously underwent elective oocyte cryopreservation perceive fertility preservation as a useful procedure to enhance the probability of motherhood.

What is known already: Elective oocyte cryopreservation is available to women who prefer to or have to defer and delay motherhood until the right time or the right partner arrives. A previous survey has shown that women are highly satisfied with their decision to cryopreserve oocytes. However, follow-up data documenting their reproductive outcomes, and their beliefs and expectations regarding the utilisation of cryopreserved oocytes are limited.

Study design, size, duration: Cross-sectional Survey.

Participants/materials, setting, methods: Women who had stored oocytes in a tertiary university-based fertility clinic between January 2009 and September 2016 were invited to complete an anonymous questionnaire about their reproductive intentions and expériences.

Main results and the role of chance: Of the 342 potential respondents, 138 (40.3%) returned completed questionnaires. The average age of respondents was 40.2 y and the reported age at first cycle of cryopreservation was 35.8 y. Eighty-three % had been single when they underwent oocyte cryopreservation while 44% of respondents still were. Almost two-thirds (65%) anticipated to use their cryopreserved oocytes and were planning to do so before the age of 45 y (range 38-55 y). Sixty-six respondents (48%) had already tried to achieve a pregnancy, of which 69% had succeeded (79% spontaneously and 21% using their cryopreserved oocytes). Sixty-five percent would consider adoption, whereas only 31,4% would turn to oocyte donation if they failed to become pregnant with their vitrified oocytes. When asked if they would ever consider to remain childless 50.4% answered yes.

Limitations, reasons for caution: The results of this survey may have been biased by the limited response rate and potential misinterpretation of questions. National and international registries of larger numbers of women who undergo elective oocyte cryopreservation as a prevention for age-related fertility decline would offer the best prospect of generating wide-reaching qualitative data.

Wider implications of the findings: After a mean follow-up of four years, "past social freezers" report an overall high degree of satisfaction with their previous decision. Even if only a subset achieved a pregnancy using these vitrified oocytes so far, the majority of respondents still have the intention to use their oocytes to realise motherhood.

Trial registration number: Not applicable.

P-510 Professionals' barriers in female oncofertility care and strategies for improvement

M. Van den Berg[1], Ö. Baysal[1], I. Beerendonk[1], D. Braat[1], W. Nelen[1], R. Hermens[2]

[1]*Radboud University Medical Centre, Obstetrics and Gynaecology, Nijmegen, The Netherlands*
[2]*Radboud University Medical Centre, IQ Healthcare, Nijmegen, The Netherlands*

Study question: What are Dutch healthcare professionals' barriers and strategies for improvement in female oncofertility care?

Summary answer: Professionals particularly perceive barriers in knowledge, attitude and organization towards fertility preservation and are open to improve oncofertility care.

What is known already: One of the most important undesirable side effects of cancer treatment in young women is the potential loss of fertility. Guidelines recommend to discuss the potential loss of fertility with all female cancer patients and, if desired, offer a referral to and counseling by a fertility specialist. Unfortunately, studies have shown that not all patients receive information on their fertility risks and options to preserve fertility and only a small proportion of these women is referred. A study on barriers for discussing fertility preservation and appropriate referral in a country with structural reimbursement has not yet been performed.

Study design, size, duration: Semi-structured in depth interviews were conducted with a total of 24 healthcare professionals. Thereafter, a selection of improvement strategies was performed with an expert panel consisting of patients and healthcare professionals to overcome these barriers.

Participants/materials, setting, methods: Oncological professionals working in Dutch female oncofertility care were recruited out of the three Dutch expertise hospitals for female fertility preservation and their affiliated hospitals. In the Dutch setting financial aspects do not play a role in oncofertility care. Professionals were asked for their barriers and improvement suggestions in individual interviews. A meeting with an expert panel was held to select improvement strategies and reach consensus on an oncofertility program.

Main results and the role of chance: In total 31 barriers and 23 facilitators were identified. Barriers have been revealed distributed over three domains; patient, professional and organization. On the patients' domain a focus on surviving cancer and starting treatment and not a focus on their fertility have been identified as barriers. On the professionals' domain a lack of awareness and a lack of knowledge, and on the organization domain no written information available, no time and FP is not discussed at multidisciplinary meetings have been identified as main barriers. The expert panel selected different strategies to improve oncofertility care. These include provision of written and online information, education of professionals, reminders for professionals, fertility should be a standard discussion item on the agenda of multidisciplinary oncology meetings and specialized oncology nurses should play a role in informing patients in oncofertility care and patient navigators at the fertility department to facilitate referral and counseling.

Limitations, reasons for caution: Selection bias could have occurred because it is likely that only professionals who are interested in oncofertility care were willing to participate. However this means that we underestimated the barriers.

Wider implications of the findings: This study was a preview for a multifaceted oncofertility program which should be developed in order to increase adherence to the national clinical guideline.

Trial registration number: Not applicable.

P-511 IVM before vitrification induces alterations of maturation rates and deleterious effects on actin and tubulin architecture of human oocytes

A. Metchat, H. Pons-Rejraji, S. Vorilhon, S. Mestres, S. Lusho, L. Chaput, S. Dollet, A.S. Grémeau, J.L. Pouly, F. Brugnon

Université Clermont Auvergne-CHU Clermont-Ferrand, Biologie de la Reproduction-AMP-CECOS, Clermont-Ferrand, France

Study question: Is it better to vitrify oocytes before or after in vitro maturation?

Summary answer: Since we observed alterations of maturation and deleterious effects on actin and tubulin architecture in oocytes vitrified before IVM, IVM should be performed before vitrification.

What is known already: Human oocyte cryopreservation is routinely used for fertility preservation of women who will be exposed to gonadotoxic treatments. After ovarian stimulation, matured oocytes are vitrified. However, this strategy cannot always be used, particularly for hormone-sensitive cancer or when ovarian stimulation is not possible. An approach including immature oocytes and in vitro maturation (IVM) could be considered in these cases. While some qualitative analyses of oocytes vitrified before or after IVM suggest that vitrification should be performed after IVM, little is known about vitrification effects on actin and tubulin cytoskeleton and on maturation of human oocytes.

Study design, size, duration: To answer to this question, we performed quantitative analyses comparing matured oocytes from three different groups: (i) oocytes vitrified before IVM, (ii) oocytes vitrified after IVM, and (iii) fresh immature oocytes. Non-vitrified (fresh) in vitro matured oocytes were used as controls. Kinetic of maturation and subcellular structures were analysed during maturation and in matured oocytes. 160 immature oocytes were collected from women without ovulation troubles from March 2017 to January 2018.

Participants/materials, setting, methods: A total of 160 immature oocytes were collected from 63 patients (≤37 years old, without ovulatory diseases) who underwent ICSI. Oocytes were matured in vitro with IVM medium (Origio) for 36 hours and vitrified in a closed system, Rapidi with RapidVit Omni and RapidWarm Omni (Vitrolife). Kinetics of maturation were analysed by Primovision™ (Vitrolife). The actin and spindle organisation were studied by immunostaining techniques, confocal microscopy (Leica SP6), and quantitative analyses (Imaris® and Fiji).

Main results and the role of chance: While the kinetics of maturation were similar for oocytes vitrified before or after IVM (17:27 before IVM versus 17:53 after IVM; $p>0.05$; h:min), a lower rate of oocytes vitrified before IVM extruded polar body (78% after IVM versus 56% before IVM, $p = 0.003$). Then, the cytoskeletal organisation of matured oocytes vitrified before or after IVM was quantitatively analysed. Using biophysical methods, our analysis revealed that spindle length and shape were significantly altered in oocytes vitrified before IVM, while oocytes vitrified after IVM appeared normal compared with fresh oocytes. By high-resolution imaging, we characterised for the first time the actin organization in human matured oocytes. Actin exhibits a complex organisation with a dense cytoplasmic network and cortical actin. Cortical actin thickness and actin filament lengths were measured in both conditions. Our results showed that the cortical actin thickness was significantly higher in oocytes vitrified before IVM compared with fresh oocytes; while it was not affected in oocytes vitrified after IVM. Analysis of actin filaments indicated that the average of filament lengths diminished similarly in both conditions compared with fresh oocytes. All these alterations observed in oocytes vitrified before IVM suggests that IVM should be performed before vitrification.

Limitations, reasons for caution: Since, we used oocytes from women without cancer; our data should be completed with an analysis of the effect of vitrification combined with IVM in oocytes from women diagnosed with a cancer. Moreover, homologous chromosome segregation during the first meiotic division should be investigated in order to detect aneuploidy.

Wider implications of the findings: Our preliminary data shows clearly that IVM should be performed before vitrification. After chromosome segregation analysis and validation on immature ovocytes from women with cancer, the protocol that we provide here, will be applied, with immature oocytes for fertility preservation.

Trial registration number: Clinical trial registration: NCT03416400.

P-512 Assessment of a sensitive and specific method to detect Ewing sarcoma minimal residual disease in testicular and ovarian tissue by RT-qPCR

L. Chaput[1], V. Grèze[2], P. Halle[3], A. Tchirkov[4], L. Véronèse[4], N. Robin[5], B. Pereira[6], H. Lejeune[7], P. Durand[8], G. Martin[8], A.S. Grémeau[1], M. Canis[1], F. Brugnon[1]

[8]Ecole Normale Supérieure de Lyon, Kallistem, Lyon, France

Study question: The aim of this study was to assess the sensitivity and specificity method to detect Ewing sarcoma minimal residual disease in human germinal tissue.

Summary answer: The detection of *EWS-FLI1* (RT-qPCR) enables sensitive and specific detection of Ewing sarcoma cells which may be contained in frozen germinal tissues for fertility preservation.

What is known already: Ewing sarcoma is a frequent solid tumor in children with high metastatic potential and high risk of infertility due to the potential toxic treatments for reproductive functions. Since the high survival rate of patients and deleterious effects of intensive chemotherapy, the cryopreservation of ovarian tissue or testicular tissue is recommended. However the risk to reintroduce cancer cells should be evaluated to ensure safety of fertility restoration with these tissues. The assessment of this minimal residual disease could be performed with frozen tissues by slow freezing or immediately after tissue collections by snap freezing.

Study design, size, duration: Ovarian tissues (OT) and testicular tissues (TT) were frozen (slow and snap freezing). After thawing, each fragment was contaminated with increasing amount of human Ewing sarcoma cells (RD-ES). The expression of *EWS-FLI1* mRNA was measured. To evaluate the invasive potential of RD-ES cells, cocultures (OT or TT / RD-ES cells) were performed. OT and TT from metastatic patients were analyzed once the high sensitivity and specificity of the detection method by RT-qPCR was demonstrated.

Participants/materials, setting, methods: OT: women with ovarian cyst (n = 12). TT: Non-obstructive azoospermia men (n = 14).

Tissues were frozen (slow/snap freezing). After thawing, they were contaminated with RD-ES cells (10, 100, 1000 cells). The expression of *EWS-FLI1* was quantified by RT-qPCR. The invasive potential of RD-ES cells was evaluated by cocultures and RT-qPCR, FISH and immunochemistry. Minimal residual disease was assessed in OT and TT of children with Ewing sarcoma once the efficiency of our *in vitro* model was demonstrated.

Main results and the role of chance: Yields of RNA extraction from OT (median weight: 39.2 mg [15.2 – 62.0]) and TT (median weight: 28.8 mg [16.6 – 48.0]) did not differ between slow or snap freezing (p = 0.54) method. The expression of *EWS-FLI1* transcript was positive in OT and TT samples contaminated with 10, 100 and 1000 RD-ES cells and was negative in uncontaminated samples. There was a strong correlation between the amount of RD-ES cells and the expression of *EWS-FLI1 mRNA* (OT: r = 0.93 and TT: r = 0.96 with p < 0.001) whatever freezing method. The sensitivity and specificity to detect the expression of *EWS-FLI1* transcript by our method was respectively 97% IC 95% [0.92-1.00] for OT and 99% IC 95% [0.98-1.00] for TT. After cocultures, we observed in germinal tissues the presence of Ewing cells by standard histology (HES coloration) and by immunohistochemistry with a diffuse nuclear pattern of ERG staining. Moreover, the expression of *EWS-FLI1* mRNA (qPCR) and the expression of t(11;22)(FISH) were clearly shown in the germinal tissues after cocultures. In OT and TT from children with Ewing sarcoma, we did not detect the expression of *EWS-FLI1* mRNA and did not observe Ewing cells by the histology methods.

Limitations, reasons for caution: The assessment of the method was performed by an *in vitro* model. An *in vivo* model by xenografting could be necessary to ensure the accuracy.

Wider implications of the findings: By our study, we demonstrated the high sensitivity and specificity of RT-qPCR to detect Ewing sarcoma minimal residual disease in human testicular tissue (TT) and ovarian tissue frozen by snap or slow freezing for fertility preservation. This is the first study to assess this measurement in TT.

Trial registration number: Clinical trial: NCT 02400970.

P-513 Texture profile analysis reveals a stiffer ovarian cortex after testosterone therapy

C. De Roo[1], K. Tilleman[1], C. Vercruysse[2], H. Declercq[2], G. T'Sjoen[3], S. Weyers[1], P. De Sutter[1]

[1]University Hospital Ghent UZ, Division of Reproductive Medicine- Department of Gynaecology, Ghent, Belgium
[2]Ghent University, Bioprint Core Facility- Tissue Engineering and Biomaterials, Department of Basic Medical Science- Faculty of Medicine and Health Science, Ghent, Belgium
[3]Ghent University Hospital, Department of Endocrinology and Center for Sexology and Gender, Ghent, Belgium

Study question: Does prolonged testosterone administration induce stiffness in the ovarian cortex?

Summary answer: An increased cortical stiffness in the most outer part of the ovarian cortex could be documented following prolonged testosterone administration in trans men.

What is known already: The importance of ovarian stroma in the development and maturation of follicles has recently gained attention. The ovarian stroma does not only contribute to the structural support of the growing follicle, but also to the bidirectional paracrine communication between the oocyte and surrounding somatic cells, thereby influencing folliculogenesis. An aberrant extracellular matrix has been described in ovaries of patients with polycystic ovary syndrome (PCOS) where a more rigid structural environment, possibly induced by endogenous testosterone, impairs normal folliculogenesis. In this context, the effect of prolonged administration of testosterone on the ovarian cortex in female to male transgender persons was studied.

Study design, size, duration: Texture profile analysis (TPA) was performed on ovarian cortex of oncological (N = 3) and transgender patients (N = 3). A total of 34 frozen-thawed cortical strips (5 × 5 mm,) were subjected to TPA in order to measure stiffness, hardness, cohesiveness and springiness of the ovarian cortex (LRXplus universal testing system). Statistical analysis was performed using repeated measurements mixed models and the Spearman's rank order correlation test (IBM SPSS Statistics 23).

Participants/materials, setting, methods: Ovarian tissue was obtained of 3 oncology patients (25.00 + 3.61 years) (11 strips) and 3 transgender men (22.67 + 2.08 years) (23 strips). Oncological indications for fertility preservation comprised acute lymphoblastic lymphoma, breast cancer and acute myeloid leukemia. All trans men received intramuscular testosterone undecanoate 1000 mg every 12 weeks during 80.72 + 32.24 weeks. Cortical strips were compressed over a distance of 50% of the original sample thickness during 2 cycles.

Main results and the role of chance: A typical TPA double compression curve of ovarian cortex is characterized by a slower upstroke in the toe region, where increasing compression resulted in a steeper upstroke prior to the peak. Release of the maximum compression causes an immediate drop in the TPA curve. Typically a bigger first curve was noted, when compared to the second curve (Peak 2 < Peak 1), reflecting an incomplete recovery of the tissue post compression, probably as a result from the breaking points seen in the first upstroke. There was no difference in fragment thickness comparing tissue fragments originating from transgender (1.43 + 0.46 mm) and oncology (1.38 + 0.38 mm) patients (p = 0.826). The most outer part of cortex fragments of ovaries originating from transgender persons (fragments < 1.4 mm; N = 10) were significantly stiffer compared to the superficial area of ovarian cortex derived from oncology patients (N = 7) (p = 0.036).

Limitations, reasons for caution: TPA is applied in biomaterial industry to determine textural properties of foods, gels and pharmaceutical matrices. This is the first application of TPA in ovarian tissue, requiring optimization of the compression protocol. Future experiences in TPA on human tissue samples might contribute to optimization and lead to a standardized setup.

Wider implications of the findings: If increased cortical stiffness impairs folliculogenesis, it is advisable to interrupt testosterone prior to fertility preservation. Also, if aiming for *in vitro* follicle activation through Hippo signaling disruption, an adapted technique for tissue preparation is necessary. Last, these TPA parameters enable to optimize biomaterial characteristics in artificial ovary engineering.

P-514 Controlled ovarian stimulation applied before ovarian cortex cryopreservation does not impact tissue histological aspect

V. Puy[1], M. Bendayan[1], A. Mayeur[1], L. Hesters[1], S. Prevot[2], M. Grynberg[3], N. Frydman[1]

[1]University hospital Antoine-Béclère- AP-HP, Reproductive Biology Unit, Clamart, France

[2]University hospital Antoine-Béclère- AP-HP, Pathology, Clamart, France
[3]University hospital Antoine-Béclère- AP-HP, Reproductive medecine & fertility preservation, Clamart, France

Study question: Is there an impact of controlled ovarian stimulation (COS) on the histological aspect of ovarian tissue cryopreserved for fertility preservation (FP)?

Summary answer: COS applied before ovarian tissue cryopreservation (OTC) allows optimizing the number of metaphase 2 oocytes vitrified when compared with IVM, without detrimental histological effect.

What is known already: Vitrification of in vitro matured oocytes (IVM) has been proposed in combination with OTC as a method for urgent female fertility preservation. However, both IVM and ovarian tissue transplantation remains experimental contrary to oocytes vitrification following COS. When COS is feasible in contexts of highly gonadotoxic treatment, vitrification of in vivo matured oocytes may be considered before OTC. However, the impact of ovarian stimulation on histological aspects of the ovary has never been described.

Study design, size, duration: This observational retrospective study conducted from 2009 to 2016 aimed to compare the histological aspect of ovarian tissue removed on the day of oocyte retrieval performed on stimulated (group 1, n = 13) or unstimulated (group 2, n = 12) ovaries. The number of metaphase 2 oocytes vitrified was also analyzed in both groups.

Participants/materials, setting, methods: Twenty-five cancer patients referred in our center for OTC before highly gonadotoxic chemotherapy were prospectively studied. Ovarian tissue was removed laparoscopically immediately after oocyte retrieval. The latter was performed after COS when feasible or from unstimulated small antral follicles. A sample of ovarian tissue was systematically addressed for pathological analysis.

Main results and the role of chance: Patient's age was similar between groups 1 and 2 (24.0 ± 6.2 versus 27.4 ± 6.3 respectively; p = 0.18). Histological aspects of ovarian tissue as well as the number of primordial follicles per mm^2 were similar between both groups. The total number of cumulus-oocyte complexes (COC) obtained in group 1 was 155 (mean 11.9 ± 5.7) and 122 (mean 8.6 ± 7.8) were vitrified. In group 2, 103 COCs were recovered (mean 9.4 ± 4.4), leading to 66 vitrified oocytes (5.5 ± 6.2) after an IVM rate of 64%.

Limitations, reasons for caution: Although our preliminary results are reassuring, histological data after thawing and further outcome after transplantation are lacking.

Wider implications of the findings: The competence of frozen-thawed ovarian tissue removed following COS constitutes an important issue. If it remains intact, oocytes vitrification after ovarian stimulation will have to be systematically considered before OTC, since this method is dramatically superior to IVM in terms of chances of pregnancy.

Trial registration number: Not required.

P-515 Dual In Vitro Maturation (Dual-IVM): an innovative fertility preservation strategy to increase the total number of cryopreserved oocytes when ovarian stimulation is unfeasible

N. Sermondade[1], C. Sonigo[2], C. Valdelièvre[2], M. Comtet[2], C. Sifer[1], M. Grynberg[2]

[1]Hôpital Jean Verdier, Histologie-Embryologie-Biologie de la Reproduction-CECOS, Bondy, France
[2]Hôpital Jean Verdier, Médecine de la Reproduction et Préservation de la Fertilité, Bondy, France

Study question: Is it feasible to perform within a short time frame two successive immature oocyte retrievals for fertility preservation (FP), especially during the same menstrual cycle?

Summary answer: Dual-IVM can be performed within a few days of interval to increase the total number of mature oocytes cryopreserved for urgent FP.

What is known already: Oocyte vitrification after IVM may constitute an alternative option for FP when controlled ovarian stimulation (COS) is unfeasible. Recent data reported that 8 to 20 cryopreserved oocytes are required to achieve reasonable success in healthy women. Since the competence of IVM oocytes is unknown, it is likely that the number of oocytes needed to obtain a pregnancy would be higher than that after COS. Combination with OTC has been proposed as an option to improve FP effectiveness. However, in women rejecting OTC, the strategy to be adopted for increasing the total number of cryopreserved oocytes can be questioned.

Study design, size, duration: Eighteen breast cancer patients, candidates for FP and presenting contraindication to COS for oncologic reasons, were prospectively included. All were offered ovarian tissue cryopreservation (OTC) combined with oocyte vitrification following IVM, and chose IVM only. They were systematically advised on reconsidering OTC and on the possibility of a second IVM cycle (IVM2), if these procedures did not require chemotherapy postponement.

Participants/materials, setting, methods: We hereby report a case-series of 18 breast cancer patients having undergone 2 successive cycles of IVM before initiation of chemotherapy. Cumulus-oocyte complexes (COC) were recovered under ultrasound guidance, and incubated 24-48 hours for IVM. Metaphase II oocytes were vitrified. When OTC was associated with IVM2, transvaginal oocyte retrieval was performed prior to laparoscopy. Outcomes of first and second IVM cycles (IVM1 and IVM2) were compared using Wilcoxon matched-paired signed rank test.

Main results and the role of chance: Median time interval between both IVM cycles was 24.5 days (ranging from 3 to 92 days). The mean number of COCs retrieved did not differ significantly between IVM1 and IVM2 (6.7 ± 2.9 *vs.* 7.1 ± 5.4 oocytes, respectively, NS). Maturation rates were not different (62 ± 23 % *vs.* 51 ± 34%, NS), leading to a similar number of metaphase II oocytes cryopreserved during IVM1 and IVM2 cycles (3.8 ± 2.6 *vs.* 4.0 ± 4.2, respectively, NS). IVM2 outcomes did not differ when it was performed during the same (n = 11/18) or different (n = 7/18) menstrual cycle than IVM1. No complication was reported during IVM1 or IVM2. Finally, performing IVM1 + IVM2 significantly increased the total number of oocytes vitrified *per* patient when compared with IVM1 alone (7.7 ± 5.7 *vs.* 3.8 ± 2.6, respectively, p < 0.001).

Limitations, reasons for caution: This study was conducted in a limited number of patients and further analysis will be required to confirm our preliminary results. In addition, the outcome of *in vitro* matured oocyte after thawing remains unknown.

Wider implications of the findings: Threshold values of cryopreserved IVM oocytes to achieve a live birth should be defined in order to assess the relevance of iterative oocyte collections.

Trial registration number: N/A.

P-516 Are Adolescents and young adults lymphoma patients less susceptible to chemotherapy than patients over 25 years old? Results of systematic prospective AMH levels follow-up

J. Bertrand-Delepine[1], G. Robin[2], D. Dewailly[2], F. Morschhauser[3], P. Pigny[4], C. Decanter[2]

[1]Hopital Jeanne de Flandre, Service de Médecine de la Reproduction et de Préservation de la fertilité, Lille, France
[2]University Hospital, Reproductive Medicine Center and Fertility Preservation, Lille, France
[3]University Hospital, Department of hematology, Lille, France
[4]University Hospital, Laboratory of endocrinology- Parc Eurasanté, Lille, France

Study question: To prospectively evaluate the influence of age and chemotherapy regimen on the longitudinal blood AMH variations in young lymphoma patients to elaborate fertility preservation strategies.

Summary answer: Adolescents and young adults (AYA) (15-24 years old) are less susceptible to chemotherapy than non-AYA (25-35 years old) even in case of alkylating regimen.

What is known already: Anti-Müllerian hormone (AMH) is now well-recognized to be a real-time indicator of growing follicle depletion and recovery in women treated by chemotherapy. Its longitudinal variations may discriminate between strong and soft protocol regarding the ovarian toxicity. It has been shown, mainly in breast cancer patients, that age, type of chemotherapy regimen and pre-treatment AMH levels are the main predictor of the ovarian recovery. Data on lymphoma are scarce but gives the opportunity to investigate the longitudinal AMH variations under chemotherapy at a younger age than breast cancer patients.

Study design, size, duration: Prospective monocentric observational study in the Fertility Observatory of the Lille University Hospital. Data were collected between 2007 and 2014. Non-Hodgkin or Hodgkin lymphoma patients (n = 122) between 15 to 35 years old were prospectively recruited before commencing chemotherapy. Patients were treated either by a non-alkylating protocol (non-alkylating group, ABVD; n = 67) or by an alkylating one (alkylating group; n = 55)P.

Participants/materials, setting, methods: Serial AMH measurements were performed at baseline (AMH0), 15 days after the start of chemotherapy (AMH1), 15 days before the last cycle (AMH2) and every 3 months from the end of chemotherapy until time + 24 months.

AMH variations were studied by ANOVA in the overall population according to the chemotherapy protocol. Then the study population was divided into 2 groups according to age: 65 AYA and 57 non-AYA.

Main results and the role of chance: Ovarian recovery in the non-alkylating group was complete and fast whereas no patients in the alkylating group recovered their initial pre-treatment value. There was no difference between the AYA and non-AYA groups regarding AMH 0 and the pattern of follicular depletion.

During the recovery phase, AMH levels re-increased more rapidly in the AYA group than non-AYA-group.

In AYA-group, the recovery phase is very fast and complete in non-alkylating group but progressive and partial in alkylating group. Only AMH+12 and AMH +24 were statistically different from AMH2 and all the serum AMH levels after chemotherapy remained different from AMH0 ($p<0,0001$).

In the non-AYA-group, the recovery phase is more progressive in the non-alkylating group. In alkylating group, serum AMH levels after chemotherapy remain low and not statistically different from AMH2.

AYA and non-AYA patients who received an alkylating protocol never recovered pre-treatment AMH values unlike those treated by a non-alkylating one. AYA patients treated by alkylating protocol highlighted higher levels of AMH during the recovery phase than non-AYA patients.

Limitations, reasons for caution: Large disparity in chemotherapy protocols in the alkylating group. The average duration of chemotherapy for patients treated with alkylating protocol was longer than treated with non-alkylating protocol.

Wider implications of the findings: These results allow for the first time developing evidence-based strategies for fertility preservation according to age and type of protocol in a large series of young lymphoma patients.

Trial registration number: DEC2015-112 and DC-2008-642

P-517 Identification and efficiency assessment of potential miRNAs targets for developing new pharmacological drugs against chemotherapy induced ovarian damage using mice model

C. Alexandri[1], I. Demeestere[2], B. Stamatopoulos[3], F. Rothe[4]

[1]*University Hospital Erasme, Research laboratory in human reproduction, Brussel, Belgium*
[2]*Université Libre de Bruxelles- Belgium- Hospital Erasme, Research Laboratory in Human Reproduction, Brussels, Belgium*
[3]*Université Libre de Bruxelles- Belgium, Laboratory of Clinical Cell Therapy, Brussels, Belgium*
[4]*Université Libre de Bruxelles- Belgium, Heuson Breast Cancer Translational Research Laboratory, Brussels, Belgium*

Study question: Can miRNA replacement approaches be used to develop a new adjuvant protective therapy to reduce chemotherapy induced ovarian damage?

Summary answer: Amongst several identified miRNAs that rapidly response to chemotherapy exposure, replacement of the selected miRNA, let-7a is feasible and efficient to reduce chemotherapy-induced ovarian damage.

What is known already: Cancer treatments as cyclophosphamide and its active metabolite, 4- hydroxycyclophosphamide can cause primordial follicle activation, apoptosis and ovarian reserve depletion. As these therapies negatively influence the ovarian function, fertility preservation is recommended. Today, several miRNA-based therapeutics have reached clinical trials, in oncology landscape. Several studies also indicate that miRNAs have a key role in follicle development as they can regulate the follicular growth, atresia and steroidogenesis. Last, miRNAs are involved in DNA-damage response, apoptosis and they can be themselves modulated during chemotherapy exposure which contributes to minimize the off-target toxicity.

Study design, size, duration: Postnatal day 3 ovaries (PND3) from C57blxCBAF1 hybrid mice were cultured under control and treated conditions-exposed to 4-hydroxycyclophosphamide (4-HC, 20μM, 1 or 24 h). Six ovarian samples (3/condition) were used for the miRNA expression profiling while 20 and 24 samples were used for the validation of miRNA levels after 1 and 24 h exposure to 4-HC respectively. Forty ovarian samples were used in mimic transfection experiments (10/condition: control, control with mimic-miRNA-transfected, 4-HC alone, 4-HC with mimic-miRNA-transfected).

Participants/materials, setting, methods: TaqMan Low Density Arrays were used for miRNA expression profiling. Custom Cards and QPCR -assays validated the differently expressed miRNAs. A functional annotation clustering was performed on DAVID database. A liposome-based system was used to deliver selected mimic-let7a into ovaries. After 48 h of mimic-transfection (plus 1 h exposure to 4-HC in treated samples), the efficiency was confirmed by fluorescence microscopy. The expression of the target genes was evaluated by QPCR. The apoptosis was also assessed.

Main results and the role of chance: The expression profiling of 384 miRNas in PND3 ovaries, revealed that miRNAs are differently expressed after chemotherapy exposure. Amongst 245 expressed genes, 74 stayed stable, 81 were upregulated and 40 downregulated after 1 h/4-HC/20 μM exposure. A set of these miRNas was selected for further validation. We found that mir-10a-5p, mir-146a-5p, mir-34a-5p, miR-494 and let-7a were significantly expressed. Then, we chose to focus on miR-10a and let-7a because they presented a stable and profound downregulated profile in all miRNA profiling assays. Moreover, their target genes are involved in DNA damage response, apoptosis and cell proliferation, based on functional annotation clustering results. As the let-7a is downregulated, we used a liposome-based system to deliver a mimic-let7a in PND3 ovaries in vitro. We evaluated the safety and efficiency of this transfection system and we found that we can successfully deliver the mimic-miRNA without causing significant apoptosis in the ovaries. The overexpressed let-7a was confirmed after transfection and was able to prevent the upregulation of the selected mRNA targets in response to chemotherapy, as genes involved in apoptosis (FASL, Bax) and in cell growth (STAT3). The potential protective effect of mimic-let7a will be confirmed by follicular count-follicle activation, DDR and apoptosis analysis.

Limitations, reasons for caution: The mimic-miRNA was delivered in vitro using the Lipofectamine/RNAiMAX in whole ovaries, avoiding dissection which could trigger the spontaneous follicle activation. Efficiency of the transfection could vary from one experiment to the other. Results must be confirmed in vivo using appropriate delivery system.

Wider implications of the findings: We identified several miRNAs target molecules involved in crucial cellular pathways during chemotherapy damage. By reducing chemotherapy-induced apoptosis, the mimic-let7a could be used for ovarian protection during treatment. Let-7a, may also affect pathways involved in follicle activation like PI3K/AKT, opening a new research area in fertility preservation by pharmacological protection.

Trial registration number: Not applicable.

P-518 Factors associated with the reproductive potential of vitrified-warmed, autologous oocytes derived from elective oocyte cryopreservation cycles

L. Sekhon[1], C. Hernandez-Nieto[2], D. Gounko[2], M.C. Whitehouse[2], J.A. Lee[2], M.J. Duke[2], C. Briton-Jones[2], B. Sandler[1], A.B. Copperman[1]

[1]*Reproductive Medicine Associates of New York / Icahn School of Medicine at Mount Sinai, Reproductive Endocrinology and Infertility, New York, U.S.A.*
[2]*Reproductive Medicine Associates of New York, Reproductive Endocrinology and Infertility, New York, U.S.A.*

Study question: What clinical factors are associated with optimal cryopreserved oocyte survival, fertilization, embryo culture, and transfer outcomes?

Summary answer: The outcome of autologous oocyte vitrification-warming cycles is optimized in younger patients who undergo transfer of blastocyst-stage embryos.

What is known already: In order to protect against the age-related fertility decline, women electively undergo oocyte cryopreservation to enhance their ability to conceive when they are ready. While enhancements in cryopreservation methodology, including vitrification techniques, have demonstrated the efficacy of elective oocyte cryopreservation as a means of fertility preservation, a relatively small proportion of women have returned to utilize their vitrified oocytes. Current data related to efficacy is limited to extrapolations from hypothetical models and case series. Given the paucity of experience, physicians seek prognostic information to guide and counsel patients and manage expectations regarding the likelihood of success from vitrified-warmed oocytes.

Study design, size, duration: This retrospective cohort study includes 1197 patients who underwent 1396 oocyte vitrification cycles, from 2010 to 2017. One hundred and eleven patients (9.3%) returned for oocyte warming (n = 118) and treatment. Fresh (n = 52) and frozen (n = 39) transfers of cleavage (n = 37) or blastocyst stage (n = 54) embryos were observed. Over half of the patients (52.3%) who warmed their oocytes were successful in creating embryos eligible for preimplantation genetic testing (PGT), that were then vitrified for future use.

Participants/materials, setting, methods: Patients presented to a private IVF clinic for elective oocyte cryopreservation. Cycles in which autologous, vitrified oocytes were warmed (n = 118) were analyzed using multivariate linear and binary logistic regression models to assess patient demographics (age, BMI, and AMH); and treatment related factors (number of oocytes cryopreserved) associated with oocyte survival and clinical outcome. The influence of these factors and the treatment approach (i.e. PGS, frozen embryo transfer (FET)) on embryo transfer success was determined.

Main results and the role of chance: One thousand and fifteen oocytes were thawed and fertilized using ICSI. Of the fertilized oocytes, 63.3% reached the cleavage stage, and 39.0% reached the blastocyst stage. Chemical and clinical pregnancies were achieved in 52.7% (n = 48/91) and 41.8% (n = 38/91) of cycles, respectively. Increased oocyte age (b = -0.6, p = 0.0003) and decreased AMH (b = -1.4, p<0.0001) reduced the number of oocytes available for warming, but not the rate of survival. Controlling for age, each additional oocyte warmed was associated with an increase in the rate of oocyte survival (b = 0.007, p = 0.04), embryos reaching the cleavage (b = 0.008, p = 0.01) and blastocyst stage (b = 0.008, p<0.0001) and being amenable to PGT (OR 1.182 [95% CI 1.051-1.33], p = 0.005) and vitrification (OR 1.212 [95% CI 1.048-1.403], p = 0.009). Oocyte age (b=-0.02, p = 0.02) and AMH (b = 0.05, p = 0.03) modified the rate of blastulation. The odds of having an embryo available for fresh transfer was independent of age, AMH or the number of oocytes warmed. Controlling for confounders (age, AMH, BMI, oocytes warmed, embryo stage, PGT, FET, embryos transferred and endometrial thickness), clinical pregnancy rate was negatively impacted by increased oocyte age (OR 0.78 [95% CI 0.60-1.01], p = 0.059) and transfer of cleavage embryos (OR 0.10 [95% CI 0.01-1.05], p = 0.05).

Limitations, reasons for caution: This analysis is retrospective and subject to confounding bias. Prospective randomization of patients to various treatment approaches (ie. transfer of day 3 vs. day 5 and screened vs. unscreened embryos) would ultimately validate our findings and define the optimal strategy for patients utilizing vitrified-warmed oocytes.

Wider implications of the findings: Women desiring elective fertility preservation should be encouraged to vitrify their oocytes at a younger age to increase their probability of future pregnancy. When possible, zygotes from warmed oocytes should undergo extended culture and be transferred at the blastocyst stage to optimize embryo selection and improve clinical outcome.

Trial registration number: This study was approved by the Western Institutional Review Board (Study Number: 1167398).

P-519 Effects of natural honey, as a new cryoprotectant, on viability and genes expression of vitrified mouse blastocysts

P. Kazemi[1], M. Dashtizad[2], F. Sarmadi[2], S. Fayazi[2], S. Esfandiari [2], P. Tirgar Bahnamiri[3], L. Sotoodeh[2]

[1]*McGill University, Department of Biology, Montreal, Canada*
[2]*National Institute of Genetic Engineering and Biotechnology NIGEB, Animal Biotechnology, Tehran, Iran*
[3]*McGill University, Biological and Biomedical Engineering, Montreal, Canada*

Study question: To investigate if natural honey can be used instead of sucrose to optimize the vitrification procedure of mouse blastocysts.

Summary answer: Natural honey with a wide range of monosaccharides, disaccharides and antioxidants can be proposed as a cryoprotectant to reduce the cellular stress caused by vitrification.

What is known already: Profound understanding of cryobiology has led to novel protocols for vitrification of blastocysts in terms of media composition. It has been demonstrated that a combined presence of permeating and non-prmeating cryoprotectants, both monosaccharides and disaccharides, can effectively increase the viability of vitrified embryos. Although these improvements resulted in high survival rates, other analyses on post warming blastocysts with normal morphology demonstrated a wide range of cellular and molecular impairments.

Study design, size, duration: The first part of the experiment was conducted to determine the optimum concentration of honey in vitrification (0.5, 1, 2 M) and warming solutions (thawing: 1, 2, 3 M; dilution: 0.5, 1, 1.5 M). The second part was designed to compare the effects of honey-based selected solutions and sucrose-based one on embryo quality.

Participants/materials, setting, methods: In vivo produced mouse blastocysts were vitrified as described by Kuwayama (Kuwayama et al., 2005) using mentioned solutions. After 12 h, vitrified blastocysts were compared with fresh blastocysts in terms of survival and hatching rate as well as the expression level of genes related to apoptosis (*Trp53*, *Bax*) and oxidative stress (*Sod2*).

Main results and the role of chance: The optimum concentrations of 1, 2 and 1 M were chosen for vitrification, thawing and dilution solutions, respectively. Our results showed a high survival rate for both treatment groups and control one. The hatching rate of vitrified blastocysts was significantly lower than fresh blastocysts (58.47%). However, no significant difference was found between sucrose-based and honey-based mediums (40.8% and 38.3%, respectively). Furthermore, real-time RT-PCR analysis data showed a reduction in the expression of *Trp53*, *Bax* and *Sod2* transcripts in the honey group (1.8-, 2.15- and 1.1-fold, respectively) compared to the sucrose group (6.15-, 2.83- and 4.05-fold, respectively).

Limitations, reasons for caution: The implantation and live birth rates are necessary to give a complete picture of natural honey effects during vitrification procedure.

Wider implications of the findings: Our study considered antioxidant properties of vitrification solutions as a new parameter for the success of the procedure.

Trial registration number: None.

P-520 Slow passive freezing for ovarian tissue shows comparable in vitro activation of primordial follicles with no difference in apoptosis compared to traditional controlled slow freezing

S. Lierman[1], K. Tilleman[1], R. Cornelissen[2], P. De Sutter[1]

[1]*Ghent University Hospital Ghent Fertility and Stem cell Team, Department for Reproductive Medicine, Gent, Belgium*
[2]*Faculty of Medicine and Health, Department of Basic Medical Science, Ghent, Belgium*

Study question: Is slow passive freezing (PSF) an alternative to the standard controlled slow rate freezing (CSF) of human ovarian tissue?

Summary answer: The PSF showed no loss on primordial follicle count, activation, apoptosis and cell proliferation compared to the traditionally CSF.

What is known already: Fertility preservation is an important issue in regard to the long-term quality of life. Cryopreservation of OT fragments is a strategy for fertility preservation for cancer patients. For the moment, CSF is the established method used to freeze cortical fragments of ovarian tissue. CFS requires expensive computerized equipment and the process is time-consuming. Moreover, there is a risk for technical failures with the potential loss of precious material. Several publications reported passive slow freezing (PSF) to be successful for testicular tissue of different animal species including for human testicular tissue (Goossens et al., 2013).

Study design, size, duration: OT strips (n = 50) from transgender patients (n = 10) were divided in 3 groups: (1)Fresh tissue; (2)CSF and (3)PSF. DMSO

(1.5 M) was used as cryoprotectant in both freezing protocols. CSF was performed with a programmable freezer including a manual seeding. For PSF, cryovials were placed in an isopropyl alcohol container in the -80°C freezer overnight allowing a cooling rate »-1°C/min. Samples were stored in LN. Strips were thawed, cultured for 2 h and for 2days (2d).

Participants/materials, setting, methods: OT strips were cultured individually in 24-well plates containing supplemented McCoy's 5a medium for 2 h and 2d at 37°C (6%O_2, 5%CO_2). The strips were fixed in 10% paraformaldehyde and embedded in paraffin. Histological sections were made for follicle count, apoptosis and cell proliferation analysis. Light microscopic evaluation was performed to study apoptosis by TUNEL en capsase-3 and cell proliferation PCNA and Ki67-staining. Statistical analysis (Wilcoxon Signed Ranks Test) was performed (SPSS vs23).

Main results and the role of chance: Both freezing procedures, PSF versus CSF, showed no loss in number of primordial follicle after 2 h of warming (54.6 ± 24.0% versus 64.1 ± 16.4%). The PSF technique, showed a significant higher amount of primary follicles when comparing the amount after 2 h and 2d of culture (30.3 ± 24.2% versus 66.1 ± 11.2% (P = 0.013)), indicating a clear activation of the follicles. This was also observed in the SRF (18.1 ± 11.2% versus 60.2 ± 15.5% (P = 0.005)). This activation shift was not significantly different between both techniques (Fisher's Exact p = 0.24). The PSF and CSF technique did not affect the apoptosis level of the oocyte nor the granulosa cells after 2d culture. There was no statistical difference in caspase-3 negative follicles after 2d of culture between PSF and CSF respectively (36.1 ± 27.4% versus 51.7 ± 33.7% for primordial follicles and 73.5 ± 22.1% versus 77.7 ± 19.9% for primary follicles). Likewise for the late apoptosis PSF versus CSF (89.2 ± 13.2% versus 73.4 ± 21.1% (TUNEL negative primordial follicles) and 80.2 ± 16.6% versus 77.9 ± 20.6% (TUNEL negative primary follicles)). For the cell proliferation PSF and CSF method showed comparable results after 2d of culture (14.5 ± 23.6% versus 13.7 ± 19.9% (PCNA positive primordial follicles and 23.1 ± 30.8% versus 18.4 ± 17.4% PCNA positive primary follicles)) and the ki67 positive staining (34.4 ± 34.1% versus 33.5 ± 35.3% (primordial) and 41.9 ± 22.1% versus 45.3 ± 24.3% (primary).

Limitations, reasons for caution: Further studies should be conducted to evaluate the true activation and maturation potential by xenotransplantation. It is also important to note, that these experiments should be repeated using OT from oncological patients as tissue characteristics might be affected by long term testosterone treatment in the OT of trans persons.

Wider implications of the findings: PSF could be an easy and cost-effective alternative to CSF for fertility preservation of ovarian tissue.

Trial registration number: This research is conducted with the approval of the local ethics committee 2015/0124 – B670201523543).

P-521 Autologous oocyte vitrification: outcomes assessment

D. Montjean, C. Geoffroy-Siraudin, M.J. Gervoise-Boyer, A. Amar-Hoffet, P. Boyer

Hopital Saint Joseph, Médecine et Biologie de la Reproduction, Marseille, France

Study question: Do maternal age and number of collected mature oocyte affect post-warming biological and clinical outcomes?

Summary answer: Oocyte survival and fertilization rates after vitrification and warming are not impaired in older patients and in patients with large number of mature oocytes collected.

What is known already: Autologous oocyte vitrification is widely proposed to women receiving ICSI treatment in our fertility centre in order to limit the number of embryos created. So far, few data have been published regarding post-warming outcomes of autologous oocytes as main studies on oocytes vitrification were conducted on donated eggs from young women. As both the number of oocytes collected at pick-up and patient age are known to affect oocyte quality, there is a need to evaluate the impact of these factors on biological and clinical outcomes after autologous oocyte vitrification and warming.

Study design, size, duration: This is a retrospective study conducted over a 6-year period. A total of 1217 autologous oocytes vitrification cycles were performed. This program allowed the cryopreservation of 8926 oocytes. To date, 1080 oocyte warming cycles were performed including 5153 oocytes.

Participants/materials, setting, methods: 970 women receiving ICSI treatment were proposed to vitrify a part of mature oocytes concomitantly to ICSI procedure on sibling oocytes. Oocytes were vitrified and warmed using Kitazato vitrification media and system. Post-warming oocyte survival rate (Number injected oocytes/Number of warmed oocytes), fertilization rate (Number of zygotes displaying 2PN/Number of injected oocytes) and early pregnancy rate per transfer (βHCG blood measurement>100UI/l) were assessed and compared between groups of age and number of collected mature oocytes.

Main results and the role of chance: The mean age of women included in the study is 32.8 years. They were divided into age groups and 3 groups based on the number of mature retrieved oocytes. Our data show that maternal age at vitrification doesn't affect post-warming survival rate (<30years: 84.3%, 30-35years:83.8%, >35years: 84.8%, p>0.05), nor fertilization rate (<30years:64.2%, 30-35years: 65.7%, >35years: 63.1%, p>0.05). However, as expected, women above 38 years have significantly lower chances to achieve a pregnancy than women under 30years (28.0% *vs* 16%, p = 0.003) but the difference observed between the other age group is not statistically significant (30-35years: 22.7%, >35years: 21.3%, p>0.05). The number of mature oocytes available after pick-up doesn't change survival rate (≤10: 83.9%, 11-15:84.6%, >15: 83.7%, p>0.05), fertilization rate (≤10: 62.8%, 11-15:64.5%, >15:63.8%, p>0.05), nor early pregnancy rate per transfer ((≤10: 22.4%, 11-15:20.8%, >15:19.6%, p>0.05). Finally, when looking at the different age groups described above, no correlation was found between survival/fertilization rates and number of mature oocyte at pick-up.

Limitations, reasons for caution: The major limitation of the study is potential confounding factors such as infertility factor, ovarian stimulation protocol and treatment used for endometrial preparation for oocyte warming cycle couldn't be taken into account.

Wider implications of the findings: Since we have shown that critical factors like maternal age and number of oocytes have no impact on post-warming biological outcomes, one can suggest that the cryopreserved oocytes that are not intended to be used could be allocated to oocyte donation program with the consent of the couple.

Trial registration number: Clinical Trials Registration number: 209 R02

P-522 UV irradiation of freeze-dried human sperm shows high DNA integrity as compared to conventionally frozen sperm

A. Arav[1], Y. Natan[2], P. Levi Setti[3], M. Leong[4], P. Patrizio[5]

[1]*Fertilesafe Ltd., R&D, Nes-Ziona, Israel*
[2]*Fertilesafe Ltd., Research and Development, Nes-Ziona, Israel*
[3]*Humanitas Fertility Center- Humanitas Research Hospital, Department of Gynaecology, Milan, Italy*
[4]*The Women's Clinic, The Women's Clinic, Hong Kong, Hong Kong*
[5]*Yale Fertility Center & Fertility Preservation, Obstetrics- Gynecology & Reproductive Sciences, New Haven, U.S.A.*

Study question: Is freeze-dried human sperm more resistant to UV irradiation than conventionally frozen?

Summary answer: Freeze-dried human sperm maintained a high DNA integrity compared to conventionally frozen sperm after UV irradiation.

What is known already: Recently, it was shown that mice sperm preserved in the dry state for 9 months in a space station and exposed to cosmic irradiation showed only minor DNA damages which were repaired by oocytes cytoplasm and resulted in normal offspring.

Study design, size, duration: Basic human experimental research using human sperm allocated to four different groups: (1) Fresh (2) Freeze-dried and rehydrated cells (3) Freeze-dried and irradiated prior rehydration. (4) Conventionally frozen and irradiated prior thawing. Each group contained 4 vials with a minimum of 10 drops. Drying duration was 48 hours. Dried samples were stored in vials at 4°C prior rehydration, and frozen samples were stored in vials in liquid nitrogen prior thawing.

Participants/materials, setting, methods: Sperm diluted 1:1 in lyophilization solution (LyoS). Freezing done by pipetting 10 µL drops into sterile liquid air (CLair, Fertilesafe, Israel). Freeze-drying done using a sterile drying device (Darya, FertileSafe, Israel) having a shelf temperature of -35°C and vacuum of

10mtorr. Samples were irradiated 30 min under a UV lamp. Rehydration was done using 0.2 mL/vial LyoS at 37°C, thawing was done on warm (37°C) microscopic slides. DNA integrity was evaluated using Halosperm G2kit (Halotech, Spain).

Main results and the role of chance: Fresh sperm concentration was $10•10^6$ cells/ml, motility was > 50% and DNA integrity was 81.06%±9.2%. Post thaw motility (after conventional freezing) was 65-80% of the fresh (normalized) same specimens. Rehydrated freeze-dried irradiated human sperm showed no significant cell loss $5•10^6$ cells/ml and no decrease in DNA integrity 84%±8.1%. After freeze-drying and rehydration cells concentration was $5.375•10^6$ cells/ml and DNA integrity was 81.3%±3.5%. The DNA integrity of the irradiated but conventionally frozen sperm was significantly lower, 9%±15% ($P<0.05$) and concentration was slightly lower $4.5•10^6$ cells/ml. Morphological analysis of irradiated conventionally frozen sperm was much different than the irradiated freeze-dried sperm displaying loss of tails and membranes and DNA showing larger halos. These results show that there was no cell loss and no additional damage to the DNA integrity due to the drying process and irradiation while at the dry state. Human sperm freeze-drying is a revolutionary technology that will allow long-term storage of sperm at room temperature and protection from UV irradiation.

Table 1 Summarizes the results of human sperm following freeze-drying, freeze thawing and irradiation.

Group	Sperm Concentration (cells/ml)	DNA integrity
Fresh control (undiluted)	$10 • 10^6$	81.06% ± 9.2%
Freeze-dried rehydrated	$5.375 • 10^6$	81.3% ± 3.5%
Freeze-dried irradiated	$5 • 10^6$	84% ± 8.1%
Frozen thawed irradiated	$4.5 • 10^6$	9% ± 15%*

*($p<0.05$)

Limitations, reasons for caution: Small number of samples and lack of data on embryonic development following ICSI.

Wider implications of the findings: These findings suggest that freeze-dried human sperm is more resistant to UV irradiation than frozen sperm. This may be due to a lesser amount of reactive oxygen species created in the dry state compared to the frozen state. Thus, freeze-drying may be preferred when storage conditions are less than optimal.

Trial registration number: N/A.

P-523 Follow-up of elective oocyte cryopreservation for age-related reasons: utilisation of vitrified oocytes and reproductive outcomes of women who return

E. Maes, J. Nekkebroeck, H. Tournaye, N. De Munck, M. De Vos

Universitair Ziekenhuis Brussel, Centre for Reproductive Medicine, Brussels, Belgium

Study question: What is the come-back rate and what are the reproductive outcomes of women who previously had their oocytes cryopreserved to anticipate age-related fertility decline?

Summary answer: Of all women who underwent elective oocyte cryopreservation, only 7.6% have so far returned to use these oocytes. Of those, 32.6% had an ongoing pregnancy.

What is known already: Oocyte vitrification has become an established and efficient technology, which has facilitated the practice of elective oocyte cryopreservation for women who defer motherhood and wish to anticipate age-related fertility decline, for various reasons. Little is known about the utilisation of the vitrified oocytes of these "social freezers" and their reproductive outcomes. Follow-up data of reproductive behavior and outcomes in these women are needed for a comprehensive appraisal of social freezing.

Study design, size, duration: We performed a retrospective observational single-centre follow-up study in a cohort of 563 women who underwent elective cryopreservation of oocytes to anticipate age-related fertility decline between January 2009 and November 2017.

Participants/materials, setting, methods: A total of 563 women underwent 902 ART cycles for oocyte vitrification. Data were collected from computerised clinical charts. We evaluated reproductive treatment choices in social freezers who returned, warmed oocyte survival rates, fertilisation rates, embryo quality, the use of donor sperm, pregnancy rates, and live birth rates.

Main results and the role of chance: Mean age at oocyte vitrification was 36.5 y [95% confidence interval (CI) 36.3–36.6]. A mean number of 8.5 [95% CI 8.1 –8.8] oocytes were vitrified per cycle. Seventy-two women (12.8%) returned to the clinic for reproductive treatment at the moment of writing. In 43% of them (31/72), donor sperm was used for artificial insemination or ICSI. 7.6% (43/563) of women requested to have their vitrified oocytes warmed for ART, at a mean age of 42.1 y [95% CI 41.5-42.7]. Their oocytes had been vitrified at a mean age of 38 y. They underwent 72 warming cycles in total; overall survival rate of warmed oocytes was 73.4 %. The fertilisation rate was 66.8% and 64 warming cycles resulted in a fresh embryo transfer. In total, 25.6% (11/43) patients had an ongoing pregnancy after oocyte warming and fresh embryo transfer; the ongoing pregnancy rate (OPR) was 32.6% (14/43). Of women who returned, 32 underwent ≥1 ART cycles with oocyte retrieval (69 cycles in total), at a mean age of 38.9 y [95% CI 37.9-39.9] and the OPR was 34.4%. Nineteen patients underwent artificial insemination (15 with donor sperm), of whom 26.3% (5/19) had a live birth. Three patients had a live birth after oocyte donation.

Limitations, reasons for caution: Due to the limited follow-up period, the return rate of social freezers is low and utilisation rates of cryopreserved oocytes are incomplete. Hence, the reproductive outcome of only a subset of social freezers is currently known. Of patients who returned for reproductive treatment, 40.3% have not used their vitrified oocytes.

Wider implications of the findings: The majority of social freezers who returned have found a suitable partner to pursue motherhood. Whether their previous decision to undergo oocyte cryopreservation has enhanced the probability of a live birth will require confirmation in larger follow-up studies.

Trial registration number: Non applicable.

P-524 Serum AMH as predictor of ovarian stimulation outcome among women undergoing oocyte cryopreservation prior to breast cancer treatment

I. Wikander[1], K.A. Rodriguez-Wallberg[2]

[1]Karolinska UNiversity Hospital, Reproductive Medicine, Stockholm, Sweden
[2]Karolinska University Hospital and Karolinska Institutet, Department of Reproductive Medicine and Oncology-Pathology, Stockholm, Sweden

Study question: Can AMH determination before hormonal stimulation in emergency fertility preservation for breast cancer help to evaluate the ovarian reserve and optimize the chance of a successful response?

Summary answer: AMH might not correlate with the ovarian reserve in patients with breast cancer prior to chemotherapy treatment, and novel biomarkers should be investigated.

What is known already: AMH is associated with the size of the follicle pool. In some studies AMH has shown to be predictive of the woman's ovarian reserve and the number of oocytes collected after hormonal stimulation. A successful fertility rescue treatment can be crucial for the woman´s future possibility of having biologically related children.

Study design, size, duration: Prospective cohort study between January 2012 and May 2016 of women with breast cancer that underwent a fertility rescue hormonal stimulation cycle in an antagonist protocol, with or without letrozole supplement, depending on their tumor estrogen receptor status, prior to chemotherapy. Stimulation started any day of their menstruation cycle, serum AMH was sampled before cycle start.

Participants/materials, setting, methods: A total of 124 women diagnosed with breast cancer were included, mean age 32,8 (range 21-42), mean BMI 23,0 (range 18-35). The mean AMH concentration was within normal ranges for age (mean 2,32 microgram/L, range 0,16-9,6). The majority of women were nulliparous. More than half (70 out of the 124 patients,56%) were on contraceptive pills at time of diagnosis.

Main results and the role of chance: There were only modest, non-significant correlations between age and AMH levels or between AMH levels and oocyte yield in the whole group. Possible explanatory variables were thus investigated. In the subset of 70 patients who had complete data on use of contraceptive pills at time of breast cancer diagnosis, sub-analysis indicated that patients who were on contraceptive pills and discontinued them at time of cancer diagnosis presented with significantly lower AMH levels than women who had not had contraceptives previously. However, women who were previously on contraceptive pills had a similar oocyte yield as women who were not on contraceptives.

Limitations, reasons for caution: Several clinicians planned and performed the stimulation of the patients and the retrieval of the oocytes. The time of the stimulation treatments varied between the patients and in some cases could not be prolonged due to planned chemotherapy initiation.

Wider implications of the findings: The predictive value of AMH determination before hormonal stimulation in emergency fertility preservation for women in breast cancer is still debatable. Measurements of serum AMH concentrations to evaluate ovarian reserve previously to fertility preservation might not correlate with the outcome in all patients with breast cancer.

Trial registration number: non-applicable

P-525 Serial serum cell- free DNA (cfDNA) quantification in lymphoma and breast cancer patients before and after chemotherapy: is there a link with the ovarian function?

C. De Canter[1], P. Pigny[2], S. El Moghrabi[3], D. Haouzi[3], S. Hamamah[4]

[1]*Hopital Jeanne De Flandre, reproductive medicine, Lille Cedex, France*
[2]*Laboratoire de Biochimie Hormonologie HMNO- Centre de Biologie Pathologie-CHRU Lille, Inserm- UMR-S 1172- F-59000 Lille, Lille, France*
[3]*Inserm U1203- IRMB, Hôpital St-Eloi- CHU Montpellier, Montpellier, France*
[4]*Service de Biologie de la Reproduction- Hôpital Arnaud de Villeneuve- CHU Montpellier, ART/PGD Department, Montpellier, France*

Study question: Can longitudinal study of serum cf-DNA levels serve to predict the recovery of the ovarian function after chemotherapy in different type of cancer?

Summary answer: Serum cf-DNA level can be used as a non-invasive promising prognostic biomarker to evaluate and predict ovarian reserve in hodgkin lymphoma and breast cancer patients.

What is known already: cf-DNA can be quantified in small amounts in serum resulting from the release of genetic materials from apoptotic/necrotic cells. Serum cf-DNA can serve to cancer diagnosis but also in predicting response to treatment. It still unclear the oocyte quality during fertility preservation procedures in the cancer area. Recently, cf-DNA has been shown to be significantly correlated to the oocyte as well as the embryo quality, suggesting that it may serve as an innovative and a non-invasive objective biomarker of the microfollicular environment and oocyte quality.

Study design, size, duration: 46 and 37 serum samples were obtained from five hodgkin lymphoma patients (mean age: 24.3 ± 1.8 years) and five breast cancer patients (mean age: 36.5 ± 1.8 years) respectively. All patients were prospectively recruited before initiation of the chemotherapy. Serum cf-DNA quantification and AMH measurements were performed at baseline, 15 days after the first cycle, 15 days before the last cycle and every 3 months after the end of chemotherapy until time 24 months.

Participants/materials, setting, methods: We performed cf-DNA qRT-PCR using Alu-115 (detecting both necrotic and apoptotic DNA) primers to evaluate serum cf-DNA level.

Main results and the role of chance: Our preliminary results revealed that the cf-DNA concentration was significantly higher in serum from breast cancer compared with Hodgkin lymphoma patients (Alu-115 mean ± SEM: 788.9 ± 129.5 vs 383.7 ± 99.6 $fg.\mu l^{-1}$, t-test $p = 0.08$). At baseline, serum AMH concentrations were 33.1 ± 9.8 and 24 ± 13.9 ng/ml (mean ± SEM) in hodgkin lymphoma and breast cancer patients, respectively. AMH concentration decreased significantly 15 days and 6 months after the first chemotherapy cycle in hodgkin lymphoma (6.7 ± 2.1 ng/ml, $p = 0.03$) and breast cancer patients (3 ± 0.03 ng/ml, $p = 0.05$), respectively. 18 months pos-chemotherapy treatment, AMH concentration remained stable in breast cancer patients (2.3 ± 0.9 ng/ml) while a tendency toward an increase of AMH concentration was observed (13.1 ± 5 ng/ml) in hodgkin lymphoma patients. Meanwhile, Cf-DNA concentration dramatically decreased 15 days after chemotherapy treatment in hodgkin lymphoma patients compared at baseline measure (441.2 ± 141.6 vs 1031.9 ± 719.7 $fg.\mu l^{-}$), and thus, until 18 months post-treatment (295 ± 141.6 $fg.\mu l^{-}$) although the tendency was not significant. In the breast cancer patients, there is no significant or tendency before, during and after chemotherapy treatment. As cf-DNA concentration has been reported to be negatively correlated to follicular size and embryo quality, our cf-DNA results question about cryopreserved oocytes quality in breast cancer and hodgkin lymphoma patients.

Limitations, reasons for caution: The few number of samples and patients and the heterogeneity of chemotherapy regimen in lymphoma patients.

Wider implications of the findings: This finding opens new perspectives in cancer patient care especially for fertility preservation program and counselling. cf-DNA may serve as a non-invasive objective biomarker of cryopreserved oocytes quality.

Trial registration number: CHACRY-1501.

P-526 Preliminary human application of optical coherence tomography for quantification and localization of primordial follicles aimed at effective ovarian tissue transplantation

S. Takae[1], K. Tsukada[2], Y. Sato[1], N. Okamoto[1], I. Maeda[3], Y. Motani[2], Y. Takahashi[1], S. Sawada[1], H. Iwahata[1], C. Nishijima[1], N. Yoshioka[1], Y. Sugishita[1], Y. Horage[1], N. Suzuki[1]

[1]*St. Marianna University School of Medicine, Obstetrics and Gynecology, Kawasaki-Kanagawa, Japan*
[2]*Keio University, Graduate School of Fundamental Science and Technology, Kawasaki city, Japan*
[3]*St. Marianna University School of Medicine, Pathology, Kawasaki- Kanagawa, Japan*

Study question: Is it possible to apply optical coherence tomography (OCT) intend for effective ovarian tissue transplantation with assessment numbers and localization of follicles on ovarian tissue?

Summary answer: OCT may detect primordial follicles non-invasively on fresh human and mice ovary coincident with ovarian reserve test.

What is known already: Primordial follicles in fixed and embedded human and bovine ovarian tissue could be detected using the current full-field OCT (FF-OCT) system. Although, in terms of effect for viability, non-invasiveness of near-infrared ray (NIR) used for OCT was indicated by glucose uptake assay and neutral red staining with bovine ovarian tissue, there are no reports about affect of OCT for oocyte to prove the reproductive ability including outcome of in vitro fertilization (IVF).

Study design, size, duration: To assess of NIR irradiation effect for oocytes, day3 mice were assigned to 4 groups: control (n = 3), 60 mW (n = 3), 110 mW (n = 4), 250 mW (n = 5). Also, to assess the affect of OCT for IVF, day 3 mice ovaries were assigned to with/without OCT group (n = 15, n = 10 respectively). The clinical study was conducted in four patients who received ovarian tissue cryopreservation from May 2016 to February 2017. Present studies were performed with informed consent and IRB approval.

Participants/materials, setting, methods: Fresh ovaries from each life stage mice were examined. And to confirm non-invasiveness of OCT, outcomes of IVF were compared among follicles from mice ovaries irradiated stepwise NIR. Also, day3 mice ovaries with/without OCT were transplanted under kidney capsule of host mice. Two weeks later, outcome of IVF with transplanted ovaries were examined. Additionally, newborns were bred and mated. Finally, OCT examination was performed using human ovary tissues. And follicle count using OCT was performed.

Main results and the role of chance: The standard OCT images were established including primordial follicle. And stepwise NIR irradiation (60-250 mW/cm^2) did not affect for IVF outcome (fertilization rate $p = 0.86$-1.00,

Blast cyst rate p = 0.86-1.00). Also, OCT examination did not affect for IVF outcome of transplanted ovaries (number of extracted oocytes p = 0.29, fertilization rate p = 0.35). Furthermore, all of newborns were shown normal appearances including reproductive ability. In the clinical study, three patients were received ovarian tissue cryopreservation for hematological disease as fertility preservation, and a patient received ovary extraction for in vitro activation intend for childbearing. Finally, OCT images of human ovary were well-accorded with histological images and ovarian reserve test on adult patients. While, OCT imaging detected primordial follicles fresh ovarian tissue from child patients (15 and 11 years-old) with unevaluable ovarian reserve by anti-Müllerian hormone and follicle stimulating hormone levels. As the result of follicle count, there were no significant differences between histology and OCT (p = 0.98).

Limitations, reasons for caution: The scanning area of commercial optical coherence tomography equipment is too small, and the scanning depth is insufficient. Therefore, it is presently difficult to assess actual ovarian reserve and follicle distribution using existing instrumentation. For the application for ovarian tissue transplantation, optimization of the OCT system is needed.

Wider implications of the findings: OCT holds the possibility for assessment of actual ovarian reserve and follicle distribution on each ovarian tissue. The selection of most suitable ovarian tissue using OCT may promote the development of effective ovarian tissue transplantation.

Trial registration number: The registraion numbers of present studies were No. 470 and 471(animal study) and UMIN000023141- No.3311 (clinical study) under IRB of St. Marianna University.

P-527 Towards fertility preservation for prepubertal boys – The role of gonadotrophins on functional maturation of Leydig and Sertoli cells in immature human testis xenografts

M. Hutka[1], P. Kadam[2], D. Van Saen[2], E. Goossens[2], R. Mitchell[1]

[1]University of Edinburgh, MRC Centre for Reproductive Health, Edinburgh, United Kingdom

[2]Vrije Universiteit Brussel, Biology of the Testis- Research Laboratory for Reproduction- Genetics and Regenerative Medicine, Brussels, Belgium

Study question: We investigated whether gonadotrophin (hCG + FSH) administration promotes germ, Sertoli, and Leydig cell development in xenotransplanted immature human testis tissue for purposes of fertility preservation.

Summary answer: Sertoli cell maturation was induced or maintained in xenografts, whilst induction of steroidogenesis required gonadotrophin administration. Germ cell differentiation did not occur in xenografted tissues.

What is known already: For prepubertal boys facing gonadotoxic (e.g. chemotherapy, radiotherapy) treatments that are likely to result in sub/infertility, there are no established options to preserve their fertility. Whilst testicular tissue may be obtained and cryopreserved prior to treatment, no clinical applications have been developed to use this tissue to restore fertility. Transplantation of immature testis tissue into adults of several species has provided a proof of principle that grafting of tissue can generate gametes capable of producing progeny. However, the factors required to functionally mature immature human testis tissue to produce gametes have not yet been determined.

Study design, size, duration: Prospective laboratory study using immature human testis tissue obtained from boys (n = 3) undergoing testicular biopsy prior to gonadotoxic treatment for fertility preservation. Tissue was obtained with informed consent for clinical cryostorage and research purposes. Ethical approval was obtained from the Local Research Ethics Committee. Host mice xenografted with testicular tissue pieces were exposed to vehicle or treatment for 12wks prior to analysis by immunohistochemistry with quantification of cellular development and function.

Participants/materials, setting, methods: Testicular tissues from three boys (8, 13 and 14 yrs) were xenografted intratesticularly into immunocompromised castrate mice (n = 12). Hosts received subcutaneous injections of vehicle or gonadotrophins (hCG, 20IU, FSH, 12.5IU), 3× weekly for 12wks. Retrieved grafts were double immunostained for VASA, MAGEA4 (germ cell), SOX9 (Sertoli cell), Androgen Receptor (AR, mature Sertoli cell), Anti-Mullerian Hormone (AMH, immature Sertoli cell), CYP11a1 (Leydig cell - steroidogenic marker) and Ki67 (proliferation marker). Results analyzed by two-factor ANOVA.

Main results and the role of chance: Testicular tissue structure and histological appearance was maintained in xenografts. Administration of hCG/FSH was required to induce steroidogenesis (CYP11A1) in Leydig cells of xenografted tissue from one patient (8 yrs), whilst for the two remaining patients (13 and 14 yrs), steroidogenesis was maintained only in the hCG/FSH-exposed xenografts. Maturation of Sertoli cells (as indicated by AR expression) was induced (8 yrs) or maintained (13 and 14 yrs) in the xenografts, however, there was no difference in the number of Sertoli cells expressing AR between vehicle and hCG/FSH-exposed xenografts (2247.48/mm^2 vs 2411.13/mm^2, p>0.05). Sertoli cell number was significantly reduced in hCG/FSH-exposed xenografts, compared to vehicle control (3015.56/mm^2 vs 2548.92/mm^2, p = 0.01), and Sertoli cell proliferation was reduced although not significantly (7.65/mm^2 vs 1.35/mm^2, p>0.05). Germ cells were maintained in xenografts and germ cell numbers were lower in vehicle-, compared to gonadotrophin-exposed xenografts, although this was not significant (115.46/mm^2 vs 517.68/mm^2, p>0.05). Interestingly, for the youngest patient (8 yrs), whilst germ cell numbers were maintained in vehicle-exposed xenografts, there was a complete loss of germ cells in those exposed to hCG/FSH. Taken together, these results indicate xenografting immature testis tissue induces and maintains Sertoli cell maturation, whilst exogenous hCG/FSH promotes steroidogenesis in xenografted tissues.

Limitations, reasons for caution: Prepubertal human testis tissue is a finite resource limiting the number of samples in these studies. Inter-individual variation between patients is also a factor. Experimental design involving direct comparison of vehicle versus treatment for each sample and statistical analysis using two-factor analysis can account for some of these limitations.

Wider implications of the findings: These findings suggest that endogenous or exogenous gonadotrophins stimulate development and function of somatic cells in transplanted immature human testicular tissues. However, further work is required to determine the factors required to generate functional gametes from this tissue in order to develop viable options for fertility preservation in prepubertal boys.

Trial registration number: Not applicable.

P-528 Impact of breast cancer prognostic factors on the response to controlled ovarian stimulation in patients undergoing fertility preservation

F. Zeghari, C. Sonigo, M. Comtet, N. Sermondade, I. Cedrin-Durnerin, M. Grynberg

Hospital Jean Verdier, Department of Reproductive Medicine and Fertility Preservation, Bondy, France

Study question: Do breast cancer (BC) prognostic factors influence ovarian function and response to controlled ovarian stimulation (COS) in patients seeking fertility preservation (FP)?

Summary answer: Neither SBRIII grade, high Ki67 expression, HER2 overexpression nor triple negative status influence COS outcomes in pre-chemotherapy BC patients undergoing FP.

What is known already: Since the development of FP, concerns about the potential impact of cancer status on ovarian reserve, function and response to COS have been raised. Studies evaluating COS outcomes before chemotherapy in FP context have reported conflicting results. On the other hand, BC tumor markers such as Scarff-Bloom-Richardson (SBR) grade, high Ki67, HER2 overexpression or triple negative status represent well established prognostic factors which might influence the treatment strategy. However, the potential impact of these factors on ovarian reserve or COS outcomes in BC patients undergoing FP has never been investigated.

Study design, size, duration: A total of 151 BC patients undergoing COS for FP were prospectively included between November 2013 and December 2016. COS was initiated regardless of the phase of the cycle, with or without letrozole supplementation. Matured oocytes and/or embryos obtained were vitrified. COS characteristics and outcomes were analyzed in all women.

Participants/materials, setting, methods: BC prognostic factors considered in the present study were SBRIII grade, Ki 67> 20%, HER2

overexpression and "triple negative" tumor. Univariate and multivariate analysis were performed to determine their impact on ovarian reserve markers (serum Anti-Müllerian Hormone (AMH) and antral follicle count (AFC)) as well as on ovarian response to exogenous FSH. Less than 8 mature oocytes vitrified, maturation rate under 70% or Follicle Output RaTe (FORT) under 35% were considered as poor COS outcomes.

Main results and the role of chance: A total of 154 COS cycles were performed and analyzed in BC patients 33.4 ± 4.1 years of age were analyzed. Mean AMH and AFC were 3.2 ± 4.5 ng/mL and 20.2 ± 14.3 follicles, respectively. HER2 overexpression was observed in 18.9% and 34.7% of tumors expressed estrogen or progesterone receptors. Triple negative status characterized 25% of tumors. BRCA1/2 mutation was found in 22.4% of patients. A mean of 9.2 ± 7.4 mature oocytes were cryopreserved per cycle.

After multivariate analysis, only serum AMH levels, AFC and smoking status were significantly associated with the number of mature oocytes obtained following COS. BC prognostic factors did not appear to have a significant influence on ovarian reserve markers, number of retrieved oocytes, maturity rate or on ovarian response to exogenous FSH assessed by FORT index, defined as the ratio of the number of pre-ovulatory follicle (16-22 mm) count on the triggering day X100 to the antral follicle (3-8 mm) count at baseline.

Limitations, reasons for caution: The main limitation is related to the patients themselves referred for FP, who usually have early stage disease. Therefore, these results cannot be generalized to patients with advanced tumoral stage. Since oocytes were not thawed, the actual impact of BC prognostic factors on live birth rate remains unknown.

Wider implications of the findings: BC prognostic factors probably have no or low impact on ovarian function in terms of ovarian reserve and response to COS. Further analysis, in particular after oocyte thawing will be needed to clarify a possible impact egg quality.

Trial registration number: Not applicable.

P-529 Effects of cancer on ovarian reserve and ovarian response to stimulation

E. Porcu[1], G. Damiano[1], L. Cipriani[1], S. Rossi[1], F. Fabbri[1], G.M. Cillo[1], F. Sacilotto[1], L. Notarangelo[1], P.M. Ciotti[1], N. Calza[1], L. Vaccarella[2]

[1]University of Bologna, Human Reproductive Medicine Unit, Bologna, Italy
[2]University of Luigi Vanvitelli Naples, Human Reproduction unit, Napoli, Italy

Study question: This study investigates differences in ovarian reserve and stimulation response in a group of cancer patients and in a control group.

Summary answer: Despite their reduced ovarian reserve, cancer patients did not show lower number of oocytes retrieved and oocyte cryopreserved when compared to healthy control group.

What is known already: Premature ovarian failure is a well recognized consequence of chemotherapy. Therefore counseling plays a critical role for these patients. A proper counsel should include fertility preservation options. Oocytes cryopreservation is a procedure accepted as non-experimental technique. The debate on the negative influence of cancer on ovarian stimulation is still open. Many studies compared oncological patients with a control group but reports are still in conflict. It is assumed that cancer can damage ovarian granulosa cells affecting their sensibility to exogenous FSH. Another theory recognizes cancer as responsible for generating a catabolic state that can increase oxidative stress.

Study design, size, duration: Retrospective study: 212 oncological patients aged 30.5 ± 6.1 years (16 to 40 years old) undergoing a fertility preservation treatment at the University of Bologna IVF Center were considered from 1997 to 2017. These patients have been compared with a control group of 733 women aged 30.6 ± 2.3 years, undergoing ovarian stimulation because of tubal or male infertility.

General characteristic and ovarian stimulation aspects were analyzed.

Participants/materials, setting, methods: Out of the 212 oncological patients, 96 had hematologic cancer, 61 had breast cancer, 35 had gynecological neoplasms and 20 had other tumors (brain, thymic, melanoma and colon). All patients were stimulated with FSH-r and GnRH antagonist or antagonist. Aromatase inhibitors were used in hormone-sensitive neoplasm. In the control group 733 women were considered. Abnormal Ovarian reserve was an exclusion criteria. Only mature oocytes were cryopreserved. T-student test was used to analyze the data.

Main results and the role of chance: Both groups presented comparable age (30.5 ± 6.1 versus 30.6 ± 2.3 P=NS) and FSH levels (6.7 ± 4.3 versus 6.6 ± 2.0 P=NS). However oncological patients showed lower AMH levels (2.18 ± 2.65 versus 3.5 ± 2.6 P<0.0001) and AFC (8.42 ± 3.9 versus 10.5 ± 3.3 P<0.0001).

No differencies in duration of ovarian stimulation in oncological patients and in healthy patients were detected (11 ± 3.4 versus 11.2 ± 2.4 P=NS).

Cancer patients needed significantly higher doses of FSH-r compared with controls (2182.5 ± 1235.3 UI versus 2025 ± 783 UI, P<0.05)

Oncological patients and controls produced a similar number of total follicles. (12.13 ± 6.7 versus 12 ± 5.2 P=NS)

On the other hand, cancer patients presented lower estradiol peak than controls (1148.65 ± 1235.38 versus 1913 ± 1490 P<0.0001).

There was no statistical difference in the number of oocytes retrieved (8.92 ± 6.24 vs 8.3 ± 4.8 P=NS) and mature oocytes cryopreserved (7.24 ± 4.75 vs 6.8 ± 4.4 P=NS) between cancer patients and control.

Limitations, reasons for caution: The estradiol peak reached during the ovarian stimulation is influenced by the use of the Aromatase inhibitors in breast cancer hormone-sensitive tumor patients.

Wider implications of the findings: Present study shows a reduced ovarian reserve in cancer patients. However, despite low AMH and AFC values, oncological women can produce the same number of oocytes suitable for cryopreservation as observed in non cancer patients.

Trial registration number: \

P-530 Protective effect of visnagin on doxorubicin-induced follicular apoptotic activation in ovarian tissue of rat

A. Ozbay, B. Avci

Uludag University Faculty of Medicine, Histology and Embryology, Bursa, Turkey

Study question: Is there any efficacy of viscagin treatment to prevent tissue damage at cellular level in doxorubicin-induced ovarian toxicity?

Summary answer: Visnagin reduces the loss of follicles and protects the ovarian reserve against the gonadotoxic effect of doxorubicin.

What is known already: Chemotherapy causes loss of primordial follicles and impaired follicular maturation. Invitro studies suggest that apoptotic changes in pregranulosa cells lead to follicular damage. As a result of doxorubicin-induced toxicity, oocytes exhibit chromosome condensation, altered gene expression and oxidative stress. Oxidative stress at the cellular level causes DNA damage. There is an increase in apoptotic activation and an increase in follicular atresia and a decrease in ovarian reserve. Visnagin is an organic chemical compound and a furanochromone. It was reported that visnagin protects against doxorubicin-induced apoptosis in cultured cardiomyocytes.

Study design, size, duration: Experimental study conducted at Uludag University School of Medicine, the department of Histology and Embryology between 2016-2017 in master's thesis and licensed by the local ethics committe. A total of 24 Wistar albino adult female rats were used in the study. Ovarian toxicity was established with doxorubicin treatment in rats. Therapeutic effect of visnagin on ovarian toxicity was evaluated light microscopically and immunohistochemically.

Participants/materials, setting, methods: Female Wistar Albino rats that were six months of age (n = 24) divided 4 groups: GroupI: intraperitoneal (ip) saline, GroupII: ip doxorubicin (21 mg/kg), GroupIII: ip visnagin (30 mg/kg), GroupIV: ip doxorubicin+visnagin injected groups for 7 days. Vaginal smear was performed on all rats before application for drug administration and ovarian dissection. Paraffin tissue sections were stained with hematoxylin&eosin to morphological analysis. Apoptotic activation of ovarian follicles at different stages of development was assessed by the TUNEL assay.

Main results and the role of chance: In the doxorubicin group, there was a decrease in the numbers of primordial (p = 0,001), secondary (p = 0,002) and graafian follicles (p = 0,001) compared to the control, visnagin and doxorubicin + visnagin groups, and a significant increase in atretic follicle counts (p = 0,001), but there was no statistically significant difference unilaminar and multilaminar

primary follicles between groups. In the doxorubicin+visnagin group, the numbers of the secondary and graafian follicles were similar to those of the control and visnagin group, and the atretic follicle numbers decreased significantly compared to the doxorubicin group (p = 0,002). In vivo administration of doxorubicin resulted in an increase in the apoptotic granulosa cells poured into the antral fluid as a morphological indicator of atretic follicles. It was observed that the connections between the granulosa cells and the oocyte were deteriorated and inclusions were formed in the follicular cells. In granulosa cells of the secondary and graafian follicles, degeneration findings were observed in all follicles, with the pyknotic nuclei more prominent in the secondary follicles. The treatment of visnagin following the doxorubicin has a protective effect against the gonadotoxicity caused by doxorubicin. This effect showed protection in the number of primordial and developing follicles and decrease in the number of atretic follicles.

Limitations, reasons for caution: The limitations of the study is an experimental study and apoptotic activation could not be confirmed with different method.

Wider implications of the findings: This is the first study to show the protective effect of visnagin against the toxic effect of doxorubicin on the ovary. Visnagin therapy following chemotherapy is effective in protecting both of the primordial follicle pool and the developing ovarian follicles.

Trial registration number: The study is not clinical trials.

P-531 Social egg freezing in Israel – Do women take advantage of their opportunities?

R. Segal, M. Dviri, S. Avraham, D. Ben-yosef, F. Ezam

Sackler Faculty of Medicine- Tel-Aviv University- Israel, Institute of Reproduction and Racine IVF Unit- Lis Maternity Hospital Tel-Aviv Sourasky Medical Center, tel aviv, Israel

Study question: Do women utilize their legal privilege to perform up to 4 elective retrievals in order to maximize their chances for a future live birth?

Summary answer: Most women will undergo only one oocyte retrieval, even though the number of cryopreserved oocytes is less than optimal to ensure a live birth.

What is known already: In Israel, oocyte freezing has been approved in 2011, allowing women between the ages of 30-40 years to self-finance up to 4 retrievals or until 20 eggs are obtained (whichever comes first).

Previous studies indicate that 15 metaphase II oocytes will result in 90% cumulative live birth rate in women ≤35 years old, compared to 35% for women >35 years old.

Limited data has been published regarding this intervention results in Israel.

Study design, size, duration: A retrospective cohort study performed at a single academic center between January 2011 and December 2017. Computerized medical records of all fresh IVF/ICSI cycles during the study period were screened to identify patients undergoing social egg freezing.

Participants/materials, setting, methods: Patient's and cycle's data were collected and analyzed including age at first cycle, marital status, superovulation protocol, ovarian reserve markers, number of treatment cycles, number of retrieved oocytes, and number of oocytes/embryos frozen.

Main results and the role of chance: During the study period, 47 women underwent a total of 61 social fertility preservation cycles (22% of preservation cycles during the study period). A total of 19 cycles were performed during 2017, as compared to only one cycle in 2011.

Seventy five percent of women were > 35 years old when the first cycle was performed, mean age at first cycle was 36.4 ± 2.1 years.

The majority of women (89%) were single, 95% of them had no children and 23.3% had ovarian reserve markers indicating reduced ovarian reserve prior to the first cycle.

Seventy percent of the women underwent only one cycle, 12% had two cycles and 8% ≥ 3 cycles.

Antagonist protocol was used in 95% of patients.

The mean number of retrieved oocytes at first cycle was 14.8 ± 11.9, with a mean of 11.9 ± 9.9 oocytes being frozen. Four women choose embryo freezing rather than egg freezing.

Only 21% of women at first cycle, yeilded ≥ 20 frozen eggs.

One woman, 34 years old, yeilded 39 frozen eggs.

25% of the cycles ended in freezing less than 5 oocytes.

Limitations, reasons for caution: The main limitation is the retrospective nature of the study and the small sample size, which may limit its power.

Wider implications of the findings: Women do not exploit their full elective preservation options, most probably due to economic burden. Women who wish to perform social freezing should be encouraged to do so prior to 35 years old, and preferably more than one cycle, in order to maximize the chances for a future live birth.

Trial registration number: not applicable.

P-532 Assessing the effects of ovarian tissue ultra-rapid cryopreservation by vitrification on primordial-stage oocytes

N. Panagiotopoulou[1], J. Stewart[2], M. Herbert[3]

[1]*Newcastle University, Institute of Genetic Medicine/ Newcastle Fertility Centre at Life, Aberdeen, United Kingdom*

[2]*Newcastle Fertility Centre at Life- Newcastle Hospitals NHS Foundation Trust, Fertility Centre, Newcastle upon Tyne, United Kingdom*

[3]*Institute of Genetic Medicine- Newcastle University and Newcastle Fertility Centre at Life- Newcastle Hospitals NHS Foundation Trust, Institute of Genetic Medicine, Newcastle upon Tyne, United Kingdom*

Study question: Is immediate post-thaw assessment of the effects of ovarian tissue vitrification on primordial-stage oocytes accurate?

Summary answer: Assessing ovarian tissue immediately after thawing does not reveal the full extent of cryodamage caused to primordial-stage oocytes by ultra-rapid cryopreservation procedures.

What is known already: To date, the optimal laboratory protocol for ovarian tissue cryopreservation remains unclear. Although slow freezing is the currently standard procedure for ovarian tissue cryopreservation, there is a need to further develop cryopreservation techniques in order to reduce the degree of cryodamage. Ultra-rapid cryopreservation by vitrification has significantly advanced in the last decade and recent studies have suggested equivalent or even better results for ovarian tissue preservation. However, high concentration of cryoprotectants used in vitrification may cause high oocyte toxicity. Observing the effects of vitrification on the primordial-stage oocyte level is important in designing vitrification protocols that will minimize cellular damage.

Study design, size, duration: This was an *in vitro* mouse model study. Six intervention groups were employed, namely fresh, no *in vitro* culture group; fresh, 24 hours *in vitro* culture group; cryo-group 1, no *in vitro* culture; cryo-group 1, 24 hours *in vitro* culture; cryo-group 2, no *in vitro* culture; and cryo-group 2, 24 hours *in vitro* culture.

Participants/materials, setting, methods: Rec8 transgenic mice were used to develop an assay to assess primordial-stage oocytes damage following ovarian tissue vitrification. All animal procedures were approved by the UK Home Office and were carried out in accordance with '3Rs' principle – replacement, reduction and refinement. Cell death – using TUNEL assay and immunofluorescence analysis of activated Caspase 3 –was assessed at two time points: immediately after thawing and after 24-hours *in vitro* culture of thawed ovarian tissue strips.

Main results and the role of chance: Assessment of cell death was determined by a Staurosporine-validated assay that involved TUNEL and Caspase-3 labelling. We found that the proportion of primordial-stage oocytes staining positive for TUNEL and/ or Caspase-3 was higher in vitrified/ thawed ovarian strips analyzed immediately after thawing than in untreated (control) ovarian strips. This increase in the number of apoptotic primordial-stage oocytes was noted regardless of the cryopreservation media used and was evident in all biological repeats. Similar results were noted following 24 hours *in vitro* culture of untreated and treated ovarian strips. Comparison of the binomial proportion of primordial-stage oocytes staining negative for TUNEL and Caspase-3 and positive for TUNEL and/ or Caspase-3 showed a statistically significant difference among the six

intervention groups; $\chi^2(5) = 93.14$, p<0.0005. Post-hoc analysis showed that after 24 hours *in vitro* culture of vitrified/ thawed ovarian tissue strips, there was a statistically significant increase in the total number of primordial-stage oocytes that stained positive for TUNEL and/ or Caspase-3 for cryo-group 2 but not for cryo-group 1 nor for the untreated group. This finding was further supported by quantitative analysis of primordial-stage oocyte DNA fragmentation using the TUNEL assay for each of the six intervention groups; Kruskal-Wallis test: $\chi^2(5) = 326.749$, P<0.001.

Limitations, reasons for caution: Although our model allows cellular assessment of vitrification effects, the use of a mouse *in vitro* model constitutes a study limitation. Significant species differences limit the transferability of our findings beyond the mouse model. Moreover, protection mechanisms available from the mouse organism were eliminated due to the *in vitro* methodology.

Wider implications of the findings: To improve the effectiveness of ovarian tissue cryopreservation, cryodamage caused to primordial-stage oocytes should be minimized. Our *in vitro* mouse model and validated cell death assay could be used as a prototypes for a human ovarian tissue model that will allow optimization of ovarian tissue freezing for fertility preservation.

Trial registration number: N/A.

P-533 Influence of breast cancer prognostic factors on in-vitro maturation outcomes in patients seeking urgent fertility preservation

M. Grynberg[1], J. Raad[2], N. Sermondade[3], A. Benoit[3], C. Sifer[3], C. Sonigo[2,4]

[1]*Department of Reproductive Medicine and Fertility Preservation- Hôpital Jean Verdier, Ile de France, Bondy, France*
[2]*Department of Reproductive Medicine and Fertility Preservation- Hôpital Jean Verdier, Seine-Saint-Denis, Bondy, France*
[3]*AP-HP- Service de Cytogénétique et Biologie de la Reproduction- Hôpital Jean Verdier, Seine-Saint-Denis, Bondy, France*
[4]*Inserm U1185- Univ Paris-Sud- Université Paris Saclay, Val de Marne, Le Kremlin Bicêtre-, France*

Study question: Do the prognostic and predictive factors for breast cancer (BC) influence *in-vitro* maturation of immature oocytes (IVM) outcomes in patients undergoing fertility preservation (FP)?

Summary answer: Patients with SBRIII tumors had significantly less cryopreserved oocytes and HER2 overexpression was correlated with a decreased risk to cryopreserve less than 5 mature oocytes.

What is known already: Overexpression of HER2, Scarff-Bloom-Richardson (SBR) grade, triple negative status as well as high Ki67 expression represent prognosis factors for BC and are involved in the management of BC patients. On the other hand, concerns exist about the potential impact of cancer status on ovarian reserve and function. Previous studies analysing Controlled-Ovarian Stimulation results for FP in cancer patients have shown conflicting findings. Nevertheless, there is no data on the potential impact of BC status and prognostic factors on IVM outcome in women undergoing urgent FP.

Study design, size, duration: From November 2013 to December 2016, we prospectively studied 321 BC patients, aged 18-41 years, and candidates for oocyte cryopreservation following IVM. Number of oocytes recovered, maturation rate and total number of cryopreserved oocytes were assessed.

Participants/materials, setting, methods: Ovarian reserve markers (Antral-Follicle Count (AFC) and serum Anti-Mullerian Hormone (AMH) levels) and IVM outcomes were compared according to BC prognostic factors (Ki67 > 20%, progesterone and/or estrogen receptors status, HER2 status and SBR grade). Then, logistic regression analysis was performed to determine the variables that could be independently associated with poor IVM outcomes determined as maturation rate < 60 % or number of mature oocytes cryopreserved < 5.

Main results and the role of chance: Overall, the mean age of the population was 32.3 ± 4.1 years. Mean AFC and serum AMH levels were 22.8 ± 13.9 follicles and 3.8 ± 3.1 ng/ml, respectively. AMH serum level was significantly lower in case of triple-negative BC as compared to ER/PR/HER2 status positive cancer (3.1 ± 2.6 ng/ml *vs* 4.0 ± 3.3 ng/ml, p = 0.02).

The mean number of recovered oocytes was 10.2 ± 9.1. After a mean maturation rate of 58 ± 26%, 5.8 ± 5.3 matured oocytes were cryopreserved per cycle. The number of retrieved and cryopreserved oocytes were significantly decreased in patients presenting SBRIII tumor as compared with SBRI or II (9.6 ± 8.7 *vs* 11.7 ± 9.8, p = 0.02 and 5.4 ± 5.4 *vs* 6.0 ± 5.8 p = 0.02 respectively).

Multivariate statistical analysis showed that HER2 positive status was positively correlated with a mean maturation rate < 60 % (OR: 0.54; 95% CI (0.30-0.97)). Ki67, SBR classification or hormonal status was not correlated with poor IVM outcomes.

Limitations, reasons for caution: The main limitation of our study is the lack of data concerning the true competence of these cryopreserved oocytes and subsequently the impact of BC prognostic factors on pregnancy rates following utilization IVM oocytes remains unknown.

Wider implications of the findings: BC prognostic factors could play a role in IVM outcome. Moreover, HER2 is likely to be involved in oocyte maturation process. Further investigations are needed to better understand these mechanisms and to objectively assess the real potential of IVM oocytes after cryopreservation.

Trial registration number: N/A.

P-534 Determination of ovarian primordial/primary follicle density in 1002 ovarian tissue biopsies and amh concentrations in 824 serum-samples for a better reflection of the ovarian reserve

J. Liebenthron[1], J. Reinsberg[2], R. Fimmers[3], N. Sänger[4], K. Van der Ven[2], H. Van der Ven[2], P. Stute[5], M. Von Wolff[5]

[1]*University Gynaecological Clinic- UniCareD, Department Reproductive Medicine and Fertility Protection, Düsseldorf, Germany*
[2]*University Gynaecological Clinic, Department for Endocrionology and Reproductive Medicine, Bonn, Germany*
[3]*University Clinic Bonn, Department for Medical Biometry- Informatics and Epidemiology IMBIE, Bonn, Germany*
[4]*University Gynaecological Clinic, Department for Endocrionology and Reproductive Medicine, Frankfurt, Germany*
[5]*Inselspital- University Clinic, Department of Obstetrics and Gynaecology, Bern, Switzerland*

Study question: Enables the follicle density of primordial/primary follicles a better reflection of the ovarian reserve in cortex pieces of patients who underwent cryopreservation of ovarian tissue in terms of fertility protection?

Summary answer: Nomograms of follicle density FD and Anti-mullerian hormone AMH are similar in adulthood but different in childhood, as well the overall correlation of both parameters.

What is known already: Several parameters are suggested to estimate the ovarian reserve. These include the female age, the concentrations of FSH and Inhibin B, the antral follicle count AFC and the concentration of Anti-mullerian hormone AMH. Comparative studies have shown that AMH and AFC best reflect the response to gonadotropins. However, the antral follicles are only a small fraction of the total amount of ovarian follicles and AMH is already known to be a poor prognostic factor for the ovarian reserve in childhood.

Study design, size, duration: This retrospective observational study included 1.002 females (28,1 y ±6.9, 3-45 y) with malignant (n = 955) and benign (n = 47) diseases who cryopreserved tissue in a single center as part of a national fertility preservation program. Patients with ovarian surgery or genetic predispositions for a reduced ovarian reserve had been excluded. Follicle densities (FD) (n = 1.002) and AMH concentrations (n = 824) were evaluated from 03.2011 to 09.2016.

Participants/materials, setting, methods: Three standardized 2-mm biopsies, obtained from different areas of prepared ovarian cortex were collected, FD analysis was performed after tissue digestion and calcein staining (counting of fluorescent/viable PROF/PRIF follicles). Serum AMH was measured (before gonadotoxic therapy starts) using the AMH Gen II ELISA Kit. Statistical nomograms of FD/AMH were drawn in relation to age as well statistical correlation analyses of FD and AMH in two age groups (≤ 25 y/≥ 25 y).

Main results and the role of chance: First-time that a nomogram of FD as a function of age and in correlation with the AMH concentration in serum-blood is published. Thus, the cortex ovary reserve was analyzed directly and

not on the basis of known surrogate parameters. AMH concentrations were lower in childhood, increased to a peak in early adulthood and decreased afterwards. In contrast, FD were highest in childhood and decreased with increasing age. Our correlation analysis of FD with AMH, the marker with the highest prognostic prediction probability for an ovarian response, allowed us to estimate to what extent the AMH concentration correlates with the density of PRIF/PROF follicles. In the age group ≥ 25 y there was a significant better correlation of AMH and the FD ($r = 0.3199$, $p < 0.0001$) compared to the younger group (≤ 25 y), $r = 0.0539$, $p = 0.4022$, probably due the fact that the ovarian volume and surface area are lower in childhood.

Due the limited prognostic value of AMH for the FD, it should be questioned, if in terms of transplantation of ovarian tissue the evaluation of the individual FD is a more valid tool to estimate the amount of ovarian tissue needed for transplantation.

Limitations, reasons for caution: This study showed the FD in single cortical biopsies. Although the analysis and averaging of three biopsies increases the accuracy of the analysis, it is still not possible to accurately determine a heterogeneous FD.

Wider implications of the findings: The analysis of ovarian reserve by FD rather than surrogate parameters is one of the strengths of this study. Nevertheless, as ovarian FD was measured, an estimation of total concentration of follicles requires a surface correction regarding small size ovaries in childhood and the larger size ovaries in young adulthood.

Trial registration number: not applicable.

P-535 Fertility nursing education and career progression framework

F. Steyn[1], J. Wilson[2], F. Pringle[3], J. Denton[4], C. Bagness[5], H. Miller[6], Y. Wedden[7], A. Denga[8], K. Best[9], J. Mutch[10]

[1]The Centre for Reproductive and Genetic Health, Nursing, London, United Kingdom
[2]Care Fertility Birmingham, Nursing, Birmingham, United Kingdom
[3]IVI uk, Nursing, London, United Kingdom
[4]Multiple Births Foundation, Nursing, London, United Kingdom
[5]The Royal College of Nursing, Midwifery and Women's Health, London, United Kingdom
[6]Bath Fertility Centre, Nursing, Bath, United Kingdom
[7]Birmingham Women's Fertility Centre, Nursing, Birmingham, United Kingdom
[8]Assisted Conception Unit- Guy's and St Thomas's NHS Foundation Trust, Nursing, London, United Kingdom
[9]Gateshead Fertility Unit, Nursing, Gateshead, United Kingdom
[10]Hewitt Fertility Centre, Nursing, Liverpool, United Kingdom

Study question: Fertility nursing is a specialist area of practice where nurses are at the forefront of an emerging care setting, do we need to provide an educational framework to support this?

Summary answer: Fertility nursing encompasses the care and practices undertaken by any registered nurse/midwife providing fertility care, an educational framework is paramount for those individuals.

What is known already: Fertility nurses have increased levels of responsibility. Political drivers, workforce requirements and nursing care require multidisciplinary collaboration; whilst it is recognised that not every nurse/midwife will aspire to masters level advanced practice, all are expected to reach the maximum potential expected of their role in the context of competence and knowledge.

Equally the need for nurses to become specialists in their particular field of practice, to enhance overall service provision, through clinical leadership and be recognised as expert practitioners includes understanding the socio economic and political dimensions to delivering care, and ensuring service meets the needs of those seeking fertility care.

Study design, size, duration: A career progression and education framework has been constructed by senior fertility nurses, professional stakeholders and peers. The framework has been published and shared with professional stakeholders for review. The framework is a publication and booklet for fertility nurses and Health care assistants throughout the UK and contains tools for self assessment for competency. The project was the focus of the group for 2017 and has taken a total of 5 months to complete.

Participants/materials, setting, methods: The project group consisted of 12 core contributors, 3 external advisers and a wider group of stakeholders. The work was mainly constructed by individuals of the core group and forwarded to the group chair for amalgamation and proofing. Teleconferences and face to face meetings took place to discuss project content and for any amendments to be made. Each member of the core group were responsible for separate parts of the document.

Main results and the role of chance: This Fertility Nursing Education and Career Progression Framework is intended to facilitate a conversation, and enable the building of a career pathway for all nurses and healthcare assistants in fertility services. The aim is to ensure development and progression of knowledge and expertise towards enhancing the quality of service provision in Fertility Nursing Care.

This framework could also be used by individual nurses to assess their ongoing competence, and prepare for re validation.

All newly appointed nurses and HCA's should have an identified mentor to support their continuing professional development.

This Fertility Nursing Education and Career Progression Framework is intended to inspire individual nurses and HCA's to progress their career to continue to provide a quality service for those seeking fertility advice and management across the care provision.

Limitations, reasons for caution: This project serves as a reminder that anyone providing care should not undertake a procedure unless competent to do so, whilst considering how they can best ensure competence and confidence to carry out activities that expands their scope of practice.

Wider implications of the findings: Negative - Professional bias from other members of the MDT, increased costs for employers and increased training needs.

Positive - Improves patient care and satisfaction, Morale boosting, better skill mix, provides a key pathway for career progression.

Trial registration number: not applicable.

P-536 Development of a quality of life causal model for men undergoing fertility treatment

K. Asazawa[1], A. Mori[2], M. Jitsuzaki[3], T. Ichikawa[4], K. Shinozaki[5]

[1]Tokyo Healthcare University, Department of Nursing, Tokyo, Japan
[2]Women's Health and Midwifery, Graduate School, St. Luke's International University
[3]University of Occupational and Environmental Health, Department of Nursing, Fukuoka, Japan
[4]Graduate School of Medicine, Chiba University, Chiba, Japan
[5]Graduate School of Health and Welfare Science, International University of Health and Welfare, Fukuoka, Japan

Study question: The purpose of this study was to create a QOL (Quality of Life) cause-and-effect model for male patients undergoing infertility treatment in Japan.

Summary answer: The QOL was influenced by psychological Distress, lack of Spousal Support, prolonged infertility period as well as the male factor in a QOL cause-and-effect model.

What is known already: Patients undergoing infertility treatment become stressed from the physical burden of treatment, and their QOL also declines. An overview of 73 studies revealed that even though the mental health problems among the men were no higher than the general population, infertile men experienced infertility-specific anxiety and socially isolated men were more vulnerable to severe anxiety. Researchers from the USA identified life stress as a factor in reducing men's fertility; two or more stressful life events in the past year negatively affected men's sperm motility and morphology however, they found that job strain had no impact on sperm parameters.

Study design, size, duration: A descriptive quantitative cross-sectional questionnaire survey.

During the study period April to August 2016, we distributed 411 questionnaires to clients eligible for participation. A total of 332 (80.8%) were returned, and 321 were usable for analyses.

Participants/materials, setting, methods: This quantitative cross-sectional survey used a self-report questionnaire for 411 infertile male patients with and without male factor infertility from four human reproductive clinics in Japan. The four scales measured the main outcomes: FertiQoL (Japanese version), Psychological Distress, Social Support (spousal and workplace). The data were analyzed with descriptive statistics, multiple regression analyses and structural equation modeling.

Main results and the role of chance: Returned questionnaires were 332 (80.8%). Male factor cause of infertility was significantly associated with the FertiQoL scale score ($F = 5.174$, $p < 0.001$). The QOL was significantly lower in those with male factor infertility than in other causes or unknown cause. The three significant predictors of QOL were: (i) distress ($\beta = -0.53$, $P < 0.001$); (ii) Spousal Support ($\beta = 0.25$, $P < 0.001$) and (iii) infertility period ($\beta = -0.09$, $P < 0.05$). The structural equation modeling revealed the same factors were related to QOL.

Limitations, reasons for caution: Of the 600 fertility clinics in Japan only four urban facilities for data collection were used and were selected by a convenience sample instead of a random sample. The diagnosis and the details of the disease condition of infertile men with male factors were not investigated.

Wider implications of the findings: Infertile male factors, mental anguish, less spousal support, and longer period of infertility were associated with poorer quality of life for infertile men. These results suggested that focusing on infertility causes, distress conditions, length of infertility period, and support for couples' partnership are needed to maintain QOL during treatment.

Trial registration number: not applicable.

P-537 Evaluation of psychological distress in male patients undergoing assisted reproductive technologies (ART) treatments

M. Mandas, D. García, S. Franci, R. Vassena, A. Rodríguez

Clínica EUGIN, Assisted Reproduction, Barcelona, Spain

Study question: Are men undergoing ART treatment more emotionally distressed, in comparison to a reference population?

Summary answer: ART male patients seem to present lower emotional maladjustment and higher resources to cope with infertility than the reference population.

What is known already: The psychological characteristics of men coping with infertility and ART are understudied. A previous report analyzed men using an online infertility support group and found that they were feeling sidelined and marginalized in the process and in the way fertility professionals responded to them. DERA is a validated instrument of 48 questions with a 5-point Likert scale format developed to measure maladjustment and resources to affront maladjustment in both women and men. The validation study was performed in 490 patients, including 220 infertile men. We now investigate emotional distress and coping resources in heterosexual men undergoing ART with their partner.

Study design, size, duration: Cross-sectional study performed on 33 men between May 2017 and January 2018. Participants completed the DERA questionnaire at the end of their treatment. We evaluated the emotional maladjustment as well as the individual and interpersonal adaptive resources men may have for coping with ART. The sum of personal and interpersonal resources indicates the adaptive resources. The sum of the remaining answers indicates the emotional maladjustment.

Participants/materials, setting, methods: Participants were Spanish male patients undergoing IVF ($n = 22$) or IUI ($n = 11$) with their partner. In 6 cases donor sperm was used (1 IVF and 5 IUI). The study was proposed to each patient by an ART nurse. The participants filled in the questionnaire on the day of the ET or IUI.

Main results and the role of chance: The mean age of participants was 36.2 ± 4.7 (range 29-52). The age of their female partner was 35.4 ± 3.5 (range 28-41). For 8 patients (75.8%) it was their first ART cycle, while 2 participants (6%) had children at the time of treatment. The sub-score of maladjustment was, on average, 51.3 ± 14.7 (range 27-90), with $P_{50} = 49$; the sub-score of personal resources 41.7 ± 4.7 (range 30–54), with $P_{50} = 42.0$; the sub-score of interpersonal resources 45.1 ± 4.7 (range 35-55), with $P_{50} = 45.5$ and the adaptive resources 86.7 ± 7.7 (range 70-109), with $P_{50} = 86$. Overall, our results (P_{50}) indicate lower maladjustment and higher resources to cope than those of the reference population of the questionnaire (54-55, 41-42, 43 and 84 for, emotional maladjustment, personal resources, interpersonal resources and adaptive resources, respectively).

When focusing on patients who needed donor sperm for their treatment, we observed a slightly higher maladjustment (53.0 ± 8, $P_{50} = 49.5$), and lower personal, interpersonal and adaptative resources (37.5 ± 4.7, $P_{50} = 35$, 40.8 ± 5.0, $P_{50} = 41.5$, and 78.3 ± 6.7, $P_{50} = 81.0$, respectively); these results should be however confirmed in a bigger cohort.

Limitations, reasons for caution: The main limitation of this study resides in the relatively low number of patients included, in line however with several studies regarding male ART patients.

Wider implications of the findings: Male patients accessing ART might benefit from individual psychological counseling and support; the impact of using donated sperm on male patients' emotional distress should be explored further in future investigations.

Trial registration number: Not applicable.

P-538 Self-care (behavioral intention) during pregnancy and postnatal depression in females who conceived with in vitro fertilization (IVF)

D. Matsuura[1], S. Okuhara[2], S. Oguma[2], Y. Kato[2], N. Sato[2], N. Ogawa[2], Y. Nojiri[2], K. Kuroda[3], S. Hayashi[3], H. Furuhashi[1], T. Awa[3], A. Tsuboi[4], S. Takikawa[4], M. Nomura[4], K. Furui[4]

[1]Clinic Mama, Counseling, Gifu, Japan
[2]Clinic Mama, Embryo culture, Gifu, Japan
[3]Clinic Mama, Nurse, Gifu, Japan
[4]Clinic Mama, Medical Office, Gifu, Japan

Study question: This study compared the incidence of postnatal depression between patients conceiving with in vitro fertilization (IVF; IVF group) and naturally (natural pregnancy group).

Summary answer: At 1 month after delivery, the IVF group showed a more marked tendency to develop postnatal depression compared with the natural pregnancy group.

What is known already: Using the Edinburgh Postnatal Depression Scale (EPDS) (full score: 30) developed by Cox et al. (1987), Okano et al. (1996) defined females showing a score of 9 or higher at 1 month after delivery as EPDS-positive, with a cut-off point of 8/9. Manabe et al. (2001) developed the Self-care Scale for Pregnant Females (full score: 160), consisting of 4 subscales: <prevention and early discovery of abnormalities in pregnancy (40)>, <preparation for delivery and mothering (40)>, <dietary habits (40)>, and <care in daily life (40)>.

Study design, size, duration: Among the 529 patients who had delivered in our facility within the period between May and December 2017, 457 and 72 were classified into the natural pregnancy and IVF groups, respectively. At one month after delivery, we evaluated the 529 patients using the 30-point EPDS revised by Okano. Furthermore, at week 12 of pregnancy, we examined the self-care consisting of 4 subscales in the Self-care Scale for Pregnant Females of Manabe.

Participants/materials, setting, methods: In both groups, those showing an EPDS score of 8 or lower and that of 9 or higher were defined as EPDS-negative and -positive, respectively. Subsequently, in the IVF group (12), scores from the Self-care Scale for Pregnant Females (<prevention and early discovery of abnormalities in pregnancy>, <preparation for delivery and mothering>, <dietary habits>, and <care in daily life>) during pregnancy (at week 12 of pregnancy) were compared between EPDS-negative (5) and -positive (7) members.

Main results and the role of chance: Compared with the natural pregnancy group, the IVF group showed significantly higher EPDS scores, with a markedly higher rate of being EPDS-positive. Furthermore, on comparing EPDS-positive and -negative members of the IVF group, the former showed significantly higher

<care in daily life>-related scores from the Self-care Scale for Pregnant Females, suggesting that they faced more marked stress when performing <care in daily life> as part of self-care during pregnancy. In addition, the duration of outpatient treatment was longer among EPDS-positive than -negative members, although the difference was non-significant. There were no significant differences in parity or a history of miscarriage.

Limitations, reasons for caution: The presence/absence of postnatal depression represents the psychological status of patients who conceived naturally or with IVF at 1 month after delivery. Similarly, their scores from the Self-care Scale for Pregnant Females represent their psychological status at week 12 of pregnancy. Stress assessment is based on an individual's perception.

Wider implications of the findings: Compared with the natural pregnancy group, the IVF group showed a more marked tendency to develop postnatal depression (higher EPDS scores). Furthermore, on comparing scores from the Self-care Scale for Pregnant Females, EPDS-positive of the IVF group showed significantly higher scores related to <care in daily life>.

Trial registration number: None.

P-539 Multidisciplinary gestational surrogacy care in absence of a legal framework

E. Van Moer[1], L. Leunens[1], V. Schutyser[1], S. Van Ginderdeuren[1], L. Gucciardo[2], H. Tournaye[1]

[1]UZ Brussel, Centre for Reproductive Medicine, Jette- Brussels, Belgium
[2]UZ Brussel, Centre for Obstetrics and Prenatal Medicine, Jette- Brussels, Belgium

Study question: How to setup gestational surrogacy care at a medical setting, in the absence of a legal framework?

Summary answer: In absence of legislation for surrogacy, thorough criteria, evaluation by and cooperation within psychology, reproductive medicine, midwifery and obstetrics are necessary to limit related risks.

What is known already: In many European countries, surrogacy is not officially allowed nor prohibited. Consequently, the persons involved are not legally protected and are exposed to several risks.

The woman who gives birth is recognized as legal mother until an adoption procedure is completed and approved in court. This implicates that theoretically the surrogate may claim motherhood and intended parents can abandon their child.

Furthermore obstetrical and fetal complications and emotional distress may occur.

Partially due to the absence of a legal framework, hospitals have a responsibility to ensure a successful outcome. Legislating gestational surrogacy is strongly adviced by fertility centres to diminish risks and responsibilities.

Study design, size, duration: In 2014, a core surrogacy team was installed at an academic fertility centre. The team consists of a gynecologist, psychologist and a midwife, all with a fertility subspecialisation. In order to implement a gestational care program, at first a literature study was conducted, secondly team visits to other surrogacy providers were scheduled and finally the team consulted a lawyer specialised in family law.

Participants/materials, setting, methods: Our research indicated that surrogacy care requires a broader approach than just conventional fertility care. Therefore, gynecologists and midwives, subspecialised in obstetrics joined the team to ensure a complete approach and follow-up, from screening to handing over of the newborn. The surrogacy-program includes a thorough screening procedure, based on clear criteria for acceptance, a clinical pathway and a detailed description of the role of each stakeholder, in order to reduce possible risks.

Main results and the role of chance: We provide a program based on altruistic surrogacy by performing IVF-treatment using only gametes of the intended parents and single embryo transfer. Only surrogacy projects where a long-standing history of friendship or kinship with the surrogate is observed are accepted.

First both intended parents and surrogate are referred to a lawyer specialised in family law where the absence of a legal framework, all risks and rights, and the adoption procedure are fully explained.

The reproductive gynecologist analyses medical indication and fertility status and is responsible for medical care and IVF-treatment.

During several consultations, the psychologist evaluates resilience, stability, motivation, interpersonal and marital relationships, coping strategies, indications of psychopathology and personality measures of intended parents, surrogate and her partner.

An obstetrician performs an obstetrical screening of the surrogate aiming to exclude any potential risk during pregnancy or childbirth.

When screening is completed, a report is submitted to the hospital's ethical committee for approval of the surrogacy treatment.

During the entire process, psychological support is provided by the psychologist assisted by the midwife. The midwife is responsible for navigating and counseling the patients, discussing the birth plan, obstetrical care and guidance during handing over after birth.

Limitations, reasons for caution: Not applicable.

Wider implications of the findings: Surrogacy is a complex process demanding a structured approach. A team coordinator who acts as single person of contact and manages all communication and cooperation is primordial to maintain patient centered care. Therefore, a midwife with reproductive and obstetrical background is best placed in order to achieve a favourable outcome.

Trial registration number: Not applicable.

Psychology and counselling

P-540 Religion, spirituality and faith: What is the real impact on assisted reproduction?

E. Ono[1], D.P.A.F. Braga[2], B.F. Zanetti[1], R.M.M. Melamed[3], A. Iaconelli Jr.[4], E. Borges Jr.[4]

[1]Instituto Sapientiae - Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific Department, Sao Paulo, Brazil
[2]Fertility Medical Group, Scientific Department, Sao Paulo, Brazil
[3]Fertility Medical Group, Psychology department, Sao Paulo, Brazil
[4]Fertility Medical Group, Clinical Department, Sao Paulo, Brazil

Study question: Is there any impact of the patient's faith, religion and spirituality on the outcomes of intracytoplasmic sperm injection (ICSI) cycles?

Summary answer: There is a significant relationship between patient's religion, spirituality and faith on ICSI outcomes.

What is known already: Worldwide, more than eight in ten people identify with a religious group. Many patients seek religion or spirituality to relieve suffering and find a source of strength to cope with the disease. It has long been documented a positive association between religious involvement and better adaptation to medical illness as well as increased level of well-being and quality of life. Lately, there has been considerable interest in exploring the impact of the spiritual and religious issues on the health of people with infertility diagnosis, however nothing is known about the influence of these factors on the results of Assisted Reproduction.

Study design, size, duration: This prospective study included 877 patients undergoing intracytoplasmic sperm injection (ICSI) cycles from April/2016 to June/2017. Patients filled a questionnaire with information on faith, religiosity, and spirituality. The results of the questionnaires were correlated with: patient's age, number of retrieved oocytes, fertilization rate, number and rate of high quality embryos, cycle's cancelation, and pregnancy result using One way ANOVA, followed by Bonferroni post hoc test and linear regression models.

Participants/materials, setting, methods: The study was performed in a private university-affiliated in vitro fertilization center. Women were asked about their religion; if they attend meetings of their religions, and in which frequency; if they keep in touch with leaders of their religions or if they pray, and in which frequency; whether their faith contributed to the decision to go through the treatment; and in a scale, from 0 to 10, how did they believe in the treatment success.

Main results and the role of chance: Patients were divided into: Catholics (n = 457), Spiritists (n = 114), Evangelicals (n = 138), Other (n = 52), and No

religion (n = 98). Eighty patients were not willing to respond to the questionnaire. The significant effects of the religions on ICSI outcomes are described in Table 1. An increased pregnancy rate was observed in patients who reported including infertility diagnosis and treatment in their prayers (31.4% vs. 5.5%, p = 0.039). The high-quality embryos rate increased among patients who answered that their faith contribute to their decision to undergo infertility treatment (38.,9% vs. 28.4% p = 0.012) and those who belief in the treatment's success (RR: 0.001–0.0013, p = 0.022), while it decreased if they affirmed that their faith was affected by their infertility diagnosis (29.9% vs. 39.2% p = 0.050) or that religiousness had negatively affected the decision to undergo infertility treatment (8.24% vs. 36.8%, p = 0.010).

Limitations, reasons for caution: This questionnaire is subjective and may not reliably reflect the actual potential of the patient's faith and degree of religiosity/spirituality. Further bias may come from how prayer, spirituality and faith are understood, duration or types of prayer, or conditions in which prayers, contact with leaders, or religious meetings are performed.

Wider implications of the findings: Spirituality plays a role in adjusting psychological aspects of an infertile patient. Given that prayer or other spiritual approaches are safe and low-risk strategies, ART professionals need to be aware of the use of these strategies as non-pharmacological, non-invasive adjunct therapies.

Trial registration number: None.

P-541 The unwillingness to be in contact with the painful experience of infertility: experiential avoidance as a mediator in relationship between infertility-related stress and depressive symptoms

A. Galhardo[1], J. Alves[2], M. Moura-Ramos[3], M. Cunha[1]

[1]Instituto Superior Miguel Torga- CINEICC-Faculty of Psychology and Educational Sciences of the University of Coimbra, Psychology, Coimbra, Portugal
[2]Instituto Superior Miguel Torga, Psychology, Coimbra, Portugal
[3]CINEICC-Faculty of Psychology and Educational Sciences of the University of Coimbra, Psychology, Coimbra, Portugal

Study question: Does experiential avoidance play a mediating role in the relationship between infertility related stress and depressive symptoms?

Summary answer: Representations about parenthood were associated with depressive symptoms indirectly, throughout the association with the impact of infertility in women's life and use of experiential avoidance.

What is known already: Experiential avoidance or psychological inflexibility is described as encompassing two related components: unwillingness to remain in touch with aversive private experiences (including bodily sensations, emotions, thoughts, memories, and behavioral predispositions), and action to change aversive experiences or the events that trigger them. It has been suggest that experiential avoidance can be seen as a vulnerability factor for the development and maintenance of psychopathology. Studies addressing experiential avoidance in people dealing with infertility are scarce but couples with an infertility diagnosis pursuing medical treatment presented significantly higher scores of experiential avoidance when compared to fertile couples and couples applying for adoption.

Study design, size, duration: Cross sectional study. Data were collected online through self-report instruments between February 2016 and June 2016. Inclusion criteria were age (18 years or older), and an infertility medical diagnosis. The study was conducted in a sample of 124 infertile women pursuing medical treatment.

Participants/materials, setting, methods: A sample of 124 infertile women pursuing medical treatment completed online the following standardized self-report measures: Fertility Problem Inventory (FPI), Acceptance and Action Questionnaire (AAQ-II), and the depression scale of the Depression, Anxiety and Stress Scale (DASS-21). Patients were invited to participate through a post on the national patients association, gave their informed consent and were asked to fill in the questionnaires. The mediation model analysis was tested with the SPSS Process macro.

Main results and the role of chance: The model examined the direct and indirect effect of representations about parenthood on depressive symptoms, by modeling the mediation effects of representations about the importance of parenthood on the impact of infertility on participants' life domains and of this on experiential avoidance. The direct effect of representations about parenthood on depressive symptoms was nonsignificant (effect = .04, SE = .02, *p* = .127). The indirect effect of representations about the importance of parenthood on depressive symptoms, while modeling the influence of the intervening variables, was statistically significant (Indirect effect = 0.03, 95%CI: [.015; 050]). An alternative model considering that people facing infertility that highly value parenthood tend to avoid situations and feelings related to children and this may be associated with higher impact of infertility on life domains (e.g. social isolation, poor sexual relationship), which would be associated with depressive symptoms was also tested. The result on the indirect effect of this serial multiple mediation model included 0 and therefore was not significant (Indirect effect = 0.01, 95%CI: [.00; 03])

Limitations, reasons for caution: The findings rely on cross-sectional and self-report data. Even though a sequential mediation effect was tested, the framework to establish the sequence of the variables is a theoretical one, and not a temporal one. The online recruitment tends to recruit more educated participants, with easy access to online platforms.

Wider implications of the findings: Results suggest that the tendency of infertile women to avoid thoughts, emotions and situations associated with parenthood, as a way of trying to escape from the infertility painful experience, induces higher suffering. Consequently, the core emotional regulation process of experiential avoidance should be addressed by psychologists in the clinical context.

Trial registration number: Not applicable.

P-542 The implications of the religious/spiritual beliefs and practices among commercial gestational carriers in the United States for international surrogacy arrangements

M. Riddle

The Pennsylvania State University, Psychology Department, University Park, U.S.A.

Study question: What are the implications of the religious/spiritual beliefs and practices of commercial gestational carriers (GCs) in the United States for mental health evaluations in international surrogacy arrangements?

Summary answer: Discussing religion/spirituality within a mental-health evaluation serves a GC's psychological best interests and may help to match them with intended parents (IPs) from other countries/cultures/religions.

Table 1 The effect of patient's religion on ICSI outcomes, controlled for patient's age.

	Patient's religion					
	Catholic	Spiritist	Evangelical	Other	No religion	p
Fertilization Rate	82.0 ± 1.7[a]	89.9 ± 9.3[b,c]	87.0 ± 3.5[e]	72.4 ± 3.7[b,d,f]	70.6 ± 3.5[b,d,f]	**0.007**
High quality embryos	2.6 ± 0.2[a]	3.6 ± 0.4[b]	3.0 ± 0.3[b,d]	0.9 ± 1.3[c]	1.2 ± 0.6[c]	**0.043**
High quality embryos rate	32.6 ± 2.3[a]	47.1 ± 3.3[b]	45.1 ± 4.3[b]	36.3 ± 9.7[c]	43.1 ± 5.1[b]	**0.043**
Pregnancy Rate	32.9%[a]	58.0% [b]	33.9%[c]	31,2.%[a]	23,0%[d]	**0.047**

a≠b, c≠d, e≠f

What is known already: Religious customs and beliefs influence both the practice and prohibition of surrogacy around the globe. It has been theorized that religious and spiritual themes are more likely to emerge among altruistic (unpaid) surrogates. Little is known about the religious/spiritual beliefs and practices of commercial surrogates in the United States (US) and how these beliefs influence the process of surrogacy. No studies to date have examined how incorporating a discussion on religious/spiritual beliefs and practices might contribute to both the psychological evaluation process of potential GCs and the matching process with IPs who are coming from other countries and cultures.

Study design, size, duration: This is a qualitative research study using a grounded theory approach. 17 GCs raised in diverse denominations of faith were recruited via an ad posting from across the United States to participate in this study. GCs were interviewed using in-depth, semi-structured interviews that were conducted via Skype. Interviews lasted between 60-90 minutes and took place over a 4-month period (January through April, 2017).

Participants/materials, setting, methods: 17 GCs had a total of 28 surrogate pregnancies (36 surrogate children). 76% (n = 13) of participants worked with international IPs. Participants came from a variety of religious backgrounds (Mormon/LDS, Catholic, Baptist, Christian). GCs were recruited via an ad posting on websites frequented by carriers and through surrogacy agencies. In-depth, semi-structured interviews were conducted via Skype. Interviews were audiotaped and transcribed verbatim. Grounded theory of analysis of data included line-by-line coding and emergent themes were identified.

Main results and the role of chance: Themes emerging from the narrative data included Gestational Surrogacy as a Religious/Spiritual "Calling"; Motivation for Surrogacy Rooted in Faith Beliefs; Gestational Surrogacy as Providing Existential Meaning and Purpose to Life; Role of Religious/Spiritual Beliefs in Relationships with IPs. Some GCs felt their surrogacy experiences were part of "God's plan" that shaped their future trajectory providing existential meaning to life. GCs felt that their decision to become a surrogate was "doing the will of God" and that they were "furthering God's kingdom". GCs felt they were providing a positive role model for their children by modeling Christian values. In the words of one GC (when asked whether it was important for mental health professionals to ask about religious/spiritual issues in the psychological evaluation): "My religion is very important to me - it's part of who I am - it's part of who I've become - I definitely think this is something that should be talked about."

Unexpected findings included reticence on the part of some GCs in sharing their belief system in their psychological evaluation for fear of being excluded based on their beliefs or feeling that their beliefs would be seen as psychopathology.

The role of chance in these results is minimal.

Limitations, reasons for caution: This is a qualitative study and, therefore, the generalizability of the findings should be treated with caution.

Wider implications of the findings: Findings suggest that religious/spiritual narratives are not the exclusive domain of altruistic surrogates. Discussing religion and spirituality can enhance the psychological evaluation and counseling of potential GCs and may also help in matching GCs to IPs, particularly when they are international arrangements representing diversity in religious beliefs and practices.

Trial registration number: Not Applicable.

P-543 Somatising the desire toward a child among Hong Kong Chinese women undergoing IVF: The mediating role of anxiety

C.H.Y. Chan, M.Y.J. Tam, B. Lau, Q.S. Wong

The University of Hong Kong, Department of Social Work and Social Administration, Hong Kong Island, Hong Kong

Study question: Does anxiety mediate the effect of importance of childbearing on physical symptoms among Hong Kong Chinese women undergoing IVF?

Summary answer: Anxiety fully mediates the effect of importance of childbearing on physical symptoms among women undergoing IVF after controlling for demographic and clinical factors.

What is known already: Anxiety is a common emotional reaction among women undergoing IVF. The unpredictable and uncontrollable nature of IVF fuels anxiety toward its process and outcome. Anxiety could be somatised and manifested in physical symptoms such as fatigue, headache, insomnia, and muscle pain. The stake and therefore the anxiety toward the IVF treatment could be heightened if the couple regards having a child as essential to themselves, their relationship and the family. Hence, this study examined whether perceived importance of childbearing escalates physical symptoms of somatization, and whether anxiety mediates the relationship between such attitude and physical distress.

Study design, size, duration: This analysis utilized the baseline data of a randomized controlled trial that compared the effectiveness of a body-mind-spirit intervention in reducing the anxiety of women during the two-week wait before pregnancy test against two control conditions (health education and spiritual intervention). 225 participants who provided complete response to the items required in this analysis was included. The baseline data was collected in between 2015 and 2017 from the Queen Mary Hospital, Hong Kong.

Participants/materials, setting, methods: Women who were going to undergo IVF were recruited. The importance of childbearing was measured by a 4-item scale; anxiety was assessed by the State-Trait Anxiety Inventory (State scale); physical symptoms were evaluated by the 14-item physical distress scale of Body-Mind-Spirit Well-Being Inventory. The mediation analysis was conducted with PROCESS macro in SPSS with 5000 bootstrapped samples, and with women's and husbands' age, previous ART treatment, subfertility years, subfertility type, and causes of subfertility controlled.

Main results and the role of chance: Perceived importance of childbearing was positively correlated with state anxiety ($r=.31$; $p<.001$) and physical distress ($r=.20$, $p<.001$), and physical distress was positively correlated with state anxiety ($r=.35$, $p<.001$). After controlling for demographic and clinical characteristics, childbearing importance was significantly associated with physical distress in the total effect model, B = 0.69, SE = 0.23, [95%CI of B = 0.22-1.15], p=.0038. However, when state anxiety was added to the model, state anxiety was significantly related to physical distress, B = 0.70, SE = 0.14, [95%CI of B = 0.42-0.98], $p<.001$, and the association between childbearing importance and physical distress was no longer significant ($p>.05$). The indirect effect was statistically significant, B = 0.36, SE = 0.10, [95%CI of B = 0.20-0.59]. In other words, full mediation by state anxiety was found in the effect of childbearing importance on physical distress. The analysis was repeated by interchanging the role of physical distress and state anxiety, such that physical distress became the mediator. However, although the indirect effect was statistically significant, the mediation was partial as the direct effect from childbearing importance to state anxiety continued to be significant too. Hence, the former model was regarded as a more parsimonious representation of the relationship among childbearing importance, state anxiety and physical distress. Statistical significance was indicated by a p-value below 0.05.

Limitations, reasons for caution: Physical distress was evaluated by self-report of the participants. Recall bias and self-selection bias may reduce the generalizability of the findings.

Wider implications of the findings: Interventions that aim at reducing anxiety during IVF treatment should take into account personal value and expectations attached to childbearing and the somatization of such concerns. Our findings also highlight the interaction among values, emotions and physical distress, and provide empirical foundation for multi-component interventions that address these aspects.

Trial registration number: HKUCTR-1984

P-544 Typology of family involvement and fertility-specific Quality of Life among Chinese couples with infertility: A cluster analysis

Y. Sylvia Hong[1], C.H.Y. Chan[1], Y.J. Hou[2], R. Li[3], W. Shang[4], C.L.W. Chan[1]

[1]University of Hong Kong, Social Work and Social Administration, Hong Kong, Hong Kong

[2]Renmin University of China, School of Sociology and Population Studies, Beijing, China

[3]Peking University Third Hospital, Obstetrics and Gynecology, Beijing, China

[4]Navy General Hospitcal, Obstetrics and Gynecology, Beijing, China

Study question: To identify subgroups of Chinese infertile couples based on their experiences with family emotional supports, economic supports and interference.

Summary answer: Four relatively distinct subgroups regarding family involvement were identified, namely, intrusive, detached, emotionally responsive, and economically supportive categories.

What is known already: Family involvements, largely divided into supports and interference were found to have mixed effects on wellbeing of married couples. As the primary social support reservoir, family supports served as protective factors for couples to overcome psychosocial distress caused by infertility. However, overwhelming interferences and unwanted inquiries from social networks could turn into detrimental stressors for married couples, especially during experiences of infertility. There are limited evidences regarding the typology of family involvements experienced by infertile couples, which constraint the development of family-oriented psychosocial services.

Study design, size, duration: A cross-sectioned study was implemented during October to December 2016. Current study recruited 429 infertile couples in a reproductive center affiliated to a public hospital in Beijing, China. Eligibility criteria for inclusion were couples who were (1) legally married; (2) medically diagnosed with infertility and (3) undergoing assisted reproductive treatments. After obtaining written consents, infertile couples were invited to take questionnaires separately and independently to avoid dyadic interference.

Participants/materials, setting, methods: Despite demographic information, family involvement scale and Fertility-specific Quality of Life were used to measure key variables. Mean age of wives and husbands were 34.21 ± 6.22 and 32.50 ± 5.12, respectively and couples had been married for six years approximately. More than half of participants received tertiary education (62.9%) and 69.4% had a full-time job. In terms of the infertility etiology, there are 252 female factor, 250 male factor, 170 both factor and 148 unexplained factor infertility.

Main results and the role of chance: Cluster analysis identified four subgroups regarding emotional responsiveness, economic supports and interference, namely, intrusive (44 pairs), detached (92 pairs), emotionally responsive (107 pairs), and economically supportive (178 supports) groups. There were significant between-group differences regarding FertiQoL scores ($F = 3.09$, $P<0.05$ for husbands; $F = 4.58$, $P<0.01$ for wives). Multiple comparison results indicated wives in intrusive subgroups show significant lowest emotional QoL, social QoL and total FertiQoL scores comparing to their counterparts in other three subgroups. For social QoL, husbands in detached subgroups show significantly lower scores than husbands in emotionally and economically supportive subgroups. Moreover, husbands in emotionally supportive subgroups show higher emotional QoL and total FertiQoL scores than husbands in intrusive and detached subgroups. In terms of relational QoL, both wives and husbands in emotionally and economically supportive subgroups reported significantly higher scores than their counterparts in detached and intrusive subgroups. No significant between-group differences on mind-body QoL for couples.

Limitations, reasons for caution: Current study carried several limitations. First of all, measures used to evaluate family supports and interference was universal, rather than being specific to infertility. Secondly, cross-sectional research design adopted by current study was constrained to draw causal inferences. Finally, self-selection bias might limit generalizability of results found in this study.

Wider implications of the findings: Despite person-centered and dyadic approach in infertility counseling, family-oriented interventions should be designed to improve quality of life for couples during experiences of infertility. Given the significance of emotional supports, it is extremely important to extend the therapeutic alliance through educating extended families regarding emotional competence and skills.

Trial registration number: Not applicable.

P-545 The mediating role of self-compassion between parental interference and quality of life among Chinese infertile couples: An actor-partner interdependence model

S.H. Yao[1], C.H.Y. Chan[2], H. Ya Jie[3], R. Li[4], C.L.W. Chan[5]

[1]*The University of Hong Kong, Faculty of Social Science, Hong Kong, China*
[2]*University of Hong Kong, Social Work and Social Administration, Hong Kong, China*
[3]*Renmin University of China, School of Sociology and Population Studies, Beijing, China*
[4]*Peking University Third Hospital, Obstetrics and Gynecology, Beijing, China*
[5]*University of Hong Kong, Social Work and Social Administration, Hong Kong, Hong Kong*

Study question: This study aims to test the mediating role of self-compassion between the relationships between parental interference and quality of life (QoL) among Chinese infertile couples.

Summary answer: Self-compassion partially mediated the negative relationships between in-law/family-of-origin interference and QoL for both husbands and wives. No partner effects have been found in current study.

What is known already: Infertility, as a collective family crisis, could involve actions of the entire family. Studies conducted in Chinese context found the overwhelming attentions and unwanted inquiries from the extended families could cause psychosocial distress for infertile couples. Parental interference became a risk factor for the wellbeing of infertile couples, though differences between in-law and family-of-origin interference wellbeing still remained inadequate. Moreover, a dearth of studies has identified self-compassion as a mediating factor between family supports and psychological wellbeing; however, few studies explore its mediating role between interference as the opposite of supports, and psychosocial outcomes, particularly in infertility context.

Study design, size, duration: A cross-sectioned study was implemented during October to December 2016. Current study recruited 431 infertile couples in a reproductive center affiliated to a public hospital in Beijing, China. Eligibility criteria for inclusion were couples who were (1) legally married; (2) medically diagnosed with infertility and (3) undergoing assisted reproductive treatments. After obtaining written consents, infertile couples were invited to take questionnaires separately and independently to avoid dyadic interference.

Participants/materials, setting, methods: Despite demographic information, family involvement scale and Fertility-specific Quality of Life were used to measure key variables. Mean age of wives and husbands were 34.23 ± 6.21 and 32.49 ± 5.11, respectively and couples had been married for six years approximately. More than half of participants received tertiary education and 69.9% had a full-time job.

Main results and the role of chance: Current study adopted actor-partner interdependence mediation model (APIMeM) to investigate the mediating role of self-compassion in the negative relationships between parental interference (in-law/family-of-origin interference) and QoL among infertile couples. For the in-law interference, APIMeM results confirmed two significant mediation effects of self-compassion in the negative relationships between in-law interference and QoL for both husbands and wives ($b=-0.057$, $p<0.01$). In terms of family-of-origin interference, APIMeM results also showed two significant actor effects for both husbands and wives ($b=-0.07$, $p<0.001$). However, no partner effects have been found in all APIM models. These significant actor effects indicated that the mediating effects of self-compassion on the associations between parental interference and QoL only existed at the individual level, rather than the intra-couple level.

Limitations, reasons for caution: Current study carried several limitations. First of all, measure used to evaluate family interference was universal, rather than being specific to infertility. Secondly, cross-sectional research design adopted by current study was constrained to draw causal inferences. Finally, self-selection bias might limit generalizability of results found in this study.

Wider implications of the findings: To mitigate the negative effects of family interference, family-oriented psychosocial education should be developed to prepare extended families to support in a way that suited infertile couples' needs. Given the mediating role of self-compassion, counseling and interventions should aim at awaking and improving couples' inner strengths during experiences of infertility.

Trial registration number: Not applicable.

P-546 Effects of infertility on quality of life in Greek infertile women

M. Souropani[1], M. Konstadoudaki[2]

[1]*Institute of Life -IVF- IASO CLINIC -ATHENS, Institute of Life -IVF -IASO CLINIC -ATHENS, ATHENS, Greece*

[2]Institute of life, Iaso clinic, athens, Greece

Study question: Can the infertility and its treatment affect the quality of life of infertile women?

Summary answer: The experience of infertility is highly stressful for women. In general, women have lower levels of fertility -related to quality of life.

What is known already: Infertility influences all the dimension of women life. Social and family pressure, well-being,change in marital relationship and in sexual satisfaction can lead to impairment in quality of life.Attention to their quality of life guarantees stability and satisfaction with life and establish an effective relationship between patient and her treatment team.Quality of life has become one of the most crucial issues nowadays and is seen as one of the measurable criteria for evaluation of treatment.Promotion of quality of life in infertile women requires a deep understanding of their problems from different aspects.

Study design, size, duration: We included 192 infertile women,who were attended the clinic Institute of Life, under at any stage of treatment, at the beginning of treatment and at the day of embryo transfer, from April to November 2017.

Participants/materials, setting, methods: This is a cross- sectional study in which 192 infertile women were (aged 30-45) participated.The subjects,who visited the Institute of life clinic, were selected through random sampling.Data were collected using a questionnaire which had two sections:demographic information and FertiQol questionnaire which measured the quality of life. The collected data were analyzed using SPSS version 16.

Main results and the role of chance: The result showed that were no significant difference between quality of life of infertile women and sociodemographic factors. A regression analysis was conducted and showed that age is characterized as a predictor of infertility.Age has be noted as a factor which is significant with infertility, on the other hand education of infertile women has be noted as a non significant factor that affects infertility in accordance with regression analysis of the present study.

Limitations, reasons for caution: We have only included women who were undergoing in vitro fertilization (IVF) treatment in the study.Due to practical reasons their partners did not participate.The result of the study may be influenced by the small sample size.

Wider implications of the findings: Data were obtained only from one clinical site. The present study would has a huge interest if also record couples or even men opinion about infertility.

Trial registration number: non clinical trial.

P-547 Health and wellbeing of adults conceived by IVF: a comparison of those who do and don't participate in a follow up study

J. Halliday[1], R. McLachlan[2], S. Farrow[1], J. Kennedy[1], K. Hammarberg[3], D. Burgner[4], L. Doyle[5], J. McBain[6], D. Amor[7], M. Juonala[8], M. Cheung[9], S. Ranganathan[10], L. Welsh[10], S. Lewis[1]

[1]Murdoch Children's Research Institute, Public Health Genetics, Melbourne, Australia
[2]Hudson Institute of Medical Research, Department of Molecular and Translational Sciences, Melbourne, Australia
[3]Monash University, School of Public Health and Preventive Medicine, Melbourne, Australia
[4]Murdoch Children's Research Institute, Susceptibility to Paediatric Infection, Melbourne, Australia
[5]The Royal Women's Hospital, Department of Obstetrics and Gynaecology, Melbourne, Australia
[6]Melbourne IVF, Reproductive Services, Melbourne, Australia
[7]Murdoch Children's Research Institute, Developmental Disability and Rehabilitation Research, Melbourne, Australia
[8]University of Turku, Department of Internal Medicine, Turku, Finland
[9]The Royal Children's Hospital, Department of Cardiology, Melbourne, Australia
[10]The Royal Children's Hospital, Department of Respiratory and Sleep Medicine, Melbourne, Australia

Study question: Will there be measurable differences in characteristics of participants and non-participants that could bias the results of a clinical review follow up study?

Summary answer: Based on questionnaire data obtained by telephone several years before, factors influencing participation in the current clinical review were not major confounders.

What is known already: As there is wide belief that common adult health problems have their origins in early life, the IVF population might be at an increased risk through epigenetic mechanisms. In our earlier telephone interview-based study of this cohort, differences between the IVF and a spontaneously conceived control group were found, i.e. increased respiratory conditions, such as asthma and hay fever, and increased hospital admissions in childhood and adolescence. In terms of clinical review, there have been few studies to date of adults conceived by ART but a small number report on cardiometabolic outcomes and suggest a difference.

Study design, size, duration: This retrospective cohort of 24-35 year olds was recruited for clinical follow up in 2016-2017. 530 IVF-conceived and 490 age and sex-matched, spontaneously conceived controls were invited to participate.

Participants/materials, setting, methods: Participants were those who had completed a telephone interview in an earlier study in Victoria, Australia, and who were willing to come to the hospital for a clinical review, which took approximately three hours, encompassing assessments of cardiovascular structure and function, cardiometabolic profile, respiratory function and growth. A comparison of characteristics (e.g. health, sociodemographic, psychosocial) of participants with non-participants was possible using the questionnaire data collected in the initial telephone interview study.

Main results and the role of chance: Of the 179 (33.8%) IVF-conceived and 81 (16.5%) controls who participated in the follow up study, females were more likely to participate than males (58% of IVF and 69% of controls). Active decline occurred in 21% of both groups and the remaining proportion did not respond to three invitations to participate. The following key variables demonstrated no significant differences between participants and non-participants within both the IVF and control study groups: number of hospitalisations in childhood, chronic illness, asthma, allergies, mental health, gestation at birth, mother's age and parity, BMI, perceived age at sexual maturity, fertility concerns, quality of life, financial status, educational attainment (level of schooling). In the IVF group, participants were younger than non-participants when initially interviewed (61% <20 years compared with 48%, $p = 0.01$) and fewer worked >37 hours/week (36% vs 46%, $p = 0.05$). In the control group, participants had more allergies than non-participants (26% vs 19.3%, $p = 0.03$), were less likely to be in a relationship (41% vs 58%, $p = 0.03$), and had more anxiety/behaviour problems (32% vs 21.5%, $p = 0.04$). In both groups, among those who had completed school, non-participants had a lower final average education score than participants ($p = 0.01$).

Limitations, reasons for caution: Comparisons are based on self-reported data without validation, but the same errors in reporting are likely to be seen across all groups. Also, there has been a time lag between the telephone interview and clinical review (5-6 years) and we have no knowledge of that intervening period in non-participants.

Wider implications of the findings: Although participation was lower than expected, the similarity of characteristics between participants and non-participants reduces concern about selection bias. Furthermore, knowing what the few differences between participants and non-participants are, enables sensitivity analyses. We therefore expect that the clinical review will contribute substantially to knowledge of long-term safety of IVF.

Trial registration number: not applicable.

P-548 Yoga as an adjuvant to enhance the outcome of IVF treatment

P. Nayar, K.D. Nayar, M. Singh, N. Aggarwal, M. Gupta, R.A. Gupta, G. Kant, R. Gahlot, K. Nayar

Akanksha IVF Centre- Mata Chanan Devi Hospital, Reproductive Medicine, new delhi, India

Study question: To study the effect of Yoga on clinical pregnancy rates in women undergoing frozen embryo transfer.

Summary answer: This study suggests Yoga can be an adjuvant to improve the pregnancy rates in couples undergoing frozen embryo transfer.

What is known already: The distress of the diagnosis and the treatment of infertility is a known, well established fact. It can be confounding variable which can lead to poor treatment compliance, and hence outcome. Yoga is system of neuromuscular retraining which helps the organism to learn the relaxation response and a faster regaining of homeostasis after stress. Utilization of the techniques may help woman to cope with the roller coaster of psychophysiological states accompanying diagnosis and management of infertility.

Study design, size, duration: The study was conducted from 01.01. 2016 to 31.12.2017 at a private infertility centre. 150 women were randomly allocated to two groups. Group A (N = 77) attended 3 months of Yoga, thirty sessions- involving asana (exercises) and pranayama (regulated breathing) before undergoing frozen embryo transfer and Group B (N = 73) underwent frozen embryo transfer after 3 natural cycle without any Yoga adjuvant. Primary outcome was clinical pregnancy rates. Secondary outcomes were change in psychological test scores.

Participants/materials, setting, methods: Women with primary infertility > 5 years, who did not conceive in the first IVF cycle and were to undergo frozen embryo transfer in subsequent cycle were enrolled.Age > 38 years, Fibroid > 5 cm, either side hydrosalpinx, adenomyosis were excluded. Psychological assessment was done at baseline (S1) and after 3 months (S2) before ET using Hamilton Depression Rating Scale (HAM- D), Hamilton Anxiety Rating Scale (HAM-A) and FertiQol.

Main results and the role of chance: The Clinical Pregnancy rates were significantly better in Group A compared to Group B(49.35% vs 32.87%: p = 0.04). There was a significant S1 to S2 reduction after YOGA therapy in Hamilton Depression rating Scale (HAM- D), Hamilton Anxiety Rating Scale (HAM-A) (p< 0.001 for HAM-D and p<0.001 for HAM-A).The improvement in quality of life as seen on FertiQol but not statistically significant.

Limitations, reasons for caution: The study was done on a single centre, replication with more subjects and in different centres is needed.

Yoga encompasses a heterogeneity of techniques, there is a need to develop a standardised protocol suitable for the infertility patients which is simple, safe and effective.

Wider implications of the findings: Integrating **yoga** as an adjuvant to infertility treatment management may provide a simple, economic non invasive method which can enhance the outcome of the IVF treatment. It is cost effective and safe.

Trial registration number: MCDH/2016/54.

P-549 Fertility knowledge of Japanese university students who aspire to be schoolteachers in the future

Y. Akizuki[1], S. Kusunoki[2]

[1]Kumamoto university, educational department, Kumaomto-shi-, Japan
[2]Kumamoto University, Graduate School of Education, Kumamoto-shi, Japan

Study question: The aim of this study was to clarify the fertility knowledge of Japanese students who just entered the education department of one university.

Summary answer: Fertility knowledge among education students is insufficient, except for questions related to aging and smoking as risk factors.

What is known already: It is obvious that aging, STDs, obesity and smoking have a negative influence on fertility. Many previous studies reported that knowledge about fertility, reproduction and infertility among high school and university students is insufficient. Very limited research investigating fertility knowledge and attitudes toward fertility education among Japanese schoolteachers has been conducted. One study showed that the majority of teachers do not have enough fertility knowledge and are not confident in teaching this topic to students. However, the fertility knowledge of younger people who aspire to become schoolteachers in the future has not been clarified.

Study design, size, duration: We conducted a quantitative, cross-sectional questionnaire survey of first-year education department students in April 2017 at one university in the Kyusyu area. Questionnaires were distributed to all 291 students in an introductory psychology class that is required for all first-year education students. Only those who consented to participate in the survey were asked to complete the questionnaire.

Participants/materials, setting, methods: Although the response rate was 100%, those who were not first-year education students were excluded, leaving 252 participants.

The questionnaire asked about sociodemographic variables, desire to have a child, life planning experience, and daily life habits. To measure fertility knowledge, including the reproduction system and infertility, the Cardiff Fertility Knowledge Scale (13 items) and six original questions were used. To assess the relationship between fertility knowledge, gender and other variables, chi-square analysis was conducted.

Main results and the role of chance: 96.1% (242) of participants were 18-19 years old and 60.3% (152) were women. Although only 8.7% (22) currently had a sex partner, nearly 90% desired to have a child in the future. Approximately 70% experienced life planning in the past and almost 60% were interested in their own fertility.

The accuracy of knowledge about the effects of aging and smoking on fertility was comparatively high (71-90%). On the other hand, less than half answered the question about STDs as a risk factor of fertility correctly. As for questions concerning infertility (definition, frequency, gender ratio of cause), accuracy was not high (39-52%). The accuracy of the timing of pregnancy during the menstrual cycle was under 30%. Although over 60% correctly answered the question concerning the frequency of sperm production, only 4% correctly answered the question about the frequency of primordial egg generation.

As for fertility knowledge and gender, the accuracy of the question 'A woman who never menstruated is still fertile' among women was significantly higher than men. For the question about the frequency of sperm production, men had a higher accuracy rate than women. However, men's accuracy rate for the question about menopause was significantly lower than women.

Limitations, reasons for caution: The limitation of this study is that all participants were selected from only one university in the Kyusyu area in Japan. Therefore, caution should be taken when generalizing the results to the general population of Japanese university education department students.

Wider implications of the findings: From the present results, in order for younger people to have a child in the future when they desire, it is essential to give them accurate fertility knowledge. Therefore, first, schoolteachers should have accurate fertility knowledge to teach students. This might contribute to decreasing infertile patients due to age.

Trial registration number: not applicable.

P-550 Psychological influence of azoospermic male infertility diagnosis among men about to start in-vitro fertilization (IVF) treatment using donor sperm

M. Sharma, K.D. Nayar, P. Nayar, N. Agarwal, M. Singh, M. Gupta, G. Kant, R.A. Gahlot, K. Nayar

Akanksha Ivf Centre- Mata Chanan Devi Hospital, Reproductive Medicine, New Delhi, India

Study question: To compare psychological stress among men undergoing assisted reproductive technology (ART) with donor sperm compared to stress among men undergoing ART with own sperm.

Summary answer: The depression scores among males with donor sperm used as compared to males using their own sperm were significantly higher. The marital satisfaction was same.

What is known already: Studies comparing women and men found that women react more strongly overall to infertility. Some studies also suggest that men's experience of infertility is connected to threats to their masculinity. So, it was thus anticipated that even after donor sperm ART, male factor infertility could influence men's psychological well being. The aim of this study was to investigate whether a diagnosis of male azoospermic infertility had any influence on their experience of anxiety, depression and spousal relationship well being as compared to male partner in couples where the diagnosis was male, female, mixed or unexplained infertility.

Study design, size, duration: A cross sectional study was conducted with 100 couples attending the Out Patient Department of Akanksha IVF, Delhi for the first IVF cycle from January 2017 up to December 2017. 50 of these were diagnosed with azoospermic male infertility requiring donor sperm (Group 1), while the remaining 50 were diagnosed with other causes of male infertility,

female infertility, mixed or unexplained infertility using husband sperm (Group 2). Data were analyzed using SPSS software version 20.

Participants/materials, setting, methods: The study population comprised of 100 male partners who consented to participate in the study. A questionnaire was given to male partners at start of the ART cycle. They were asked to answer without communicating with their partners. They filled questionnaires on Beck's Anxiety Inventory (BAI), Beck's Depression Inventory (BDI) and Couple Satisfaction Index-16 (CSI-16). Data was analyzed. Means, standard deviation and ranges were used in descriptive statistics. Mann-Whitney test was performed for the scores.

Main results and the role of chance: The age and duration of infertility were analyzed in both the groups and the following values were ascertained. The mean age in the group of males requiring donor sperm (Group 1) was 36.86 ± 4.40 years and the mean age in the other group, (Group 2) was 36.76 ± 5.10 years. The mean value of duration of infertility in the donor treated sperm was 6.20 ± 3.07 years while the duration of infertility in Group 2 was 5.52 ± 3.79 years. The p-value of comparisons of age and duration of infertility in both the groups is 0.917 and 0.664 respectively. So, the demographic variables of both the groups were comparable.

The Mann-Whitney test was performed on the Beck's Anxiety Inventory score, Beck's Depression Inventory score and the Couple Satisfaction Index-16 scores of both the groups. The U score was 931.5 for the comparison of the Beck's Depression Inventory in the two groups, with a p-value of 0.028, signifying greater depression scores in the donor sperm usage group. The anxiety levels, analyzed by BAI, were concluded to be non significantly different ($U = 1065.5$, $p = 0.203$). The CSI-16 scores depicting marital relationship was also comparable ($U = 1202.5$, $p = 0.743$).

Limitations, reasons for caution: The infertility treatment are not covered under insurance in India, so, the study included subjects who were financially secure, well educated and from an urban background, a wider study in a public setup would be more descriptive of the general population.

Wider implications of the findings: The psychological state of men with azoospermic infertility needs to be given more consideration and may need counseling.

Trial registration number: MCDH/ 2017/6

P-551 Can men's dyadic coping strategies make the difference? The role of man's dyadic coping strategies for his and his partner's adjustment to infertility

C. Chaves[1], M.C. Canavarro[1], M. Moura Ramos[2]

[1]*University of Coimbra, Faculty of Psychology and Educational Sciences, Coimbra, Portugal*

[2]*Centro Hospitalar e Universitário de Coimbra, Reproductive Medicine unit, Coimbra, Portugal*

Study question: Does the association between the impact of infertility stress and marital and emotional adjustment is mediated by dyadic coping (DC) by oneself and by partner?

Summary answer: Significant indirect effects were found between infertility stress impact and marital adjustment through DC strategies by the self, for men, and by partner, for women.

What is known already: In previous literature, emotional and marital adjustment to infertility showed great variability. Research is now focused in examining factors that predict a better adjustment. Individual coping strategies were found to explain partially this variability in infertile individuals' adjustment. Nevertheless, in other fields of expertise, DC strategies were associated with dyadic adjustment and distress levels, being even a stronger predictor of relationship quality than individual coping strategies. As infertility is a dyadic experience, it seems plausible that strategies triggered inside the relationship to cope with stressors (DC strategies) influence couples' adjustment, but until now this association has not been studied.

Study design, size, duration: The study was cross-sectional and included 67 heterosexual couples with infertility (n = 134 participants). Participants were recruited in a public fertility treatment unit.

Participants/materials, setting, methods: Participants are 67 couples that were referred to a reproductive medicine unit for fertility problems. They were consecutively recruited by the researcher. Written informed consent was obtained. Self-report measures assessing sociodemographic data, infertility-related stress (Fertility Problem Inventory), dyadic coping (Dyadic Coping Inventory), dyadic adjustment (Dyadic Adjustment Scale – Revised) and depression and anxiety symptoms (Hospital Anxiety and Depression Scale) were filled out by participants.

Main results and the role of chance: The final sample was composed by 67 couples, with a response rate of 73%. Couples were on average in a relationship for approximately 6 years ($M = 5.98$; $SD = 3.10$) and were trying to conceive for approximately 3 years ($M = 3.01$; $SD = 1.67$). Mean age of participants was 34.67 and 32.73, for males and females, respectively. Most participants were highly educated and had medium socio-economic status. There is an indirect effect of the impact of infertility in one's life on marital adjustment through men's perceived dyadic coping efforts employed by the self (Estimate: .181; 90% BCCI -.356, -.061) and women's perceived dyadic coping efforts of the partner (Estimate: -.236; 90% BCCI -.422, -.126). These models explained 38% and 30% of marital adjustment variance for women and men, respectively. Regarding the emotional adjustment of infertile couples, infertility stress impact had an indirect effect only on depressive symptoms through men's dyadic coping by oneself.

Limitations, reasons for caution: Due to the small sample size and the cross-sectional design, the results must be analysed with caution. Moreover, the sample comprised mainly highly educated individuals, from urban areas, which restrain the generalization of findings to all infertile couples' population.

Wider implications of the findings: The results highlight the importance of men's dyadic coping strategies for the marital adjustment of couples, as well as for men's emotional adjustment. Findings emphasize the importance of involving men in the fertility treatment process, reinforcing the dyadic nature of infertility processes.

Trial registration number: not applicable.

P-552 Endometriosis and/or wish for a child: Implications on partnership, sexuality and psychological well-being

M. Schick[1], A. Germeyer[2], S. Hecht[2], S. Rösner[2], T. Strowitzki[2], B. Ditzen[1], T. Wischmann[1]

[1]*Institute of Medical Psychology, University Hospital Heidelberg, Heidelberg, Germany*

[2]*Department of Gynecologic Endocrinology and Fertility Disorders, Heidelberg University Women's Hospital, Heidelberg, Germany*

Study question: Goal was to investigate the relationship between psychological well-being and partnership of women with and without endometriosis and/or wish for a child and their partners.

Summary answer: Study emphasizes the importance of partnership for psychosocial well-being. Participants having EM and no desire for children scored the highest on stress, depression and anxiety.

What is known already: Endometriosis (EM) is a common, gynecological, inflammatory disorder, often associated with severe dysmenorrhea, pelvic pain, dyspareunia and infertility. It is well known that partnership positively influences the course of various diseases. Furthermore, a positive relationship between partnership and perceived stress can be found in infertility treatment, with partnerships being able to buffer high levels of stress associated with treatment. However, there are still few studies on the reciprocal effects of endometriosis on partnership and sexuality.

Study design, size, duration: A quantitative study was devised, approved by the Ethics Committee of the Heidelberg Medical Faculty. The study took place from September 2016 to December 2017 with N = 108 participants.

Participants/materials, setting, methods: Participants completed a questionnaire with items regarding endometriosis (EHP-5, Endometriosis Health Profile), wish for a child (Screen-IVF), partnership (SHP, Swiss Household Panel), sexuality (FSFI, Female Sexual Function Index), psychosocial well-being (DASS, Depression Anxiety Scales), pain (DSF, German Pain Questionaire) and sociodemographic items. All women undergoing laparoscopy during their treatment at Heidelberg University Women's Hospital and their partners were invited to participate in the study. Data were analyzed using independent t-test analysis and ANOVA.

Main results and the role of chance: In total, N = 58 women (Ø age: 30.9) and N = 50 men (Ø age: 35.0) participated in the study. 93.4% lived in partnership (Ø 7.0 years) and 9.3% already had children. 87.6% had a present wish for a child, on average since 3.1 years. EM was clinically confirmed in N = 78 (72.2%) participants respective their partners. Of all subjects, 57.5% had high school or university graduation. The sample was split in three groups: Participants with EM and wish for a child (EM+C+; N = 63), participants with EM and without wish for a child (EM+C-; N = 15) and participants with no EM but wish for a child (EM-C+; N = 30). Sociodemographic variables did not differ between the groups, besides group EM+C- was younger than the other groups (p≤.001). The groups differed significantly from each other in terms of partnership satisfaction (p≤.080), with group EM+C+ having the highest and the men of group EM+C- the lowest partnership satisfaction (p≤.001). Group EM-C+ had the highest intercourse frequency (p≤.034) and group EM+C- reported most dyspareunia (p≤.001). Satisfaction with sexual intercourse was comparably high in all groups. Furthermore, the groups differed in terms of perceived stress (p≤.004), anxiety (p≤.002) and marginal in depression (p≤.068), with group EM+C- reporting the highest scores.

Limitations, reasons for caution: Generalization of findings is limited due to small sample and the unequal distribution of groups, based on the difficulty of diagnosing women with endometrioses outside of family planning. Furthermore, participants in this sample had an above-average high educational background.

Wider implications of the findings: The study highlights the importance of partnership for psychosocial well-being. Participants with EM and no desire for children showed lower partnership satisfaction, but higher scores on stress, depression and anxiety, compared to participants with EM and desire for children. The causal relation of these factors needs to be explored further.

Trial registration number: None.

P-553 Mothers to be without a partner - current data on a German-wide documentation on issues raised by single women in fertility counselling

B. Mayer-Lewis[1], P. Thorn[2], M. Schick[3], T. Wischmann[3]

[1]*Staatsinstitut für Familienforschung an der Universität Bamberg, Familienforschung, Bamberg, Germany*
[2]*Practice for Couple and Family Therapy, Infertility Counselling- German Society for Fertility Counselling, Moerfelden, Germany*
[3]*Heidelberg University Medical School, Center for Psychosocial Medicine- Institute for Medical Psychology, Heidelberg, Germany*

Study question: What do we know about women without a partner seeking fertility counselling in Germany?

Summary answer: Our study shows that of all documented fertility counselling sessions with individuals approx. a quarter (26%) were used by women without a partner.

What is known already: Delaying child birth is a common phenomenon in many industrial countries. In Germany in 2015, 51% of all first-time-mothers were 30 years or older. In order to fulfil their wish for a child, an increasing number of women decide to build a family even though they lack a partner. So far, there is only little international data regarding women considering solo mothership and there are no studies in Germany.

Study design, size, duration: After the development of evaluation instruments, a first German-wide online assessment of counselling sessions was carried out between 2015 and 2017. The study included 517 valid documentations from psychosocial fertility counsellors and 197 feedback forms from women and men with the desire for a child who took up professional counselling.

Participants/materials, setting, methods: The study was conducted in cooperation between the State Institute for Family Research at the University of Bamberg, the Institute of Medical Psychology at Heidelberg University Hospital and the German Society for Fertility Counselling. Data was collected via an online questionnaire addressed to all German professionals offering psychosocial fertility counselling and to all men and women who sought counselling.

Main results and the role of chance: In 26% of all counselling sessions with individuals (n = 282), women stated that childlessness was the result of a lack of partner. These women were aged between 26 and 48 yrs. with a mean age of 38 yrs. 79% of them planned pregnancy with the assistance of medical treatment and sperm donation. Though most intended to use sperm donation only, approx. 5% already had concrete plans for using either both egg and sperm donation or solely embryo donation. Nearly 14% of the women who had already worked out concrete plans for using reproductive assistance, or had already started treatment, took advantage of treatment possibilities abroad. However, during counselling, nearly 33% of all single women discussed the possibility of treatment abroad. 61% of all women without partner were interested in specific forms of medical treatment of which 33% were egg or embryo donation and 2.5% social freezing. The most important issues during counselling were as follows: 84% managing future parenthood; 75% managing emotional distress; and 61% information regarding legal regulations. This data shows the need for comprehensive counselling addressing both current (such as legal information and emotional distress during treatment) and future issues (such as parenting a child after donor conception).

Limitations, reasons for caution: We only report on those women without partner who took up counselling; other single women may have different needs and perspectives. We also only examined those opting for medical treatment and not for private solutions. Some women of the target group may not have been addressed by an online survey.

Wider implications of the findings: The data shows that approx. a quarter (26%) of individuals seeking fertility counselling are women without a partner. Analysing the collected data enables counsellors to develop needs-orientated offers for women planning solo motherhood.

Trial registration number: not applicable.

P-554 Effects of family-centered postpartum care for postpartum depression among previously infertile couples

S.H. Lee[1,2,3], L.S. Huang[1,4], M.C. Lee[2,5,6], M.S. Lee[2,4]

[1]*Chung Shan Medical University, School of Nursing, Taichung, Taiwan R.O.C.*
[2]*Chung Shan Medical University, Institute of Medicine, Taichung, Taiwan R.O.C.*
[3]*Chung Shan Medical University Hospital, Department of Nursing, Taichung, Taiwan R.O.C.*
[4]*Lee Womens' Hospital, ART center, Taichung, Taiwan R.O.C.*
[5]*Chaoyang University of Technology, College of Management, Taichung, Taiwan R.O.C.*
[6]*Taichung Hospital- Ministry of Health and Welfare, Family Medicine, Taichung, Taiwan R.O.C.*

Study question: The purpose of this study was to develop and evaluate a family-centered postpartum care for postpartum depression among previously infertile couples.

Summary answer: For husbands, the mean score of EPDS in the experimental groups had significantly lower than that of the control groups after intervention.

What is known already: Postpartum depression (PPD) is a significant mental health problem that occurs more frequently in the first 4 weeks postpartum and also may occur later or during the first postpartum year. The correlation between paternal and maternal depression was positive, but little is known about the effects of family-centered postpartum care for postpartum depression among couples receiving assisted reproductive technology.

Study design, size, duration: This is a randomized controlled trial for previously infertile couple who will be divided into experimental group and control group based on Edinburgh Postpartum Depression Scale (EPDS≧10 points, either husband or wife)checked 4 weeks after delivery. There were 180 couples recruited in the screening stage. Forty-nine couples were randomized assign into two groups. The experimental group consists 21 couples and the control group consists 19 couples in the final stage.

Participants/materials, setting, methods: Experimental group will receive health education CD/booklet at the 5th week, and telephone consultation for 20 minutes during 6th-9th weeks after delivery. The self-administer questionnaire is composed of subjects' profiles, Edinburgh postpartum depression scale, self-esteem questionnaire, Brief parenting stress questionnaire and social support questionnaire. Generalized estimating equation(GEE) will be used for multi-variant time-series data analysis by SPSS/PC

window 19.0 to evaluate the effects and difference of long-term change with the intervention.

Main results and the role of chance: For husbands, the mean score of EPDS in the experimental groups had significantly lower than the control groups after intervention(Exp(B) = 0.12, 95%c.I. = 0.025-0.569, p<0.05). But, for wives, the mean score of EPDS in the experimental groups had not significantly lower than the control groups after intervention(Exp(B) = 0.457, 95%c.I. = 0.165-1.268, p>0.05). The couples still had high demand for information of postpartum care during 3 to 6 months after delivery. The most helpful education method perceived by husbands in 3th and 6th months was booklet(86%), and then telephone consultation(62%) and booklet(62%). The most helpful education method perceived by wives in 3th and 6th months was telephone consultation(86%), and then telephone consultation(72%).

Limitations, reasons for caution: The study was performed by a self-administered questionnaire which might involve a recognition problem in meaning or definition of questions asked.

Wider implications of the findings: Through this study, a family-centered postpartum care for postpartum depression in previously infertile couple model can be developed as a reference for care and policy.

Trial registration number: not applicable' for non-clinical trials

P-555 Cortisol diurnal profile in women with high anxiety may be associated with progesterone levels in infertile women

M. Moura-Ramos[1], M.C. Canavarro[2], A.P. Sousa[1], S. Antunes[3], H. Lopes[1], T. Almeida Santos[4]

[1]Centro Hospitalar e Universitário de Coimbra, Serviço de Reprodução Humana, Coimbra, Portugal
[2]University of Coimbra, Faculty of Psychology and Educational Sciences, Coimbra, Portugal
[3]Centro Hospitalar e Universitário de Coimbra, Serviço de Patologia Clínica, Coimbra, Portugal
[4]University of Coimbra, Faculty of Medicine, Coimbra, Portugal

Study question: Can anxiety be associated with an impaired reproductive function in women with infertility?

Summary answer: Women with anxiety symptoms above the normal range may have altered diurnal cortisol rhythm, especially in the situations where progesterone levels are low.

What is known already: The effect of stress in infertility has been addressed in previous studies, but findings are still inconsistent. In large cohort of couples trying to conceive, it was found that preconception stress, assessed by alpha amylase, was associated with a longer time to pregnancy, but the mechanism of this effect remains unclear. Also, it has been suggested that ovulation may be linked with stress, although this hypothesis needs further research.

Study design, size, duration: This study is part of a prospective study evaluating biopsychological correlates in couples with infertility. The design of the current study was cross-sectional. Participants were women from heterosexual couples attending a reproductive medicine unit for infertility diagnosis. Written informed consent was obtained from all participants.

Participants/materials, setting, methods: Women were consecutively recruited by the researcher at their first visit at the unit. Progesterone was measured at the 23rd day of the cycle. Five samples of saliva were collected in the previous day for determination of salivary cortisol, to obtain the diurnal profile: at awakening, +30', +45', at 16 h and by bedtime. In the same day, symptoms of anxiety were assessed using the Hospital Anxiety and Depression scale.

Main results and the role of chance: The final sample was composed by 44 women. Mean age of participants was 31.31 (SD = 3.17). Most participants were highly educated and had medium socio-economic status.

Women were grouped in "low" and "high" anxiety according to the cutoff score for the HADS for the anxiety scale (7). Groups based upon the progesterone level were dividing using the cut off value of 9 ng/ml (<9=likely inadequate luteal function, ≥9=suggestive of adequate luteal function). Results showed that there was a significant interaction effect between the diurnal cortisol profile, levels of anxiety (low vs. high) and progesterone level (<9=likely inadequate luteal function, ≥9=suggestive of adequate luteal function) (F = 2.848; p = 0.05). Further analysis revealed differences across the groups (F = 4.750, p=.038). The diurnal profile of the cortisol was equal across the two groups of progesterone levels in women with low anxiety. In the group of high anxiety, the group with progesterone levels suggestive of inadequate luteal function had a different profile, with peaked cortisol values at the third cortisol measurement.

Findings highlight that women with anxiety symptoms above the normal range may have altered diurnal cortisol rhythm, especially in the situations where progesterone was low.

Limitations, reasons for caution: Main limitation was the small of number of patients that were included in the final sample. In addition, the study was cross sectional, and therefore no causal inference can be established. Finally, the absence of absolute cut off scores for defining ovulation may affect the consistency of the findings.

Wider implications of the findings: The findings challenge the notion that there is a linear association between stress and infertility. Our findings suggest that psychobiological stress is associated with the progesterone output, although future prospective should clarify the predictive effect of psychobiological stress in ovulation.

Trial registration number:

P-556 Preliminary data on communication to parents of donor-conceived offspring regarding the risks of inherited diseases

E. Buyse[1], G. Verheyen[2], I. Pletincx[3], B. Andrea[4], H. Tournaye[2], M. Bonduelle[5], J. Nekkebroeck[6]

[1]UZ Brussel, Centre for Medical Genetics/ Centre for Reproductive Medicine, Brussels, Belgium
[2]UZ Brussel- Vrije Universiteit Brussel, Centre for Reproductive Medicine, Brussels, Belgium
[3]UZ Brussel, Centre for Reproductive Medicine, Brussels, Belgium
[4]UZ Brussel, Centre for Medical Genetics, Brussels, Belgium
[5]UZ Brussel- Vrije Universiteit Brussel, Centre for Medical Genetics, Brussels, Belgium
[6]UZ Brussel- Vrije Universiteit Brussel, Centre for Medical Genetics/ Centre for Reprodcutive Medicine, Brussels, Belgium

Study question: How to manage the communication of genetic risks to parents? What's the impact of this risk on the desire for other children using donor gametes?

Summary answer: Description of our experience on communication of genetic risks to parents with donor-conceived offspring and how this information influences the wish for a consecutive child.

What is known already: Little is known about the communication of newly identified genetic risks in donor-conceived offspring and the preferences and needs of their parents. More studies on risks of inherited diseases in donor-conceived offspring focus on medical evaluation and genetic screening and their limitations and challenges. Studies show an international variability in genetic evaluations, education and informed consent processes (Sims et al., 2010; Isley & Callum, 2013; Dondorp et al., 2014; Isley et al., 2016).

However, there is limited knowledge about the wish for a second child using the same donor with a (minor) genetic risk (Squires & Simoglou, 2013).

Study design, size, duration: Between June 2015 and December 2017, a qualitative study was performed with 27 parents who have one or more children, conceived using gametes from anonymous sperm donors (n = 23), oocyte donors (n = 3) or both (n = 1). The genetic risk presented after the donors had been qualified for donation. All parents were treated in our fertility unit with gametes from our internal or from an external bank. Twenty two parents had a wish for a second child.

Participants/materials, setting, methods: Semi-structured interviews were performed with the parents at our Medical Genetics unit, asking them about: (1) the way they were informed about the genetic risk, (2) their perceptions of the communication by health-care providers, (3) their perceived risk, and if applicable (4) how they would like to realise their wish for a second child.

Main results and the role of chance: Twenty one parents were informed about a minor genetic risk by the fertility department when seeking treatment to conceive a second child, 4 parents without seeking treatment, and 2 parents received an e-mail from an external sperm bank. Both parents informed by e-mail, were upset and preferred being informed face-to-face. In the group with the wish for a second child, 2 parents were aghast and worried that they would

never know the risk if they didn't ask for the treatment. Eleven parents (40%) experienced the risk-communication as emotionally taxing, 10 parents (37%) felt comfortable during this contact. Two parents (7%) regarded the communication as unnecessary; both of them have a wish for a second child. Independent of the medical risk, 55% perceived the risk as high, 14% as moderate and 33% as low.

Of the parents wishing for a second child who perceived the risk as high, 7 had doubts (58%) about the way to fulfil their wish, 3 (25%) asked for a different donor, while 2 (17%) asked for the same donor. With a low risk-perception, 6 (67%) wanted to use the same donor, 2 (22%) had doubts and 1 (11%) wanted to use a different donor.

Limitations, reasons for caution: The small sample size undermines the representability of the results to a whole population. Variation in how future parents were counselled upon intake may affect how they experienced the communication. Because of the descriptive study-design findings may be open for interpretation.

Wider implications of the findings: This research may be a pre-cursor to future research. The issues reported can be used to achieve a higher quality of care. These findings may be a starting point for developing guidelines on counselling, exploring the (ir)relevance of minor genetic risks for parents with donor-offspring and the impact on secrecy.

Trial registration number: No randomized controlled trial.

P-557 Obsessive symptoms and the need of gamete donation as predictors of treatment dropout in infertile patients

L. Jurkowski[1], J.M. Gómez Penedo[2], N. Bossi[3], C. Granados[3], E. Polak de Fried[3]

[1]CER Medical Institute, Psychology, Buenos Aires, Argentina
[2]Conicet UBA, Psychology, Buenos Aires, Argentina
[3]CER Medical Institute, Human Reproduction, Buenos Aires, Argentina

Study question: Can psychological symptoms and medical diagnosis be a predictor of dropout in infertile patients?

Summary answer: In infertile patients high scores of obsessivity and the need of gamete donation could predict the possibility of dropout.

What is known already: Infertility diagnosis and treatment is a burden for some patients and this relates to psychological symptoms that have an impact on their quality of life and medical treatments. There is an agreement in the literature that psychological burden is referred as one of the reason of treatment dropout but there are no studies about specific symptoms related to this abandonment. As far as we know, there are no publications regarding treatment discontinuation and the need of gamete donation.

Study design, size, duration: Prospective and relational study part of a wider research program in psychology and infertility from the CER Medical Institute from Buenos Aires, Argentina. Over a period of six months, from March-August 2017, 187 patients completed a questionnaire.

Participants/materials, setting, methods: 187 new patients from infertile couples, 120 women(Age: x̄ 38.21 +/-5.18 years) and 67 men(Age: x̄ 39.61 +/-7.42 years) agreed to complete the Symptom Checklist-90-R(SCL-90-R) (Derogatis, 1994), a self-reported questionnaire, in the waiting room before their first appointment at the fertility clinic.The SCL-90-R is a standardized instrument that assesses a wide range of current psychological symptoms. Medical data is obtained from clinical records. Logistic regression was made with the SPSS 24. Statistical significance = $p < 0.05$.

Main results and the role of chance: In the total sample, the likelihood of the patient dropping out was significantly predicted by: a) levels of obsessivity, $\beta = 1.32$, SE=.66, Wald(1) = 6.157, $p < .05$, and, b) gamete donation (female or male), $\beta = 1.26$, SE=.48, Wald(1) = 6.96, $p < .01$. Both higher levels of obsessive symptoms and the need for a gamete donation increase the odds of dropping out. When looking at women, the need effect of gamete donation remain significant, $\beta = 1.32$, SE=.62, Wald(1) = 4.58, $p = .03$. On the other hand, in the men sample, obsessivity significantly predict drop out, $\beta = 6.13$, SE = 2.99, Wald(1) = 4.19, $p = .04$.

Limitations, reasons for caution: It was a small sample and limited in time so results should be generalized with caution.

Wider implications of the findings: This study shows that the impact of knowing the need of gamete donation and obsessive symptoms could predict treatment discontinuation in infertile patients.It would be helpful to be aware of this in fertility clinics in order to incorporate a psychopathological screening to provide patients with help and improve treatment adherence.

Trial registration number: N/A.

P-558 The evaluation of patients' experience with manual vacuum aspiration: Comparison with other methods of miscarriage managements and infertility procedures

W.C. Cheung, G.W.S. Kong, A.K.W. Yiu, A.S.Y. Hui, J.P.W. Chung, T.C. Li

The Chinese University of Hong Kong, Department of O&G 1 F, Shatin- New Territories, Hong Kong

Study question: How do women perceive manual vacuum aspiration (MVA) in comparison with other methods of miscarriage management and infertility procedures?

Summary answer: Even though MVA was associated with the highest pain score in comparing with infertility procedure, women highly accepted MVA procedure.

What is known already: Previous studies reported that MVA was as effective as electric vacuum aspiration and it had fewer side effects than the use of misoprostol. However, it is not known the efficacy and acceptability of MVA in comparing with three other measures of first trimester miscarriage.

Study design, size, duration: This comparative cohort study took place in a university based teaching hospital with recruiting 55 women underwent MVA over a 12 months period. The data of women underwent suction curettage (n = 53), medical evacuation (n = 59) and expectant management (n = 58) were retrieved from our previous randomized controlled trial.

Participants/materials, setting, methods: Patient's psychological status was systematic assessed through various instruments including impact of event (IES), state-trait anxiety inventories (STAI), Beck depression inventory (BDI), general health questionnaire (GHQ), and client satisfaction scale (CSQ). Women were asked to rate their pain score of (1) MVA, (2)oocyte retrieval (OR), (3) hysterosalpingogram (HSG), (4) embryo transfer (ET). The number of days of bleeding and abdominal pain was recorded by a symptom log sheet.

Main results and the role of chance: As regarding the pain experience of infertility procedures, women at MVA procedure (6.4 ± 1.7) had significantly higher ($p = 0.000$) pain level than HSG (5.1 ± 2.8), OR (4.5 ± 3.0) and ET (0.9 ± 1.8). However, there was no difference in client satisfaction level. Among all groups, there was no difference in IES, BDI, GHQ and CSQ scores. In comprising the 4 different methods of miscarriage management, the anxiety score in women who underwent MVA (54.9 ± 9.4) was significantly lower ($p = 0.041$) than that in the expectant group (60.8 ± 13.0), and found similar to suction curettage (58.5 ± 10.6) and medical management group (59.7 ± 12.9). The duration of bleeding (in days) of MVA group (9.7 ± 4.1) was significantly shorter than the medical (15.1 ± 6.6) and expectant (12.8 ± 5.8) management group, but there was no difference from suction curettage group (10.7 ± 5.8). Four groups of women had no difference in the duration (in days) of abdominal pain. The complete evacuation rate of MVA group (94.5%) was significantly higher than medical (71.2%) and expectant (79.3%) management group, but there was no significantly difference between MVA and suction curettage group (98.1%).

Limitations, reasons for caution: Due to the comparative cohort study design, the finding should be interpreted with caution.

Wider implications of the findings: Even though MVA group had similar client satisfaction level compared with other methods of miscarriage management, it was also associated with the highest pain score. Therefore, further study is required to examine methods to reduce the pain during MVA is deemed desirable.

Trial registration number: not applicable.

P-559 Counselling in decision making by couples for assisted reproductive technology – A key role in quality care

N. Agarwal, K.D. Nayar, P. Nayar, R. Gahlot, M. Singh, M. Gupta, G. Kant, D. Nayar

Akanksha IVF Centre- Mata Chanan Devi Hospital, Reproductive Medicine, New Delhi, India

Study question: How couples decide for fertility treatment and what is the role of counselling?

Summary answer: Key factors in deciding for fertility treatment are finance, society pressure and prognosis. Counselling can help couples to choose the appropriate treatment.

What is known already: Coping with the emotional challenges of infertility can be difficult for couples. More stressful is the task of decision making in seeking fertility treatment. When they embark on assisted reproductive treatment (ART) they may experience many different emotions, from joy and excitement to grief and disappointment. This can be emotionally and physically challenging, Clinicians need to develop the skills to communicate about the treatment modalities available to be able to reduce the emotional suffering, to prepare them for fertility treatments, and explore the options and implications when making decisions about starting, changing or stopping treatments.

Study design, size, duration: Longitudinal study was performed at fertility centre in Delhi, India where 900 patients were interviewed during the year, January 2017 - December 2017, who consented to participate in study. They were divided into two groups: Group A (n = 348) who were ready for ART and Group B (n = 552) who did not accept ART due to factors like finance, social pressure and prognosis explained for the ART. Data were analyzed using SPSS software version 20.

Participants/materials, setting, methods: Group B was counselled for accepting ART. 333 patients accepted ART after counselling while 219 did not accept ART. Chi square test was applied to find out the role of counselling and extent to which finance, social pressure and prognosis influence the decision of couple for accepting or rejecting ART treatment.

Main results and the role of chance: Chi-square test for independence was calculated comparing frequency for accepting ART treatment in patients with social pressure. A significant interaction was found (X^2 [1] = 12.83, $p<0.05$) and Cramér's phi coefficient = 0.476 which shows strong association that is 71.43% of them accepted ART treatment after counselling as compared to 28.57% who did not accept.

Similarly significant interaction was found between prognosis of ART and accepting ART after counselling (X^2 [1] = 5.79, $p<0.05$). In Patient with good prognosis ,79.17% of them accepted ART treatment after counselling as compared to 20.83% who did not accept and patient with poor prognosis ,44.45% still opted for ART after counselling and Cramér's phi coefficient = 0.34 which shows moderate association.

Chi-square test for independence was calculated comparing non- modifiable factor finance with accepting or rejecting ART after counseling. Although patients accepted ART after counseling but was found to be not significant.

In Conclusion, we found in our study counselling helped significantly in couples for accepting ART treatment when they were effected by peer pressure and worried about final outcome of ART. Counselling may have a role in patients with financial problems also but finance is limiting factor for accepting ART.

$P<0.05$ was considered significant.

Limitations, reasons for caution: Although it is prospective study, it has limitation of small sample size.

Wider implications of the findings: When couples first meet with specialist, most of them have not made any decisions and are seeking information and advice. Understanding how couples reach consensus about accepting reproductive treatment and counseling appropriately holds promise to improve quality of care and increase long-term decisional satisfaction for patients and their partners.

Trial registration number: MCDH/ 2017/7

P-560 Fertility- and early menopause-related information needs of young breast cancer survivors

E.M. Sparidaens[1], I. Beerendonk[2], D. Braat[2], W. Nelen[2]

[1]*Radboud university medical center, Obstetrics and Gynaecology, Tilburg, The Netherlands*

[2]*Radboud university medical center, Obstetrics and Gynaecology, Nijmegen, The Netherlands*

Study question: What are the fertility- and early menopause-related information needs and preferences of Dutch young breast cancer survivors?

Summary answer: Extensive information about fertility is desired by young breast cancer survivors, especially on the risk of infertility, possible treatments and long-term consequences of early menopause.

What is known already: Approximately 10-15% of women diagnosed with breast cancer are in their reproductive age. Treatment can impair their fertility, which is disturbing since half of them desire to have a subsequent pregnancy after treatment. Current guidelines focus on informing breast cancer patients on the possibility of reduced fertility mainly prior to treatment, because this is the moment to decide about fertility preservating options. However, it is equally important to address information needs on fertility and possible early menopause after treatment has been completed and the wish to conceive becomes topical.

Study design, size, duration: A qualitative study consisting of semi-structured in-depth interviews with professionals and patients. In May 2015 13 professionals (oncologists, surgeons, gynaecologists, nurses) were interviewed about their experiences with information provision concerning fertility during follow-up. Based on these results a topic guide has been developed, which was used in 18 interviews with patients between April 2016 and December 2017. Furthermore, after each interview, patients composed a priority list with the five most important items of information provision.

Participants/materials, setting, methods: Interviewed professionals were active in the Radboud university medical center (Radboudumc) and four peripheral hospitals in the Netherlands. Interviewed patients were treated in the Radboudumc or Rijnstate Hospital. Eligible for participation were women between 20-45 years at the time of the interview who had completed their initial treatment, i.e. surgery and chemo- or radiotherapy. The number of interviews was determined by data saturation. Data were analyzed in accordance with grounded theory.

Main results and the role of chance: The risk of infertility was discussed with most of the women before starting treatment, although half of them weren't satisfied with the information they received. After treatment had ended, also the majority of participants indicated that they received too little information and many reported having brought up the topic themselves. Most women looked up fertility and early menopause online and described struggling to find reliable information specific to their situation. They expressed the need for an information tool on fertility and early menopause aimed at young breast cancer survivors. Among other items, this tool should include information such as the chance of still being fertile and when to expect their menstruation cycle to resume. They want to know the risks of pursuing a pregnancy, for themselves as well as for the future child. When is the best moment to do so and what contraception should be used in the meantime? They seek advice on how long they should try to conceive before approaching a fertility specialist. With regard to early menopause, they want to know which symptoms to expect and especially what the long term risks are for their general health. They value advice on dealing with these problems.

Limitations, reasons for caution: Limitations include focusing on breast cancer survivors and a shortage of quantitative data. We started to provide quantitative data through patients' priority lists, but given the sample size statistic measurements couldn't be performed. It would be interesting to confirm data in a larger population also including other types of cancer.

Wider implications of the findings: In-depth insight in the information needs of young breast cancer survivors concerning fertility and early menopause was obtained. In the following months information materials will be developed

and subsequently tested within this population. This supports professionals to improve information provision to meet the needs and preferences of their patients.

Trial registration number: not applicable.

P-561 Impact of infertility diagnosis on male sexuality and self esteem

L. Leis[1], M. Vieira[2], C. Busso[3], M. Cassará[3], C. Glina[3], L. Tso[3], R. Romano[4], S. Glina[2]

[1]Projeto Alfa, Psicology, São Paulo, Brazil
[2]Projeto ALFA, Urology, São Paulo, Brazil
[3]Projeto ALFA, Reproductive Medicine, São Paulo, Brazil
[4]Projeto Alfa, Reproductve Medicine, São Paulo, Brazil

Study question: Does infertility diagnosis impact on male sexuality and self esteem?

Summary answer: Diagnosis of infertility does not seem to affect male self esteem. However, in couples presenting with combined infertility factors, male partners showed orgasmic dysfunctions.

What is known already: Studies show that the diagnosis of infertility, specially male infertility, negatively interferes in male auto esteem, confidence and sexuality.

Study design, size, duration: Cross sectional, descriptive study.

Participants/materials, setting, methods: One hundred twenty two men during in vitro fertilization were included, between March 2017 and December 2017. Sexual Quotient- male version- (SQ-M) was used to evaluate sexuality and Rosenberg Self-Esteem Scale to evaluate self esteem. In associations involving diagnosis, fixed factor analysis of variance was used. In associations involving sexual dysfunctions, Fisher's exact test was used. Adopted $p = 0.05$ statistically significant.

Main results and the role of chance: 27% of couples presented male, 50% female and 22,1% combined infertility factor. There was no association between self esteem and infertility factor ($P = 0.851$). In couples presenting with combined infertility, male partner had difficulties in achieving orgasm ($P = 0.043$). In couples with male infertility, male partner showed higher self confidence in sex ($P = 0.045$) than in couples with female or combined factors. No associations were found between sexuality/auto esteem and duration of infertility, previous pregnancies or education.

Limitations, reasons for caution: I n our sample, the majority of the couples presented female infertility, what might have generated a sample bias.

Wider implications of the findings: Diagnosis of infertility has a negative impact on male sexuality. In those couples psychological follow up should be encouraged.

Trial registration number: Not applicable.

P-562 'myFertiCare': quantitative evaluation of an online application for infertile couples

K. Fleischer[1], E.M. Sparidaens[2], D. Braat[2], J. Logger[2], W. Nelen[2]

[1]Radboud University Medical Center, Department of Obstetrics and Gynaecology, Nijmegen, The Netherlands
[2]Radboud university medical center, Obstetrics and Gynaecology, Nijmegen, The Netherlands

Study question: Is it feasible to develop and successfully implement an online application to support couples undergoing ICSI with surgically retrieved sperm during their treatment trajectory?

Summary answer: myFertiCare, an online application providing personalized and interactive features has been quantitatively evaluated. Since it meets Human, Organizational en Technological aspects, successful implementation is concluded.

What is known already: The Internet is an important and low threshold source of information and support for couples undergoing ART. We hypothesized that an online application can be a suitable instrument to support couples during their full treatment trajectory. By providing personalized information and offering the opportunity of communication, it is possible to decrease infertility-specific anxiety and stress, increase knowledge and enhance patient-centred care.

Study design, size, duration: A quantitative study in which 314 couples were invited to evaluate 'myFertiCare'. A questionnaire was based on the HOT-fit framework, assuming a 'fit' between Human, Organizational and Technological factors is needed to successfully implement an eHealth tool. Therefore, it consisted of validated questionnaires covering these domains. Moreover, attention was payed to the effect on patient knowledge, experienced patient-centeredness and treatment burden. Non-users of myFertiCare received an adjusted questionnaire, to discover motivations for not using.

Participants/materials, setting, methods: The questionnaires were distributed between June and August 2017 in the Radboud university medical center in Nijmegen, the Netherlands. Eligible for participation were couples undergoing ICSI with surgically retrieved sperm, who had had the opportunity to use myFertiCare during their treatment trajectory. Each couple received one questionnaire together. Both couples that did and did not actually use myFertiCare could participate. Furthermore, user statistics were analyzed.

Main results and the role of chance: Response rate was 48%. After exclusion, 142 questionnaires were included for analysis. Participants appreciated myFertiCare on human, organizational, as well as technological aspects. At the human and technology domain, myFertiCare showed good system usability, high user satisfaction and good information and interface quality. The visualized treatment trajectory was the most appreciated functionality of the application. At the organizational domain, the information provided to patients about the application appeared to be complete. Unfortunately, non-users of the application often didn't recall receiving information about the possibility to use myFertiCare. Among the health care providers, knowledge about all opportunities myFertiCare offers to couples could be improved.

myFertiCare turned out to improve knowledge about treatment of infertility, to increase the degree of experienced patient centered fertility care and to decrease the experienced treatment burden.

User statistics showed that myFertiCare was mainly used by the female partner, and most activity was seen at the beginning of treatment.

Limitations, reasons for caution: Although we conclude that myFertiCare has been successfully implemented, we also assessed some pitfalls. This provides us the opportunity to further develop the application based on patients' needs and preferences and to improve the infrastructure surrounding myFertiCare, so that all couples are optimally aware of the opportunities myFertiCare offers them.

Wider implications of the findings: Since myFertiCare has been successfully implemented, the use of the application can possibly be expanded to other fertility treatments, and also to other fertility clinics, both in the Netherlands and abroad. Further research can be done to explore possibilities of using the application format in other medical departments.

Trial registration number: not applicable.

P-563 Factors affecting the disclosure management of infertility of expatriate women in Hong Kong

D.A. Niederberger, H.Y.C. Chan, L. Liu

The University of Hong Kong, Social Work and Social Administration, Hong Kong, China

Study question: What are the emotional and socio-cultural factors affecting women's decisions to disclose their infertility to various members of their social support network?

Summary answer: Various Infertility-related stigmas affected women's disclosure decision. Women tended to consider their infertility disclosure from a two-pronged approach – protection and productivity.

What is known already: Infertility affects up to 15% of reproductive-aged couples worldwide with negative psychological, physical, social and economic impacts. Women experienced the higher stress as well as feelings of shame and guilt due to their infertility. Studies showed that higher perceived social support could ameliorate the emotional distress for women with infertility. However, existing evidence has revealed a perplex relationship between social support and women's disclosure patterns as social stigma associated with infertility would negatively influence women's decision of disclosure. Therefore, this

study explored the complex relationship between a woman's social support network and the extent to which infertility-related information was disclosed.

Study design, size, duration: This study employed a qualitative design with semi-structured individual interviews. As a methodological innovation, this study applied Infertility Disclosure Map (IDM) to enact a visual, tangible representation of woman's social support network and the extent of their disclosure of infertility-related information. Six participants were recruited. The interviews were conducted between March 2015 and March 2016.

Participants/materials, setting, methods: Participants were English-speaking expatriates living in Hong Kong aged 18 or above. They were diagnosed of primary infertility and were undergoing ART procedures in Hong Kong at the time of the study. Exclusion criteria included inability to give written informed consent, condition with cognitive impairment or major psychiatric disorders. Participants were recruited from a locally-based, online social networking forum, targeting English-speaking expatriates in Hong Kong. The interviews were audio-taped, transcribed and thematically analysed with NVivo.

Main results and the role of chance: Six female participants aged between 33 and 40 were recruited. They had varies ethnic backgrounds including Caucasian, Chinese and Latin/Asian. Three of them had one children and the other had no children. The duration of infertility ranged from 1.75 to 6.5 years. Consistent with existing findings indicating that many women have experienced stigmatization from their infertility, five of the six participants experienced some forms of stigmatization. However, perceptions of stigma among participants were divergent, which included: infertility is the woman's fault; infertility is a disease; voluntary childlessness is shameful; and age discrimination on the desire for biological children. Extending the existing models that explain women's disclosure decision-making, the findings illustrated a two-pronged approach utilized by participants in deciding whether to conceal or disclose information about their infertility – protection and productivity. Protection of self, spouse and even the recipients of the information so as to avoid pain, worry and embarrassment was a significant consideration that prompted participants to withhold information. Productivity, namely the usefulness of the disclosure to participants was the other key component in participants' decision-making process. The usefulness includes emotional support from others, tangible support to facilitate treatment, information gathering, and altruistic purpose of helping others with infertility.

Limitations, reasons for caution: Major limitations include the small sample size and insufficient representation from individuals from different cultural backgrounds.

Wider implications of the findings: With a deeper understanding of the complex reasons and emotions influencing women's decisions to disclose their infertility to various members of their social support network, counsellors and other helping professionals could better assist the women to manage their infertility treatment as well as improving their psychological wellbeing.

Trial registration number: Not applicable.

P-564 Psychological wellbeing and relational stress of women with a predicted poor ovarian response at the start of IVF treatment

Z. Donarelli[1], S. Gameiro[2], G. Lo Coco[3], L. Salerno[1], S. Gullo[4], A. Volpes[5], A. Allegra[5], J. Boivin[2]

[1]Andros Day Surgery Clinic, Psychology Unit, Palermo, Italy
[2]Cardiff University, School of Psychology, Cardiff, United Kingdom
[3]University of Palermo, Department of Psychology and Educational Sciences, Palermo, Italy
[4]Andros Day Surgery Clinic, Medical Statistic Unit, Palermo, Italy
[5]Andros Day Surgery Clinic, Reproductive Medicine Unit, Palermo, Italy

Study question: Do women predicted to have a poor ovarian response (POR) at the start of IVF treatment report higher psychological and relational stress, than non-POR women?

Summary answer: Prior to IVF treatment the predicted POR group showed higher psychological difficulties (relational stress) than women without a predicted poor ovarian response.

What is known already: The Bologna Criteria are used to predict a poor response to ovarian stimulation based on age, ovarian response and number of oocytes retrieved in a previous cycle. It is estimated that between 5.6% and 35.1% of women undergoing ART will exhibit a POR. Although it is known that poorer prognosis is associated with higher stress during treatment, suggesting that women with POR may need additional/tailored psychosocial support, to date no studies have examined associations between a POR classification/diagnosis and psychological adjustment.

Study design, size, duration: This cross-sectional case-control study is part of a longitudinal study of infertile couples undergoing IVF in a private clinic between February 2013 and September 2015.

Participants/materials, setting, methods: 257 women (POR = 50; non-POR = 207, based on the Bologna criteria) filled out questionnaires (response rate 65%) on well-being (FertiQoL and FPI) and relational stress (ECR, Commitment Inventory, ENRICH), after physicians informed patients about POR. 16 out of 50 of the cases reported a history of POR. The two groups were compared on well-being and relational stress using multivariate analysis of covariance, controlling for cause and duration of infertility. Effect size was expressed by partial eta squared.

Main results and the role of chance: Wilks's λ was significant, $F(1, 241) = 2.34$, $P < 0.01$, $\eta p^2 = .10$, showing a difference between the two groups. Contrast analyses revealed that patients with POR reported lower quality of life on the relational domain ($z = 9.35$, $p < .01$, $\eta_p^2 = .04$); lower level of commitment on couple identity and relational agenda ($z = 4.76$, $p < .05$, $\eta p^2 = .02$; $z = 3.94$, $p < .05$, $\eta p^2 = .02$, respectively); higher anxiety and avoidance in close relationships ($z = 6.48$, $p < .05$, $\eta p^2 = .03$; $z = 4.27$, $p < .05$, $\eta p^2 = .02$, respectively); and higher FPI sexual stress ($z = 8.13$, $p < .01$, $\eta p^2 = 0.03$), than non-PORs women.

The group difference remained significant after controlling for cause and duration of infertility, $F(1, 241) = 1.99$, $P = 0.02$, $\eta p^2 = .09$.

Limitations, reasons for caution: The questionnaires were completed immediately after the POR diagnosis and the influence of preexisting levels of infertility stress cannot be excluded. Moreover, uncontrolled factors explaining the association between POR status and distress could have been relevant. Finally, no measures of mental health disorders, such as anxiety or depression, were collected.

Wider implications of the findings: POR status is associated with higher relational stress and the cause of this association could be due to the awareness of their risk of a POR. The findings provide support for the importance to address specific relational issues in women with POR at the early stage of ART treatment.

Trial registration number: Not required.

P-565 A pregnancy loss in the first fertility treatment is a postitive predictor of birth in the following treatment

M.C. Krog[1], S.S. Malchau[2], A. Pinborg[3], A.M. Kolte[4], H.S. Nielsen[4]

[1]Copenhagen University Hospital- Rigshospitalet, Recurrent Pregnancy Loss Unit- The Fertility Clinic 4071, Copenhagen Ø, Denmark
[2]Copenhagen University Hospital Hvidovre, Department of Obstetrics and Gynecology, Hvidovre, Denmark
[3]Copenhagen University Hospital- Rigshospitalet, The Fertility Clinic 4071, Copenhagen, Denmark
[4]Copenhagen University Hospital- Rigshospitalet, Recurrent Pregnancy Loss Unit- The Fertility Clinic 4071, Copenhagen, Denmark

Study question: What is the chance of a birth in the second treatment after a pregnancy loss (PL) compared to no pregnancy in the first treatment?

Summary answer: The chance of a birth in the second treatment is significantly higher after a PL compared to a negative pregnancy test after the first treatment.

What is known already: When infertile couples experience an early PL during fertility treatment, it is generally considered to be a positive predictor of future birth because the couple were able to achieve a pregnancy. Previous studies on this topic in the ART population are conflicting. A study in 12,174 Chinese patients found no difference in birth rate in the second treatment after a PL compared to negative pregnancy test. In contrast, a PL in the first treatment was a positive predictor of a birth among 112,549 UK patients in the two following treatments (compared to no pregnancy in the first treatment).

Study design, size, duration: A Danish national cohort study of 32,975 infertility patients including total register data on their first two fertility treatments. We used data from the mandatory Danish ART register and included treatments from 1994 to 2012. Both intra-uterine inseminations and ART treatments were included and treatments with egg-donation were excluded.

Participants/materials, setting, methods: Detailed data from the first and second treatment in every Danish patient attending both public and private Danish fertility clinics were retrieved. An accurate registration of births was obtained by cross-linking treatments with the Danish National Birth Register by the personal social security number. A positive s-hCG without a resulting birth was categorized as a pregnancy loss. Data is presented as percentages and differences were accessed using the Pearson chi-square test and one-way ANOVA.

Main results and the role of chance: Outcome of the first treatment was devided into three groups; 1) no pregnancy (n = 26,852, 81.4%), 2) pregnancy loss (n = 3092, 9.4%) and 3) birth (n = 3031, 9.2%). Mean maternal age differed at time of first treatment between the groups 1) 32.9 years, 2) 32.9 years and 3) 31.2 years, respectively (p<0.0001). In the second treatment, only 17.3 % (n = 4640) in group 1 achieved a birth compared to 22.7 % (n = 702) and 23.8 % (n = 722) in group 2 and 3, respectively, which also was significantly different (p<0.0001). The reoccurrence of another pregnancy loss in the same couple (group 2) in the second treatment was 11.7% (n = 362) compared to the first occurrence of a pregnancy loss in the second treatment in group 1) 8.6% (n = 2304) and 3) 11.0% (n = 333), (p<0.0001).

Limitations, reasons for caution: This is a nationwide study and the analyses are restricted to the first encounter with fertility treatment, irrespective of type of treatment. Current results are not reflecting the treatment regime as a whole.

Wider implications of the findings: Our study confirms that a pregnancy loss compared to a negative pregnancy test is a positive predictor of birth in the following treatment. The findings can not be explained by maternal age and will be useful when counselling patients who experience a pregnancy loss in their first treatment.

Trial registration number: Not applicable.

P-566 Stress and depression among couples with recurrent pregnancy loss - focusing both on the male and the female partner

S. Hedegaard[1], A.M. Kolte[1], M.C. Krog[1], L.R. Olsen[2], H.S. Nielsen[2]

[1]Recurrent Pregnancy Loss Unit, Fertility Clinic 4071, Copenhagen University Hospital

[2]Child and Adolescent Mental Health Center, Mental Health Services, Capital Region of Denmark

Study question: What is the prevalence of psychological stress and moderate/severe depression in couples with recurrent pregnancy loss (RPL)?

Summary answer: Male partners revealed no increased frequency of stress and depression, but we confirmed our previous finding of significantly increased frequencies among female partner with RPL.

What is known already: In a previous large study of women with RPL, we have shown that psychological stress and major depression are significantly more common among women with RPL than other pregnancy planners. Emotional distress among male partners is much less studied, but one study investigated 76 male partners of RPL using the Beck Depression Inventory and found that 14,9% of the men were considered mildly depressed.

Study design, size, duration: The study is a cross-sectional study, where we compared the prevalence of stress and depression among 226 men and 342 women in RPL couples referred for evaluation and treatment at the Danish national RPL Unit from 2015-2018. We defined RPL as three or more pregnancy losses before 12 weeks' gestation. Results among men were compared to a Danish population study performed in 2000.

Participants/materials, setting, methods: From March 2015, all couples have been asked to complete the Major Depression Index (MDI) and Cohen's Percived Stress Scale (PSS) as part of standard evaluation before first consultation. Of the invited patients, 226 men (57%) and 342 women (80%) participated.

Main results and the role of chance: Of the men in the RPL couples 5/226 (2.2%) had a score on the MDI corresponding to moderate/severe depression, as did 27/342 (7.9%) of the participating women.

In a Danish population study from 2000 using the same psychometric scales, 2.2% of the men aged 20-79 years reported symptoms corresponding moderate/severe depression. The prevalence of moderate to severe depression among men in RPL couples was not different from the Danish background population (P = 0.96).

The prevalence of moderate/severe depression among the female partners of RPL couples is comparable to our previous results in a different cohort of RPL women (8.6%) (P = 0.73). In our previous study the response rate was 69 % compared to 80 %.

Among the men in the RPL couples 26/226 (11.5%) reported a high stress level (defined as ≥ 19 on the PSS scale), as did 97/338 (28.7%) of the women. When compared to the stress levels reported in our previous study on a RPL female cohort we find a significantly lower frequency of high stress level (P < 0.001). The lower occurrence of high stress level in the most recently collected cohort maybe explained by selection.

Limitations, reasons for caution: The response rate among men is relatively low compared to women; this may bias the results. We are unaware if some of the non-responders suffer from depression or high stress level. Furthermore, the comparison group is a population sample and we are thus unaware if they suffer from reproductive problems.

Wider implications of the findings: To our knowledge, this is the first larger scale questionnaire study of emotional distress among men with RPL. We did not find a high prevalence of neither stress nor moderate/severe depression. Furthermore, we confirmed previous findings regarding stress and depression among women with RPL, highlighting the emotional toll of RPL.

Trial registration number: N/A.

P-567 Quality of life of transgender women and men during hormonal treatment

S. Feigl, J. Wegscheider, K. Feil, K. Winkler-Crepaz, B. Böttcher, B. Toth

University Hospital Innsbruck, Dept. for gynecological endocrinology and reprod. medicine, Innsbruck, Austria

Study question: Does quality of life change during cross-sex hormonal treatment in transgender individuals and are quality of life aspects comparable with non-transgender individuals?

Summary answer: Quality of life in transgender individuals improves during cross-sex hormonal treatment.

What is known already: Social understanding and support for transgender individuals have steadily improved, but knowledge about their socio-psychological development is scarce. There are few studies that show better physical and mental health after hormonal treatment or sexual reassignment surgery but aspects such as socio-economic integration, self-perception and acceptance have been neglected.

Study design, size, duration: Since no suitable questionnaire was available, we developed a transgender questionnaire. Validation of the questionnaire was performed by repeated completion after one week. The questionnaire includes demographic data, 45 questions about trans-identity, physical, mental and sexual wellbeing as well as social background and acceptance. Validation of the questionnaire was performed with item-total correlation, internal consistency (Cronbach's α) and test-retest reliability (intraclass correlation coefficient). Chi^2Test, Wilcoxon- test and independent sample t-tests were used for statistical analysis.

Participants/materials, setting, methods: Transgender individuals receiving hormonal treatment in the University hospital of Innsbruck and matched controls were included. Transgender individuals answered the questions twice, representing the time point before and after start of treatment whereas the controls answered it once except those who validated the questionnaire.

Main results and the role of chance: So far 26 transgender individuals and 44 controls were included. Median age of transgender individuals was 25,8 (min-max: 18-50) years, 26,7 (min-max: 18-52) years in controls. Quality of life improved during hormonal treatment in transgender individuals. This was mainly true for self-confidence and physical perception. We also observed less

discrimination and more support from the social environment after at least 6 months of hormonal treatment.

Limitations, reasons for caution: Our study was conducted by a limited number of participants. Transgender individuals may already experience a different quality of life due to social acceptance and access to medical facilities.

Wider implications of the findings: Hormonal treatment options for transgender individuals raise the urge to better understand and support transpersons. Our study shows a possible way to monitor and optimize quality of life and psychosocial aspects during hormonal treatment.

Trial registration number: not applicable.

P-568 Remote access to embryo images and video during their cycle enhances a patients In Vitro Fertilisation (IVF) experience

D. Bui, E. Debenham, N. Hesketh, S. McArthur, K. Waite, M. Bowman

Genea, Embryology, Sydney, Australia

Study question: Does providing patients remote access to images and video of their embryos developing during an IVF cycle enhance their experience?

Summary answer: The majority of patients surveyed indicated that viewing their embryo images during cycle enhanced their experience of IVF treatment.

What is known already: With the advent of online self-diagnosis and in turn patients understanding and expecting certain service standards during their treatment, there is a shift in how medical providers are adjusting their interactions and delivery of treatment to patients. Patients who have a tangible image from ultrasound scans respond better and feel more informed about their treatment options than those without an image (Carlin et al 2014). The advent of time-lapse imagery of embryo development allows not only scientists to view in great detail the growth of an embryo but opens up opportunities for patients to have access to this information.

Study design, size, duration: Patients undertaking an oocyte retrieval were recruited on a voluntary basis over an 8 month time period from May-2017 to January-2018. Patients who participated were sent an optional survey to complete after embryo culture but before pregnancy outcome. A total of 149 responses were collated from 358 patients who participated in the trial. The survey consisted of a number of questions on usability, enhancement of IVF experience and communication using a 5 level Likert scale.

Participants/materials, setting, methods: Participants were recruited on a voluntary basis to trial an embryo viewing portal through a phone or PC application (Grow™, Genea Sydney). This app allows patients to log on and view their embryos growing in-situ via a direct link with image collating software Geri Connect using the Geri embryo monitoring incubator (Genea Biomedx, Sydney). Still and time-lapse video were uploaded at specific time points and patients received ongoing communications from embryologists regarding their embryo development.

Main results and the role of chance: 149 patients took part in the trial and completed the survey. The average age of the recruited cohort was 35.9, with 62% of patients falling into the <38 age group and 38%in the > = 38 age group. First cycle patients accounted for 39% of the recruited cohort and the remaining 61% had at least one previous cycle either at Genea or elsewhere. Overall, 85% of participants either strongly agreed or agreed that their IVF experience was enhanced by having access to their embryo images during treatment. Technical issues in the usage of the application and a requirement for greater information were the main contributors to the 15% of either neutral or negative scores. Feedback collected during the survey collation pointed towards a variety of reasons for this enhancement with inclusion of partner in the cycle, giving greater understanding and education, feeling more connected with treatment and also provides an element of feeling more in control during treatment. Patient feedback continues to be collected and assessed to improve the patient experience whilst undergoing treatment for infertility.

Limitations, reasons for caution: The cohort of patients that elected to take part in the trial may have been a positively biased group. No data has yet been collected to determine if negative pregnancy outcomes would impact the score of enhancement.

Wider implications of the findings: The introduction of an application for patients to view their developing embryos enhances the delivery of information by providing greater education and allowing patients to feel more involved across their treatment as well as providing a more personal experience thereby aligning IVF with trends in medical management of patients.

Trial registration number: Not applicable.

P-569 Is mitochondrial DNA quantification (NGS) a useful tool for embryo viability assessment?

D. Lorenzi[1], M. Bilinski[1], M. Fabbro[2], V. Rovera[3], S. Gonzalez Klikailo[3], F. Noblia[3], S. Papier[1,3], F. Nodar[1,3]

[1]NOVAGEN, Reproductive Genetics, Ciudad Autónoma de Buenos Aires, Argentina
[2]NOVAGEN, Bioinformatics, Ciudad Autónoma de Buenos Aires, Argentina
[3]CEGYR, Reproductive Medicine and Genetics, Ciudad Autónoma de Buenos Aires, Argentina

Study question: Is there a relationship between human blastocyst mitochondrial DNA (mtDNA) content and female age, embryo chromosome ploidy and clinical pregnancy?

Summary answer: This study demonstrates no association among mtDNA score, female age and pregnancy outcome. However, a relationship between mtDNA score and embryo ploidy was observed.

What is known already: Recently, there are controversial publications about the clinical relevance of mtDNA quantification in human blastocysts. The increase of mtDNA may be a sign of elevated metabolism related to high energy requirements in stressed embryos.

Some studies found no association between this parameter and chromosomal ploidy, maternal age or pregnancy outcome. However, some laboratories, based on their evidence, apply this quantification as an implantation potential biomarker between euploid embryos.

Different methodologies have been used for mtDNA assessment, principally next generation sequencing (NGS) platforms and real-time polymerase chain reaction (qPCR), with consistent results between them.

Study design, size, duration: A cohort of 384 blastocysts obtained from 144 couples, with an average female age of 35 years old (21-45), undergoing preimplantation genetic testing for aneuploidies (PGT-A) were retrospectively included. The data was collected between April 2016 and December 2017 from a single center. Mosaic embryos (between 20%-80%) were excluded from this analysis.

Participants/materials, setting, methods: Trophectoderm biopsies from 384 blastocysts (PGT-A) using NGS (Veriseq-Illumina) were assessed.

For each sample, reads were aligned to the human reference genome (hg19) and the mtDNA genome separately. Reads mapped to the mtDNA were divided by the number of reads that mapped to the nuclear DNA. The resulting values were mathematically adjusted by correction factors previously reported for embryo ploidy and gender.

mtDNA scores were analyzed regarding embryo aneuploidy, maternal age and clinical pregnancy (T-test).

Main results and the role of chance: Regarding all blastocysts analyzed, 189 (49%) were euploid and 195 (51%) aneuploid. The amount of mtDNA was significantly higher in aneuploid embryos ($P = 0.002$). However, the amount of mtDNA was not different between embryos from younger (<38 years, n = 147) and older women (≥38 years, n = 41) ($P = 0.2161$).

During the period covered, 46 normal embryos were transferred after thawing, resulting in 25 ongoing pregnancies (54%). The mtDNA score from euploid blastocysts that achieved a clinical pregnancy was no significantly different from those that did not result in an ongoing pregnancy ($P = 0.4118$).

A mathematical adjustment was performed in order to correctly normalize the relative mtDNA content regarding embryo gender and chromosome ploidy.

From our in-house data, mtDNA score was only statistically associated with chromosomal aneuploidy suggesting that high levels of mtDNA may have a negative impact resulting in an inadequate chromosome segregation.

Limitations, reasons for caution: This is a retrospective study. Despite NGS approach for mtDNA quantification has been validated by others methodologies, these techniques should be applied in order to confirm these results.

Wider implications of the findings: This study contributes evidence that mtDNA quantification in euploid embryos have no clinical impact in pregnancy outcome. The results demonstrate that mtDNA levels are independent to female age. However, mtDNA score reveals a strong association with embryo aneuploidies.

Trial registration number: Not applicable.

P-571 Impact of microfluidic sperm sorting on embryo quality and comprehensive chromosome screening outcomes of couples with repeated implantation failure

E. Pabuccu[1], R. Pabuccu[2], S. Sertyel[3], D. Demirkıran[3], H. Gunes[3], S. Dogan[4], A.H. Haliloglu[5], Ö. Şahin[1]

[1]Ufuk University School of Medicine, Obstetrics and Gynecology, Ankara, Turkey
[2]Ufuk University School of Medicine- Centrum Clinic IVF Center, Obstetrics and Gynecology, Ankara, Turkey
[3]Centrum Clinic IVF Center, Embryology, Ankara, Turkey
[4]Centrum Clinic IVF Center, Andrology, Ankara, Turkey
[5]Ufuk University School of Medicine, Urology, Ankara, Turkey

Study question: What is the impact of the microfluidic sperm selection technique for IVF/ICSI on embryo quality and euploidy rates in couples with Repeated Implantation Failure (RIF)?

Summary answer: When microfluid chip-sorted spermatozoa is used for IVF/ICSI, a higher number of top quality blastocysts and better euploidy rates were observed compared to standard selection.

What is known already: Aneuploidy is the most common type of chromosome abnormality and the leading cause of implantation failure in humans. Oocyte and spermatozoa equally contribute to embryonic aneuploidy however, womens' age is the well-known factor. We are still unable to modify the quality of oocytes, however several sperm selection techniques have gained attention. Being one of those, microfluidic sorting technology has been proposed in order to pick the best spermatozoas with better genomic integrity and physiological quality. It is of interest whether utilizing this technique will reveal better embryo morphology and euploidy rates in couples with RIF undergoing pre-implantation genetic screening (PGS).

Study design, size, duration: This was a retrospective analysis of assisted reproductive technology (ART) cycles performed at the Centrum Clinic IVF Center located in Ankara, Turkey between 2016 and 2017. In total, data from 171 patients were obtained for the analysis that accounts for 491 embryos. In group 1 (STANDARD), a total of 127 cycles and 366 embryos, in group 2 (CHIP) 44 cycles and 125 embryos were evaluated in terms of embryology data and euploidy rates.

Participants/materials, setting, methods: Only patients with complete patient records on clinical, IVF/ICSI cycle characteristics, and PGS (Next Generation Sequencing) analysis could be included in the retrospective analysis. Main indication for PGS was RIF history of couples. Women with age > 43, BMI > 35, with documented uterine abnormalities, trombophilia and azoospermic males were excluded. In CHIP group, microfluid sorted spermatozoas were obtained for IVF/ICSI. On the day of biopsy, 5–10 trophectoderm cells were sent to the laboratory.

Main results and the role of chance:

Table 1 Basal characteristics, stimulation outcomes and embryologic data.

	STANDARD (N = 127 cycles, 366 embryos)	CHIP (N = 44 cycles, 125 embryos)	*p* value
Female age (years)	37.3 ± 4.8	37.4 ± 4.9	NS
AMH (ng/ml)	1.69 ± 1.4	1.8 ± 1.6	NS
FSH (mIU/mL)	8.8 ± 4	7.8 ± 2	NS
TSH (IU/mL)	2.06 ± 0.9	2.1 ± 1.2	NS
Sperm concentration (mil./ml)	22 (1-130)	29 (1-120)	0.03
Total motility (A+B+C) %	46.8 ± 19	48.5 ± 17	NS
DFI % (TUNNEL Assay)	23.5 ± 14	17.1 ± 7.9	NS
Total duration (days)	11.2 ± 2	11.3 ± 1	NS
M2 oocytes (n)	4 ± 2.7	5.4 ± 6.5	NS
2PN (n)	3.7 ± 2.6	4.3 ± 3.5	NS
No of cleavage embryos	3.6 ± 2.4	4.1 ± 3.1	NS
No of blastocysts	3.0 ± 2.1	3.5 ± 2.7	NS
No of top quality blastocysts (5AA, 5AB, 5BA, 4AA)	0.8 ± 1.4	1.6 ± 2.7	0.04
Euploid blastocyt %	7	23	<0.001
Mosaic embryos %	2.7	4	NS
Cost USD (excluding IVF/ICSI, including PGS and/or chip-sorting)	864.5 ± 557	1436 ± 645	<0.001

According to the univariate linear regression analysis;

– female age (β: 0.09, p = 0.24)
– sperm concentration (β: 0.09, p = 0.23)
– collected oocytes (β: 0.2, p = 0.008
– top quality blastocyst formation (β: 0.2, p = 0.001)
– microfluidic chip sorting (β: 0.35, p<0.001) parameters were found to influence (p<0.25) **embryo euplodiy** (%, dependent variable).

When backward multivariate linear regression analysis was performed, chip sorting was the only significant parameter (p = 0.002), whereas top quality blast formation did not reach enough significance (p = 0.06).

Limitations, reasons for caution: Major limitations are retrospective design, limited patient number, lack of DFI data following chip sorting and pregnancy outcomes of the groups. Chip-sorting is not a routine in our center and offered to those with RIF history only, because it comes with a significant cost. Moreover, literature data is very limited.

Wider implications of the findings: Successful euploid-blastocyst formation is the consequence of a perfect fertilization and mitosis. When comparable women age and number of oocytes are considered, chip sorted spermatozoas may influence our results in terms of better blastocyst formation and euploidy when DFI is relatively high (>15% in both groups). Cost should be considered.

Trial registration number: Not applicable.

P-572 Role of male factor in embryo aneuploidy

B. Rodriguez-Estrada[1], J. Sarasa[1], M. Enciso[1], I. Vilella[1], I. Jurado[1], J. Luna-Romero[1], L. Ortega[2], J. Aizpurua[2]

[1]iGLS, Genetic laboratory, Alicante, Spain
[2]IVF Spain, IVF laboratory, Alicante, Spain

Study question: Are sperm quality parameters relevant predictors of embryo aneuploidy?

Summary answer: Sperm apoptosis levels and male age are significantly correlated with different types of embryo aneuploidy in egg donor cycles.

What is known already: Embryonic chromosomal aneuploidy plays an important role in human reproduction causing implantation failures, miscarriages and a wide variety of genetic syndromes. While contribution to embryo aneuploidy has been largely attributed to female factor, focusing on maternal age, male role keeps uncertain. Infertile men often display unconventional semen parameters, nonetheless, wider implications in relation to aneuploidy have not been clarified. There are few studies in which sperm parameters are considered to be involved with embryo aneuploidy. To our knowledge, there is an absence of female factor-controlled studies.

Study design, size, duration: This is a retrospective observational study including data from a total of 102 egg donation cycles undergoing Preimplantation Genetic Testing for Aneuploidy (PGT-A) at blastocyst stage and comprehensive analysis of sperm quality parameters between January and October 2017. Egg donor cycles are optimal to study male factor avoiding maternal effect. Paternal influence on embryo aneuploidy and clinical outcomes were explored in all cases.

Participants/materials, setting, methods: 102 male patients aged 25-64 (41,74 ± 6.9) undergoing egg donation cycles with PGT-A participated in the study. Comprehensive sperm analysis including volume, concentration, total count, motility, morphology, vitality, proportion of apoptotic spermatozoa and DNA integrity was performed in all cases. All embryos were cultured to blastocyst stage, biopsied and PGT-A tested by Next Generation Sequencing (Illumina VeriSeq protocol). Analysis of the association between the different male parameters studied, embryo aneuploidy and clinical outcomes was performed.

Main results and the role of chance: In the study group, no influence of conventional semen parameters on embryo aneuploidy was found. Differences in sperm total count, motility, morphology, vitality, sperm DNA integrity did not impact embryo aneuploidy levels.

Interestingly, in normozoospermic samples, sperm apoptosis significantly correlated with the proportion of aneuploid embryos presenting sex pair abnormalities. Sperm presenting high levels of live apoptotic spermatozoa produced a significantly increased number of embryos with aneuploidies affecting the sex-chromosomes (Spearman Test, $R = 0.348$, $p = 0.044$).

Additionally, male age was found to influence the presence of complex aneuploid embryos, i.e. with 2 or more chromosomes affected (Spearman correlation Test, $R = 0.246$, $p = 0.044$). Men over 40 y.o. showed 1.5× more embryos with several aneuploidies than younger men (46.46%±6.39 vs. 31.15% ±5.98, U-Mann Whitney, $p = 0.0037$).

Finally, a significant influence of sperm apoptosis was also observed beyond preimplantation embryo development, affecting the likelihood of pregnancy after single euploid embryo transfer. The group of males that failed to achieve pregnancy presented significantly higher levels of live apoptotic spermatozoa compared to the ones who accomplished a positive beta (13.40%±1.25 vs. 9.04%±0.972, Student's t-test, $p = 0.004$), and an ongoing 12-weeks pregnancy (12.61%±1.19 vs. 8.15%±1.02, Student's t-test, $p = 0.004$)

Limitations, reasons for caution: The retrospective and unicentric design of this study may be a reason for caution. It is important to note that the number of patients included was limited and should be increased to confirm the results. Further prospective studies are needed to validate our findings.

Wider implications of the findings: Evidence shown raises the question of whether male age and sperm apoptosis should be taken into account as predictive markers for cases at risk of embryo aneuploidy and whose outcomes may be improved through PGT-A. Corrective methods are strongly recommended to palliate sperm apoptosis even if levels are not pathological.

Trial registration number: not applicable.

P-573 Haplotyping and copy-number profiling of single cells by massive parallel sequencing

H. Masset[1], M. Zamani Esteki[2], E. Dimitriadou[3], C. Melotte[3], S. Debrock[4], K. Peeraer[4], A. Ardeshirdavani[5], D. Alcaide[5], A. Sifrim[2], J. Aerts[5], Y. Moreau[5], T. Voet[2], J.R. Vermeesch[1]

[1]Laboratory for Cytogenetics and Genome Research, Department of Human Genetics, Leuven, Belgium
[2]Laboratory of Reproductive Genomics, Department of Human Genetics, Leuven, Belgium
[3]University Hospitals Leuven, Center for Human Genetics, Leuven, Belgium
[4]University Hospitals Leuven, Leuven University Fertility Center, Leuven, Belgium
[5]STADIUS Center for Dynamical Systems- Signal Processing and Data Analytics Department, Department of Electrical Engineering ESAT, Leuven, Belgium

Study question: Provide a high-throughput and comprehensive methodology for haplotyping and copy-number profiling single cells to overcome the limitations of SNP arrays by using massive parallel sequencing.

Summary answer: Genotyping-by-sequencing allows for accurate concurrent haplotyping and copy-number profiling of single cells and can be used for preimplantation genetic testing (PGT).

What is known already: PGT embodies not only the diagnosis of disease alleles for Mendelian disorders (PGT-M), but also allows detection of aneuploidies and structural rearrangements genome-wide, PGT-A and PGT-SR, respectively. Genome-wide haplotyping of single cells became feasible through karyomapping. We recently developed haplarithmisis that enables concurrent haplotyping and copy-number profiling of single cells using SNP arrays. These methodologies are being implemented as a generic method for PGT-M in many IVF laboratories. SNP arrays come at a stable cost and the resolution is limited. To provide comprehensive screening of a single cell whole-genome sequencing is necessary, which is currently too expensive and computationally heavy.

Study design, size, duration: To address the limitations of SNP array and the cost of sequencing, we exploit a reduced representation sequencing strategy on a single cell by performing genotyping-by-sequencing (GBS). Proof-of-principle experiments were performed on single cells from HapMap cell lines. For all embryo samples informed consent was given.

Participants/materials, setting, methods: Three different restriction enzymes were tested to digest DNA and reduced representation libraries were generated. Sequencing was performed on an Illumina HiSeq2500 system. Downstream analysis was evaluated and optimized to allow haplotyping with the interactive web application HiVA, which is based on haplarithmisis. Subsequently, an internal validation was performed by comparing GBS with SNP array. Furthermore, nine embryos in three families with different PGT-M indications were analysed.

Main results and the role of chance: For the HapMap samples, a total of 7 single cells of two individuals was used to assess genome-wide haplotype accuracy. Haplotypes from both GBS and SNP array data were generated through HiVA. The concordance rate reached 99% for both maternal and paternal haplotypes. In the internal validation, for a total of 9 embryos from three families with different indications for PGT-M, we obtained 100% accuracy.

Limitations, reasons for caution: This study is limited by the sample size.

Wider implications of the findings: We present a novel NGS-based methodology for haplotyping single cells through massive parallel sequencing. By applying a reduced representation sequencing methodology and the advancing sequencing technologies, we envision that this methodology will a valuable alternative to SNP array technology for genotyping, haplotyping and copy number profiling of single cells.

Trial registration number: not applicable.

P-574 Feasibility of artificial intelligence for predicting live birth from a blastocyst image

Y. Miyagi[1], T. Habara[2], R. Hirata[2], N. Hayashi[2]

[1]Medical Data Labo, Department of artificial intelligence, Okayama, Japan
[2]Okayama Couple's Clinic, Infertility, Okayama, Japan

Study question: Can artificial intelligence (AI) applied toward blastocyst images have strong potential to predict the probability of becoming an alive neonate?

Summary answer: Classifiers using AI applied toward a blastocyst image have strong potential to show the probability of an alive neonate being the outcome.

What is known already: None of the features of morphological structures have been conclusively assessed as having prognostic value for the further developmental competence of oocytes. Preimplantation genetic testing for aneuploidy to examine chromosomal profiles is an invasive technique for the embryo, which bring with it considerable ethical arguments. The chromosomal profile of the biopsy specimen does not always represent the profile of the rest of the embryo.

Study design, size, duration: Logistic regression, naive Bayes, neural network, random forest, nearest neighbors and deep learning were examined as machine learning method of AI. The images of the blastocyst of live birth (n = 80) and of abortion because of chromosomal abnormalities (n = 80) were used in retrospective study. The 10-fold ross validation method was used for making classifiers.

Participants/materials, setting, methods: We developed a system for using the machine learning approach of AI to predict the probability of live birth from a blastocyst image. An image was obtained from the fifth day after oocyte retrieval. The off-line images of which training data were augmented were transferred to the AI, then the classifier by the AI was made as the accuracy was higher and the variances were lower as much as possible.

Main results and the role of chance: The logistic regression with L2 regularization was the best among the above mentioned machine learning methods. Only a few seconds are needed to complete analysis of each image. The accuracy, sensitivity, specificity, positive predictive value and negative predictive value for predicting those in the abortion category were 0.619, 0.600, 0.638, 0.626 and 0.629, respectively. Area under the curve of the receiver operator curve was 0.594 ± 0.045 (mean ± standard error). Estimated probability of belonging to the live birth category was found significantly related to the probability of live birth ($P<0.02$).

Limitations, reasons for caution: Though the logistic regression showed the best result among the six machine learning methods examined, further investigation in the future might prove other machine learning methods superior.

Wider implications of the findings: This method does not harm the embryo, which can be transferred after establishing the prediction. It offers economic and time savings for patients and/or clinical institutes, gives quick and efficient diagnosis of the classification.

Trial registration number: not applicable.

P-575 Preimplantation genetic screening (PGS) with next generation sequencing (NGS) in recurrent spontaneous abortion patients (RSA); does it help?

B.C.F.K. Brunet[1], M.B. Toorabally[2], J. Shen[1], J. Wang[1], L. Cai[1], J. Xie[1], Y. Cui[1], J. Liu[1], W. Wu[1]

[1]*The State Key Laboratory of Reproductive Medicine- Clinical Center of Reproductive Medicine- First Affiliated Hospital- Nanjing Medical University, Gynecology and obstetrics, Nanjing, China*
[2]*First Affiliated Hospital- Nanjing Medical University, Cardiology, Nanjing, China*

Study question: Does PGS using NGS increase the live birth rate in recurrent spontaneous abortion patients?

Summary answer: PGS using NGS successfully increases the live birth rate in recurrent spontaneous abortion patients.

What is known already: Advances in PGS with the newest NGS technology, considered the main technique for selecting embryo to result in healthy pregnancy, has the ability to accurately know the ploidy status and select an embryo prior to implantation thereby removing aneuploidy, which is one of the most common cause of recurrent spontaneous abortion, as the cause of spontaneous abortion in the equation for RSA. RSA patients are considered the best candidates for PGS however, limited data exist about the effectiveness of this technique.

Study design, size, duration: This retrospective study included a total of 161 patients with a history of recurrent spontaneous abortion undergoing artificial reproductive technology at our hospital from the year 2015 to 2017. We included 67 patients in the PGS group and 94 patients in the control no PGS group. The comprehensive chromosome screening was done using NGS.

Participants/materials, setting, methods: All patients underwent controlled ovarian stimulation and oocytes retrieval. In the PGS group, ICSI, trophectoderm biopsy and blastocyst cryopreservation was performed before single frozen balanced/euploid embryo transfer detected by NGS molecular cytogenetic analysis. For the no PGS group, IVF or ICSI was followed by single or double embryo transfer with fresh or frozen embryos. The primary outcome was live birth.

Main results and the role of chance: After 209 cycles on 161 patients, a total of 70 embryos were transferred (0.97 per cycle) in the PGS group, of which 37 (53.6%) implanted, resulting in a live birth rate of 47.8%. In the no PGS group a total of 166 embryos were transferred (1.21 per cycle), of which 48 (28.9%) implanted, resulting in a live birth rate of 26.5%. The higher live birth rate in the PGS group was statistically significant ($p<0.05$). The analysis revealed aneuploidy in 123/240 (51.25%) of blastocyst tested in the PGS group, among which 31(12.9%) had single chromosome loss (monosomy), 24 (10.0%) displayed single chromosome gain (trisomy), 21/240 (8.75%) had dual chromosomal abnormality, 13 (5.42%) showed complex chromosomal abnormality and 34/240 (14.2%) were observed with mosaicism.

Limitations, reasons for caution: This study is a single center retrospective study with a small study population. Any findings can only be indicative and the improved live birth rate after PGS with NGS should further be investigated in a larger population.

Wider implications of the findings: Our findings show that PGS with NGS improves the live birth rate in recurrent spontaneous abortion patients. If confirmed, these results could encourage the routine use of PGS with NGS to reduce the time to achieve pregnancy and avoid the physical and emotional burden of a miscarriage.

Trial registration number: Not applicable

P-576 Whole exome sequencing identified of MEI1 mutation causing human non-obstructive azoospermia

Y. Tan[1,2], C. Tu[2], L. Meng[1], S. Yuan[1], W. He[1,2], A. Luo[2], J. Du[1,2], G. Lin[2], G. Lu[1,2]

[1]*Reproductive & Genetic Hospital of CITIC-Xiangya, Genetic Center, Changsha-Hunan, China*
[2]*Central South University, Institute of Reproductive and Stem Cell Engineering, Changsha, China*

Study question: What's the genetic etiology of non-obstructive azoospermia (NOA) in a consanguineous Han Chinese family?

Summary answer: A novel homozygous missense mutation in *MEI1* gene, c.1585 T>A, might be the genetic cause of NOA in this family.

What is known already: *Mei1* knockout mice have been reported to present with NOA and only two polymorphic alleles (SNP3 (C1791A) and SNP4 (C2397T)) of the human *MEI1* gene were associated with azoospermia. No causative mutation has been identified in *MEI1* in men with NOA.

Study design, size, duration: Genomic DNA samples from a consanguineous Han Chinese family, 50 sporadic NOA patients (with normal 46, XY karyotype and no Y-chromosome microdeletions) and 200 fertile male controls with randomly matched age (32 ± 2.7 years) who had at least one child were obtained.

Participants/materials, setting, methods: Whole exome sequencing was performed to identify the genetic cause of NOA in two affected brothers of a consanguineous Chinese family. Histological analysis was performed for the biopsied testicle sample in the proband. Mutation screening was performed using Sanger sequencing for 50 NOA patients and 200 fertile male individuals, and *in silico* analysis was conducted for functional characterization of the mutation. Expression analysis of various tissues of human and mouse was performed by using RT-PCR.

Main results and the role of chance: We identified a homozygous missense mutation (NM_152513.3: c.1585 T>A, p.Phe529Ile) in a new gene, *MEI1*, which co-segregated with the NOA phenotype in this family. The identified missense mutation results in the substitution of a conserved phenylalanine residue with isoleucine in the SCOP domain of MEI1, which might resulted in protein misfolding. Histological analysis demonstrated a lack of spermatozoa in the proband's seminiferous tubules due to meiotic arrest. Expression analysis showed that *MEI1* is expressed specifically in adult human and mouse testis. For mutation screening, we only detected one heterozygous mutation of the c.1585 T>A in *MEI1* in a cohort of 200 fertile controls. We did not find any association between the two polymorphic alleles (SNP3 (C1791A) and SNP4 (C2397T)) of the human *MEI1* gene and NOA.

Limitations, reasons for caution: All novel putative disease-causing mutations may only be clinically reported as 'variants of uncertain significance' (VUS), unless and until the mutation is functionally characterized and more patients with a similar phenotype are discovered with the same mutation.

Wider implications of the findings: To the best of our knowledge, this is the first report of the identification of *MEI1* as a new causative gene with an autosomal recessive mode of inheritance for human NOA.

Trial registration number: Not applicable.

P-577 Novel inactivating mutations in the FSH receptor cause premature ovarian insufficiency with resistant ovary syndrome

W. He[1,2], J. Du[1,2], X.W. Yang[1], W. Li[1,2], W.L. Tang[2], G.X. Lu[1,2], G. Lin[1,2], F. Gong[1,2], Y.Q. Tan[1,2]

[1]*Central South University, Institute of Reproductive and Stem Cell Engineering, Changsha, China*
[2]*Reproductive and Genetic Hospital of CITIC-Xiangya, Genetic Center, Changsha, China*

Study question: What is the genetic aetiology of three resistant ovary syndrome (ROS) pedigrees from thirteen Chinese Han families with non-syndromic premature ovarian insufficiency (POI)?

Summary answer: Four novel mutations of the FSHR gene were the genetic aetiology of these three ROS families, respectively.

What is known already: To date, only 15 FSHR-inactivating mutations have been described in women affected by POI, each of them is a missense mutation.

Study design, size, duration: Thirteen Han Chinese families with POI were recruited from the Reproductive and Genetic Hospital of CITIC-Xiangya. Genomic DNA samples from the thirteen portends and their family members were obtained.

Participants/materials, setting, methods: To identify the genetic cause of POI in the affected women from these families, the proband in each family was subjected to whole-exome sequencing and the putative disease-causative variations were confirmed by Sanger sequencing. Bioinformatic and in vitro functional analyses were performed for the functional characterization of the FSHR mutations, which aimed to address the clinical relevance of the three novel point mutations.

Main results and the role of chance: Four novel mutations, two homozygous mutations (c.419delA(p. Lys140Argfs*16), c.1510 C>T(p. Pro504Ser)), and a compound heterozygous mutation (c.44 G>A(p. Gly15Asp) and deletion of exons 1 and 2) of FSHR gene were identified in the three non-syndromic POI-with-ROS families. A donor splice site mutation in STAG3 (c.1573 +5 G>A) and a missense mutation in DMC1 (c.106 G>A) were identified in two of the thirteen families, one in each family. Bioinformatic analysis predicted that the three novel point mutations in FSHR are deleterious and are associated with POI in the three families, which was confirmed by in vitro functional analysis in which FSH-induced cAMP production was abolished for all receptors.

Limitations, reasons for caution: All novel putative disease-causing mutations may only be clinically described as 'variants of uncertain significance' unless and until more patients with a similar phenotype are discovered in the same mutation.

Wider implications of the findings: To the best of our knowledge, c.419delA is the first report of a truncation mutation of FSHR, and c.44 G>A is the first missense mutation in the signal peptide-encoding region of FSHR causing POI. Our findings expand the mutational spectrum of FSHR and are valuable for the genetic diagnosis of POI.

Trial registration number: not applicable.

P-578 The effect of paternal trans fatty acid diet on expression pattern of PPAR genes in the ovary of rat offspring

F. Nanavakenari[1,2,3], G. Javadi[1], B. Ebrahimi[2], A. Alizadeh M. Masouleh[2], M. Shahhoseini[3]

[1]*Science and Research Branch- Islamic Azad University, Biology, Tehran, Iran*
[2]*Royan Institute for Reproductive Biomedicine- ACECR, Embryology- Reproductive Biomedicine Research Centre, Tehran, Iran*
[3]*Royan Institute for Reproductive Biomedicine- ACECR, Genetics- Reproductive Biomedicine Research Centre, Tehran, Iran*

Study question: Does the intake of trans fatty acids in paternal diet affect on body weight index and also expression pattern of *PPAR* metabolic genes in the ovary of rat offspring?

Summary answer: Paternal intake of trans fatty acids will increase the female offspring's body weight in rats and decrease the expression of *PPAR* genes in their ovary.

What is known already: Studies on maternal exposures and the risk of diseases in the offspring is growing. But paternal associations are often not considered. Trans fatty acids in industrial oils have harmful effects on human health and cause to significant changes in expression pattern of several metabolic genes. PPARs are nuclear receptors that involve in many metabolic functions in different organs including ovary.

Study design, size, duration: The study included 20 adult female Wistar rats (5 in each groups) that their fathers were fed in the following groups for 60 days. C: Standard diet group (control group), CT: The trans fatty acid group, E: The group contains vitamin E, ET: The group containing vitamin E + trans fatty acid.

Participants/materials, setting, methods: ovary of rat offspring was isolated. Total RNA was extracted from ovary using TRIzol reagent. A Nanodrop (Thermo Fischer) was used to quantify total RNA extraction and cDNA synthesis was performed. Using designed primers the mRNA expression of *PPAR* family genes were measured by real time polymerase chain reaction. Expression data was analyzed by SPSS- one way ANOVA.

Main results and the role of chance: There was a significant difference between the mean body weight of the groups under study ($F(3,36) = 10.24$; $p<0.001$). According to the findings, the mean body weight of the CT and ET groups were significantly higher than the E and C groups from 5 and 10 wk of age, respectively. The mRNA expression levels of *PPAR* genes were decreased in ovary tissue in group CT, and increased in group E, although these differential expressions were only significant for the *PPARγ* member gene in group E ($p<0.05$). There were no significant differences in *PPARs* in group ET.

Limitations, reasons for caution: In order to have robust data concerning the effect of trans fatty aicds on expression of metabolic genes, an even larger dataset would be required.

Wider implications of the findings: We imply that excessive consumption of trans fatty acids can have bad genetic/epigenetic effects on human reproduction, and vitamin E can diminish this consequence by its antioxidant function.

Trial registration number: NA.

P-579 Next-generation sequencing (NGS) based preimplantation genetic testing for products of reciprocal translocation (PGT-TR) improves diagnosis of the patients by verification of their classical karyotyping results

S. Pukszta[1], C. Cybulska[1], M. Mickiewicz[1], M. Zborowska[1], J. Liss[2], K. Lukaszuk[2]

[1]*Invicta Sp. z o.o., Molecular Biology Laboratory, Gdansk, Poland*
[2]*Invicta Sp. z o.o., Reproduction and Fertility Centre, Gdansk, Poland*

Study question: Can results of next-generation sequencing based preimplantation genetic testing for products of reciprocal translocation (PGT-TR) be useful for verification patient's postnatal karyotype result?

Summary answer: Molecular karyotyping of embryos provides information that helps to localize the breakpoints more accurately, leading to verification of classical karyotype results of the patients.

What is known already: Classical banding karyotype and fluorescence in situ hybridization (FISH) are classical techniques used for detection and description of reciprocal translocations. The application of molecular techniques, e.g. aCGH and NGS allows for description of unbalanced products of chromosomal rearrangements in higher resolution. The patients who are carriers of balanced reciprocal translocations routinely are identified by classical karyotype and results are provided to the laboratory conducting preimplantation genetic testing during course of IVF treatment. These results serve as the reference information in the prediction of localization and size calculation for putative products of translocations.

Study design, size, duration: Study was performed from December 2016 to January 2018 and included 352 cases of reciprocal translocations. PGT-TR outcomes were analyzed for presence and localization of the breakpoints based on patients' classical karyotype results provided to the laboratory.

Participants/materials, setting, methods: Biopsy samples were subjected to whole genome amplification (WGA) and whole genome library were constructed. Ion Personal Genome Machine System was used for whole genome sequencing. The Torrent Suite Software was used to generate BAM files. The BAMs files were uploaded to the Ion Reporter Software used for genotyping. Results with MAPD value (the Median of the Absolute values of all Pairwise Differences) less than 0.2 were qualified for further interpretation.

Main results and the role of chance: The localization of breakpoints in molecular karyotyping were overlapped with classical karyotyping in 668 out of 704 positions. Remaining 36 spots, which is 5.1% of all breakpoints analyzed, were subjected to further investigation specifically. The differences in localization ranged from 5 to 26 mega bases (Mb). In case when data derived from two or more embryos and re-localization of the breakpoint's coordinates affected of classical band descriptions laboratory ask the clinics for verification provided result of postnatal karyotype. All verifications resulted in new description concordant with molecular coordinates obtained during preimplantation testing.

Limitations, reasons for caution: The reliability of this technique may be lower in case of rearrangements where the breakpoints are located near telomeres or centromeres what may have effect on precision of established coordinates.

Wider implications of the findings: The application of next generation sequencing in preimplantation genetic testing for chromosomal rearrangements enhances the quality of diagnosis in the infertility clinics and have potential effect on reproductive risk calculation and prognosis to the patients.

Trial registration number: Not applicable.

P-580 Comparison of mitochondrial DNA content in euploid and aneuploid embryos at cleavage stage and blastocyst stage with NGS

A. Liñán Tegedor[1], A. Bayram[2], A. Arnanz[1], I. Elkhatib[3], C. Rubio[4], C. Rupali[5], N. Garrido[6], H. Fatemi[7], B. Lawrenz[8]

[4]Igenomix Foundation- Valencia- Spain, Genetic laboratory, Valencia, Spain
[5]Igenomix Dubai- United Arab Emirates., Genetic laboratory, Dubai, India
[6]IVI Valencia, IVI Foundation, Valencia, Spain
[7]IVI Middle East Fertility Clinic LLC, Medical Director, Abu Dhabi, Iran
[8]IVI Middle East Fertility Clinic LLC, Scientific Director, Abu Dhabi, Germany

Study question: Is the mitochondrial DNA-content (mtDNA) and its dynamics in cleavage stage and blastocyst stage embryos different in euploid and aneuploid embryos when measured with NGS?

Summary answer: mtDNA-content is comparable in euploid and aneuploid embryos at cleavage stage, however, it is significantly higher in aneuploid embryos at blastocyst state.

What is known already: Mitochondria and their DNA (mtDNA) are lately increasingly investigated regarding their ability as a potential marker for embryo viability and implantation chances and an increased number of mtDNA-copies in the blastocyst seems to be associated with decreased implantation-rates. Replication of mtDNA is not initiated during the first 3 days of embryo development and because of cell division, mtDNA-content is expected to decline from cleavage to blastocyst stage biopsy. Increased mtDNA-numbers at blastocyst stage are found with advanced female age and in aneuploid embryos. However, so far, data on the mtDNA-content in euploid and aneuploid embryos at cleavage stage is rare.

Study design, size, duration: Retrospective, blinded, observational study including 35 patients (118 embryos) which underwent preimplantation genetic testing (PGT-A) from August 2016 to January 2017. This study validated the chromosomal status of D5 embryos previously diagnosed on D3 and determined the mtDNA-content. Double biopsy (D3 and D5) was performed to all embryos that reached blastocyst stage on D5 and were not selected for transfer (including surplus euploid embryos that could not be vitrified according to the UAE law).

Participants/materials, setting, methods: Infertile patients with normal karyotype undergoing preimplantation genetic screening with fresh oocytes and with ≥5 MII or more than 4 embryos to biopsy on D3. For embryo biopsies at D3, only embryos with ≥5 nucleated blastomeres and < 25 % fragmentation and for blastocyst biopsy, only hatching blastocyst were evaluated. Relative values of mitochondrial DNA were directly obtained from the software and were analyzed using IGenomix algorithm for day 3 and day 5 biopsies.

Main results and the role of chance: After genetic screening at cleavage stage, there were 70 aneuploid and 48 euploid embryos. In the group of aneuploid embryos, mean mtDNA-content on D3 was 50.8 with a range from 31.7 to 99.4, a 95% confidence interval from 47.1 to 54.4 and a standard deviation (SD) of 15.3. In the group of euploid embryos, mean mtDNA on D3 was 51.1 with a range from 35.2 – 99.6, a 95% confidence interval from 47.3 to 54.8 and SD of 13.0. No significant correlation between mtDNA on D3 and the chromosomal status of the embryos was found ($p = 0.628$).

After blastocyst biopsy, the results of the genetic screening revealed 51 aneuploid and 62 euploid embryos. In the group of aneuploid embryos, mtDNA-content was 22.8 with a range of 12.2 – 48.4, a 95% confidence interval of 20.8 to 24.9 and SD of 7.3. In the euploid embryos, the results were 20.6 for the mean mtDNA-content with a range of 12.8 to 45.4, a 95% confidence interval of 19.0 – 22.2 and SD of 6.2. A significant difference in mtDNA on D5 between aneuploid and euploid embryos ($p = 0.034$) was found with Mann-Whitney test.

Limitations, reasons for caution: It is a bivariate analysis (aneuploidies versus mtDNA-content), and not controlled by other covariates that could potentially bias the relationship we are studying. At blastocyst stage, 5 embryos with trophectoderm Mitoscore values above 1.000 were considered as "outliers" and therefore excluded from the comparison between euploid and aneuploid embryos.

Wider implications of the findings: The fact that mtDNA-content is similar in euploid and aneuploid cleavage stage embryos, however significantly higher in aneuploid blastocysts supports the idea that mtDNA-content might have a direct impact on chromosome segregation during embryo development. It seems that embryos under energetic stress are forced to increase the biogenesis as compensation.

Trial registration number: not applicable.

P-581 Whole-genome methylomic profiling of iPSC-derived granulosa-like cells and adult granulosa cells implicates novel pathophysiological pathways of polycystic ovarian syndrome

C.C. Huang[1], M.J. Chen[1], S.U. Chen[1], H.N. Ho[1], Y. Yu-Shih[1,2]

[1]National Taiwan University Hospital, Obstetrics and Gynecology, Taipei City, Taiwan R.O.C.
[2]Fu Jen Catholic University Hospital, Department of Obstetrics and Gynecology, New Taipei City, Taiwan R.O.C.

Study question: Were the epigenetic aberrations (esp. DNA methylation) involved in the pathophysiology of polycystic ovarian syndrome (PCOS)?

Summary answer: Common differentially methylated pathways were found between iPSC-derived granulosa-like cells (GLCs) and adult granulosa cells (GCs), which might be related to the pathophysiology of PCOS.

What is known already: Although the heritability of PCOS is considered as high as 70% from the twin study, there is no definite candidate gene found. Epigenetic aberrations had been found to be involved in the pathogenesis of metabolic disorders such as type 2 diabetes and could possibly also contribute to the etiology of PCOS.

Study design, size, duration: This is a case-control study conducted from 2014-2016. Eleven patients of PCOS and 4 control subjects who underwent in-vitro fertilization treatment were recruited for the collection of ovarian GCs. Another 2 patients of PCOS and 2 control subjects were recruited for the collection of skin fibroblasts.

Participants/materials, setting, methods: Luteinized ovarian GCs were collected during oocyte retrieval and were purified by Ficoll gradient and cell culture. Patient-specific iPSC were established from skin fibroblasts and were then differentiated into GLCs using multistep approaches with cocktails of growth factors. Whole-genome DNA methylation profiles were obtained using Infinium Methylation EPIC Beadchip in both adult GCs and iPSC-derived GLCs. Other validation methods included real-time PCR, western blotting, immunofluorescence, flow cytometry, and in vivo and in vitro differentiation assays.

Main results and the role of chance: We demonstrated a successful derivation of PCOS-specific iPSCs from fibroblasts of women with PCOS by applying the safer, non-viral episomal reprogramming and differentiate them into ovarian GLCs through a cocktail of growth factors. Gene expression analyses revealed the GC specific markers including anti-Mullerian hormone (AMH), type 2 AMH receptor, follicle-stimulating hormone (FSH) receptor, luteinizing hormone (LH) receptor and estrogen synthetase cytochrome P450 19A1 (CYP19A1) all expressed in differentiated GLCs derived from PCOS and non-PCOS iPSCs. When integrating the results of whole-genome DNA methylomic analysis in iPSC-derived GLCs and adult GCs, a commonly overexpressed cAMP-response element binding protein (CREB) pathway in the PCOS group was found. Western blot also revealed a higher expression of CREB binding protein in the iPSC-derived GLCs and adult GCs in the PCOS group. The aberration of DNA methylation could explain the hereditary trait and the susceptibility to environmental influence of PCOS. The methylomic aberrations existed after cell reprogramming and re-differentiation, and this might suggest that the development origin of PCOS could start from very early stage.

Limitations, reasons for caution: The population of PCOS is highly heterogeneous and our case number is small. Further validation in a larger cohort is necessary.

Wider implications of the findings: Our findings not only provide new perspectives on the pathophysiology and therapeutic choices of PCOS, but also provide new knowledges on the stem cell and epigenetic research.

Trial registration number: Nil.

P-582 Optimized NGS based protocol for the detection of small duplications/deletions in preimplantation embryos from carriers of balanced translocations and inversions

C.M. Garcia Pascual[1], L. Navarro-Sánchez[1], L. Martínez-Merino[1], L. Rodrigo[2], C. Simón[3], C. Rubio[1]

[1]*Igenomix, PGS Research, Valencia, Spain*
[2]*Igenomix, PGD Molecular Cytogenetics, Valencia, Spain*
[3]*University of Valencia- INCLIVA- Igenomix, Obstetrics and Gynecology, Valencia, Spain*

Study question: Is it possible to develop an accurate, automated and fast Next Generation Sequencing (NGS) based Preimplantation Genetic Testing for structural rearrangements (PGT-SR) protocol?

Summary answer: NGS can be applied to identify duplications and deletions ≥6 Mb in carriers of balanced translocations/inversions offering high sensibility and specificity in trophectoderm biopsies.

What is known already: Chromosome translocations are the most frequent structural chromosomal abnormalities in humans. In carriers of balanced translocations and inversions, small duplications and deletions can arise because of adjacent meiotic segregation. The presence of inter-chromosomal effect has been described inducing a higher risk of aneuploidies for chromosomes not involved in the rearrangement. Array-CGH (comparative genomic hybridization) and FISH (fluorescence in-situ hybridization) have been used to detect these alterations. Currently, NGS is widely applied in PGT for aneuploidy (PGT-A) and to increase the resolution for its application in PGT-SR, improved NGS protocols are needed to detect deletions/duplications ≥6 Mb.

Study design, size, duration: From July to January 2017, an optimized NGS protocol to detect unbalances ≥6 Mb was developed and validated using 10 Coriell cell lines with deletions of known sizes (5.8-20 Mb). To test the sensibility and specificity of the protocol a set of experiments using pools of 4-6 cells mimicking trophectoderm biopsies was set up (n = 38). Then, 136 trophectoderm biopsies with unbalances of expected sizes according to the reported karyotype ranging from 6.4-57.8 Mb were analysed.

Participants/materials, setting, methods: In the cell lines experiments, a total of 38 samples, with a minimum of three samples per cell line were analyzed. A modified Reproseq protocol was employed for genome amplification, library preparation and purification, using Ion Chef™ and S5 sequencer (Thermofisher). A customized workflow was developed using the Ion Reporter software version 5.4 for analysis and interpretation of the sequencing data. Afterwards, 136 trophoblast biopsies were analysed following the protocol developed with cell lines.

Main results and the role of chance: Using the pools of cells with deletions of different sizes, we set the detection limit of our protocol in 6 Mb. The percentage of detection was 100%. In trophoblast biopsies from 35 patients, we analysed 136 embryos and 99.3% of them were informative. The percentage of unbalanced embryos was 44.8% (61/136). Full chromosome aneuploidies for chromosomes not involved in the rearrangements were observed in 38.9% (53/136) of the biopsies: 16.9% (23/136) of them in unbalanced biopsies and 22.1% (30/136) in balanced biopsies. Additionally, this protocol can be completed in 12-13 hours, from the preparation of the sample (lysis, preamplification, amplification, purification, pooling and quantification) to the release of the results.

Limitations, reasons for caution: It could be variability in the number of cells retrieved in the biopsy and their integrity accounting for potential amplification failures or non-informative results. Also, the whole genome amplification could result in false positives/ negatives. Nevertheless, in the validation study no false positives/negatives were observed.

Wider implications of the findings: Formerly, FISH or array-CGH were the techniques used for PGT-SR. These techniques have disadvantages. Here in, we describe an improved, mostly automatized, fast, and accurate protocol for detecting small del/dup up to 6 Mb. An additional advantage is that PGT-A and PGT-SR could be performed with similar equipment.

Trial registration number: Does not apply.

P-583 Exome sequencing in a consanguineous family including spontaneous ovarian hyper-stimulation cases with unknown triggers

S. Viville[1,2], E. Yagmur[3], F. Mantar[4], M. Ben-Rhouma[2], M. Gultomuk[5], N. Findikli[6], M. Bahceci[7], J. Muller[8,9], O. Okutman[1,2]

[9]*Hôpitaux Universitaires de Strasbourg, Laboratoire de Diagnostic Génétique, Strasbourg, France*

Study question: Ovarian hyper-stimulation can rarely occur spontaneously in patients not undergoing ovulation induction therapies. Could we determine underlying factors via high throughput sequencing?

Summary answer: By using whole exome sequencing, a homozygous autosomal mutation has been identified in two affected sisters in the family.

What is known already: Spontaneous ovarian hyper-stimulation syndrome (sOHSS) is a rare case of OHSS, defined as OHSS appearing in patients with no history of stimulatory infertility treatment. Cases of sOHSS have been reported in women with severe primary hypothyroidism, polycystic ovary syndrome while pregnant, gonadotroph pituitary adenoma, and normal pregnancy. So far, mutations in FSH receptor (FSHr) have been identified only in cases of sOHSS triggered by pregnancy, no causative mutation has been identified for non-pregnant sOHSS cases with unknown triggers.

Study design, size, duration: This is a case control study carried on a consanguinous Turkish family comprising four siblings in which 2 sisters showing well-documented recurrent sOHSS with no currently known triggers. Affected sisters had sOHSS sporadically without pregnancy, TSH levels are normal, no tumors or pituitary adenomas have been detected.

Participants/materials, setting, methods: Saliva samples have been collected from parents and all siblings. Genomic DNA was extracted from saliva using Oragene DNA self-collection kit (DNA genotek, Ottowa, Canada) according to the manufacturer's instructions. Whole exome sequencing of parents and four sisters was performed by the Institute of Genetics and Molecular and Cellular Biology microarray and sequencing platform, member of the 'France Génomique programme'. Suspected mutations were confirmed via Sanger sequencing.

Main results and the role of chance: A homozygous autosomal mutation on chromosome 10 has been identified in two affected sisters. Parents and one of the fertile sisters are carrier while the third fertile sister is wild type. Results were confirmed with Sanger sequencing. The identified mutation alters the wild type donor site and most probably affecting splicing. Functional studies are planned in order to highlight underlying mechanism related to the identified mutation.

Limitations, reasons for caution: Our study contains only one family presenting this very rare form of female infertility.

Wider implications of the findings: Our results provide a new understanding for the pathogenesis of sOHSS and help us to identify underlying trigger in our patients. It may help to define novel therapeutic approach to patients with similar symptoms.

Trial registration number: Not applicable.

P-584 Comprehensive comparison of trophectoderm (TE) and inner cell mass (ICM) by next generation sequencing (NGS)

I. Elkhatib[1], B. Lawrenz[2], A. Linan[1], A. Arnanz[1], A. Bayram[1], H. Fatemi[2]

[1]IVI Middle East Fertility Clinic LLC, IVF laboratory, ABU DHABI, United Arab Emirates
[2]IVI Middle East Fertility Clinic LLC, IVF Clinic, Abu Dhabi, United Arab Emirates

Study question: Does the chromosomal information of trophectoderm (TE) accurately predict the chromosomal information of the inner cell mass (ICM)?

Summary answer: The observed discordance rate between TE and ICM was 15.9%. Hence, further exploration on the implication of mosaicism due to mitotic errors is mandatory.

What is known already: The most important cause for implantation failure is chromosomal imbalance in the embryo. Identification of a chromosomally normal embryo is possible due to current techniques available; however, mosaicism can complicate interpretation of the result. Whereas meiotic errors of the oocyte result in uniform aneuploidies, errors occurring during the first three mitotic division of the embryo might lead to mosaicism. TE biopsy is commonly used to infer the chromosomal status of the ICM, hence in case of mosaicism, TE biopsy might not represent the correct chromosomal status of the ICM and could therefore lead to a misdiagnosis of embryo´s chromosomal status.

Study design, size, duration: Observational, blinded study, including 88 embryos, that underwent PGS prior embryo transfer, between August 2016 and January 2017. NGS technique used to compare the chromosomal status of the trophectoderm and the inner cell mass in blastocysts on embryos that were not selected for transfer (including surplus euploid embryos that could not be cryopreserved according to the UAE law).

Participants/materials, setting, methods: Infertile couples with normal karyotype undergoing PGS with fresh oocytes, female partner with age 18 to 45 years and a body mass index of 19 to 30. Only expanded blastocyst with distinguishable ICM were biopsied. The genetic laboratory was blinded regarding the identity of the couple and the origin of the sample.

ICM biopsy was performed as described in the validated procedure by Capalbo et al. 2013.

The patients were counseled and consents were obtained.

Main results and the role of chance: Out of the 88 embryos, in which trophectoderm and ICM biopsy could be performed, 14 embryos (14/88 = 15.9%) had a discrepant chromosomal status between ICM and trophectoderm.

In depth analysis of the embryos with discordant findings of trophectoderm and ICM, in 4 embryos (4/14 = 28.57%; 4/88 = 4.54%) ICM revealed an euploid finding and trophectoderm an aneuploid finding (= false-positive for trophectoderm biopsy). In 3 embryos (3/14 = 21.42%; 3/88 = 3.41%), ICM reported an aneuploid finding and trophectoderm an euploid finding (= false-negative of trophectoderm biopsy). Therefore in total 7 discrepancies (7/14 = 50%; 7/88 = 7.95%) regarding the embryo diagnosis (euploid / aneuploid; aneuploid / euploid) for whole chromosome analysis. The other 7 embryos (7/14 = 50%; 7/88 = 7.95%) had different chromosomal abnormalities in ICM and trophectoderm.

Limitations, reasons for caution: To thoroughly identify the exact rate of mosaicism, more embryos should be included in future studies.

Moreover, the well known methodological artefacts linked to the whole-genome amplification, warrant careful interpretation of the current findings.

Wider implications of the findings: Mosaicism in the embryo results from mitotic errors during the first cleavage divisions and different proportions of the embryo can be affected. Our results of false-positive TE biopsy question the accuracy of aneuploidy results from TE biopsy in regards of being representative for the whole embryo.

Trial registration number: Not applicable.

P-585 Segmental aneuploidy (SA) in oocytes and preimplantation embryos

A. Pomante[1], M.C. Magli[1], C. Albanese[1], M.C. Fasolino[1], A. Crippa[1], A.P. Ferraretti[1], L. Bernardini[2], L. Gianaroli[1]

[1]S.I.S.Me.R., Reproductive Medicine Unit, BOLOGNA, Italy
[2]Presidio Ospedaliero Levante Ligure, U.O. OstGin Materno Infantile, La Spezia, Italy

Study question: Does the detection of SA reflect a real event or is it an artifact?

Summary answer: Sequential biopsies of the same oocyte or embryo indicate that SA most probably are a real event.

What is known already: SA, the loss or gain of chromosomal fragments, has been detected in ~6% of spontaneous abortions. Some are compatible with life and the affected children carry a range of congenital abnormalities. The current cytogenetic techniques used in preimplantation genetic testing for aneuploidy (PGT-A) have shown that SA occur at appreciable frequencies. However, the possibility exists that whole genome amplification (WGA) may induce artifacts resulting in SA.

Study design, size, duration: This retrospective study includes 285 PGT cycles from January 2014 to December 2017. According to clinical indications, biopsy was performed on polar bodies (PB, n = 66 cycles), blastomeres (n = 169 cycles) or trophectoderm cells (TE, n = 50 cycles). In cases of SAs involving loss or gain in excess of 15 Mb, embryos were excluded from transfer and, depending upon the patients' consent, re-biopsy was performed. The aim was to evaluate the repeated occurrence of SA in following biopsies.

Participants/materials, setting, methods: Whole genome amplification and array comparative genomic hybridization (a-CGH) (Illumina) was done on cells biopsied from oocytes and / or embryos of IVF patients with normal karyotype from our PGT-A program. The chromosome analysis of sequential biopsies was performed at later stages, after the conclusion of the treatment cycle. Re-biopsies was done in 48 cases and included sequential blastomere biopsy, TE and BF.

Main results and the role of chance: The occurrence of SAs was significantly lower in oocytes (4.5%; 13 oocytes over 288 analyzed), compared with 13% in blastomeres (105/821; P<0.001), 11% in TE cells (P<0.005), and 15% in BF (P<0.001). The analysis of sequential biopsies revealed that in 6 of 13 oocytes (46%), SA occurred repeatedly: 2 were reciprocal in PB1 and PB2, while 4 were also detected in the following stages. In blastomeres, SA were confirmed in 11 of 16 samples (69%): 5 had the same SA, 4 had the opposite SA, and 2 cases involved the whole chromosome. In TE cells, we had 19 sets of sequential biopsies, of which 15 were confirmed (79%): 3 had the same SA plus 4 case involving the whole chromosome, and 5 had the opposite SA plus 3 cases involving the whole chromosome. In all, 32/48 SAs detected in one biopsy occurred also in subsequent biopsies as the same anomaly (n = 8), opposite anomaly (n = 15) or involving the whole chromosome (n = 9). Excluding the 9 re-biopsies involving the whole chromosomes, SAs were confirmed in 23/48 subsequent biopsies (48%). The highest incidence of SA was found in chromosomes 1, 2, 9 and 16.

Limitations, reasons for caution: The cytogenetic analysis on blastomeres and TE cells did not take into consideration the occurrence of mosaicism for which each biopsy might be not representative of the whole embryo.

Wider implications of the findings: These data could be relevant for PGT-A, where the detection of de novo SA seems to reveal an event that has either meiotic or mitotic origin. The transfer of embryos carrying SA should be strictly followed-up to gain knowledge on implantation and on the genetic status of any resulting fetus.

Trial registration number: Not applicable.

P-586 MiNtagSNP: A tagSNPs selection algorithm for informativity maximization in Preimplantation Genetic Diagnosis (PGD) through the use of Single Nucleotide Polymorphism (SNP)

N. Castejon Fernandez[1], D. Amoros[2], S. Gonzalez-Reig[3], H. Blanca[4], V. Penacho[3], F. Galan[5], M. Fernandez[4], L.A. Alcaraz[6]

[1]Bioarray, Bioinformatic, ELCHE ALICANTE, Spain
[2]Bioarray, Bioinformatic, Elche, Spain
[3]Bioarray, Sequencing, Elche, Spain
[4]Bioarray, Pgd/pgs, Elche, Spain
[5]Bioarray, Medical counseling, Elche, Spain
[6]Bioarray, Technical direction, Elche, Spain

Study question: Could a tagSNP-algorithm be used for finding usefull informative SNPs for a PGD case?

Summary answer: MiNtagSNp is an application for designing single and multi-population genotyping panels based on the linkage disequilibrium of SNPs and additional constraints imposed by the user.

What is known already: PGD has become a standard of care when dealing with stopping the transmission of heritable-diseases. At first sight it seems that the directly sequencing of the disease locus is the best option to discard sick and carrier embryos, but because of the Allele drop-out effect (ADO) the disease allele could be present but silent.

Ancient methods aimed the amplification of polymorphic Short Tandem Repeats (STRs) to detect mutant and wild allele. However, even when the technology has evolved quickly is still deficient to face these kind of problems.

Study design, size, duration: We performed a new tagging-approach that combines the correlation calculations of Linkage Disequilibrium criteria in order to select informative SNPs (Informative success: heterozygous in one of the both parents and homozygous in the other one)

Number of tagSNP selected and the number of informative-tagSNP finding were calculated to evaluate our algorithm.

TagSNPs were obtained for three regions-of-interest and compared with the results obtained by a STRs approach. Time execution, sensitivity and specificity were also evaluated.

Participants/materials, setting, methods: *In-silico* and *in-vitro* approaches were achieved in order to evaluate our algorithm.

For the *In-silico set,* phased SNPs were obtained for the 404 individuals of the European super-population registered in 1000Genomes db.

Sequencing data from 15 trios (parent couple + child) obtained from the Coriell Institute and 15 trios (appropriately informed) from our own laboratory were used to perform two *in-vitro sets.*

Main results and the role of chance: An SNP is a genetic variation when a single nucleotide in the DNA-sequence is altered and kept through heredity thereafter. A tagSNP is a polymorphic site that represent others in a DNA-region; using tagSNP we could ensure that disease embryos may be discard for the transferred phase because not onlythose that shows the disease allele are discard, even those with thehaplotype associated to it. But there is no software specially designed for accurately use them for PGD till now.

MiNtagSNp automates the design of tagSNP genotyping panels with maximum likelihood of informative success, while minimizing the number of tagSNP to assay. This approach makes MiNtagSNP different from other applications that only considers if one SNP can be tag of a region, block, or set of SNPs, without considering if the informativity problem solution is maximized or not.

An extensive experimental study on various datasets including three regions of interest of the evaluation approach shows that MiNtagSNP uses fewer tagSNPs than the state-of-the-art methods, maximizing the prediction accuracy and the informativity problem solution.

Limitations, reasons for caution: Consanguineous couples may have large homozygous regions due to the heritance of the same alleles; these regions could interfere with MiNtagSNP approach.

Wider implications of the findings: We develop an efficient computational framework for tagSNP selection that is able to identify smaller tagSNP sets, than the other studied algorithms, usefull for PGD cases and always outperform in terms of the tagSNP size and number of choosen informativity-SNPs.

Trial registration number: none.

P-587 Aneuploidy rescue in preimplantation embryos

C. Albanese, M.C. Magli, A. Pomante, A. Crippa, S. Azzena, I. Camera, A.P. Ferraretti, L. Gianaroli

S.I.S.Me.R., Reproductive Medicine Unit, Bologna, Italy

Study question: How do human embryos try to rescue an aneuploid condition?

Summary answer: One possible mechanism involved in aneuploidy rescue includes the active extrusion of aneuploid cells into the blastocoelic fluid (BF).

What is known already: Embryos try to rescue aneuploidy, although the majority of chromosomal errors are probably unlikely to be corrected, especially if they involve many chromosomes. Accordingly, most of arrested embryos carry multiple chromosomal errors, suggesting that chromosomal abnormalities are tightly related to embryonic arrest. Some embryos with total or partial aneuploidy can form blastocysts that are morphologically indistinguishable from those with a euploid status. Their implantation potential depends on the proportion of aneuploid cells. Several processes can contribute to the self-correction of aneuploidy, including the formation of micronuclei, cellular fragmentation, and apoptosis.

Study design, size, duration: This retrospective analysis includes a subset of 156 embryos from 71 patients with normal karyotype that underwent PGT-A from January 2010 to December 2017. Embryos were biopsied at the blastocyst stage by removing 6-8 trophectoderm (TE) cells and the BF. The aim of the study was to compare the number of chromosome errors in TE-DNA and in the corresponding BF to verify whether the BF could be a sort of collector of aneuploid DNA.

Participants/materials, setting, methods: Whole genome amplification and array comparative genomic hybridization (a-CGH) (Illumina) was done on TE cells. Before vitrification, the BF was collected and stored for later analysis that was performed by operators blinded to the results of the corresponding TE cells. Results were reported on a per-chromosome basis, but cases of segmental aneuploidy (SA) involving loss or gain of chromosomal fragments in excess of 15 Mb were also described.

Main results and the role of chance: Chromosomal results from the analysis of 156 BFs and TEs from the same embryo showed a ploidy concordance of 93.6%, namely 104 cases of total concordance (66.6%), and 42 of partial concordance (27%). The remaining 10 blastocysts (6.4%) had a ploidy discordance. The overall mean number of aneuploid chromosomes was significantly higher in

BFs than in TE cells (1.9 versus 1.3 respectively, P = 0.01). In the cases of partial concordance, this figure was 4.0 versus 2.2 respectively (P = 0.002). Both values were significantly more frequent in the group of partial concordance in comparison to the group of total concordance (1.1; P<0.001). In the 10 discordant cases, 4 were aneuploid for TE cells and euploid for BF, while the remaining 6 blastocysts had the opposite condition. SA were found in 19 embryos (11.4%). In 7 cases they were present in both TE and BF, while in the remaining 15 cases, 8 were in BF (TE was either normal or aneuploid for the whole chromosome) and 4 in TE cells (BF was aneuploid for the whole chromosome).

Limitations, reasons for caution: A higher number of observations is necessary to support the hypothesis that the embryo actively tries to extrude aneuploid cells into the BF.

Wider implications of the findings: The higher incidence of chromosome abnormalities including SA in BFs could reflect a mechanism that embryos have against aneuploidy. The following outcome depends on the grade of mosaicism in the embryo, but also on its capacity to activate a rescue system to gain a euploid, or prevalently euploid, condition.

Trial registration number: Not applicable.

P-588 Presence of genomic dna in extracellular vesicles (EVs) secreted from human embryos: a new source for non-invasive pre-implantation diagnosis?

L. Corti[1], F. Spinella[2], E. Giacomini[3], S. Makieva[1], A.M. Sanchez[3], M. Surdo[2], A. Biricik[2], F. Fiorentino[2], P. Viganò[3]

[1]IRCCS San Raffaele Scientific Institute, Obstetrics and Gynaecology Department, Milan, Italy
[2]GENOMA Group, Molecular Genetics Laboratory, Rome, Italy
[3]IRCCS San Raffaele Scientific Institute, Reproductive Sciences Laboratory- Division of Genetics and Cell Biology, Milan, Italy

Study question: To investigate the nature of DNA contained in embryo-derived EVs and to study whether it could predict the genetic status of the embryo.

Summary answer: Parental mutated and healthy alleles can be detected in embryo-derived EVs using direct and indirect DNA analysis.

What is known already: EVs are heterogeneous populations of endogenous nano- and micro-sized cell-derived membrane vesicles that are released by different cell types and their cargo can affect the phenotype and activity of target cells. Previously we demonstrated, for the first time, that conditioned media from human embryos cultured in vitro between day 3 and 5 of development contain EVs with predominant exosomal nature. The embryonic origin of EVs was confirmed by the presence of specific proteins and RNAs.

Study design, size, duration: This study was conducted to characterize the genetic cargo of EVs released from embryos during in vitro culture. Initially, we characterized the presence of genomic DNA in embryo-derived EVs. Subsequently, we studied the utility of the amplifiable vesicular DNA in the context of non-invasive pre-implantation diagnosis (PGD).

Participants/materials, setting, methods: Embryos undergoing PGD analysis were cultured up to blastocyst stage and underwent trophectoderm biopsy. The spent medium was collected at day 5 of embryo culture, EVs were isolated, lysed and subjected to DNA amplification. The DNA fragmentation and coverage were assessed with TapeStation and Short Tandem Repeats (STR)/Next Generation Sequencing (NGS) analysis. The parental STR-mutation associated analysis and direct gene mutation detection were performed on EV-amplified DNA. Concordance between trophectoderm biopsy and EV-analyses was deduced.

Main results and the role of chance: In EVs derived from grouped embryo culture (n = 4 pools of 50 embryos), STR analysis confirmed the presence of 8 common markers. The DNA in EVs was less fragmented and more enriched compared to the free DNA in the medium. In single embryo culture, only 11out of 24 samples were analysed due to DNA amplification issues. NGS analysis confirmed a good DNA coverage and parental STRs used in PGD linkage analysis were identified. In 11 of samples suitable for analysis, the only maternal allele was detected in 6 out of 11 (54.5%), the only paternal allele was detected in 3 out of 11 (27.3%), whereas both maternal and paternal alleles were present in 2 out of 11 (18.2%) cases. Allele drop-out might be an explanation for these findings possibly due either to the high rate of DNA fragmentation or the limited DNA amplified. In one case, the presence of the maternal mutated allele causing congenital deafness was confirmed in the EV-DNA by the direct analysis of 35delG in CX26 gene.

Limitations, reasons for caution: Improvement of DNA amplification and analyses when utilizing EV-cargo is needed to increase the efficacy of the methodology. Additional clinical data must be obtained before this approach can be evaluated for routine integration into PGD programs.

Wider implications of the findings: The detection of mutated or healthy alleles (maternal and/or paternal) in embryo-derived EVs is encouraging in a non-invasive PGD context.

Trial registration number: not applicable.

P-589 Monopronuclear embryos derived from testicular sperm extraction followed by intra cytoplasmic sperm injection revealed extremely high euploidy rate with next generation sequencing

S. Mizuta[1], H. Matsubayashi[1], Y. Tamura[2], M. Santo[2], Y. Araki[2], T. Takeuchi[3], K. Kitaya[1], T. Ishikawa[1]

[1]Reproduction Clinic Osaka, Reproductive Medicine, Osaka, Japan
[2]Nippon Reprogenetics Inc., Lab, Maebashi, Japan
[3]Reproduction Clinic Tokyo, Reproductive Medicine, Tokyo, Japan

Study question: To investigate the incidence and euploidy rate of monopronuclear (1PN) embryos derived from testicular sperm extraction (TESE) followed by intra cytoplasmic sperm injection (ICSI).

Summary answer: TESE-ICSI derived 1PN embryos showed significantly higher incidence than those with ejaculated sperms, however the euploidy rate of TESE-ICSI derived 1PN embryos was extremely high.

What is known already: It has been reported that 1PN embryos were observed around 5% both from in vitro fertilization (IVF) and ICSI, and that blastocyst formation rate of 1PN embryos was significantly lower than that of two nuclear (2PN) embryos (especially in ICSI). Embryos derived from 1PN may be considered abnormal which are unsuitable for embryo transfer. However, a recent study revealed that 1PN embryos contained normal embryos similar to those of 2PN embryos by preimplantation genetic screening (PGS). We asked whether 1PN embryos derived from TESE-ICSI showed similar euploidy rate as ejaculated sperms by next generation sequencing (NGS) because of their immaturity.

Study design, size, duration: A single-center retrospective study was performed. Patients who generated 1PN embryos were asked to participate in this study, and gave written informed consent for the study between April 2016 and November 2017. All 1PN embryos were cultured until blastocyst stage followed by NGS. Finally, embryos reached blastocyst and performed NGS were from TESE-ICSI (n = 5), IVF (n = 20) and ejaculated sperm-ICSI (n = 12). Rates of 1PN and euploidy were compared among three groups.

Participants/materials, setting, methods: The average age of patients who provided embryos was 39.7 years. Trophectoderm biopsy was performed using laser system (Saturn 5 Active™, RI Ltd., Falmous, UK). Whole genome amplification was carried out using the SurePlex DNA Amplification System (Illumina Inc., San Diego, USA), and further chromosome profiles were analyzed by VeriSeq-PGS kit (Illumina). The Chi-squared tests were performed to analyze differences in distribution between the two groups. Statistical significance was defined as P < 0.05.

Main results and the role of chance: The incidence of 1PN embryos by TESE-ICSI (10.1%, 402/3982) was significantly (P<0.001) higher than that of IVF (4.0%, 413/10374) or ejaculated sperm-ICSI (4.2%, 756/18009), while 2PN rate on ejaculated sperm-ICSI (70.7%) was significantly (P<0.001) higher than that of IVF (54.7%) or TESE-ICSI (53.5%). Polypronuclear (3PN or more) incidence in IVF (8.8%) was significantly (P<0.001) higher than that of ejaculated sperm-ICSI (3.5%) or TESE-ICSI (2.5%). Blastocyst formation rate of 1PN embryo was 27.8% (97/349) in IVF, which was significantly (P<0.001) higher than that of ejaculated sperm-ICSI (10.6%, 61/578) or TESE-ICSI (14.2%, 48/337). Trophectoderm biopsy can successfully be performed from 1PN embryos with similar rate among three groups; 100% (20/20) in IVF, 92.3% (12/13) in

ejaculated sperm-ICSI, and 100% (5/5) in TESE-ICSI. The euploidy rate of 1PN embryos was 30.0% (6/20) in IVF, 41.7% (5/12) in ejaculated sperm-ICSI and 100.0% (5/5) in TESE-ICSI. Of all 1PN embryos, female embryos were significantly (P<0.05) higher (62.2%, 23/37) than in male embryos (37.8%, 14/37). The male/female embryo ratio was 9/11 in IVF, 5/7 in ejaculated sperm-ICSI, and 0/5 in TESE-ICSI, respectively. We did not perform embryo transfer of these euploid embryos because these embryos were to be discarded (allowed to be used for this study).

Limitations, reasons for caution: Since this study is a single center retrospective observational study with a small sample size, multi-center larger scale studies are needed to conclude. Since we did not perform other tests to track biparental inheritence of the 1PN embryos, uniparental diploidy owing to endoreduplication of a haploid oocyte cannot be excluded.

Wider implications of the findings: We, for the first time, revealed that TESE-ICSI derived 1PN embryos showed significantly higher incidence and higher euploidy rate than those with ejaculated sperms. Although several mechanisms have been proposed to account for normal 1PN embryos, we speculate premature pronuclear breakdown by immature testicular sperm might occur in the embryo.

Trial registration number: N/A.

P-590 Chromosomal mosaicism in spontaneous abortions: a case-control molecular cytogenetics study of 1280 specimens by interphase FISH

S. Vorsanova[1], O. Kurinnaia[1], Y. Yurov[2], A. Kolotii[1], I. Demidova[1], V. Kravets[1], M. Zelenova[2], K. Vasin[2], M. Gordeeva[1], S. Fedorenko[2], I. Iourov[2]

[1]Academician Yu.E. Veltishchev Research Clinical Institute of Pediatrics- N.I. Pirogov Russian National Research Medical University- Ministry of Health of the Russian Federation- Moscow, Laboratory of molecular cytogenetics of neuropsychiatric diseases,
[2]FSBSI «Mental Health Research Center»- Moscow, Laboratory of cytogenetics, Moscow, Russia C.I.S.

Study question: What is the contribution of mosaic aneuploidy and polyploidy to spontaneous abortion (SA)?

Summary answer: Aneuploidy/polyploidy was found in 52,8% of 1280 SA specimens; chromosomal mosaicism was observed in 49,1% of abnormal cases.

What is known already: Numerical chromosomal abnormalities are the most common genetic cause of SA during the first trimester. Classical cytogenetic methods have shown that chromosomal abnormalities are found in approximately 15% of SA. Many previous studies have indicated that chromosomal mosaicism frequently contributes to SA and can be potentially associated with intrauterine mortality.

Study design, size, duration: Using interphase FISH with chromosome-specific DNA probes selected according to the involvement in causative chromosome imbalances, we have performed a case-control study of chromosomal mosaicism in spontaneous abortions.

Participants/materials, setting, methods: We have analyzed 1280 chorionic villus samples of SA (first trimester) by interphase multiprobe FISH using DNA probes for chromosomes 1, 9, 13/21, 14/22, 15, 16, 18, X and Y.

Main results and the role of chance: Numerical chromosomal abnormalities were detected in 676 cases (52.8%) of 1280 SA samples. Multiple aneuploidy/polyploidy were observed in 7.5% of abnormal samples (51 samples) or in 4.0% of all the SA samples. Autosomal trisomy was found in 46.5% of abnormal samples (314 samples) or in 24.5% of all the samples. Chromosome X aneuploidy was found in 21.3% of abnormal samples (144 samples) or in 11.2% of all the samples. Polyploidy was found in 20.4% of abnormal samples (138 samples) or in 10.8% of all the samples. In 4.3% of abnormal samples, mosaic autosomal monosomy was observed. Among all the cases of chromosomally abnormal SA, mosaicism was detected in 49.1%. Consequently, mitotic non-dissociation and/or anaphase lagging causing mosaic chromosomal pathology is likely to be one of the most frequent genetic causes of fetal death. Beside highlighting the role of chromosomal mosaicism in intrauterine fetal death, it is shown that chromosomal mosaicism uncovered by interphase mFISH significantly contributes to SA.

Limitations, reasons for caution: Current study is limited to numerical chromosomal abnormalities of chromosomes 1, 9, 13/21, 14/22, 15, 16, 18, X and Y.

Wider implications of the findings: These data demonstrate that chromosomal mosaicism is highly frequent in SA. Furthermore, interphase FISH seems to be a valid approach towards uncovering chromosomal mosaicism in large scale case-control studies.

Trial registration number: Not applicable.

P-591 Application of SMRT Sequencing in preimplantation genetic testing (PGT) for reciprocal translocation carriers

L. Hu[1], J. Zhou[2], D. Cheng[3], K. Luo[4], F. Gong[4], Y. Tan[4], P. Xie[5], D. Wang[2], G. Lu[6], K. Wang[7], G. Lin[4]

[6]National Engineering and Research Center of Human Stem Cells, National Engineering and Research Center of Human Stem Cells, Changsha, China
[7]Columbia University, Institute for Genomic Medicine, New York, U.S.A.

Study question: Can SMRT sequencing be used in in preimplantation genetic testing (PGT) for balanced reciprocal translocation carriers?

Summary answer: Although it is still needed to be optimized and evaluated, SMRT Sequencing could be another option for PGD, especially for balanced reciprocal translocation carriers.

What is known already: Fluorescence in situ hybridization (FISH)-PGD and comprehensive chromosome screening have been used to identify unbalanced embryos and prevent recurrent spontaneous abortion for reciprocal translocations carriers. Array CGH, MicroSeq, and MaReCs were successfully applied for discrimination of normal embryos and balanced embryos. However, detection of both copy number variants (CNVs) and structural variants (SVs) during PGT in a single sequencing testing remains unsolved. Single Molecule, Real-Time (SMRT) Sequencing enables accurate localization of CNVs and SVs simultaneously with long-read whole genome sequencing. However, its application in PGT is rarely tested.

Study design, size, duration: This proof-of-principle study included totally 2 couples with balanced reciprocal translocation in CITIC-XIANGYA. Besides regular PGT with next-generation sequencing (NGS) and MicroSeq, we performed SMRT sequencing for both translocation carriers and all 6 Day-6 blastocysts.

Participants/materials, setting, methods: Two patients with balanced translocation participated in the study after signing informed consent. We performed SMRT Sequencing on gDNA of the carriers to identify the translocation breakpoints with about 6× coverage. SMRT Sequencing (~10× coverage) and NGS were then performed with the MDA-amplified whole genome amplification (WGA) products. Specific primers spanning the breakpoints were designed to verify the SMRT sequencing results. Results of SMRT sequencing were compared to those of NGS to evaluate its efficiency.

Main results and the role of chance: We successfully detected the breakpoints of the two reciprocal translocations. For SMRT sequencing of the six embryos, both CNVs and target breakpoint could be detected by using blasr-PBhoney. The results of CNVs detected by SMRT sequencing was comparable to that of NGS. The existence of the breakpoints in the embryos was validated by PCR. However, there are numerous SVs are derived from artificial noise in low coverage, e.g. Blunt ligation could induce target DNA self-ligated before adapter ligation; adapter was not recognized in sequencing process. BAMsplit was developed for reads selection and SVs could be screened by using CNV. Each family has 1 unbalanced embryo, 1 balanced embryo, and 1 normal

embryo. The two normal embryos were transferred. Both patients got pregnant. By prenatal diagnosis, 2 babies were confirmed normal without balanced translocation, which consisted with our breakpoint analysis.

Limitations, reasons for caution: Due to current costs of the SMRT sequencing, it is hard to sequencing the whole genome with a high coverage, which may influence the accuracy of PGT. Besides, artificial noise affect the efficiency of SVs detection. This limitation may be solved by developing new methodology of both sequencing and bioinformatics.

Wider implications of the findings: This proof-of-principle study suggest that SMRT Sequencing could be another option for PGD, especially for balanced reciprocal translocation carriers. However, there are still a lot of problems remain to be solved before future clinical application.

Trial registration number: not applicable.

P-592 Comparison of euploid embryo formation after natural or mild stimulation

M. Terribile, M. Wilding, I. Parisi, T. Pehlivan, V. Hall, G. Nargund

Create Fertility, Embryology, London, United Kingdom

Study question: To compare the efficiency of euploid embryos analysed with next-generation sequencing (NGS) after natural and mild stimulation in a preimplantation genetic screening program.

Summary answer: Our study on patients undergoing NGS cycles suggests that natural modified stimulation did not lower the likelihood of euploidy in developing embryos.

What is known already: Mild stimulation cycles aim to achieve multiple follicular recruitment balancing the quantity and quality of oocytes with reduction of health risks to the patient in normoresponder patients. Natural modified protocols assist the production of a single, high quality follicle and therefore egg in low responders. Some papers have suggested that the cumulative pregnancy rate is comparable between natural modified and mild stimulation, however this has not been demonstrated at the present time. In this work, we test the effectiveness of these protocols by examining the percentage of production of normoploid embryos diagnosed with PGS-NGS.

Study design, size, duration: In this retrospective observational research study we included 96 patients undergoing PGS at Create Fertility St Pauls, London. Between 2015 and 2017 in a PGS-NGS program 550 eggs were collected resulting in 136 embryos biopsied. Data related to the stimulation type (natural modified or mild stimulation) was retrospectively analyzed. The outcome measures were fertilization rate, blastocyst formation and euploid rate.

Participants/materials, setting, methods: Patients with normal karyotype undergoing PGS with fresh oocytes, aged between 25 and 49 years old, with a body mass index between 19 and 30 were included. Blastocysts were scored according to the standard Gardner grading system and laser-assisted trophectoderm biopsy was performed on day 5/6 post oocytes retrieval. Preimplantation genetic screening was performed with next-generation sequencing. Chi-squared test was used for statistical analysis with $P<0.05$ considered significant.

Main results and the role of chance: A total of 550 oocytes were collected, 132 "natural modified" vs 418 "mild" respectively. No statistical difference was observed in fertilization rate between the two groups (82 vs 260, NS). A better blastocyst formation was observed in the natural modified group, (27% vs 46% respectively, $p<0.001$). After 5 or 6 days of culture, 136 embryos were analyzed with PGS-NGS (49 vs 87, NS). In 10 samples no results were obtained (3 vs 7, NS). On a total of 126 biopsies with results 18 embryos were euploid (4 vs 14, NS) and 108 were abnormal (42 vs 66, NS) with a euploid rate of 4.88% for natural modified and 5.38% for mild stimulation.

Our results suggest that more embryos are able to grow to blastocyst stage in the natural modified group, in equivalent culture conditions. Secondarily, the percentage of the euploid embryos between the two groups is not statistically different.

These data suggest that natural modified cycles are as effective in producing high quality eggs than mild cycles in their distinctive patient groups, leading to lower embryo wastage and a more efficient use of embryos in IVF cycles.

Limitations, reasons for caution: This study was limited by its retrospective design. Prospective data on the outcomes of embryo transfers is needed to determine their true implantation potential.

Wider implications of the findings: This study showed that euploid rates for blastocysts are not significantly different in natural or mild stimulation cycles. This suggests that the natural modified stimulation approach is an efficient and safe protocol in a program of assisted reproduction.

Trial registration number: not applicable.

P-594 Novel loss of function mutations of follicle-stimulating hormone receptor in a patient with premature ovarian insufficiency identified by infertility gene panel using next generation sequencing

S. Van Dooren[1], A. Sassi[2], J. Désir[3], S. Costagliola[4], V. Janssens[5], M. Bonduelle[6], A. Gheldof[6], D. Daneels[6], A. Delbaere[2]

[1]UZ Brussel, Centre for Medical Genetics & BRIGHTcore, Jette- Brussels, Belgium
[2]Erasme Hospital- Université Libre de Bruxelles, Fertility Clinic- Department of Obstetrics and Gynecology, Brussels, Belgium
[3]Erasme Hospital- Université Libre de Bruxelles- Brussels- Belgium, Department of Genetics, Brussels, Belgium
[4]Université Libre de Bruxelles, IRIBHM- Institute of Interdisciplinary Research in Human and Molecular Biology-, Brussels, Belgium
[5]Université Libre de Bruxelles -, IRIBHM- Institute of Interdisciplinary Research in Human and Molecular Biology, Brussels, Belgium
[6]UZ Brussel- Vrije Universiteit Brussel, Centre for Medical Genetics- Reproduction and Genetics- Reproduction and Genetics and Regenerative Medicine, Brussels, Belgium

Study question: Can an infertility gene panel (GP) approach uncover genetic etiology of premature ovarian insufficiency (POI) in a patient with primary amenorrhea (PA) and hypergonadotropic hypogonadism?

Summary answer: Analysis of GP using next generation sequencing (NGS) identified two new rare inactivating mutations of FSHR which are very likely responsible for the POI phenotype.

What is known already: Inactivating mutations of FSHR are an extremely rare cause of POI. Sixteen inactivating mutations of the receptor have been reported so far in POI patients affecting either the extracellular domain (ECD) or the transmembrane domain (TMD) of the FSHR whether in homozygous or compound heterozygous state. In patients with previously characterized FSHR mutations, the phenotype varied depending on the level of inactivation of the receptor. In most cases, patients presented with a primary amenorrhea and streak ovaries. Some mutations were associated with partial or normal breast development, secondary amenorrhea and normal sized ovaries containing preantral and even small antral follicles.

Study design, size, duration: Analysis of a panel of 31 genes implicated in POI was performed in a 32 years old Belgian patient presenting an idiopathic POI with PA diagnosed at the age of 17 and normal breast development. This patient consulted our fertility clinic for assisted reproduction with oocyte donation and gave her written informed consent to be tested for a genetic etiology of POI.

Participants/materials, setting, methods: We performed GP using NGS @ BRIGHTcore in a patient with POI. FSH and AMH levels were respectively 74UI/L and 1.4ug/L. Karyotype and array CGH were normal. Transvaginal pelvic ultrasound and laparoscopy showed small ovaries with no antral follicles. Transient transfection of COS7 cells was performed with a plasmid containing wild-type FSHR cDNA as well as the two novel FSHR variants identified by GP analysis. Cell surface expression of FSHR variants was tested by FACS.

Main results and the role of chance: NGS identified the presence of two new compound heterozygous FSHR missense mutations: c.646 G>A (Gly216Arg) in exon 8 (ECD) and c.1313 C>T (Thr438Ile) in exon 10 (TMD) of the receptor. Both mutations were predicted to be deleterious and/or probably damaging by in silico analysis. The in vitro functional study showed that the expression of both FSHRs variants was barely detectable at the cell surface of transfected COS7 compared to wildtype FSHR. Two experiments showed similar results.

Limitations, reasons for caution: Mutations segregation in patient's family was not evaluated. As FACS experiments used antibodies that recognize an epitope located in the ECD of FSHR, it is possible that the c.646 G>A mutation

alters the epitope recognition by the antibodies without altering the cell surface expression of the receptor.

Wider implications of the findings: FSHR mutations are found in less than 1% of POI patients rendering the single gene analysis approach inefficient. We report new FSHR inactivating mutations in a patient presenting PA and hypergonadotropic hypogonadism demonstrating the interesting contribution of a specific GP using NGS to uncover genetic etiologies of idiopathic POI cases.

Trial registration number: P2016/196/CCB B406201628264

P-595 Higher resolution aneuploidy screening with targeted NGS may increase the pool of transferrable embryos despite inclusion of segmental and mosaic range diagnostic categories

S. Morin[1], A. Tiegs[2], C. Jalas[3], Y. Zhan[3], J. Landis[3], S. Neal[2], J. Franasiak[2], R. Scott- Jr.[2]

[1]*IVI/RMA Northern California, Reproductive Endocrinology and Infertility, San Francisco, U.S.A.*
[2]*IVI/RMA New Jersey, Reproductive Endocrinology and Infertility, Basking Ridge, U.S.A.*
[3]*Foundation for Embryonic Competence, Genetics, Basking Ridge, U.S.A.*

Study question: How does the higher resolution of next generation sequencing based aneuploidy screening, inclusive of segmental error and mosaic range diagnostic categories, influence the proportion of transferrable embryos in PGT-A cycles?

Summary answer: The higher resolution capability of targeted NGS (tNGS) for PGT-A produces fewer whole chromosome aneuploidy calls. If mosaics/segmentals are considered transferrable, more embryos are available.

What is known already: Euploid embryos, screened with qPCR, have been prospectively demonstrated to produce higher implantation rates than unscreened embryos. Early reports suggest that an embryo diagnosed as euploid with higher resolution NGS platforms produce even higher implantation rates than lower resolution approaches. However, some concern has been raised that inclusion of additional diagnostic categories (segmental and mosaic range) in NGS reports may significantly limit the pool of transferable embryos by reducing the number of euploids available. Given lack of quality data regarding the reproductive potential and long term safety of these embryos, some have suggested limiting their inclusion on clinical reports.

Study design, size, duration: This was a retrospective cohort study of 13,465 embryos from 2,830 cohorts utilizing tNGS based aneuploidy screening at a single IVF center between July 2016 and November 2017. This represented all PGT-A cycles at the center after the reference laboratory switched from qPCR based PGT-A to a tNGS platform. Aneuploidy screening results were compared to a large, published retrospective cohort of 15,169 embryos analyzed with qPCR based PGT-A in 2014 by our group.

Participants/materials, setting, methods: Targeted NGS embryos were placed into one of four categories: aneuploid (whole chromosome aneuploidy present), segmental (only abnormality was deletion/duplication), mosaic range (no other whole chromosome or segmental aneuploidy), euploid. Diagnostic results were compared to published 2014 cohort using qPCR / SNP microarray with respect to 1) Percentage aneuploid diagnoses per embryo and 2) Percentage of cohorts with at least 1 euploid available. Relationship between age and each diagnostic category was evaluated by logistic regression.

Main results and the role of chance: The age of the female partners ranged from 21 to 46 years. The percentage of the 13,495 embryos with aneuploid calls was significantly reduced with tNGS compared to qPCR/SNP microarray (32.4% vs. 41%, $p<0.001$). Mosaicism and segmental rates in tNGS cohorts were 3.6% and 7%, respectively. The no result rate was significantly lower with tNGS than the qPCR/SNP microarray cohort (1.2% vs. 2.8%, $p<0.001$).

A total of 80.7% of the 2,830 tNGS cohorts featured at least one euploid embryo for transfer. The likelihood that a cohort produced all aneuploid embryos increased as the age of the female partner increased ($p<0.001$). However, more than 90% of cohorts produced at least one euploid embryo for transfer for all ages <35 years; 80% of cohorts did so through age 38. It wasn't until age 42 that the majority of cohorts produced no euploid embryos for transfer. The percentage of cohorts in which the only available embryo for transfer was segmental or mosaic was 1.3 and 2.5%, respectively. Thus, 96.2% of cohorts produced a clear clinical strategy (euploid available or all aneuploid embryos).

Female age was strongly associated with whole chromosome aneuploidy. However, there was no association between age and segmental or mosaic range diagnoses.

Limitations, reasons for caution: These data reflect the experience of one PGT-A strategy. While NGS-based methods are now widely used, the amplification strategy, opportunity for concomitant genotyping, bioinformatic customization, and thresholds for intermediate calls can vary widely. This may explain wide variation in reported prevalence of mosaicism. Higher mosaicism rates may alter these conclusions.

Wider implications of the findings: If segmental and mosaic range embryos are considered for transfer, the pool of eligible embryos is increased with tNGS (despite inclusion of additional abnormal diagnostic categories), as whole chromosome aneuploidy calls are less frequent. Data from nonselection studies are needed to define reproductive potential and health outcomes of these embryos.

Trial registration number: Not applicable.

P-596 Clinical implementation of a POI gene panel in idiopathic patients

A. Gheldof[1], S. Van Dooren[2], K. Stouffs[2], A. Sassi[3], D. Daneels[2], J. Désir[4], M. Bonduelle[2], A. Delbaere[3]

[1]*Centrum Medische Genetica, Centrum Medische Genetica, Brussel, Belgium*
[2]*Centrum Medische Genetica, Reproduction and Genetics, Brussel, Belgium*
[3]*Erasme Hospital- Université Libre de Bruxelles- Fertility Clinic, Department of Obstetrics and Gynecology, Brussels, Belgium*
[4]*Erasme Hospital- Université Libre de Bruxelles- Fertility Clinic, Department of Human Genetics, Brussels, Belgium*

Study question: Can a small NGS based gene panel be clinically incorporated in order to identify the genetic cause in idiopatic POI patients?

Summary answer: We have developed a gene pannel consisting of 21 literature evidence based genes which has allowed us to investigate 32 idiopathic POI women.

What is known already: Premature ovarian insufficiency (POI) has been shown to occur in 1% of all women under 40 years old. Already known etiologies are mainly karyotype abnormalities, X fragile premutation, auto-immunity and iatrogenic factors. During recent years, genetic causes, ranging from chromosomal aberrations to single nucleotide alterations, have been shown to contribute to POI, as 31% of POI patients have a familial history. To date, different genetic tools have been used in order to the uncover genetic etiology of POI, but few reports have focused on the contribution of a specific female infertility gene panel in the POI assessement.

Study design, size, duration: We have performed a specific female infertility gene panel by NGS. This GP is restricted to 21 genes implicated in POI and selected according to the evidence based literature findings. Genes where only limited associations have been reported were excluded. This approach allows a more accurate diagnostic route, and an easier clinical workflow in terms of data interpretation.

Participants/materials, setting, methods: We have applied our GP to a cohort of 32 idiopathic POI cases recrutted prospectively from our hospital since june 2016. These patients presented a normal caryotype, no fragile X premutation, no pathogenic nor likely pathogenic CNV at array CGH and no adrenal nor ovarian antibodies. The GP analysis was performed (Capturing Based) on an Illumina HiSeq1500 machine.

Main results and the role of chance: We have identified six rare variants at the heterozygous state (HTs) and one variant at the homozygous state (HOs). Two of them are likely pathogenic and probably responsible for the POI phenotype as they implicate NOBOX and DIAPH 2 genes which inheritance is dominant. The remaining ones are of uncertain significance (VUS): One is homozygous in the XPNPEP2 gene (X-linked dominant inheritance) while the remaining ones implicate the *STAG3*, *HFM1*, *FOXO1* and *MCM8* genes in which the inheritance is recessive.

Limitations, reasons for caution: The implication of the identified variants in the POI physiopathology needs to be further documented by familial

segregation of mutations and phenotypes, as well as functional studies are required. Furthermore, the limited gene set of our panel has to be taken into account.

Wider implications of the findings: Our data shows that a specific GP restricted to a relative small number of genes is useful and rapid genetic tool identifing rare variants in 21,8% of patient. This GP should be integrated as a first line assessment of idiopathic POI idiopathic cases before large GP and Exome sequencing.

P-597 Preliminary analysis of chromosome abnormalities in inversion preimplantation genetic diagnosis cycles using comprehensive chromosome screening

P. Xie, L. Hu, Y. Tan, S. Zhou, G. Lu, G. Liin

[1]National Engineering and Research Center of Human Stem Cell- Changsha 410078- China
[2]Institute of Reproduction and Stem Cell Engineering- Central South University- Changsha- Hunan 410078- China-
[3]Reproductive and Genetic Hospital of Citic-Xiangya- Ch

Study question: To determine the factors associated with unbalanced chromosomal rearrangement in blastocysts originating from the parental inversion.

Summary answer: The risk of generating unbalanced blastocysts originating from the parental inversion is affected by the inversion segment proportion and gender of pericentric inversions carriers.

What is known already: Inversion carriers have an increased risk of having fertility problems, recurrent miscarriages or an abnormal chromosomal offspring. Previous studies in spermatozoa suggested the probability of generating unbalanced spermatozoa is affected by many factors including, e.g. the length of the inverted segment, the position of the breakpoints. Study in translocation carriers suggested sperm FISH cannot be used as a reliable predictor of blastocysts and preimplantation genetic diagnosis (PGD) outcome. However, there is few studies analyzed the PGD outcome of inversion carriers.

Study design, size, duration: A retrospective study from October 2011 to October 2017, a total of 482 blastocysts originating from 145 oocyte retrieval cycles from 128 couples with one of the partners carrying inversion were investigated. The mean maternal age was 32.08 years (20–44 years). Meanwhile, a total of 1228 blastocysts from 406 age-matched patients with normal karyotype were analyzed as control group.

Participants/materials, setting, methods: Trophectoderm biopsy of blastocysts was performed on the 5th or 6th day of development. Whole genome amplification (WGA) was performed on all samples, and the WGA was analyzed with SNP array or NGS. The inversion was classified into two categories: paracentric and pericentric inversions. Further, the blastocysts from pericentric inversions carriers were analyzed according to inversion segment proportion of the length of the inversion over the length of the whole chromosome and the gender.

Main results and the role of chance: For paracentric inversions, we detected chromosome abnormalities in 44/162 embryos (27.16%) while 117 showed a normal chromosome (72.22%). Seven embryos (5/162, 3.08%) with unbalanced rearrangement originating from the parental inversion were identified. For pericentric inversions, first, the pericentric inversions were divided into 3 groups according to the inversion segment proportion (<30% group, 30-50% group, >50% group), the normal embryo proportion was 58% (56/99), 69.23% (57/84), 7.37% (63/133). The unbalanced rearrangement originating from the parental inversion was 3/99 (3.03%), 9/84(10.71%), 44/133(33.08%) respectively in three groups, with significant difference ($p<0.01$). Second, we analyzed the unbalanced rearrangement from maternal and paternal inversion, interesting, the unbalanced rearrangement proportion originating from paternal inversion was higher than maternal inversion in >50% group (43.64%(24/55) vs 25.64%(20/78), $P<0.05$. Further, In order to determine whether an interchromosomal effect (ICE) occurred in blastocysts obtained from inversion carriers. Aneuploidies unrelated to inversion chromosome were identified in both inversion carriers and control group. In the samples from inversion carriers, a total of 20768 chromosomes were examined and 182(0.88%) aneuploidies were identified. In the control group, 54032 chromosomes were assessed and 510 (0.94%) aneuploidies were identified. There was no apparent ICE detected in blastocysts of inversion carriers.

Limitations, reasons for caution: Due to the difficulty in recruiting patients with inversion, the sample size of this study is moderate and more cases should be added.

Wider implications of the findings: Our results indicate the risk of generating unbalanced embryos is low for paracentric inversions, however, the risk is affected by inverted segment proportion and gender for pericentric inversions. There was no apparent ICE detected in blastocysts of inversion carriers. This study may provide data for genetic counseling of inversion carriers.

Trial registration number: not applicable.

P-598 Non-invasive preimplantation genetic testing – aneuploidy screening (PGT-A) using spent culture medium (SCM)

Q.S.Y. Yeung, Y.X. Zhang, J.P.W. Chung, T.C. Li, G.W.S. Kong, K.W. Choy

The Chinese University of Hong Kong, Obstetrics & Gynaecology, Hong Kong, Hong Kong

Study question: Could the same genome profile be identified if spent culture media (SCM) instead of trophectoderm (TE) were used for aneuploidy screening (PGT-A)?

Summary answer: PGT-A using SCM was capable but not as efficient as using TE in euploid identification.

What is known already: By comprehensively screening all 24 chromosomes, PGT-A has been shown to increase implantation and ongoing pregnancy rates. However, the current practice of PGT-A requires an invasive biopsy procedure on the embryo, usually at the blastocyst stage. While the embryologists performing this delicate procedure are usually skilled, the long term effect of laser ablation at the site of biopsy and the removal of a small cell mass from a preimplantation embryo remains unknown for the babies born. It would be ideal if euploid embryos could be accurately identified via a non-invasive approach.

Study design, size, duration: This is a prospective study comparing PGT-A results of SCM samples to the routine results based on TE of the same embryos. Couples undergoing PGT-A cycles were recruited from a university hospital infertility centre. The study is still ongoing, and this interim review is consisted of 70 blastocysts from 24 PGT-A cycles between March 2017 and September 2017.

Participants/materials, setting, methods: All recruited cycles underwent intracytoplasmic sperm injection (ICSI). Normally fertilized embryos were individually cultured in sequential media, with change of simple to complex media on day 3. Blastocysts were biopsied on day 5 or day 6. The complex media in which these embryos were cultured since day 3 were collected. After whole genome amplification (WGA), TE samples were analysed by array comparative genomic hybridization (aCGH) and SCM samples were analysed by next generation sequencing (NGS).

Main results and the role of chance: All TE samples were subjected to routine PGT-A by aCGH (GenetiSure Pre-Screen 8×60 K microarray, Agilent), from which 69 (98.6%) produced an interpretable result. For SCM from the 70 corresponding embryos, 60 samples (85.7%) had cell free DNA that were successfully amplified. These WGA products were then subjected to NGS (Veriseq, Illumina), with 39 of them (65.0%) giving an interpretable result. There was an 88.2% concordance rate in sex determination. When SCM results were classified into euploid and aneuploid, the concordance rate with TE results was 71.8%. Overall, 12 euploids were identified by SCM, in which 6 were also euploids based on TE biopsy, 3 contained low level of mosaicism, 1 involved a segmental error on one chromosome, and 2 false negatives probably due to presence of cumulus cells in the SCM. Interestingly, there were 3 aneuploids identified by SCM which were euploids by TE biopsy. These three embryos were already transferred based on their euploid status as established from TE, resulting in 2 miscarriages and 1 ongoing pregnancy.

Limitations, reasons for caution: Our study was limited by the small sample size. While sperm contamination could be eliminated by using ICSI, further care might be needed in oocyte denudation to avoid maternal contamination. Several rinsing could be incorporated into the media change on day 3 of embryo development.

Wider implications of the findings: Spent culture media from embryos have the potential to become the first non-invasive method in euploid identification and gender determination. Gamete and embryo handling may be refined to allow better accuracy and consistency. Much research is needed to elucidate the origin of cell free DNA found in SCM.

Trial registration number: Research Licence R3004 by the Council on Human Reproductive Technology of Hong Kong.

P-599 Model ensembling and synthetic features in PGS cycles with single embryo transfer

O.O. Barash, K.A. Ivani, S.P. Willman, N. Huen, M.V. Homer, L.N. Weckstein

Reproductive Science Center of the San Francisco Bay Area, U.S.A.,

Study question: Can model ensembling and synthetic features be used to evaluate the impact of the wide range of clinical, as well as morphological and kinetic parameters of embryo development *in vitro* on the clinical pregnancy rates in autologous IVF PGS cycles with single embryo transfer.

Summary answer: Model ensembling and synthetic features can be used evaluate the impact of factors affecting clinical outcomes in IVF PGS cycles with high accuracy and superior predictive performance.

What is known already: Comprehensive chromosomal screening has been proven as the best option to increase clinical outcomes in autologous IVF cycles for advanced maternal age patients. Recent advances in statistical learning (also known as Machine learning or Artificial Intelligence) coupled with a steady increase in the number of IVF cycles with PGS has created a background for effective, non-bias and reproducible data analysis via model ensembling.

Study design, size, duration: 1029 cycles of IVF PGS treatment with single embryo transfer between January 2013 and November 2017 were included in the study (average age 35.5 ± 4.8). 175 clinical factors (age, BMI, AMH, FSH, AFC, stimulation protocol, stimulation duration, gonadotropin dosage, gravidity history, diagnosis, etc.) and 145 morphological and kinetic parameters of embryo development (number of eggs retrieved, number of 2PN, blastulation rate, embryo morphology, euploidy rate per cycle, number of embryos biopsied on day 5 and day 6, number of euploid embryos per cycle, fertilization rate, etc.) were recorded for each IVF PGS cycle. Clinical pregnancy rate (PR) was defined by the presence of a fetal heartbeat at 6-7 weeks of pregnancy. To find the optimal combination of prediction algorithms loss-based supervised learning method was employed.

Participants/materials, setting, methods: From 320 original features 3247 synthetic features were created (by Weight of Evidence for columns, Encoding of categorical levels of the feature, Cross Validation Target Encoding, Time series, etc), tested and 609 features were selected for each IVF PGS cycle. 104 statistical models were trained and ensembled in the final model. Predictive accuracy was evaluated by 5-fold cross-validation and AUC value (ROC curve).

Main results and the role of chance: Combined predictions from multiple weak learners (generalized logistic regression, random forest, gradient boosting, etc.) processed by Generalized Model Stacking produced a predictive performance of AUC = 0.8047. The probability of positive clinical outcome was calculated for each IVF PGS cycle and ranged from 0.239 to 0.850 (baseline prediction – 0.63). A number of previous biochemical pregnancies, blastocysts morphology and time when embryo became available for biopsy had highest variable importance in the ensembled model (0.82, 0.52 and 0.43, respectively). These results were confirmed by univariate analysis: the statistically significant difference in ongoing PR was detected between the groups of patients with and without a history of previous biochemical pregnancies (72.36% (479/662) and 43.88% (136/310), respectively, $\chi 2 = 73.72$, OR = 3.349, CI 2.527-4.438). Similarly, significant difference in ongoing PR was detected between embryos biopsied on day 5 versus day 6 (69.34% (405/584) and 54.28% (241/444), respectively, $\chi 2 = 24.53$, OR = 1.906, CI 1.475-2.463) and between PGS cycles where good versus fair embryos were transferred (67.95% (422/621) and 57.62% (208/361), respectively, $\chi 2 = 10.61$, OR = 1.560 CI 1.193-2.040).

Limitations, reasons for caution: Retrospective study and heterogeneity of patients included.

Wider implications of the findings: Analysis of the data proved that history of previous biochemical pregnancies, embryo morphology and timing of blastocyst biopsy have the biggest impact on clinical pregnancy rates in IVF PGS cycles with SET. Ensemble methods of statistical learning offer superior performance over their singleton counterparts and essentially help to transform medical records into medical knowledge.

Trial registration number: Not applicable.

P-600 Low progression of sperm motility kinetics related aneuploidy ratios of a fertilized embryo

E. Lee[1], T.E. Shin[1,2], J. Park[1,2], H. Kwon[1], B. Jeon[1], H. Kang[1], K.Y. Kang[1], Y.J. Cho[1], D.K. Kim[3], Y.S. Kim[4], I.S. Kang[4], M.K. Koong[4], T.K. Yoon[4], J.J. Ko[5], J.H. Lee[1,2]

[4]*CHA Fertility Center Seoul Station- CHA University, Ob/Gyn – Colleage of Medicine, Seoul, Korea- South*
[5]*Institute of Reproductive Medicine, Biomedical Science- College of Life Science, Pan-Gyo, Korea- South*

Study question: Does the sperm motion kinetic profile have an effect to aneuploidy ratios of in-vitro fertilized embryos?

Summary answer: We found that there is a specific relationship between aneuploidy ratios of in-vitro fertilized embryos and the Computer Assistant Sperm Analysis (CASA) profiling of sperm.

What is known already: Sperm motion kinetics is related to the sperm centrioles complex, which is involved in sperm directional movement. This is because a sperm's centriole complex is related to the microfilament of sperm motility. But the sperm motion kinetics profile has not reported that there is a co-relationship with aneuploidy ratios of embryos.

Study design, size, duration: We performed a retrospective study about the relationship between the sperm motion kinetics analysis data and the pre-implantation genetics screening data. We tried to set up a prediction model for aneuploidy ratios of fertilized embryos. Total number of analysis sampleanalysis' sample number is 1504 and the sample was collected from March 2017 to December 2017.

Participants/materials, setting, methods: We performed the sperm profile analysis using the CASA system before conducting in-vitro fertilization with the ICSI. Then we analyzed sperm kinetics profiles and the PGS outcome (normal and abnormal ratios). We calculated sperm speed (VSL, VCL and VAP) and its progression (LIN = VSL/VCL, STR=VSL/VAP, WOB=VAP/VCL, ALH and BCF). Then, normal and abnormal PGS ratios were compared to each of the sperm's speed and progression ratios.

Main results and the role of chance: Straight of sperm kinetics profiling showed a significantly high normal PGS ratio compared to the curved sperm kinetics profiling. This was especially true when a sperm's head balance in movement had a stronger relationship with the PGS abnormal outcome ratios. Therefore, the abnormal embryo of PGS had a different chromosomal desegregation pattern, just like having a high population of large chromosomal aneuploidy ratios, such as 1 to 10 chromosomes. The spindle of the sperm is localized at the sperm neck region. The moving direction of the sperm is associated with the sperm neck connection and the tail microfilament is associated with the rolling movement to move forward. Then after fertilization, sperm nuclear and spindle changed into a paternal nuclear formation and was distributed as chromosomal segregation. It is possible that a specific moving pattern of a has some effect to chromosomal segregation in the fertilized embryo.

Limitations, reasons for caution: This is a retrospective study and a limited number of normal IVF-ICSI cycles were used for analysis.

Wider implications of the findings: Low straightness profile of sperm kinetics for male patients may be recommended to perform PGS analysis before embryo transfer, in order to save IVF cycles and time.

Trial registration number: It is no application trial registration.

P-601 Validation of using the mitochondrial genome for clinical embryo identification

S. Myers[1], M. Barry[2], M. Jasper[1]

[1]*RHS Ltd, RHS Ltd, Thebarton, Australia*
[2]*Fertility SA, Fertility SA, Adelaide, Australia*

Study question: Can analysis of PG-Seq™ low pass next generation sequencing data for PGT-A also provide genetic information for the identification of embryos in a clinical scenario?

Summary answer: RHS' PG-Seq™ and Embryo ID Single Nucleotide Variant (SNV) Panel readily generates a unique embryo signature providing a simple novel identification protocol.

What is known already: PG-Seq™ with DOPlify® WGA provides superior amplification of the mitochondrial genome. The mitochondrial genome contains single nucleotide variants (SNVs) that can be used to differentiate individuals. Additionally, mitochondrial DNA (mtDNA) is maternally inherited, providing a novel opportunity for DNA-based confirmation of maternal origin of embryo biopsies. During Preimplantation Genetic Testing for Aneuploidy (PGT-A) by Next Generation Sequencing (NGS), biopsies from different patients are often processed together. The mitochondrial genome is sequenced during PGT-A and has the potential to be used to differentiate the maternal origin of the analysed embryos.

Study design, size, duration: A large putative panel of mitochondrial SNVs was compiled from published literature and by comparative analysis of PG-Seq™ data in IGV. Any SNVs associated with disease-related markers, that were monomorphic or that were in regions of low depth of coverage using DOPlify®, were excluded. Two panels comprising 14 and 33 SNVs were assessed using multiple patient embryos and a large in silico dataset.

Participants/materials, setting, methods: Embryos from 50 PGT-A patients and a dataset of 380 publicly available human mtDNA sequences representing the global population was compiled. PG-Seq™ analyses 48 embryo biopsies in a single NGS run. Combinations of mtDNA sequences modelling 4 embryos per patient (ie 12 mtDNA genomes), 2 embryos per patient (ie 24 mtDNA genomes), or 1 embryo per patient (ie 48 patients) were tested. Ten thousand randomly selected mtDNA genome combinations were run for each scenario.

Main results and the role of chance: A total of 47 SNVs were assessed. Using the 380 mtDNA sequences, 177 SNV signatures were observed, with 125 being unique to one individual and 52 being shared by 2 or more individuals. Using the embryo biopsy data, all 47 SNVs were conserved within a patient's cohort. The 14 SNV panel differentiated 20 of 50 patients' embryos. The 34 SNV panel differentiated 28 of 50 patients' embryos. In combination, the 47 SNVs differentiated 48 patients' embryos. In the 10,000 simulated cases using the 380 mtDNA genome database and modelling embryos from 12 patients, on average, the 14 SNV panel differentiated 83.7% of embryos, and the 47 SNV panel differentiated 86.7% of embryos. In the simulated cases with embryos from 24 patients, on average, the 14 SNV panel differentiated 71.4% of embryos, and the 47 SNV panel differentiated 75.2% of embryos. In simulated cases with embryos from 48 patients, on average, the 14 SNV panel differentiated 55.9% of embryos, and the 47 SNV panel differentiated 61% of embryos. Should embryo signatures match in a clinical setting, the rest of the mtDNA genome can be used to further differentiate samples.

Limitations, reasons for caution: Maternally-related patients will share mtDNA genomes. In this case, it will not be possible to distinguish between embryos from these patients using the Embryo ID panel or the rest of the mitochondrial genome. De novo mutations within the SNVs are rare but possible, which may result in matching errors.

Wider implications of the findings: RHS' Embryo ID panel has the potential to improve PGT-A practice by providing a DNA-based confirmation of maternal origin and sibling embryo identification. This could be used for sample tracking within an IVF or genetic service provider laboratory. Embryo ID will be incorporated into a future release of PG-Seq™ software.

Trial registration number: -

P-602 The optimal time and whole genome amplification method for spent culture media in pre-implantation genetic testing

Z. Shuang[1], X. Pingyuan[1,2], L. Ping[3], L. Guangxiu[2,4], L. Ge[1,2,4]

[1]*Institute of Reproductive & Stem Cell Engineering, Research Department, Changsha-Hunan, China*
[2]*China and National Engineering and Research Center of Human Stem Cell, Research department, Changsha-Hunan, China*
[3]*BGI- BGI-Shenzhen, Research Department, Shenzhen-Guangdong, China*
[4]*Reproductive and Genetic Hospital of Citic-Xiangya, Research Department, Changsha-Hunan, China*

Study question: What is optimal time to collect samples and whole genome amplification (WGA) method for spent culture media in pre-implantation genetic testing (PGT)?

Summary answer: The media from Day5-6 has the highest DNA concentration and the highest specificity and sensitivity for comprehensive chromosome screening (CCS) combined with the PicoPLEX amplification.

What is known already: Recently, in order to reduce costs associated with biopsy and minimize the possibility of damage, blastocoels fluid and spent culture media are being explored for non-invasive PGT (NI-PGT). But the extensive use of NI-PGT has been hotly debated due to the accuracy of the procedure, particularly regarding the possible of cumulus-corona radiate cells contamination. Also the degraded cell free DNA in spent culture media is difficult to amplification and may fail to test. For embryonic genetic screening of spent IVF media to become reliable, several steps must be optimized. These include improving DNA collection methods, DNA amplification, and screening techniques.

Study design, size, duration: This was an experiment study including 9 donated intracytoplasmic sperm injection (ICSI) embryos. Each embryo was cultured in a separate single 25 µl droplet of sequential media (G1 and G2, Vitrolife) to the blastocyst stage. About 20 µl spent culture media was collected at 9 am of Day3/4/5/6 separately and the blastocoel fluid was aspirated before the biopsy. In general, each embryo had four spent culture medium samples, a blastocoel fluid and a TE biopsy sample.

Participants/materials, setting, methods: All the spent culture medium and blastocoels fluid samples were used quantitative-PCR to qualify the amount of DNA. For the non-invasive PGT, all the samples were subject to three WGA methods (PicoPLEX, MALBAC, DOP-PCR) separate and sequencing in BGI-500 with about 15 Mb total reads (36 bp+10 bp barcodes). The TE biopsies underwent the conventional PGS procedure, and concordance of TE biopsies and spent culture media results was assessed.

Main results and the role of chance: The average DNA concentration was 0.58, 0.10, 0.3, 0.71, 0.43 pg/µl by q-PCR in Day1-3, 3-4, 4-5, 5-6 and BF samples. For WGA, we have modified the methods to eliminate the effects of degraded DNA, and the mean concentration after amplification was 21.16, 21.12, 25.52, 28.41, 23.31 ng/µl (PicoPLEX); 20.65, 10.41, 24.12, 43.23, 20.58 ng/µl (DOP-PCR); 6.63, 6.12, 9.02, 9.51, 10.35 ng/µl (MALBAC) in Day1-3, 3-4, 4-5, 5-6 and BF samples. For the 45 NI-PGT samples, the amplification rate for each methods were 77.78% (35/45) (PicoPLEX), 64.44% (29/45) (DOP-PCR) and 80% (36/45) (MALBAC) separately. But the results showed that PicoPLEX had the highest reproducibility than the other two methods. And the amplification rate was much higher in Day4-5 (92.59%) and Day 5-6 (96.29%) than Day 3-4 (74.07%), Day 1-3 (44.44%) and BF (62.96%) samples. Though Day 4-5 and Day 5-6 have higher amplification rate, the concordance rate of genetic screening results compare to TE samples were much higher in Day 5-6 (76.92%, 20/26) samples than Day 4-5 (52%, 13/25). And it should be noted that some media sample from Day 1-3 and Day 4-5 were euploidy female while the corresponding TE samples were male. These results indicated the cumulus-corona radiate cells contamination.

Limitations, reasons for caution: At the time of writing the sample size is relatively modest and is need recruiting more populations to the further prospective controlled study. Even though, we have explored the optimal process for NI-PGT, the sensitivity and specificity are still to improve in NI-PGT compare to conventional PGS.

Wider implications of the findings: This is the first study to compare different WGA method and DNA collection methods in different culture stage. And the results of the study might help to reduce maternal contamination and improve the accuracy of the NI-PGT in clinical application.

Trial registration number: NA.

P-603 The interval between human chorionic gonadotropin (hCG) priming and oocyte retrieval effects euploidy rate in PGS cycles

C.C. Huang[1], C.I. Lee[3], M.S. Lee[2], H.H. Chen[1], C.H. Chen[1], T.H. Lee[3]

[1]Division of Infertility, Lee Women's Hospital, Taichung, Taiwan
[2]Institute of Medicine, Chung Shan Medical University, Taichung, Taiwan
[3]Department of Obstetrics and Gynecology, Chung Shan Medical University Hospital, Taichung, Taiwan

Study question: Does the interval between hCG priming and oocyte pick up (hCG-OPU interval) affect the euploidy rate in preimplantation genetic screening (PGS) cycles?

Summary answer: The hCG-OPU interval affects euploidy rate in PGS cycles.

What is known already: The optimal time interval of hCG-OPU has been encountered controversy, whether prolonged interval (>36 h) has any influence on the euploidy rate of blastocyst. In most IVF programs, the commonly practiced interval was 32 to 36 h. However, several studies had shown that ideal IVF performance can be obtained when oocyte retrieval was done more than 36 h (up to 39 h) after hCG priming to increase more high quality oocyte or cleaving embryos.

Study design, size, duration: This is a retrospective study. The *next-generation sequencing* (*NGS*) - PGS outcome data from blastocysts biopsied was conducted to identify differences in euploidy rate. This study included 2090 biopsied embryos from 499 patients undergoing PGS between January 1, 2016 and October 31, 2017.

Participants/materials, setting, methods: All blastocysts were analyzed by the hCG-OPU interval (34-35, 35-36, 36-37, 37-38 and 38-39 hours), women age (≤38 and > 38 years) and the infertility groups (oocyte donor, normal-responders, poor-responders and hyper-responders). Logistic regression analysis was performed to identify whether the hCG-OPU interval is associated with the euploidy rate. Our primary outcome was the effect of the hCG-OPU interval in euploidy rate by women age and the infertility groups.

Main results and the role of chance: According to logistic regression analysis, the hCG-OPU interval (OR: 1.102, 95% CI: 1.010-1.202, p = 0.028) and women age (OR: 0.931, 95% CI: 0.916-0.947, p<0.001) were associated with the euploidy rate. In the patients with age ≤38 years, the euploidy rate within the group of hCG-OPU interval 34-35 hours (32.1%, 37/138) was statistically lower than that in groups of interval 35-36 (42.3%, 113/331; P = 0.046), 36-37 (43.6%, 207/594; P = 0.017) and 38-39 hours (47.2%, 42/122; p = 0.011). In the older patients (age > 38 years), the euploidy rate in group of interval 34-35 hours (9.8%, 12/44) was significantly lower than that in groups of interval 35-36 (24.0%, 36/150; p = 0.048) and 38-39 hours (27.3%, 12/44; p = 0.039). In all infertility groups, the interval 34-35 hours showed the lowest euploidy rates (oocyte donor: 37.5%, poor-responders: 18.2%, hyper-responders: 31.3% and normal-responders: 23.6%). However, the interval of 38-39 hours in all infertility groups showed higher euploidy rates (oocyte donor: 52.6%, poor-responder: 41.2%, hyper-responders: 35.8% and normal-responders: 44.2%) than that in 34-35 interval. Furthermore, in normal-responders, the euploidy rates of interval 38-39 (44.2%, 42/95) and 37-38 hours (36.7%, 94/256) were significantly higher than that in interval 34-35 hours (23.6%, 21/89; p = 0.003 and 0.024, respectively).

Limitations, reasons for caution: Retrospective study of patients included.

Wider implications of the findings: Our findings indicate that hCG-OPU interval in PGS is associated with euploidy rate regardless with different groups of women age or infertility groups. Especially 34-35 interval shows a adverse effect on euploidy rate. This is a importance finding as embryo biopsy in the forms of PGS is increasingly applied.

Trial registration number: No formal funding has been received for this study.

P-604 Is it the best choice for balanced translocation-carrier couples to get children by PGD method?

X. Lu, Y. Feng

Shanghai Jiao Tong University School of Medicine- Ruijin Hospital, Center for Reproductive Medicine- Department of Obstetrics and Gynecology, Shanghai, China

Study question: If it is the best way that balanced translocation-carrier couples should get children with preimplantation genetic diagnosis(PGD) method.

Summary answer: IVF-ET with PGD may not the best choice for translocation-carrier couples to get healthy babies.

What is known already: In order to reduce the high miscarriage rate of balanced translocation-carrier couples, PGD is the most recommended way. But some other studies reported that the cumulative live birth rate of natural pregnancy cycles is as high as 60-80% in couples with structural chromosome rearrangements, and balanced translocation-carrier couples obtained high implantation rate per blastocyst and delivery rates in IVF-ET without PGD cycles.

Study design, size, duration: A retrospective analysis of 441 couples with balanced translocation-carrier was performed. The patients come to our genetic counseling clinic from Oct. 2002 to Oct. 2012. And we obtained their pregnancy outcomes when they made return visits or by phone and e-mail follow-up way.

Participants/materials, setting, methods: Patients were grouped according to different preferences as expectant management, intrauterine insemination, regular in-vitro fertilization and embryo transfer (IVF-ET) without preimplantation genetic diagnosis (PGD), IVF-ET with PGD, or gametes donation. Pregnancy loss rate, pregnancy success rate defined as delivery of at least one healthy child or an ongoing pregnancy in the third trimester, cumulative pregnancy rate, and average cost of per pregnancy success were calculated.

Main results and the role of chance: The couples for expectant management, IVF-ET without PGD, IVF-ET with PGD may gain a successful pregnancy out of every 1.64, 3.22, and 4.66 times per treated cycle (p<0.01). The pregnancy loss rate of couples for expectant management, IVF-ET without PGD, IVF-ET with PGD were 39.13%, 25% and 25%, while the cumulative pregnancy rate of couples were 67.74%, 39.13%, and 23.07% (p<0.01), and the average cost of per pregnancy success were about ¥3286, ¥116,000, and ¥238,000.

Limitations, reasons for caution: This study relied on retrospectively investigate and survey, which may have led to some degree of recall bias.

Wider implications of the findings: If the doctors tell the balanced translocation-carrier couples the detail information of these different ways to get pregnant, it may help them choose a suitable method to get healthy babies.

Trial registration number: No.

P-605 Filling the gap of short-read next generation sequencing in PGD by long-read approach

D.N.Y. Ho[1], C.H. Au[1], J. Lau[1], E.Y.L. Wong[1], K.A. Rocha[2], L. Xue[2], T.W. Shum[2], Y.C. Law[2], Y.Y. Ng[2], I.H. Lok[2], O.S. Tang[2], S.T.S. Lam[3], T.L. Chan[1], E.S.K. Ma[1]

[1]Hong Kong Sanatorium & Hospital, Division of Molecular Pathology- Department of Pathology, Hong Kong, Hong Kong
[2]Hong Kong Sanatorium & Hospital, IVF Centre, Hong Kong, Hong Kong
[3]Hong Kong Sanatorium & Hospital, Clinical Genetic Service, Hong Kong, Hong Kong

Study question: Structural chromosomal abnormality is a common phenotype in PGD cases. A cost effective strategy to distinguish the disease chromosome from the wild-type is challenging.

Summary answer: The uprise of long-read next generation sequencing (NGS) provides a direct and cost effective approach to identify the precise breakpoint for non-carrier embryo selection.

What is known already: In the past, haplotype reconstruction could be the way to access the carrier status of individual embryo in PGD cases with structural chromosomal abnormality, including balanced translocation, inversion, deletion and/or duplication. However, a significant drawback is the

unpredictable recombination events. Currently, the advances in long-read NGS create the opportunity to identify the exact breakpoint at a relatively lower cost, but it has never been used in the preparation of PGD.

Study design, size, duration: Two PGD cases were studied so far using long-read NGS. The first patient was an ectrodactyly male with a 610 kb pathogenic duplication identified by aCGH. The second patient diagnosed with karyotype 46,XX,t(2;13)(q33.3;q12.1) and already went through the PGD cycle. After breakpoint identification, specific PCR primers were used to target the mutations. The breakpoint was validated by Sanger sequencing. The whole-genome-amplified biopsy samples were subjected to the breakpoint analysis. Haplotype reconstruction was performed by microsatellite markers.

Participants/materials, setting, methods: We performed PCR-free whole genome sequencing on peripheral blood DNA using MinION sequencing (Oxford Nanopore Technologies). The data was obtained within a 48-hour sequencing run and aligned. The specific genomic breakpoints have been revealed and PCR primer pairs were designed for breakpoint amplification and Sanger Sequencing. Day5/6 trophectoderm biopsies were subjected to whole genome amplification (SurePlex DNA Amplification System, Illumina) and the products were used for PGD analysis.

Main results and the role of chance: In the ectrodactyly case, we identified the genomic breakpoint by nanopore whole-genome sequencing and the duplication was found to be exactly 683.9 kb. The breakpoint was confirmed by PCR and Sanger sequencing. In family study, the breakpoint was completely linked to the ectrodactyly phenotype and concordant with haplotypes of 5 microsatellite markers flanking the duplication. Trophectoderm biopsies were collected for in vitro fertilization PGD and the patient specific breakpoint PCR assay was performed on the WGA products. Three out of seven embryos were identified to inherit the duplication, hence carrier of the disease chromosome. The carrier status of all embryos was further confirmed by haplotyping. A similar strategy was used to detect the breakpoint of the t(2;13) translocation in the trophectoderm biopsy samples. The long-read sequencing came across the aberration site on derivative chromosome 13 and gap PCR were used to define the embryos with or without balanced translocation. Overall, the result of breakpoint PCR analysis and the haplotype reconstruction were concordant.

Limitations, reasons for caution: The limitation of nanopore whole-genome sequencing is the fact that it is PCR-free and may require micrograms of DNA. Multiple MinION runs may be required to identify the target disease sites.

Wider implications of the findings: Long read next generation sequencing is an emerging technology for whole-genome structural variant detection with single base pair resolution. We demonstrated its potential to accurately determine the genomic breakpoint in the ectrodactyly and t(2;13) patients and may represents a novel strategy for PGD of unknown structural aberration.

Trial registration number: not applicable.

P-606 Excluded cells during blastocyst formation: is aneuploidy the reason?

M. Parriego, L. Coll, M. Devesa, M. Boada, B. Coroleu, A. Veiga

Dexeus University Hospital, Department of Gynaecology- Obstetrics and Reproduction, Barcelona, Spain

Study question: Is the exclusion of cells at compaction during blastocyst formation due to aneuploidy?

Summary answer: No higher aneuploidy rate is observed in excluded cells when compared to the corresponding trophectoderm biopsies. The ploidy status among them is highly concordant.

What is known already: Time-lapse technology has allowed the detection of developmental anomalies that could not be properly assessed with single observations. The exclusion of cells from compaction during the blastocyst formation is occasionally observed.

The incidence of chromosomal abnormalities decreases through embryo development. While some aneuploidies are compatible with the blastocyst stage and onwards, developmental arrest during culture is the main mechanism against severe chromosomal abnormalities. Embryo self-correction of chromosomal abnormalities has also been proposed. Aneuploidy rescue through the exclusion of the abnormal cells from the developing embryo could be one of the potential mechanisms for self-correction.

Study design, size, duration: Retrospective observational study performed from July 2016 to November 2017. Chromosome content of 17 pairs of trophectoderm biopsies and excluded cells from blastocysts of PGT-A patients were analysed.

Participants/materials, setting, methods: Cells excluded from compaction during blastocyst formation and the corresponding biopsied trophectoderm cells from 15 PGT-A patients were analysed to determine their chromosomal constitution. Only fully hatched blastocysts with left over cells in the zona pellucida were considered. Excluded cells as well as trophectoderm biopsies from hatched blastocysts were separately processed by a-CGH or NGS.

Results regarding ploidy concordance were evaluated. The specific chromosomal constitution of the sample pairs was analysed.

Main results and the role of chance: Seventeen pairs of trophectoderm biopsies and excluded cells were analysed. In 3 cases there was no DNA amplification of the excluded cells.

Ploidy concordance was observed in 13 of the 14 pairs that could be analysed. Discordant results were found in one blastocyst diagnosed as a mosaic that showed euploidy in the corresponding excluded cells.

Five of 14 trophectoderm samples were diagnosed as euploid. All their complementary excluded cells showed the same euploid chromosomal constitution.

In 8 of 9 cases diagnosed as aneuploid after trophectoderm biopsy, the excluded cells were also aneuploid. Full concordance of the chromosomal constitution was observed in 4 of them while certain differences were detected in the remaining 5. There seems to be a tendency for more severe chromosomal abnormalities in the excluded cells.

A high ploidy concordance is observed among trophectoderm cells and cells excluded from compaction in biopsied PGT-A blastocysts.

Limitations, reasons for caution: Retrospective observational study with limited sample size.

Wider implications of the findings: According to our results, exclusion of certain cells during blastocyst development does not seem to be related to aneuploidy rescue.

Trial registration number: Not applicable.

P-607 Polymorphic variants of chromosomes decrease cleaved embryos rate in vitro fertilization and embryo transfer treatment

L. Saijiao, Z. Danni, Z. Ying, Y. Jing, L. Ao

Renmin Hospital of Wuhan University, Department of Reproductive Medicine Center, Wuhan, China

Study question: This retrospective study comprehensively analyzed the correlation between chromosome polymorphisms and the outcome of IVF–embryo transfer treatment for infertile couples.

Summary answer: Polymorphic variants of chromosomes affect the embryo cleaved rate of in vitro fertilization and embryo transfer treatment.

What is known already: Studies indicate that chromosome polymorphisms may cause certain clinical effects, such as infertility and spontaneous miscarriage. Little report has studied whether chromosomal variation, other than Y chromosome variation, affects the outcome of IVF–embryo transfer treatment.

Study design, size, duration: During the period from October 2014 to November 2017, 1415 infertile couples who had received their first IVF–embryo transfer treatment cycle in our hospital were selected for this retrospective study, and the frequency of chromosomal polymorphic variations was calculated.

Participants/materials, setting, methods: 1415 infertile couples were divided into four groups: 1182 couples with normal chromosomes (Group 1). 129 couples with $1qh^{+/-}$, $9qh^{+/-}$ or $16qh^{+/-}$ (Group 2) ;56 couples with ps+, pss or pstk+ of the acrocentric chromosomes (Group 3); And 48 couples with pericentric inversion of chromosomes 9 (Group 4).The fertilized rate, embryo cleaved rate, good quality embryos rate, clinical pregnancy rate(CPR), implantation rate and early stage miscarriage rate after IVF-embryo transfer treatment were compared.

Main results and the role of chance: There were no statistically significant differences among the four groups in patient's fertilization rate, good quality embryos rate, clinical pregnancy rate(CPR) and implantation rate. But the chromosomal polymorphism groups (Group 2, Group 3 and Group 4) had lower cleaved embryos rate comparing with control group (Group 1) (95.83, 95.05, 89.90 and 97.5% respectively, P<0.05). The first trimester pregnancy loss rates in Group 4 patients were higher than in control group (25% versus 4.4%, P<0.05), but not in Group 2 and Group 3.

Limitations, reasons for caution: The limitations are the number of heteromorphism carriers was insufficient. Furthermore, the chromosome analysis method in the present study had a 400-550 BPHS banding resolution; some potential variations could not be distinguished from common polymorphism variations. Therefore, a greater number of samples and more sensitive techniques are needed.

Wider implications of the findings: Chromosomal polymorphism carrier could decrease cleaved embryos rate. chromosome 9 pericentric inversion may increase first trimester pregnancy loss and impact IVF outcomes. We should afford individual genetic counseling suggestion according to the polymorphism types.

Trial registration number: not applicable.

P-608 Level of embryonic mosaicism do not seem to be influenced by extrinsic features: analysis of 298 mosaic embryos

M.G. Minasi[1], F. Fiorentino[2], A. Ruberti[1], A. Biricik[2], E. Cursio[1], S. Bono[2], A. Colasante[1], E. Cotroneo[2], V. Casciani[1], F. Scarselli[1], R. Polese[1], M.T. Varricchio[1], M. Baldi[2], F. Spinella[2], E. Greco[1]

[1]European Hospital, Center for Reproductive Medicine, Rome, Italy
[2]GENOMA Group, Molecular Genetics Laboratories, Rome, Italy

Study question: Is the percentage of embryo mosaicism related to culture and/or patient characteristics?

Summary answer: The rate of mosaic cells detected in an embryo does not seem to be correlated to different culture conditions nor to patient's origin.

What is known already: Embryonic mosaicism is defined as the contemporary presence of two or more genetically different cell lines in the same embryo. It is a common phenomenon in human embryos due to mitotic errors after fertilization and could have an impact on embryo developmental and implantation potentials. It has been reported that mosaic embryos hold the potential to implant, leading to the birth of healthy babies. Anyway, the extent of mosaicism can influence the success rate. Lower aneuploidy percentage has been demonstrated to maintain higher chances of resulting in the birth of healthy babies compared to embryos with higher mosaicism levels.

Study design, size, duration: In this preliminary study, only cycles where at least one mosaic embryo was found, were enrolled. In 195 IVF cycles performed in 185 patients, 298 mosaic embryos were obtained. Mean female and male ages were 35.39 ± 4.22 and 38.83 ± 5.79 years old, respectively. All biopsies were performed at blastocyst stage and diagnosed with either array-CGH or NGS-based PGS. Single embryo cultures were performed in standard or time-lapse incubators at 37°C, 6%CO_2, 5%O_2 in sequential or 1-step media.

Participants/materials, setting, methods: Embryos were divided in two groups on the basis of their mosaicism percentage: ≤40% (N = 160) and >40% (N = 138). Differences among culture systems (culture media and incubators), embryo quality (morphological grade at embryo and blastocyst stages, day of biopsy and morphokinetic development) and patient's characteristics (female body mass index [fBMI], FSH dose, female and male ages, antral follicle count [AFC] and seminal parameters) were analyzed in the two groups.

Main results and the role of chance: One-step and sequential media were employed for 20.0% and 80.0% and for 16.7% and 83.3% of the embryos in ≤40% and >40% groups, respectively. Time-lapse and standard incubators were used for culturing 58.8% and 41.2% and 63.0% and 37.0% of the embryos in ≤40% and >40% groups, respectively. The rates of day-3 excellent, good and poor morphology grades were 72.3%, 22.7% and 5.0% in ≤40% group and 73.9%, 20.1% and 6.0% in >40% group, respectively. The rates of excellent, good and poor blastocyst grades were 31.9%, 28.1% and 40.0% in ≤40% group and 32.6%, 32.6% and 34.8% in >40% group, respectively. Biopsies were performed on day-5, day-6 or day-7 in 57.5%, 38.7%, 3.8% and in 61.6%, 34.8%, 3.6% of the blastocysts in ≤40% and >40% groups, respectively. Normospermic, oligoastenoteratospermic and testicular men were 26.9% and 27.4%, 39.8% and 38.5%, 33.3% and 34.1% in ≤40% and >40% groups, respectively. None of these values reached a statistical significance. The morphokinetic development did not show statistical differences at any time-points, neither at embryo nor at blastocyst level. No differences were found between the two groups according to the distribution of the fBMI, the dose of FSH, the AFC and the female/male ages.

Limitations, reasons for caution: The number of mosaic embryos enrolled in the study need to be enlarged. It should be reasonable to test also other different mosaicism level cut-offs. A comparison with both euploid and aneuploid blastocysts obtained in the same cycles could better clarify the role of embryonic mosaicism.

Wider implications of the findings: To date, a lot of different culture systems are available and the decision about which of them should be preferred is extremely subjective. Our study suggests that the level of embryonic mosaicism is not ascribable to culture conditions or to patient's origin.

Trial registration number: Not applicable.

P-609 Cryptic complexity identified by whole-genome mate-pair sequencing in complex chromosomal rearrangements: implications on preimplantation genetic diagnosis and reproductive genetic counseling

C. Aristidou[1], E. Constantinou[1], A. Alexandrou[1], A. Theodosiou[1], M. Mehrjouy[2], M. Bak[2], N. Tommerup[2], C. Sismani[1]

[1]The Cyprus Institute of Neurology and Genetics, Department of Cytogenetics and Genomics, Nicosia, Cyprus
[2]University of Copenhagen, Wilhelm Johannsen Centre for Functional Genome Research- Department of Cellular and Molecular Medicine, Copenhagen, Denmark

Study question: Two Complex Chromosomal Rearrangement (CCR) cases were characterized in detail in order to provide more precise abnormal pregnancy risk estimations and better genetic counseling.

Summary answer: Cryptic rearrangement complexity increases abnormal pregnancy risk in couples with CCRs and reproductive problems.

What is known already: CCR carriers are at high risk for chromosomally unbalanced pregnancies, which may lead to recurrent miscarriages or affected offspring. The nature of each rearrangement, including the number of chromosomes and breakpoints involved, have significant implications on the percentage of unbalanced gametes following meiotic segregation of CCRs. As a result, reproductive risk in CCR carriers may remain underestimated with the use of conventional, low-resolution methods. Detailed characterization of CCRs is therefore crucial to unravel potential higher rearrangement complexity, and subsequently, aid in better prenatal preimplantation genetic diagnosis (PGD) and reproductive genetic counseling in couples with reproductive problems.

Study design, size, duration: Non applicable.

Participants/materials, setting, methods: In the present study, whole-genome mate-pair sequencing (WG-MPS) was used to further characterize and delineate the breakpoints of a rare, paternally-transmitted t(6;7;10) CCR in a phenotypically normal father and daughter, and a de novo t(6;7;8;12) CCR in a female patient with mild intellectual disability. Results were validated with Sanger sequencing and Fluorescence In Situ Hybridization (FISH).

Main results and the role of chance: WG-MPS allowed accurate reconstruction of all derivative (der) chromosomes involved, and interestingly, cryptic complexity was revealed in both cases.

In the rare, paternally-transmitted CCR, WG-MPS detected an additional cryptic translocation breakpoint on der(6). FISH using a chromosome (chr) 6 custom-designed probe and a chr10 control probe confirmed that the interstitial chr6 segment, created by the two chr6 breakpoints, was translocated onto der(10). Previous sperm-FISH investigations in the father analyzing the possible segregation patterns revealed that only two combinations out of sixty-four (3.1%) are balanced. Identification of a cryptic breakpoint in this study and accurate delineation of the full CCR complexity, suggest that the number of possible segregation patterns is even higher, and concurrently, the percentage of balanced gametes becomes even lower.

In the de novo t(6;7;8;12) CCR, WG-MPS revealed a chromothripsis rearrangement involving thirty-eight translocation breakpoints and two heterozygous deletions. Haploinsufficiency of the SOX5 gene, disrupted by two breakpoints and a heterozygous chr12 deletion, most probably underlies intellectual disability in the patient. Since it has been generally estimated that there is an additional ~3.5% risk per breakpoint for unbalanced gamete production, it is expected that this massively complex rearrangement will have a significant impact on the patient's reproduction risk.

Limitations, reasons for caution: Even though WG-MPS can successfully delineate the full complexity of CCRs, an applicable strategy for PGD still remains very challenging.

Wider implications of the findings: In concordance with available literature, this study highlights the importance of investigating CCRs using a combination of conventional and next generation sequencing-based methods in order to delineate their full complexity, and thus provide better abnormal pregnancy risk estimations and reproductive genetic counseling in CCR couples.

Trial registration number: Non applicable.

P-610 Introducing direct CGG repeat analysis in preimplantation genetic diagnosis (PGD) for fragile X syndrome: an overview of clinical outcomes for 116 patients

R. Cabey[1], D. Nusblat[1], J. Gay[1], E. Armenti[1], B. Chu[2], N. Goodall[2], R. Prates[2], M. Konstantinidis[2]

[1]CooperGenomics, genetic counseling, Livingston- New Jersey, U.S.A.
[2]CooperGenomics, laboratory, Livingston- New Jersey, U.S.A.

Study question: Does incorporating analysis of CGG repeat number in PGD embryos have a significant effect on the clinical outcomes for fragile X premutation carriers?

Summary answer: Performing CGG repeat analysis for embryos provides patients with an additional layer of information that can assist with the embryo transfer decision making process.

What is known already: Fragile X mental retardation gene (*FMR1*) CGG repeat testing has been the routine method of analysis on living individuals and prenatal samples. Historically, PGD for fragile X syndrome has been performed via linkage analysis alone. While differentiating between the normal allele and the expanded allele has been extremely beneficial for patients, it lacks the ability to further distinguish between intermediate, premutation and full mutation embryos. As a result, patients and physicians have been making decisions concerning embryos without potentially impactful clinical information.

Study design, size, duration: Outcome data was obtained on 116 patients, who underwent PGD for fragile X syndrome via a linkage-based technology (Karyomapping; Illumina, USA), and direct CGG repeat analysis, between 01/2014 and 12/2017. Trophectoderm biopsy samples from 852 embryos were received from 194 IVF cycles.

Participants/materials, setting, methods: This cohort of patients carried either an intermediate, premutation, or full mutation *FMR1* allele and the average maternal age was 34.03 ± 0.32 (standard error of the mean). As 33 patients banked embryos from multiple IVF cycles, a total of 160 PGD tests were performed; 148 of these included aneuploidy screening via aCGH or NGS (Illumina, USA). Following exclusion of embryos with no diagnosis, sex aneuploidy, or that were untested, results were obtained in 771 embryos.

Main results and the role of chance: CGG repeat results were obtained in 756/771 samples (98.05%). Overall, the maternal normal allele was inherited in 48.59% of embryos. Of the embryos that inherited the expanded allele, 70.97% remained in the premutation or intermediate range. The following rates of expansion from premutation to full mutation in embryos were observed: 0% (0/74) in the maternal premutation group of 55-59 CGG repeats, 7.78% (7/90) in the 60-69 group, 9.52% (4/42) in the 70-79 group, 30.30% (10/33) in the 80-89 group, 91.67% (22/24) in the 90-99 group, and 100% (47/47) in the 100-199 group. Notably, 3.02% (12/397) of embryos contracted from the maternal expanded allele size (ranging from 57 to >200). The number of embryos per PGD test increased to (6.73 ± 0.71) when patients banked embryos, compared to those who did not (4.91 ± 0.29). There was a significant increase in the average number of embryos available for transfer from 1.33 ± 0.11 (euploid and normal *FMR1* alleles) to 2.07 ± 0.17 when including premutation embryos (P<0.001). Follow up from patients revealed that 70 normal allele embryos, 8 premutation, and 2 normal or premutation embryos were transferred; resulting in 38 live births and 6 ongoing pregnancies. Subsequent confirmatory testing was pursued by 5 patients revealing concordant results with PGD.

Limitations, reasons for caution: A little over 100 patients were evaluated in this study, but clinical outcomes were not obtained on all. In addition, a large portion of patients did not pursue prenatal or postnatal confirmatory testing via outside laboratories. Continued follow up will aid in providing additional analysis.

Wider implications of the findings: This data set presents useful groundwork for understanding the clinical implications of CGG repeat testing in PGD embryos. The differentiation between premutation and full mutation PGD embryos provides more complete diagnostic information; therefore highlighting the need for counseling regarding options for embryo transfer.

Trial registration number: not applicable.

P-611 External verification of the Agilent Technologies OnePGT solution for PGT-M on blastomere and trophectoderm biopsies from UZ Leuven

C. Melotte[1], E. Dimitriadou[1], M. Zamani Esteki[2], H. Masset[3], K.O. François[4], J. Allemeersch[4], R. Richards[4], S. Moeys[4], J. Theuns[4], J.R. Vermeesch[1]

[1]Leuven University Hospital, Center for Human Genetics, Leuven, Belgium
[2]Center for Human Genetics- KU Leuven, Laboratory of Reproductive Genomics, Leuven, Belgium
[3]Center for Human Genetics- KU Leuven, Laboratory for Cytogenetics and Genome Research, Leuven, Belgium
[4]Agilent Technologies, Agilent Technologies, Leuven, Belgium

Study question: To assess the level of concordance between OnePGT (Agilent Technologies) and Gold Standard reference data of embryo biopsies for preimplantation genetic testing for monogenic disorders (PGT-M).

Summary answer: A conclusive result was obtained for 113/118 (95.8%) embryos analyzed for PGT-M, with a concordance of 100% between the results of OnePGT and the Gold Standard.

What is known already: OnePGT is an innovative next-generation sequencing (NGS)-based solution for all-in-one Preimplantation Genetic Testing (PGT) of *in vitro* fertilized (IVF) embryo biopsies. OnePGT can be used to genetically profile IVF embryos by testing a single- or few-cell biopsy to 1) identify those free of a specified Mendelian disorder or translocation and/or 2) prioritize chromosomally normal i.e. euploid embryos for transfer in a single workflow. This enriched level of information can hence improve success rate of implantation and live birth.

Study design, size, duration: A total of 118 whole genome amplified-embryo biopsies previously analyzed with SNParray and the siCHILD algorithm were submitted for analysis with the OnePGT solution. These samples, together with gDNA from the parents and reference family member(s), originated from 16 families encompassing 15 unique single gene disorders. Both affected and unaffected embryos were included. Data analysis and interpretation was kept blinded and concordance with SNParray/siCHILD results was conducted only after the OnePGT results were recorded.

Participants/materials, setting, methods: Twelve families segregated a dominant, 1 family an X-linked and 3 families an autosomal recessive disorder. In 5 families, the phasing reference was a child of the IVF-parents while for the other families the parents of the carrier IVF-parent were available as phasing references. DNA-samples were library prepped with OnePGT reagents and sequenced on a NextSeq 500 instrument (Illumina). The NGS data was analyzed with the proprietary OnePGT software tool, in particular the PGT-M pipeline.

Main results and the role of chance: The library preparation was successfully performed on a total of 189 samples (including embryo's and respective family members). A conclusive call was achieved for 113 embryonic samples from a total of 118 (95.8%), with 5 embryos receiving an inconclusive call (4.2%). The root cause of these inconclusive calls included cross-over or breakpoints in close proximity of the disease locus (4/5), and nullisomy of the

chromosome of interest (1/5). For two of the inconclusive cases, the Gold Standard result was also inconclusive indicating a biological reason for failure. In addition, one embryonic sample inconclusive in the Gold Standard protocol received a conclusive result in OnePGT. For concordance analysis, both the inconclusive results from OnePGT and Gold Standard were excluded. A 100% concordance was obtained for the 112 embryo samples analyzed with OnePGT when compared with the Gold Standard result, of which 50 unaffected embryos were correctly called as unaffected and 62 affected embryos were correctly called as affected.

Limitations, reasons for caution: This study is limited by the population size which is not sufficient to calculate % specificity, % sensitivity or positive predictive value. For Research Use Only. Not for use in diagnostic procedures.

Wider implications of the findings: The results of this study indicate that the OnePGT solution is able to accurately determine the disease status of embryo biopsies, both from blastomere and trophectoderm sample types, for a wide range of single gene disorders.

Trial registration number: not applicable.

P-612 A proposed method to minimize male gamete contribution to aneuploidy in the embryo cohort

A. Melnick, A. Parrella, S. Cheung, P. Xie, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can a new method to select spermatozoa enhance the genomic competence of the male gamete and yield euploid embryos in couples with all abnormal conceptuses?

Summary answer: Microfluidic selection yields spermatozoa with high progressive motility and genomic integrity, enabling the generation of chromosomally normal embryos despite history of recurrent, total aneuploid conceptuses.

What is known already: The presence of a male factor can negatively impact embryo cleavage and chromosomal status. In addition, dysfunction of the male genital tract increases sperm chromatin fragmentation that, particularly in cases of double strand breaks, can lead to aneuploidy of the male gamete. Thus, in couples with a relatively young female partner, the recurrent appearance of aneuploid embryos may reflect the contribution of the male gamete.

Study design, size, duration: In a 16-month period, 4 couples with history of high Sperm Chromatin Fragmentation (SCF) and embryo aneuploidy after several ART attempts underwent a successive cycle of ICSI where semen specimens were processed in a microfluidics chamber. Fertilization and clinical pregnancy rate were assessed and compared between different sperm preparation methods. SCF was assessed by TUNEL and sperm aneuploidy by FISH analysis. Chromosomal analysis was carried out by preimplantation genetic testing for aneuploidy (PGT-A) on conceptuses.

Participants/materials, setting, methods: Consenting men had their ejaculates screened by standard semen analysis according to WHO 2010 criteria. Ejaculate specimen were processed by density gradient and MFSS. SCF was measured by TUNEL utilizing a commercial kit (In Situ Cell Death Detection Kit, Roche). At least 500 spermatozoa were counted under fluorescent microscopy with an adopted threshold of 15%. FISH analysis was carried out on at least 1000 spermatozoa by 9 chromosome probes.

Main results and the role of chance: In a total of 18 cycles, the average age for the men was 44.5 ± 15 years. The average semen parameters were: concentration of 14.9 ± 23.5×10^6/mL, motility of 26.3 ± 17%, 2.0 ± 0% normal morphology. The SCF was 34 ± 12% and the sperm aneuploidy rate was 4 ± 2%. In 13 cycles, after selection by density gradient, the total motility rose to 48.7 ± 9%. The mean of oocytes injected was 7.1 ± 4 with a fertilization rate of 68.7%. The euploidy rate was 3 embryos out of 30 (10%). These euploid embryos were transferred in two patients and two clinical pregnancies were established, both resulting in miscarriages. In 5 cycles, where the sperm was processed by MFSS, the total motility increased to 98.3%±2 (P<0.0001). The sperm morphology became 4% and the SCF reduced to 1.8 ± 1 (P<0.001). The average number of injected oocytes was 5.7 ± 3 with a subsequent fertilization of 78.1%. Following MFSS processing, there were 7 euploid blastocysts out of 14 (50%) that, after transfer, yielded a pregnancy in all four patients (100%) (P<0.001).

Limitations, reasons for caution: This is a pilot study on a small number of subjects. However, this microfluidic method is capable of selecting spermatozoa with better morphology, higher chromatin integrity, and presumably lower sperm aneuploidy, which may likely yield euploid embryos in couples with subtle male factor infertility.

Wider implications of the findings: According to this study, the selection of a genomically competent male gamete may enhance the euploidy of the conceptus. Couples with a relatively young female partner and recurrent aneuploid embryos may benefit from MFSS selection to improve reproductive outcome due to an occult male factor.

Trial registration number: N/A.

P-613 Genomic profiling of spermatogenetic function in azoospermic men

B. Chin, S. Cheung, C. O'Neill, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can sequencing of the genome shed light on the genes involved in the spermatogenic function of the seminiferous tubules of azoospermic men?

Summary answer: Men with secretory azoospermia have a mutated set of genes with compromised function responsible for the impaired meiotic process.

What is known already: Azoospermia represents about 1% of all men in the fertile age and about 15% of the infertile men. Azoospermia is seldomly due to pre-testicular factors, but the most common forms are testicular and post-testicular. While the post-testicular type is due to obstruction, whether congenital or acquired, the most puzzling type remains the secretory azoospermia where scattered dysfunctional seminiferous tubules strive to proceed through the germline meiotic process toward the generation of spermatozoa.

Study design, size, duration: Over a period of 2 years, NGS assessment was carried out on surgically retrieved spermatozoa from 9 azoospermic men, who were categorized as obstructive (OA) or non-obstructive (NOA) based on their spermatogenetic profile. Specific gene mutations and ICSI pregnancy outcomes were assessed and compared between the two groups.

Participants/materials, setting, methods: Consenting men being treated at our center for infertility provided their specimens. DNA extraction was carried out from at least 500 spermatozoa followed by PCR-based random hexamer amplification (average DNA concentration 395 ± 217 ng/ul and quality of 1.7 ± 0.1 nm). Following DNA sequencing of the specimens by NGS, gene mutations, including duplications and deletions, were detected by CASAVA and VarScan2 software programs.

Main results and the role of chance: Our analysis included a total of 9 consenting men with an average age of 45.2 ± 8 yrs. Six OA patients were treated by epididymal aspiration or testicular biopsy with an average concentration of 2.0 ± 3×10^6/ml and a motility of 0.5 ± 1%. In all OA cases, the reason for the obstruction was a prior vasectomy. Also these men underwent 6 cycles with a pregnancy and delivery rate of 50%. Three NOA men underwent testicular biopsies that yielded spermatozoa in all cases. They were treated by ICSI in 3 cycles with a pregnancy and delivery of 66.7%. NGS reported no difference in aneuploidy of spermatozoa from the OA and NOA groups. The sequencing of DNA was carried out on 70,000 genes of which only 2 were mutated in the obstructive patients, while non-obstructive azoospermic men had 123 genes mutated (P<0.0001). Among the genes mutated, the most represented were related to mRNA transcription (n = 26) followed by genes involved in spermatogenesis (n = 15), DNA repair (n = 14), centrosomal function (n = 13), and apoptosis (n = 12).

Gene expression analysis by RNA sequencing reported 12 genes, of which 9 were significantly underexpressed (P<0.001). Their functions included calcium mobilization (CXCL16), acrosomal integrity (ACR), and overall regulatory genes of spermatogenesis (ZMYND15).

Limitations, reasons for caution: This is still a limited number of observations carried out on men being screened for infertility. Moreover, testicular

specimens were donated by patients with specimens that yielded spermatozoa and it should be extended to include men with spermatogenic arrest and germ cell aplasia.

Wider implications of the findings: NGS screening of infertile men will help characterize the spermatogenic function of the seminiferous tubule. This will help designate patients who benefit from testicular sampling versus those who would not. Moreover, querying the genome and the epigenome will help shed light on the etiology of this severe form of infertility.

Trial registration number: N/A.

P-614 Reassessing the prevalence of aneuploidy in sperm retrieved from different levels of the male genetic tract

S. Cheung, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: We questioned the notion that sampling epididymal and testicular tissues yields spermatozoa with higher incidence of aneuploidy than those found in the ejaculate.

Summary answer: With the adoption of advanced molecular genetic techniques, we confirmed that surgically retrieved spermatozoa have at least comparable incidence of aneuploidy compared to ejaculated spermatozoa.

What is known already: Previous studies, including our own, evidenced, in a few men and by only 4 chromosome probes on about 100 cells, that these testicular spermatozoa have a remarkably higher (13%) occurrence of aneuploidy. This notion, however, did not translate into a higher incidence of miscarriages nor a lower rate of pregnancy. Moreover, ICSI offspring generated from surgically retrieved gametes did not suffer from an increased aneuploidy than those generated from ejaculated specimen. In light of the availability of more accurate molecular genetic techniques, we have decided to challenge this dogma.

Study design, size, duration: Nine chromosome FISH was carried out on 2 donor controls, the ejaculates of 67 men, and surgical specimens of 9 azoospermic men. DNA sequencing technology was carried out on the ejaculates and surgical samples of 20 men. A combined assessment was performed on non-azoospermic (non-NOA) men with high DNA fragmentation in their ejaculate. ICSI pregnancy outcome was also recorded and compared. Additionally, an analysis was carried out to compare obstructive (OA) and non-obstructive (NOA) men.

Participants/materials, setting, methods: Consenting men treated for infertility provided their specimens. FISH was performed on at least 1000 spermatozoa with a threshold of >1.6% with 2-3% FISH error. DNA was extracted and amplified from a comparable number of spermatozoa by PCR-based random hexamer amplification (average DNA concentration 610 ± 102 ng/ul and quality of 1.7 ± 0.1 nm). By NGS, duplications and deletions by Copy Number Variants (CNVs) were then calculated for all chromosomes by CASAVA and VarScan2 software programs.

Main results and the role of chance: A total of 76 couples were included in our study (maternal age 35.8 ± 4 yrs and paternal age 39.4 ± 8 yrs). Aneuploidy by FISH yielded 0.9% for the donor control but rose in the study group to 3.6% in the ejaculated, 1.2% for the epididymal, and 1.1% for testicular spermatozoa. NGS yielded 1.2% for the control while in the study was 11.1% for the ejaculated specimen and decreased to 1.8% in the epididymal and 1.9% for the testicular ($P<0.0001$). The ICSI pregnancy rate for the ejaculated specimen was 47.2% and 55.5% for the surgically retrieved.

Paired aneuploidy assessment in the same individual (non-NOA) on the ejaculated and testicular samples evidenced a sperm chromatin fragmentation (SCF) of 20% in the ejaculate while on the testicular spermatozoa was only 8%. Aneuploidy assessment by FISH evidenced 2.8% in the ejaculated and 1.2% in testicular biopsy while with NGS became 8.4% and 1.3% in testicular biopsy ($P = 0.02$), respectively. The pregnancy rate was 0% with ejaculated while 100% with the testicular spermatozoa.

An additional aneuploidy assessment by NGS in exclusively azoospermic men evidenced, in the OA 6.7% while in the NOA 5.1%.

Limitations, reasons for caution: This is still a limited number of observations carried out on men screened for infertility. If confirmed, this study may suggest that testicular sampling is safe in terms of retrieving euploid spermatozoa and may be considered in non-azoospermic men in order to obtain cells with lower SCF.

Wider implications of the findings: This study challenges the dogma that testicular spermatozoa conceal a higher proportion of aneuploidy. This implies that testicular gametes do not contribute to chromosomally related pregnancy losses. Moreover, this may explain why offspring from testicular biopsy do not evidence higher autosomal or gonosomal aneuploidy than those resulting from ejaculated spermatozoa.

Trial registration number: N/A.

P-615 Differential expression of testicular function can shed light on why some NOA men successfully yield spermatozoa

L. Zimmerman, C. O'Neill, A. Parrella, M. Irani, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, CRMI, New York, U.S.A.

Study question: Can RNA-sequencing analysis of testicular biopsy samples of NOA men indicate a spermatogenic defect and identify the best candidates for surgical retrieval?

Summary answer: By sequencing transcripts of NOA men, we identified differential gene expression profiles suggesting maturation arrest in NOA men who failed to yield spermatozoa after TESE.

What is known already: Men with non-obstructive azoospermia (NOA) can typically be categorized into three varying degrees of impaired testicular function: hypospermatogenesis, maturation arrest, or germ cell aplasia (sertoli cell–only syndrome). Although it can be difficult to analyze these conditions during a targeted testicular biopsy, a detailed assessment is of great importance, as the likelihood of retrieving no spermatozoa via testicular aspiration occurs in 50% of NOA cases. To supplement histology assessment of testicular tissue, RNA-sequencing can be utilized to differentiate gene expression profiles of NOA men with spermatozoa from men without spermatozoa.

Study design, size, duration: Over 9 months, surgical samples from 5 NOA men undergoing testicular sperm extraction (TESE) were assessed for differential expression by RNA-sequencing and grouped for comparison based on the presence of spermatozoa in their respective samples. Gene expression profiles of these men were compared to a control group with acquired obstructive azoospermia (OA).

Participants/materials, setting, methods: Among the NOA study group ($n = 5$), 2 patients had spermatozoa in their surgical samples, whereas 3 patients did not possess any spermatozoa, even after an extensive search of the samples (71 ± 10 minutes) by several embryologists. Samples were processed for RNA isolation and sequenced by Illumina HiSeq at 2×150 bp configuration per lane with ~58 M reads per sample. A log fold change of >2 and a FDR $P<0.05$ were considered significant.

Main results and the role of chance: Quantitative analysis of RNA extracted from the samples averaged a concentration of 41.1 ± 29 ng/μL and an RNA integrity number of 4.6 ± 1. Upon differential expression analysis, gene ontology enrichment analysis indicated a differential expression of genes related to spermatogenesis, with 30.8% of genes related to a compromised spermatogenic function significantly under-expressed in NOA patients with no spermatozoa identified, and 16.7% of spermatogenesis-related genes significantly under-expressed in NOA patients with spermatozoa, compared to an OA control. Most interestingly, differentially expressed genes unique to NOA patients without spermatozoa were related to the regulation of meiosis (TEX11; $P = 0.0002$) and were significantly under-expressed, with 77.8% of genes involving synaptonemal complex assembly affected (HORMAD1, SYCE1, SYCE3, SYCP1, SYCP2, and TRIP13; $P<0.0001$), as well as processes related to the regulation of chromosome organization (MEIOB; $P<0.00001$) and chromosome segregation (STAG3; $P<0.01$). These gene families were normally transcribed in NOA patients from whom spermatozoa were successfully retrieved as compared to the control. These findings suggest a maturation arrest of germ cells in NOA patients who failed to yield spermatozoa via TESE.

Limitations, reasons for caution: This study would benefit from an increased sample size to confirm findings. Although it is currently difficult to query the epigenome and gain consistent and predictive information on the

infertility status of these men, this method represents a way to identify novel markers to understand the etiology of this condition.

Wider implications of the findings: While the etiologies of NOA are not fully understood, RNA-sequencing may help gauge the spermatogenetic progress of male germ cells, potentially enabling reproductive urologists to select the best candidates for successful sperm retrieval. This may also serve to better counsel severe male factor patients and provide realistic expectations for procreation.

P-616 Factors affecting the probability of finding at least one euploid embryo

M.A. Tufekci[1], S. Kahraman[2], C. Pirkevi Cetinkaya[3], Y. Kumtepe[3], C. Cinar Yapan[1], M. Cetinkaya[1]

[1]Memorial Hospital Sisli, Reproductive Genetics Diagnostic Laboratory, Istanbul, Turkey
[2]Memorial Hospital Sisli, ART and Reproductive Genetics Diagnostic Centre, Istanbul, Turkey
[3]Memorial Hospital Sisli, Embryology Laboratory, Istanbul, Turkey

Study question: What clinical factors affect the probability of finding at least one euploid embryo?

Summary answer: The number of biopsied blastocysts and female age were found to be significantly associated with the probability of finding at least one euploid embryo.

What is known already: It is well known that the number of embryos available for transfer is significantly lower in patients undergoing preimplantation genetic screening (PGS) compared to regular IVF simply because of chromosomal selection. Thus, the clinical evaluation of a patient applying for PGS is important in order to maximize the probability of finding at least one euploid embryo for transfer. There have been various studies investigating factors which might affect the probability of finding euploid embryos, such as the number of generated embryos, the number of oocytes and AMH (Ata et al., 2012., Kahraman et al.,2016, La Marca et al., 2017).

Study design, size, duration: This retrospective cohort study was conducted in a private IVF center between September 2011 and December 2017. A total of 2001 PGS cycles were analysed and 5952 trophectoderm samples were diagnosed either by array Comparative Genomic Hybridization (aCGH) and by next generation sequencing (NGS).

Participants/materials, setting, methods: The probability of finding at least one euploid embryo per cycle was evaluated according to maternal age, body mass index (BMI), AMH, number of cumulus-oocyte complexes (COCs), and number of biopsied blastocysts using multivariate analysis as a generalized linear mixed model. Four categories were defined for COCs: <4; 4-9; 10-15; >15.

Main results and the role of chance: Maternal age, body mass index (BMI), AMH, the number of cumulus-oocyte complexes (COC), and the number of biopsied embryos were introduced in the multivariate analysis as independent factors. The probability of finding at least one euploid embryo per cycle was defined as the target variable. The analysis showed that the generated model was statistically significant (F:57.155, p<0.001). Female age and the number of biopsied blastocysts were found to be statistically significant in the multivariate analysis. With a one unit (year) increase in female age, the likelihood of finding at least one euploid embryo decreased by 18.6% [OR (95%CI): 0.814 (0.789, 0.840), p<0.001)]. With a one unit increase in the number of biopsied blastocysts, the likelihood of finding at least one euploid embryo increased by 78.9% [OR (95%CI): 1.780 (1.627, 1.948), p<0.001)]. The number of trophectoderm biopsies was found to be the most significant variable affecting the probability of finding at least one euploid embryo after adjustment for age.

Limitations, reasons for caution: The study population is limited to a single IVF setting, results may show variation with different IVF clinics. This study is based on trophectoderm biopsy samples, cleavage stage biopsies have been shown to have higher aneuploidy rates.

Wider implications of the findings: The estimated probabilities of finding at least one transferable embryo based on age and number of biopsied embryos enables more accurate counselling of patients.

Trial registration number: Not applicable.

P-617 Querying gene expression to profile human spermatogenesis in infertile men

N. Pereira, A. Parrella, C. O'Neill, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: We question whether gene products isolated from men with different categories of infertility may shed light on their seminiferous tubule function and gamete competence.

Summary answer: Loss of expression of DNA repair and apoptotic genes provide information on the ability to successfully treat couples by assisted reproductive technology (ART).

What is known already: The limitation of evaluating human semen characteristics, even according to the most stringent criteria, is known to provide limited information on the performance of spermatozoa even when used for ART. Standard semen analysis is ill-defined in predicting reproductive outcome in men with unexplained infertility. For this purpose, attempts have been made to detect ploidy, DNA integrity, highly detailed morphology and maturational status of the spermatozoon. Epigenetic assessment by profiling RNA transcripts in the sperm cell has been proposed as an alternative method to screen the male partner for infertility and predicts pregnancy outcome.

Study design, size, duration: In an 18-month period, we assessed the expression of genes in relation to spermatogenesis and reproductive outcome. RNA-Sequencing (RNA-Seq) was carried out on the specimens of 19 consenting men. By sequencing the genome, we assessed ejaculated specimens of 5 infertile couples that were compared to 5 fertile and 3 donors acting as controls. Additionally, 5 non-obstructive azoospermia (NOA) men were compared to one obstructive azoospermia (OA) control.

Participants/materials, setting, methods: Ejaculated spermatozoa and testicular biopsy tissue was used to isolate total RNA using a spin column commercial kit. The nucleic acid quality and spermatozoal RNA concentration was assessed. The RNA samples were then made into paired-end libraries. Pilot paired-end 76 bp RNA-Seq using an Illumina platform (NextSeq 500) was carried out and expanded to 60 M reads. Expression values were calculated in Fragments Per Kilobase Of Transcript Per Million Fragments Mapped reads (FPKM) and normalized read counts.

Main results and the role of chance: The study group (N = 19) had a mean age of 35.9 ± 3 and normal sperm parameters, RNA concentration was 14.3 ± 6 ng/μL (9.1-21.3) with an RNA integrity number of 5.9 ± 1.7. The control couples (n = 3) with a female age of 38.3 ± 5 and male age of 33.6 ± 7 years evidenced normal semen parameters and delivered 3 healthy offspring. Five men underwent ICSI with their female partner (mean age of 35.6 ± 3 years) and achieved a fertilization of 79.3% (30/42), and all delivered. Additionally, 5 men underwent ICSI (female partner with a mean age of 34.8 ± 1 years) and achieved a fertilization rate of 71.4% (30/42), however, they failed to obtain a pregnancy. A total of 86 genes were differentially expressed ($P<0.001$) between the infertile and control cohorts. Of them, 24 genes were overexpressed and 62 under-expressed. Specifically, DNA repair genes *(APLF*, *CYB5R4*, *ERCC4* and *TNRFSF21)* and apoptotic modulating genes (*MORC1*, *PIWIL1* and *ZFAND6*) were remarkably under-expressed (P<0.001) in study cohort. MORC1 and PIWIL1 were also significantly under-expressed in NOA men (P<0.0001). Additional 26 genes DNA repair related, were unique to NOA men. Among those, 8 genes were linked to specimens that yielded spermatozoa while the remainder 18 were specific of men with spermatogenic arrest.

Limitations, reasons for caution: This study profiles men with various stages of spermatogenesis and must be confirmed in a larger cohort. While the contribution of the female partner cannot be excluded, gene expression profiling of infertile men may serve as an assay to measure reproductive potential of the male gamete and seminiferous tubule function.

Wider implications of the findings: Deep sequencing of sperm RNA is a reliable and reproducible technique that may aid in the diagnosis and screening of infertile men. Epigenetic analysis evidenced that DNA repair and apoptosis

genes are linked to seminiferous tubules function indicating their involvement in meiosis and apoptosis typical of germ cells.

Trial registration number: N/A.

P-618 The karyotype of the blastocoel fluid demonstrates low concordance with both trophectoderm and inner cell mass

O. Tšuiko[1], D. Zhigalina[2], T. Jatsenko[3], N. Skryabin[2], O. Kanbekova[4], V. Artyukhova[5], A. Svetlakov[5], K. Teearu[6], A. Trošin[7], A. Salumets[3], A. Kurg[6], I. Lebedev[2]

[5]Krasnoyarsk Center for Reproductive Medicine, Department of Embryology, Krasnoyarsk, Russia C.I.S.
[6]University of Tartu, Department of Biotechnology, Tartu, Estonia
[7]East-Tallinn Central Hospital, Women's Clinic, Tallinn, Estonia

Study question: Is blastocoel fluid (BF) karyotype comparable to inner cell mass (ICM) and trophectoderm (TE) cells derived from the same blastocyst?

Summary answer: BF has an increased karyotype discordance rate between ICM and TE and does not adequately represent the status of the rest of the embryo.

What is known already: In assisted reproductive technology (ART) different biopsy methods are used to obtain embryonic material for genetic analysis. Recently, the discovery of amplifiable cell-free DNA in blastocoel fluid (BF) made it the object of attention by representing a potentially less invasive way of obtaining DNA for preimplantation genetic screening (PGS). However, the use of BF-DNA for PGS still remains questionable, as few of the preliminary studies showed contradictive results regarding aneuploidy detection rates and karyotypic concordance between BF and different biopsied samples. Therefore, additional studies are warranted to investigate the potential use of BF-DNA for diagnostic purposes.

Study design, size, duration: In the present study we utilized the most widely used VeriSeq™ PGS (Illumina Inc, USA) platforms for next generation sequencing (NGS)-based comparative chromosome analysis of BF-DNA and TE and ICM cell populations from 16 cryopreserved blastocysts, donated for research by patients who have undergone IVF treatment. The study was approved by the Bioethics Committee of the Biological Institute of the National Research Tomsk State University. All the patients have signed an informed consent.

Participants/materials, setting, methods: All BF, TE and ICM samples derived from a single blastocyst were whole-genome amplified and analysed following the Illumina next-generation sequencing (NGS) VeriSeq™ PGS protocol. Data analysis and genome-wide profile visualization was performed by applying standard settings on Illumina BlueFuse Multi v4.3 Software with embedded aneuploidy calling algorithm. Prior to embryo analysis, mixing experiments were performed in three replicates using aneuploid cell lines to mimic embryonic mosaicism and evaluate NGS sensitivity in mosaic aneuploidy detection.

Main results and the role of chance: Internal validation of mixing experiments revealed that Veriseq™ PGS NGS-platform is able to distinguish mosaic losses and gains that are present in at least 20% of cells. Next, after WGA of embryo samples, a sufficient amount of DNA was detected in all of ICM and TE samples (16/16), but only in 14 out of 16 BF biopsies (87.5%). Following sequencing and quality control, genomic profiles were obtained for 10 BF samples (10/16, 62.5%) and compared to corresponding TE and ICM, while the karyotypes of TE and ICM were obtained and compared in 14 embryos out of 16 (87.5%). The analysis revealed that BF-DNA was burdened with mosaic aneuploidies and the total number of affected chromosomes in BF was significantly higher compared to the TE and ICM ($P < 0.0001$), while no difference was observed between TE and ICM. Thus, only 40.0% of BF-DNA karyotypes (4/10) were fully concordant to TE or ICM, compared to 85.7% between TE and ICM (12/14), making TE more representative of embryonic chromosomal status than BF ($P<0.03$).

Limitations, reasons for caution: The major limitation was the number of embryos analyzed. Additionally, BF aspiration was performed after embryo thawing, which can potentially affect DNA quality and subsequent results. Finally, we sequenced the whole trophectoderm cell population, which is opposite to TE biopsy, when only a small number of cells are analyzed.

Wider implications of the findings: Using BF-DNA as a single source of DNA for PGS can potentially lead to an increased rate of false positive findings, at least using current approach. Blastocentesis cannot be ruled out in the future, although the improvement of current sample handling protocols and aneuploidy calling algorithm may be warranted.

Trial registration number: not applicable.

P-619 Comparison of the times to achieve an ongoing pregnancy in advanced maternal age patients with PGS and young IVF patients without PGS

M. Cetinkaya, M.A. Tufekci, C. Cinar Yapan, Y. Kumtepe Colakoglu, H. Yelke, S. Kahraman

Istanbul Memorial Hospital, Assisted Reproductive Technologies and Reproductive Genetics Center, Istanbul, Turkey

Study question: Do young IVF patients achieve an ongoing pregnancy earlier than older patients applying for PGS?

Summary answer: Kaplan-Meier survival analysis based on the number of frozen embryo transfers showed that PGS patients achieved an ongoing pregnancy with significantly less number of transfers.

What is known already: It has been shown that more than 40% of the blastocysts are aneuploid increasing with advanced maternal age (Schoolcraft et al., 2010). These chromosomal abnormalities adversely affect IVF outcomes even in younger patients (Munne, 2012). Transfer of euploid embryos have been shown to result in higher implantation rates especially when trophectoderm biopsy was used (Scott et al., 2013). Evaluation of the time between pick-up and transfer as days may be influenced by many patient and clinical factors, thus misrepresenting the interpretation of survival analysis. To overcome this bias, each embryo transfer cycle is used as a time unit.

Study design, size, duration: This retrospective cohort study includes 2400 frozen-thawed embryo transfer cycles (FET) of 1956 couples whose embryos were frozen, thawed and transferred between August 2011 and December 2017. Blastocysts of young patients with a good ovarian reserve were frozen and transferred later (freeze-all group; n = 1456). Aneuploidy screening was routinely applied for advanced maternal age (>37), patients with an history of abnormal fetal karyotype and with repeated implantation failures (>2) (PGS group; n = 914).

Participants/materials, setting, methods: The mean female age was 29.8 ± 4.2 and 35.1 ± 4.9 for the freeze-all and the PGS groups, respectively ($p<0.0001$). The mean number of cumulus oocyte complexes and metaphase II oocytes was 21.6 ± 10.5 and 17.3 ± 8.7 for the freeze-all group and 14.6 ± 9.7 and 12.1 ± 7.9 for the PGS group, respectively ($p<0.0001$). The mean number of frozen blastocysts was 6.7 ± 3.9 and 4.9 ± 3.5 for the freeze-all and the PGS groups, respectively ($p<0.0001$). PGS was done either with aCGH or NGS.

Main results and the role of chance: In the Kaplan-Meier survival analysis performed, at most four subsequent FET cycles were taken into consideration for each patient. However, once a patient reached an ongoing pregnancy, any further FET cycles were not cumulatively counted since the purpose of the study was to determine the number of FET cycles required to obtain an ongoing pregnancy. When survival curves were compared in the Kaplan-Meier analysis, it revealed that achieving an ongoing pregnancy was one cycle earlier in the PGS group than the freeze-all group ($p<0.0001$). The overall ongoing pregnancy rate of FET cycles with PGS was significantly higher when compared to transfers without PGS (49.3% vs. 44.1%, respectively ($p<0.05$)), despite a higher average age in PGS cycles (29.8 ± 4.2 and 35.1 ± 4.9, respectively) and a significantly lower AMH level in the PGS group (5.6 ± 3.9 and 3.2 ± 2.9, respectively). Additionally, FET cycles with PGS were 1.19 (1.0589 to 1.3527 95 %CI) fold more likely to result in an ongoing pregnancy when compared to non-PGS FET cycles with significantly less frozen embryos (6.7 ± 3.9 and 4.9 ± 3.5*, respectively) [*number before aneuploidy screening].

Limitations, reasons for caution: Self-evidently PGS patients received an euploid blastocyst transfer. The number of embryo transfers is directly related with the number of vitrified blastocysts and therefore with ovarian reserve.

Wider implications of the findings: PGS may be offered to young IVF patients with a good ovarian reserve to decrease the time to achieve an ongoing pregnancy.

Trial registration number: not applicable.

P-620 Alterations in global epigenetic profile (DNA methylation and histone modifications) of cumulus cells in women with endometriosis

Study question: This study aimed to evaluate global DNA methylation and histone methylation/ acetylation levels in cumulus cells of infertile patients with endometriosis.

Summary answer: Differential epigenetic changes (DNA methylation and acetylation/ methylation of lysine 9 of histone3 (H3K9ac and H3K9me2) in cumulus cells were detected in endometriosis patients.

What is known already: Two epigenetic mechanisms, DNA methylation and post-translational modifications of histone residues (H3K9ac and H3K9me2 as the markers of gene activation and silencing, respectively), are known to regulate the gene expression and their modifications being the main reasons of human diseases.

Although the precise etiology of endometriosis is poorly understood, several evidences recommend that epigenetic factors are associated with the molecular aspect underlying endometriosis. Ovarian cells such as cumulus cell, which surrounds oocyte is one of the main cells that influence by endometriosis.

Study design, size, duration: This study was conducted on 12 infertile endometriosis patients and 12 normo-ovulatory patients with tubal factor infertility or egg donors). All women, who were diagnosed with endometriosis either by laparoscopy or pathological examination, constituted the study group. Endometriosis was categorized according to the revised American Fertility Sterility classification. Cumulus-oocyte complexes were obtained from follicles during ovarian puncture. Only cumulus cells with metaphase II oocytes were selected for this study.

Participants/materials, setting, methods: Chromatin extracts from cumulus cells were prepared following fixation with formaldehyde and then shearing into fragments by sonication. Nucleosome ELISA was performed on chromatin fractions using antibodies against H3K9ac (activating mark), H3K9me2 (repressing mark) and MeCP2 (as a marker of DNA methylation). Relative assay level for incorporation of MeCP2, H3K9me2 and H3K9ac proteins in chromatin fractions were calculated by normalizing ELISA signals (after background subtraction) to core histone H1 content.

Main results and the role of chance: Our data revealed that cumulus cells of endometriosis patients were globally DNA hypermethylated compared to the cells from controls ($P = 0.03$). Furthermore, a significant hyperacetylation as well as hypermethylation at histone H3K9 ($P = 0.04$ and $P = 0.01$, respectively) was observed in endometriosis samples compared to the control group.

Limitations, reasons for caution: For getting more comprehensive information, we need to analyze epigenetic alterations in cumulus cells that are involved in the ovarian functions in infertile endometriosis patients.

Wider implications of the findings: These results clearly show that epigenetic profile such as DNA methylation and histone acetylation/methylation were significantly altered in cumulus cells of endometriosis patients and these alterations may be responsible for infertility in such patients.

Trial registration number: not applicable.

P-621 Customising the limit of detection for PGT-A and PGT-SR using NGS

K. Warren, S. Myers, M. Jasper

RHS Ltd, RHS Ltd, Thebarton, Australia

Study question: What is the lower limit of detection for segmental copy number variations by Next Generation Sequencing using PG-Seq™?

Summary answer: Whilst aneuploidy detection can be achieved from 300,000 reads, detection of a 100 kb microdeletion requires over 13 million reads, or sequencing 1-2 samples per run.

What is known already: Next generation sequencing platforms provide a highly flexible and customizable workflow to attain a variety of levels of resolution for the detection of segmental aberrations unlike other DNA analysis platforms previously used for preimplantation genetic testing (PGT). In simple terms higher resolution for the detection of smaller genetic aberrations can be achieved by reducing the number of samples in a single sequencing run to increase the total reads for each sample available for analysis.

Study design, size, duration: Library Preparation and 48 sample multiplex NGS was performed according to standard PG-Seq™ protocol (RHS Ltd). Initially, to evaluate the minimum number of mapped reads required to detect a 7 Mb segmental loss and 31 Mb gain, PG-Seq™ NGS files were randomly downsampled to produce files containing reads ranging from approximately 500,000 to 100,000 reads. The minimum number of reads required to detect incrementally smaller chromosome aberrations was determined in silico.

Participants/materials, setting, methods: Individually sorted 5-cell aliquots from a segmental deletion and duplication cell line (GM14485, Coriell Institute) were analysed using PG-Seq™ according to manufacturers instructions.

Main results and the role of chance: Downsampling and analysis of sequencing read data showed the detection of both the 7 Mb deletion and 31 Mb duplication indicated that detection was still possible using 100,000 mapped reads. However, the PG-Seq™ quality control score increased as mapped reads declined from approximately 300,000 to 100,000 mapped reads per sample. In silico modelling indicated the detection of a 100 kb segmental copy number variation would require 6-19 million mapped sequencing reads per individual sample. To achieve >6 million reads for a single sample would require no more than 3 samples to be sequenced on a MiSeq sequencer. A higher level of confidence for reporting would be achieved for samples with mapped reads of 13-19 million, and no more than 1-2 samples could be sequenced in a single MiSeq run.

Limitations, reasons for caution: In silico data analysis does not replace the need for validation of NGS workflows using cell line or clinical samples to determine the resolution of the chosen workflow.

Wider implications of the findings: In silico analysis of sequencing data highlights the technical limitations and financial implications for the detection of small segmental aberrations by NGS.

Trial registration number: -

P-622 OnePGT proof of concept for PGT-M and PGT-SR on blastomere and trophectoderm biopsies

E. Coonen[1], A. Paulussen[1], J. Dreesen[1], J. Dumoulin[2], C. Van Uum[1], M. Drusedau[1], E. John[1], K. Derks[1], R. Van Golde[1], M. Zamani Esteki[1], C. De Die-Smulders[1]

[1]Maastricht University Medical Centre, Clinical Genetics, Maastricht, The Netherlands
[2]Maastricht University Medical Centre, Center for Reproductive Medicine, Maastricht, The Netherlands

Study question: Investigating the OnePGT product as a single assay for preimplantation genetic testing for monogenic disorders (PGT-M) and preimplantation genetic testing for aneuploidies (PGT-SR) for blastomere and trophectoderm embryo (TE) biopsies.

Summary answer: OnePGT accurately determined the single gene disorder status of 48/48 embryos for PGT-M, and the presence of an unbalanced translocation in 33/33 embryos for PGT-SR.

What is known already: OnePGT is a next-generation sequencing (NGS) haplarithmisis-based solution for Preimplantation Genetic Testing (PGT) of in vitro fertilized (IVF) embryo single-cell or TE biopsies. OnePGT is a wet- and dry lab solution allowing concurrent PGT-M, PGT-SR of whole-genome amplified (WGAed) products biopsied from IVF embryos in a single assay. This innovative product provides a sample-to-answer solution, from wet lab to cloud-based analysis software, which has haplarithmisis in its heart.

Study design, size, duration: To test the performance of Agilent's OnePGT solution, we performed a blinded clinical verification study on 109 embryos (32 couples) donated to Maastricht UMC+ for research purposes. For PGT-M, 67 embryos (20 couples) that are previously analyzed with conventional STR-PCR PGD as well as phasing reference (a close relative) samples (PGT-M) were processed in our facility. For PGT-SR a total of 36 embryos (11 couples), previously analyzed with FISH or arrayCGH PGD, were tested.

Participants/materials, setting, methods: In total 36 couples (109 spare embryos unsuitable for uterine transfer) were participated in this study. These embryos were affected with monogenetic disorder, unbalanced translocation or had poor morphology. All embryos were re-biopsied, WGAed and processed according to the OnePGT library preparation protocol. Subsequently, NGS libraries were sequenced and analyzed via the PGT-M or PGT-SR pipeline in the OnePGT software in a blinded fashion. The onePGT diagnoses were then compared with the conventional PGD method.

Main results and the role of chance: For the 36 embryos for which both OnePGT and the conventional PGD methods gave a conclusive result, 100% concordance was demonstrated. The main reason for inconclusive results were loss-of-heterozygosity-like regions in the reference family members, affecting 10 embryos. Another 14 samples were found to be affected by the common chromosome instability (CIN) phenomenon, such that the copy number discrepancies between OnePGT and STR-PCR were confirmed by SNP-array analysis supporting the OnePGT results. The quality control module of the OnePGT software identified 8 samples with no genomic DNA but with a high mitochondrial DNA content.

Regarding the PGT-SR analysis, a conclusive result was obtained for all samples (36/36, 100%). Of the 36 embryos, 3 were found to be with CIN, as shown by copy number discrepancies between OnePGT and FISH/arrayCGH, which were further confirmed by an orthologous method (Agilent GenetiSure PreScreen). Overall, the OnePGT diagnoses on 33 embryos were 100% concordant with the gold standard conventional PGD.

Limitations, reasons for caution: Although the sample-size (number of embryos) in this study is not sufficient to reach to the 0.9 statistical power, we have increasingly expanded the samplesize in collaboration with UZ Leuven.

Wider implications of the findings: OnePGT is a single-assay solution for both PGT-M and PGT-SR, applicable on single-cell or TE WGAed genomes derived from cleavage-stage or blastocyst-stage IVF embryos, respectively.

Trial registration number: The study was funded by Agilent Technologies.

P-623 Clinical impact of reporting embryo mosaicism for preimplantation genetic testing for aneuploidy (PGT-A)

K. Xu, C. Zhang, J. Wei, X. Qin, S. Lee, M. Mason, Z. Rosenwaks

Cornell University Medical College, The Center for Reprod. Medicine & Infertility - IVF/PGD, New York, U.S.A.

Study question: Reporting mosaicism allows prioritizing embryo transfer. This study examines the clinical impact of reporting mosaicism in PGT-A practice.

Summary answer: Of 813 PGT-A patients, about 5% (43) had only euploidy-mosaic embryos. Those embryos, accounted for 6.6% of analyzed embryos, are transferrable but with caution.

What is known already: Mosaicism in early preimplantation embryos is recognized as a common phenomenon and it appears to be readily detectable in D5/6 biopsied specimens with next generation sequencing platform. Transfer of mosaic embryos may result in healthy babies (Greco et al., NEJM, 2015). Although it is generally believed that the results of chromosomal ploidy and mosaicism detected in biopsied specimens are likely correlated to the healthy status of the embryos, controversy exists as to whether or not to report mosaicism due to insufficient knowledge on this biological or artefactual phenomenon.

Study design, size, duration: PGS data were collected from 813 cycles and 4423 embryos from January 1 to December 31, 2017. Patients (average age = 38.4) were divided into three groups: ≤34, 35 to 40, and ≥41. Embryo biopsies were performed on D5 or D6. Illumina's VeriSeq PGS platform was used for sequencing and data analysis.

Participants/materials, setting, methods: Euploidy was defined as no gain/loss detected in any chromosomes screened. Euploidy-mosaic (Eup-M) was defined as an absence of whole chromosome gain/loss, but with low confidence combined with a profile of one or more whole chromosome(s) or segmental region(s) that showed 25 to 80% gain or loss. Embryos with mosaic chromosomes coupled with the presence of one or more whole chromosomal gain/loss were excluded from this classification since those were defined as aneuploidy.

Main results and the role of chance: Of 813 patients, 205 (25.2%) have all aneuploidy embryos. In 569 patients at least one or more euploid embryos were available for transfer. An overall of 396 embryos were identified as Eup-M. The distribution of euploidy, euploid-mosaic and aneuploidy embryos in three age groups are tabulated below:

Ch. Status/ Age	≤34 (#)	35-40 (#)	≥41 (#)	Overall (#)
Euploidy	53.4% (639)	36.1% (812)	13.8% (135)	34.0% (1586)
EUP-M	13.1% (157)	8.8% (197)	4.3% (42)	6.6% (396)
Aneuploidy	33.5% (401)	55.1% (1240)	81.9% (800)	55.2% (2441)
Total # embryos	1197	2249	977	4423

More euploid-mosaic embryos were present in younger women than that in older women because the latter had more aneuploid embryos which also had mosaic chromosomes. Frequently, only one (32.9%, 187/569) or two (10.4%, 59/569) mosaic embryos were detected in PGT-A cases, up to 6 mosaic embryos were observed in one patient. In 43 patients (7.6%, 43/569), only mosaic embryos were available for transfer.

Limitations, reasons for caution: In patients (~8%) who have only euploid-mosaic embryos available for transfer, extensive genetic counseling should be recommended to assist in decision making. Further study is warranted to follow the pregnancy results from transfers of those embryos.

Wider implications of the findings: The frequencies of mosaicism appears to be relatively low as indicated in this study. However, mosaicism will affect embryonic development and may create real issues for PGT-A where biopsied specimens may not precisely reflect the inner cell mass and/or the whole embryos, thus may lead to false-negative or false-positive results.

Trial registration number: N/A.

P-624 Paternal factors in recurrent pregnancy loss: a proteomic insight

G. Mohanty[1], S. Kar[2], L. Samanta[1]

[1]*Ravenshaw University, Redox Biology Laboratory- Department of Zoology, Cuttack-Odisha, India*

[2]*Kar Clinic And Hospital, Obstetrics and Gynaecology, Bhubaneswar- Odisha, India*

Study question: Do differential protein expression lead to aberrant embryo development leading to loss of foetus in idiopathic recurrent pregnancy loss (iRPL)?

Summary answer: Differential protein expression in spermatozoa of partners may be the contributing factor towards impaired embryo development and pregnancy loss in patient with iRPL.

What is known already: Defective paternal genome has been attributed to be an important cause for spontaneous recurrent pregnancy loss (RPL). Controlled level of reactive oxygen species (ROS) is essential for normal sperm function while elevated levels results in increase in oxidative damage to sperm chromatin, induce mutations, oxidize proteins, and membrane lipids. There is enhanced ROS generation in spermatozoa of partners of iRPL resulting in augmented lipid peroxidation, protein carbonylation and thionylation.

Study design, size, duration: This prospective study consisted of male partners of iRPL patients (n = 16) with no female factor abnormality as revealed by gynaecologic investigation including karyotyping and age matched fertile healthy volunteers (n = 20). All samples were collected during 2013-2015 after getting institutional ethical approval and written consent from the participants.

Participants/materials, setting, methods: Seminal ejaculates were collected by masturbation after 2-3 days of sexual abstinence and analysed according to World Health Organization criteria. Samples from each group after separation by 2D-DIGE were subjected to mass spectrophotometric analysis to identify differentially expressed proteins (DEPs).STRING and Cytoscape softwares were used for pathway analysis.Two key proteins, HSPA2 and GPx4 of the identified pathways were validated by Western blot analysis.

Main results and the role of chance: Based on the relative abundance of the common protein spots 27 were overexpressed and 9 were underexpressed, while 18 proteins spots were identified with low abundance. A fold change >2 was considered as overexpressed or underexpressed. A total of 6 spots were picked for protein sequencing analysis owing to their abundance and position on the gel. This included GPx4, JIP4, ZN248 to be overexpressed while HSPA2,GSTM5, TF3C1, CC74A was underexpressed in RPL group. Owing to its greater coverage, HSPA2 was subjected to single nucleotide polymorphism (SNP) analysis wherein of 444 SNPs were synonymous and 56 were found to be nonsynonymous SNPs. It was found that 18 SNPs were deleterious using a combinatorial servers-SIFT, Polyphen, Provean, nsSNP analyser and SNPs and GO. Protein structural analysis with these amino acid variants was performed by using HOPE, ConSurf, Swiss PDB viewer, Chimera and NOMAD-Ref servers to check their solvent accessibility, molecular dynamics and energy minimization.

Limitations, reasons for caution: 2D-DIGE though a robust technology in terms of reproducibility, has a limitation because all the identified differential protein spots needs to be subjected to mass spectrophotometry to identify all DEPs. Secondly, increasing the sample size would augment the biological variability and statistical power of the study.

Wider implications of the findings: This pilot study showed that in case of iRPL paternal factors play a role which can be further analysed to develop biomarkers for iRPL. Additionally, our in silico analysis suggests that screening of SNP variants of HSPA2 such as V106E, D55Y, T301R, R314P,S343Pmay be useful for predicting outcome.

Trial registration number: Not applicable.

P-625 The effect of the duration of elevated progesterone during the late-follicular phase of ovarian stimulation on live birth rates following IVF/ICSI

C. Roelens[1], S. Santos-Ribeiro[1,2], A. Racca[1,3], S. Mackens[1], P. Drakopoulos[1,4,5], H. Tournaye[1], C. Blockeel[1,6]

[1]*Universitair Ziekenhuis Brussel, Centre for Reproductive Medicine, Jette, Belgium*
[2]*Santa Maria University Hospital, Department of Obstetrics- Gynecology and Reproductive Medicine, Lisbon, Portugal*
[3]*University of Genoa, Academic Unit of Obstetrics and Gynecology, Genova, Italy*
[4]*Centre Hospitalier Universitaire de Liège, Department of Reproductive Medicine, Liège, Belgium*
[5]*Vrije Universiteit Brussel, Faculty of Medicine and Pharmacy - Department of Surgical and Clinical Science, Brussels, Belgium*
[6]*University of Zagreb - School of Medicine, Department of Obstetrics and Gynecology, Zagreb, Croatia*

Study question: Does a longer exposure to late-follicular elevated progesterone (LFEP) hinder live birth rates (LBRs) after fresh embryo transfer?

Summary answer: LBRs are only weakly affected by the duration of LFEP.

What is known already: The overproduction of progesterone (P) during ovarian stimulation has been associated with endometrial genetic/epigenetic changes in the luteal phase and, most importantly, lower LBRs after a fresh embryo transfer. Therefore, in daily clinical practice, P levels on the day of human chorionic gonadotrophin (hCG) administration are often measured and a freeze-all strategy is adopted whenever LFEP (>1.50 ng/ml) occurs. However, a recent retrospective analysis has concluded that also the duration of LFEP >1.00 ng/ml prior to hCG administration may affect clinical pregnancy rates. We assessed whether this result was reproducible, namely when using LBR as the primary outcome.

Study design, size, duration: We performed a retrospective cohort analysis including all women undergoing ovarian stimulation for IVF/ICSI in a university-affiliated tertiary referral centre between January 2010 and March 2015. A total of 4312 cycles were included. To minimize potential confounding, only patients with GnRH antagonist pituitary suppression who underwent fresh embryo transfer using autologous oocytes were included. Couples with planned embryo biopsy, managed natural cycles or in-vitro maturation were excluded from the analysis.

Participants/materials, setting, methods: The primary outcome was live birth, defined as a live born delivery after 24 weeks. LBRs were compared among different P elevation duration groups (0 days, 1 day, 2 days or ≥3 days) using multivariable regression analysis to account for potential confounders. This analysis was repeated using two cut-offs of LFEP: 1.00 and 1.50 ng/ml.

Main results and the role of chance: The average female age of the cohort was 34.0 ± 5.0 years. The mean number of oocytes retrieved was 9.3 ± 5.7 and 64.7% of the fresh embryo transfers were performed at cleavage stage (day 3), with a single embryo being transferred in 51.0% of all cases.

In the univariable analysis, the duration of LFEP >1.00 ng/ml was not associated with a significant decrease in LBR. Specifically, LBRs were 25.8%, 24.1%, 23.6% and 24.2% according to whether the patient had LFEP >1.00 ng/ml lasting for 0, 1, 2 or ≥3 days respectively (p = 0.259). However, LBR for the same LFEP durations, but using LFEP >1.50 ng/mL as the threshold, lowered significantly as the duration of LFEP increased: 25.8%, 18.4%, 15.1% and 13.8%, respectively (p<0,001).

Although the duration of LFEP >1.50 ng/mL predicted LBR independently in the univariable analysis, the relative frequency of having such LFEP levels for 2 or ≥3 days was exceedingly rare (1.2% and 0.2%, respectively). Moreover, the duration of LFEP >1.50 ng/ml was no longer a statistically significant LBR predictor in the multivariable regression analysis performed (which accounted for female age, number of preceding IVF/ICSI cycles, type/dose of exogenous gonadotrophins, endocrine profile at hCG administration, number of oocytes retrieved, embryo stage, number and quality at transfer).

Limitations, reasons for caution: Although this study includes a large sample set and adjusts for multiple potential confounding, the results are limited by its retrospective nature and the inability to include all relevant potential confounders (e.g. smoking habits). Better extrapolation could be obtained by validating these results prospectively.

Wider implications of the findings: Although LBRs were discretely lower if LFEP >1.50 ng/ml lasted for more than 1 day, such an event seemed rare and was no longer significant when accounting for potential confounding. Therefore, one may postulate that the clinical value of measuring P prior to hCG administration is limited.

Trial registration number: not applicable.

P-626 Efficacy of metformin therapy to reduce pregnancy-induced hypertensive disorders in women with silent impaired insulin-sensitivity

J. Romero[1], E. Spinedi[2]

[1]*Perinat Clinic, Reproductive Endocrinology, La Plata, Argentina*
[2]*La Plata Medical School, CENEXA UNLP-CONICET, La Plata, Argentina*

Study question: Could metformin therapy, throughout pregnancy, be effective to reduce the risk of late pregnancy-induced hypertensive disorders (PIHD) in women with defective insulin-signaling system function?

Summary answer: Metformin therapy, throughout pregnancy, reduced the development of third trimester gestation-induced hypertensive disorders in women with silent defective insulin-signaling system function from 23.6% to 13.8%.

What is known already: Pregnant women with impaired insulin sensitivity are at a high risk for developing pregnancy-induced hypertensive disorders (PIHD). Previous data support that 2 h-insulinemias greater than 215.25 pM after 75 g-glucose overload could be a predictor for detecting women at high risk of developing PIHD. Indeed, compared with pregnant women at low risk (2 h-insulinemias lower than 215.25 pM), those at high risk displayed a 4-fold higher occurrence of gestational hypertension and pre-eclampsia. Additionally, it is accepted that metformin (MTF) therapy is able to prevent poor pregnancy outcome in women diagnosed for gestational diabetes mellitus (GDM).

Study design, size, duration: We performed a 2-year-prospective study in 226 multiparous women that became spontaneously pregnant either under oral MTF therapy (2 g/day; n = 29) or not (n = 198). During gestational week 25-26, women were subjected to an oral glucose tolerance test (OGTT) measuring insulinemias on both sample-times. Thereafter, women were classified at low (being the 2 h-insulinemias lower than 215.25 pM) or at high (being the 2 h-insulinemias greater than 215.25 pM) risk for developing PIHD (LR-PIHD and HR-PIHD, respectively.

Participants/materials, setting, methods: Overnight fasting pregnant women (age 29-37 years) were bled before (sample time-zero) and 2 h after 75 g-oral glucose load (OGTT). Glucose (enzymatic-colorimetric assay) and insulin (chemiluminescence) plasma concentrations were determined in samples times zero and 2 h from the OGTT. Finally, HOMA-IR score (glucose in mM x insulin in mIU/mL x 0.044) and Glucose (in mg/dL) to Insulin (in mIU/mL) ratio (G:Ir) were calculated for both time-samples. Anthropometric data were recorded throughout pregnancy.

Main results and the role of chance: Biochemical data indicate that 125 and 101 women were at LR-PIHD and HR-PIHD, respectively, MTF-treated women pertained to the HR-PIHD group. Comparing data from HR-PIHD MTF-treated (n = 29) versus MTF-untreated women (n = 72), although time-zero glycemias were similar, time-2 h glycemias were significantly ($P<0.05$) lower in MTF-treated than in MTF-untreated women. Plasma insulin and HOMA-IR values were statistically similar in both groups, regardless of the sample-time examined. Finally, G:Ir values were significantly ($P<0.05$) higher in MTF-treated than in MTF-untreated women although in sample-time zero only. While 17/72 MTF-untreated women developed any PIHD, conversely, PIHD was noticed in 4/29 MTF-treated women. Starting woman body mass index, weight-gain throughout pregnancy, gestational length, multiparity and, the appearance of polihydramnios and newborn respiratory distress were similar among groups; none stillbirth was noticed. Although mean values of weight at birth were similar among groups, macrosomic babies were born to MTF-untreated mothers only (3/72). Finally, while PIHD (hypertension/pre-eclampsia) were developed by 17/72 (23.6%) MTF-untreated women, a better pregnancy outcome was noticed in MTF-treated women because only 4/29 (13.8%) developed PIHD. Data indicate that pregnancy outcome in women at HR-PIHD, due to their impaired insulin sensitivity (2h-insulinemias >215.25 pM), could be highly benefited if treated with MTF throughout pregnancy.

Limitations, reasons for caution: Data emerging from this prospective study need to be corroborated by studying the beneficial effect of MTF therapy throughout gestation, on poor pregnancy outcome in a larger sample-population of pregnant women at high risk of developing PIHD, defined as having 2 h-insulin values greater than 215.25 pM during an OGTT.

Wider implications of the findings: We have established that by applying the simple criterion ¨2-h insulinemia > 215.25 pM during an OGTT¨, pregnant women with silent impaired insulin sensitivity are at high risk of developing PIHD, however, such increased risk could be reduced when these women are treated with MTF throughout pregnancy.

Trial registration number: Not applicable.

P-627 Expression of reproductive hormone receptors and contraction-associated genes in porcine uterus during the estrous cycle

K.S. Lee[1], J.K. Joo[2], M.S. Jo[2], G.Y. Yun[2], S.E. Han[2]

[1]*Pusan Nat. University School of Medicine, Dept. of Ob/Gyn, Pusan, Korea- South*
[2]*Pusan National University Hospital, Obstetrics and Gynecology, Busan, Korea- South*

Study question: What is mechanism of uterus contraction activity in a porcine model?

Summary answer: hormonal receptors and contraction-associated proteins were dynamically regulated depending on the estrous cycle.

What is known already: Contraction of uterus tissue frequently occurs throughout the estrous cycle and is regulated by several endogenous factors, including estradiol, progesterone, luteinizing hormone, follicle-stimulating hormone, oxytocin (OXT) and contraction-associated proteins (CAPs).

Study design, size, duration: Experimental study.

Participants/materials, setting, methods: mRNA and protein expression levels of reproductive hormonal receptors, including estrogen receptors, progesterone receptor and luteinizing hormone/choriogonadotropin receptor in addition to CAPs including OXT, OXT receptor (OXTR), hydroxyprostaglandin dehydrogenase 15-(NAD) and gap junction α-1 protein, were examined in the porcine uterus according to the follicular and luteal phases.

Main results and the role of chance: hormonal receptors and CAPs were dynamically regulated depending on the estrous cycle. In conclusion, genes associated with uterine contraction and its regulatory hormonal receptors in the porcine uterus were differently regulated in the follicular and luteal phases.

Limitations, reasons for caution: These experiments were limited to only mRNA measurements, these result differ from those of the current study due to the distinct environmental conditions for other animals.

Wider implications of the findings: Genes associated with uterine contraction and its regulatory hormonal receptors in the porcine uterus are critically involved in the remodeling and contraction of uterine tissue and may be required to modulate the physiological status of the uterus.

Trial registration number: not applicable.

P-628 Effects on body weight and waist/hip circumference during a 1-year three-component lifestyle RCT in obese PCOS women

L. Jiskoot[1], R. Timman[2], A. Beerthuizen[2], J. Busschbach[2], J. Laven[1]

[1]*Erasmus Medical Center, Department of Reproductive medicine room HS416, Rotterdam, The Netherlands*
[2]*Erasmus Medical Center, Section of Medical Psychology and Psychotherapy, Rotterdam, The Netherlands*

Study question: Is a multidisciplinary one-year cognitive-behavioural lifestyle treatment more effective to decrease weight and waist/hip circumference than usual care?

Summary answer: A three-component lifestyle program for women with PCOS achieved a weight loss of 5%. A self-induced weight loss by publicly available services is less effective.

What is known already: Obesity in women with polycystic ovary syndrome (PCOS) negatively affects all clinical features. There is a large number of small uncontrolled (two-component) trials demonstrating that losing 5 to 10% of initial body weight has shown promising results on reproductive, metabolic and psychological level. Weight loss programs seem to be effective in the short term; however, most of the initial weight loss is regained within 1 year. The biggest challenge is to achieve a reasonable and sustainable weight loss. More intensive (three-component) trials are needed to enhance adherence and achieve a sustainable weight-loss of 5 to 10%.

Study design, size, duration: The present study is a longitudinal randomized controlled trial (RCT) to study the effectiveness of a three component 1-year

cognitive-behavioural lifestyle intervention in overweight/obese women with PCOS. A total of 209 participants are randomly assigned to three groups: 1) CBT provided by the multidisciplinary team or; 2) CBT provided by the multidisciplinary team and Short Message Service (SMS) or; 3) usual care: encourage weight loss through publicly available services (control group).

Participants/materials, setting, methods: Women with menstrual cycle disorders are systematically screened using a standardised protocol. Data of 209 women diagnosed (according this protocol) with PCOS according to the Rotterdam criteria, a Body Mass Index above 25 kg/m2 were included between September 2009 and August 2016. Outcome variables were measured at the start of the study, at three, six, nine and twelve months. Mixed modelling is applied for longitudinal analyses of the data.

Main results and the role of chance: The reduction in BMI within one year was -2.18 kg/m^2, 95% confidence interval (CI) [-2.72, -1.64] in the lifestyle intervention group (P<0.001), and -0.91 kg/m^2, 95% CI [-1.59, -0.23] in the control group (P<0.009), a difference of -1.27 95% CI [-2.14, -0.41] (P<0.004). The mean weight loss in the lifestyle intervention group was -6,39 kg, 95% confidence interval (CI) [-7.93, -4.85] (P<0.001) and -2,44 kg 95% CI [-4,37, -0,50], in the control group (P = 0.014), a difference of 3.96 kg, 95% CI [-6.43, -1.49] (P<0.002). Body Mass Index at baseline was no predictor for weight loss. The chance of a 5% BMI reduction was 7.19 times larger in the lifestyle intervention group than in the control group.

Waist circumference significantly decreased in both groups: - 4.84%, 95% CI [-6.48, -3.21] and -4.75%, 95% CI [-6.98, -2.51] respectively, but there was no difference between the lifestyle intervention and controls (P .944). Hip circumference also decreased significantly: -4.17%, 95% CI [-5.04, -3.31] versus -2.14%, 95% CI [-3.30, -0.97] and significantly more (P .006) in the lifestyle intervention group.

Limitations, reasons for caution: All PCOS patients with a BMI > 25 kg/m^2 and eligible for ovulation induction treatment are obligated to follow the lifestyle modification protocol prior to fertility treatment. After inclusion of 150 patients, we applied an interim power analysis to the complete cases.

Wider implications of the findings: These findings support that three-component multidisciplinary cognitive- lifestyle interventions should be incorporated in daily practice to support women with PCOS to achieve a healthy weight loss of at least 5%.

Trial registration number: Registered at the Netherlands National Trial Register with number NTR2450 on August 2nd, 2010.

P-629 The influence of cadmium, copper, lead, selenium, and zinc concentrations in follicular fluid on embryo developmental dynamics by time-lapse microscopy

A. Wdowiak[1], M. Artur[2], B. Szymon[2]

[1] *I Medical University of Lublin- Poland, Diagnostic Techniques Unit- Faculty of Health Sciences, Lublin, Poland*
[2] *Medical Center Ovum, Embryology Department, Lublin, Poland*

Study question: This study investigated the influence of cadmium (Cd), copper (Cu), lead (Pb), selenium (Se), and zinc (Zn) in follicular fluid (ff) on the dynamics of embryo development.

Summary answer: Zinc concentrations in ff affect the dynamics of embryo development from tC to t4. Pb impede the dynamics of embryo development from tF to t4

What is known already: The negative impact of the environment in which the oocyte grows affects the quality of the embryo and the time at which subsequent developmental stages are reached. The oocyte can probably be damaged by a toxic microenvironment during the primordial stage of follicle development and at the time of oocyte maturation. One suggested cause of egg-cell damage is the deleterious effects of excess amounts of heavy metals.

Study design, size, duration: The present study was conducted in medical center 'Ovum" between March 2016 and April 2017. The study involved 220 women undergoing ICSI treatment for the first time. The inclusion criteria were: age below 35 years, FSH level ≤ 10 mIU/mL, AMH level ≥ 1.5 ng/mL, and Body Mass Index (BMI) ≤ 30 kg/m^2. Women with severe endometriosis, metabolic disease, or leiomyoma were excluded from the study.

Participants/materials, setting, methods: The ovarian stimulation was carried out according to the short protocol: injections of gonadotropin-releasing hormone analogue were followed by human (group A,n = 110) and recombinant (groupB,n = 110) FSH administration. The growth of embryos was monitored with time-lapse system.The trace metals measurements were performed by the electrothermal-atomic absorption spectrometry method. After six weeks, the presence of the embryo cardiac activity were assessed via ultrasound. The relationship between concentrations of trace metals and embryo kinetic data were analyzed.

Main results and the role of chance: Pregnancy was achieved in 57 women – 29 (26,36%) of them were stimulated with hFSH and 28 (25.45%) were stimulated with rFSH.No statistically significant difference was found between the two groups with regards to the type of gonadotropins used (Chi^2 = 0.278, df = 1, p = 0.575).Comparing time of embryo development in groups A and B it was noted that almost all successive stages of embryo development (except tF) occurred earlier in women who achieved pregnancy than in women in whom pregnancy was not achieved.In both groups possitive correlations were found between mean level of Zn and the embryonic development periods: tC-t2, t4 and negative correlations occurred for the Pb levels with times tF–t4.In regards to other trace metals, we have observed no significant relationships. ROC curve analysis showed no statistically significant differences between accuracy of using FSH and trace metals levels to predict pregnancy after IVF.

Limitations, reasons for caution: The results of this study where ICSI was performed with ejaculated sperm and for male-factor infertility cannot be generalized to all ICSI offspring because the indications for ICSI have nowadays been extended and ICSI is also being performed with non-ejaculated sperm and reported differences may thus either decrease or increase.

Wider implications of the findings: It has been hypothesized that zinc supplementation may improve achivement pregnancy in patients undergoing ICSI. It raises the need for further research into this problem by larger research groups.

Trial registration number: 8/07/2016

P-630 Non-invasive detection of dominant follicle metabolite composition in PCOS women receiving rFSH, clomiphene citrate or aromatase inhibitor for ovarian stimulation

M. Acet[1], N. Celik[2]

[1] *private, obstetric and gynecology, İstanbul, Turkey*
[2] *Department of Biochemistry- Behcet Uz Children's Hospital- Izmir-Turkey, Biochemistry, Izmir, Turkey*

Study question: Does metabolite composition of dominant follicle change in women with PCOS receiving rFSH, clomiphene citrate (CC) or aromatase inhibitor (AI).

Summary answer: While CC use changes the developing follicle metabolite content negatively rFSh or AI will not cause any change.

What is known already: Although conventional ovarian stimulation drugs used in assisted reproductive technology cycles allow selection and maturation of oocytes they may lead to retrieving of compromised quality oocyte that may cause fertilization failure or compromised embryo development. rFSH, CC and AI are the three most commonly used drug groups for ovulation stimulation. Although a number of studies have looked at the metabolites compostion of reproductive tissues MRS-based approach to identify the impact of drugs used for ovarian stimulation on human follicular fluid has not been carried out.

Study design, size, duration: This is a case controlled study, enrolled 26 women who undergoing IVF/ICSI due to PCOS.

Participants/materials, setting, methods: A total of 21 infertile PCOS women equally assigned to three groups consisting of women receiving rFSH or CC or aromatase inhibitor. Each group of women underwent MR spectroscopy of a dominant follicle before hCG injection as soon as the detection of a follicle with a mean diameter of at least 16-18 mm. N-acetylaspartate (NAA), lactate (Lac), creatine (Cr), and choline (Cho) content of follicle were measured as ppm.

Main results and the role of chance: Four fold decrease in Cho signal was detected in subjects receving CC compared to fertile subjects. Cho signal of subjects taking rFSH or AI were significantly higher than in the CC group.

Significantly increased Lac signal was detected in the dominant follicle of subjects taking CC. Three-fold higher Cr signals was detected in fertile subjects compared to CC group. Likewise, Cr peak of subjects taking rFSH or AI were significantly higher than in Cr signal of CC group.

Limitations, reasons for caution: The low number of patients being studied is the basic limitation of our study.

Wider implications of the findings: Prediction of the developmental capacity of egg before OPU with spectroscopy may increase the accuracy of best quality embryo selection. Thus, it may be possible to see the developmental defects of the growing oocyte before OPU and to take treatment steps for improving oocyte developmental potential.

Trial registration number: NA.

P-631 Experimental study of rat bone marrow stem cell on polycystic ovary syndrome model of rattus norvegicus decreasing fas ligand expression and apoptotic index

S. Siahaan[1], B. Santoso[1], W. Widjiati[2]

[1]Faculty of Medicine- Universitas Airlangga, Obstetrics & Gynecology, Surabaya, Indonesia
[2]Faculty of Veterinary Medicine- Universitas Airlangga, Veterinary Anatomy, Surabaya, Indonesia

Study question: This study aims to compare Fas ligand expression and apoptotic index in rat ovaries with or without the administration of Rat Bone Marrow Stem Cell.

Summary answer: There was a decrease of Fas ligand expression and apoptotic index in the administration of rat bone marrow stem cell in rat with PCOS model.

What is known already: Hiroyuki et al. conducted further research by comparing ovarian expression and localize of FAS and Fas Ligan (FasL), caspace-9. This study found TdT-mediated dUTP-Biotin nick-end-labeling (TUNEL) which indicates positive result, highly increase in Polycystic Ovary Syndrome (PCOS) ovaries compared with healthy ovaries (p<0,005), FasL level and caspace-8 increase.

Study design, size, duration: This study used experimental design with post-test only control group design conducted on rats with PCOS model. The large sample of the study, based on Federer's formula with the amount of 27 rats. The study was conducted on January to May 2016.

Participants/materials, setting, methods: The large sample of the study, based on Federer's formula with the amount of 9 rats/group, was then divided into three groups which are rats without treatment, PCOS model rats, and PCOS model rats with stem cell. The dependent variables in this study were Fas ligand expression and apoptotic index. If the distribution is normal, the data analysis used ANOVA test. If it is not normal, the data analysis used non-parametric Kruskal Wallis test.

Main results and the role of chance: The characteristics of the research subjects (age and weight) of rats were in normal distribution. It was found that there was no significant difference in the weight of rats (P = 0.924) and the age of rats (p = 0.556). There was no significant difference on Fas ligand expression in the three groups (p = 0.002). There was no significant difference on apoptotic index for three groups (p = 0.002). The comparison of Fas ligand expression and apoptotic index between the untreated rats and PCOS model rats was 1.6000 + 1.126 vs 3.377 + 1.065, p = 0,001; 2.533 + 1.322 vs 5.822 + 2.892, P = 0.001. There was significant difference on Fas ligand expression and apoptotic index in PCOS model rats and PCOS model rats with stem cell (3.377 + 1.065 vs 0.933 + 0.529, p<0,0001; 5.822 + 2.892 vs 1.400 + 0.812, p<0,0001). There was no significant difference between the untreated rats and PCOS model rats with stem cell (1.6000 + 1.126 vs 0.9333 + 0.529, p = 0.148; 2.533 + 1.322, p = 0.148 vs 1.400 + 0.812, p = 0.217). There was strong correlation between the decreased Fas ligand expression and apoptotic index (R = 0.94286).

Limitations, reasons for caution: The use of rats as samples could not represent women with PCOS as a whole.

Wider implications of the findings: The result of the study is in line with the previous literature regarding benefit of stem cell in PCOS. Stem cells have the effect on Fas ligand and apoptotic index at PCOS cases.

Trial registration number: Not applicable.

P-632 Cumulative live birth rate after in vitro maturation (IVM) in patients with polycystic ovary syndrome (PCOS): retrospective analysis of 1,110 cycles

N.A.V. Ho[1], D.T. Pham[1], H.A. Le[1], M.T. Ho[1], N.L. Vuong[2]

[1]IVFMD, My Duc Hospital, Ho Chi Minh City, Vietnam
[2]Department of Obstetrics and Gynecology, University of Medicine and Pharmacy at Ho Chi Minh City, Ho Chi Minh City, Vietnam

Study question: What is the cumulative live birth rate after IVM in patients diagnosed with PCOS?

Summary answer: The cumulative live birth rate after IVM is satisfactory, and similar to that achieved after IVF.

What is known already: IVM is an emerging assisted reproductive technology technique that eliminates risk of ovarian hyper-stimulation syndrome in patients with PCOS. However, there is a lack of data on the effectiveness and safety of IVM cycles.

Study design, size, duration: This retrospective cohort study included 1,110 PCOS patients (1,110 IVM cycles, 1,206 transfers). The most common indication for IVM was ovulation induction failure (93.5%). Mean age, body mass index (BMI), and anti-Müllerian hormone levels were 28.8 ± 3.5 years, 21.9 ± 3.2 kg/m^2, and 12.5 ± 3.6 ng/mL, respectively. The majority of patients had primary infertility (81%); mean infertility duration was 3.6 ± 2.5 years.

Participants/materials, setting, methods: Women who were diagnosed with PCOS (Rotterdam criteria) underwent IVM at a large center in Ho Chi Minh City, Vietnam between 2014 and 2016. Human chorionic gonadotropin (hCG) priming was used in 921 patients. Exclusion criteria included uterine abnormalities, donor or pre-implantation genetic screening/diagnosis, loss to follow-up cycles and cycles without embryo transfer. Data on the number of live births 12 months after initiation of IVM were used to calculate the cumulative live birth.

Main results and the role of chance: Mean number of immature oocytes retrieved per patient was 15.9 ± 10.2. Maturation and fertilization rates were 69.0 ± 23.9% and 68.7 ± 22.5%, respectively. First embryo transfer was fresh in 76.5% of patients and frozen in 20.4%. No case of ovarian hyperstimulation syndrome (OHSS) was reported. The ongoing pregnancy rate and live birth rate per embryo transfer were 33.6% and 26.8%, respectively, and the 12-month cumulative live birth rate was 29.1% (66% in singleton and 34% in twins). Median time to ongoing pregnancy and live birth were 2.4 and 8.8 months, respectively. The cumulative live birth rate was the same with or without hCG-priming (30.1% vs 24.3%, p = 0.13), but median time to live birth was shorter in hCG-priming vs non hCG-priming cycles (8.7 vs 9.6 months, p<0.001) since a freeze-only strategy was used when hCG-priming was not given. Multivariate logistic regression analysis revealed that BMI, number of IVF attempts and number of good embryos were significant independent predictors of live birth after IVM.

Limitations, reasons for caution: The retrospective design of this study was the most important limitation. In addition, pregnancy-related complications (e.g. pre-eclampsia and diabetes mellitus) were not documented.

Wider implications of the findings: Cumulative live birth rate after IVM in PCOS women was acceptable and similar to that after IVF. IVM is a convenient, low cost option in these patients and has been shown to eliminate the risk of ovarian hyper-stimulation; therefore, IVM may be an alternative to IVF in PCOS women.

Trial registration number: not applicable.

P-633 Natural cycle cryopreserved embryo transfer: is a washout period needed after a failure of fresh embryo transfer?

Y. Mizrachi, E. Horowitz, A. Ravhon, A. Shalev, S. Allouche, E. Gold, M. Finkelstein, Z. Steinfeld, J. Farhi, A. Raziel, A. Weissman

IVF Unit, Department of Obstetrics and Gynecology- Edith Wolfson Medical Center- and Sackler Faculty of Medicine- Tel Aviv University., Tel-Aviv, Israel

Study question: Does delaying modified natural cycle (mNC) frozen embryo transfer (FET) after a failed fresh embryo transfer (ET) improve the live birth rate (LBR)?

Summary answer: In mNC FET cycles, delaying FET after a failed fresh cycle does not improve the LBR.

What is known already: The optimal timing of FET after a failed fresh IVF-ET cycle is controversial. While some studies suggest that a "washout" period is unnecessary, others support the postponement of FET after a failed fresh cycle for at least one menstrual cycle, out of concern that there may be residual effects of the controlled ovarian stimulation, which may interfere with the subsequent cycle. Until now, published studies included only artificial FET cycles, and the use of the natural cycle, which is a popular and effective method for FET, has not been investigated.

Study design, size, duration: A retrospective cohort study reviewing all first FET cycles performed after failed fresh ET attempts, between 2009 and 2016 (n = 212).

Participants/materials, setting, methods: The study included patients aged 18-45, who underwent FET in a single university-affiliated IVF unit. Only mNC FET cycles were included, where hCG was used for ovulation triggering, and vaginal progesterone was given as luteal support. Cycles were divided according to the time interval between oocytes retrieval and FET into immediate FET group (<50 days) and delayed FET group (≥50 days). Clinical pregnancy was defined as fetal heart activity on ultrasound.

Main results and the role of chance: Overall, 127 patients had an immediate FET and 85 patients had a delayed FET. Mean age was 32.6 ± 5.1 and 34.0 ± 5.6 respectively (p = 0.06), and mean number of previous failed cycles was 3.3 ± 2.6 and 4.0 ± 3.0, respectively (p = 0.09). The immediate and the delayed FET groups did not differ with regard to LBR (22.8% vs. 14.1%, respectively, p = 0.11) or clinical pregnancy rate (27.6% vs. 20.0%, respectively, p = 0.21). On multivariate regression analysis, delaying mNC FET was not associated with live birth (aOR 0.56, 95%CI 0.25-1.22) or clinical pregnancy (aOR 0.61, 95%CI 0.30-1.24), after controlling for woman's age, infertility diagnosis, fresh ET protocol, and the number of embryos transferred. The study was powered to detect a 2-fold increase in the LBR, with alpha of 0.05 and power of 80%.

Limitations, reasons for caution: The study limitations include its retrospective design and small sample size. It was not sufficiently powered to detect a small difference in LBR.

Wider implications of the findings: These data should reassure patients and clinicians who desire to proceed with FET immediately after fresh IVF failure.

Trial registration number: IRB reference number 0220-17-WOMC

P-634 iTRAQ-based proteomic profile of ovarian granulosa cells from women with PCOS undergoing IVF/ICSI

H. Zhongying, W. Fan, Q. Ma, W. Huang

West China Second University Hospital Sichuan University, Department of Obstetrics and Gynecology, Chengdu, China

Study question: To investigate the differences of protein expression in ovarian granulosa cells between women with PCOS and the controls patients receiving IVF/ICSI.

Summary answer: This study reveals the differences of protein expression in granulosa cells from PCOS women and the controls undergoing IVF/ICSI.

What is known already: The pathogenesis of PCOS, the most common cause of ovulatory disturbance leading to infertility, is not clear, particularly with regard to proteins expressed in the ovarian granulosa cells from PCOS women. Proteomic analysis is a powerful technological tool for investigations of human diseases. iTRAQ is a quantitative method that has frequently been used in proteomic studies and demonstrated to be effective and accurate in characterizing various diseases. However, iTRAQ has not been applied in the proteomics profile of granulosa cells proteins from PCOS women undergoing IVF.

Study design, size, duration: Eight women undergoing IVF/ICSI with tube factor or male factor infertility were enrolled in this study. Four patients with PCOS and insulin resistance were included in PCOS group. The other four with regular ovulatory cycles, normal basal FSH and LH levels, and with 15 or more antral follicles were included as the control. Standard long GnRH agonist protocol was used in both groups. The dose of gonadotropin for ovarin stimulation is FSH 100-150IU/d.

Participants/materials, setting, methods: The granulose cells were collected soon after oocyte retrieval. The protein expression profile of each sample was detected by isobaric tags for relative and absolute quantitation (iTRAQ) technique coupled with liquid chromatography-tandem mass spectrometry (LC-MS/MS). The up- and down-regulated proteins were analyzed based on Gene Ontology and KEGG enrichment pathway. The proteins were analyzed in terms of molecular function, cell location and biological processes for finding the key protein molecules.

Main results and the role of chance: The estradiol levels in serum on hCG administration day were comparable in PCOS group and the controls. There was no difference in the number of ooccytes retrieved between the two groups. A total of 3556 protein were identified, among which 486 differentially expressed, including 406 up-regulated and 80 down-regulated protein in granulosa cells from women with PCOS. Gene ontology analysis showed that most differentially expressed proteins were located in the extracellular region.The differential expression proteins in PCOS groups and the controls were mainly related to the protein binding and catalytic activity of some enzymes, and play important role in the cellular process, metabolic process, biological regulation and regulation of biological process. KEGG enrichment analysis linked 373 differentially expressed protein to 27 different metabolic pathways, with most proteins involved in the metabolic pathways, biosynthesis of secondary metabolites, ribosome, and microbial metabolism in diverse environments.

Limitations, reasons for caution: The differentially expressed protein need to be verified by Western blot.

Study funding:This study was supported by grants from the National Natural Science Foundation of China (81200453), Science & technology department of Sichuan Province (2014KJT062-2014SZ0001), and Chengdu science and Technology Bureau (2015-HM01-00494).

Wider implications of the findings: These iTRAQ results provides new insights into the pathogenesis of PCOS, which may facilitate the discovery of novel therapeutic targets to treat female infertility associated with PCOS.

Trial registration number: None.

P-635 To compare the effect of metformin plus myoinositol vs metformin alone in terms of clinical pregnancy rate in infertile PCOS women

R. Mahey[1], A. Agrawal[2], G. Kachhawa[2], I. Kriplani[3], V. Kulshrestha[2], R. Kumari[2], R. Khadgawat[2], A. Kriplani[4]

[1]All India Institute of Medical Sciences-, Obstetrics & Gynaecology, Delhi, India
[2]All India Institute of Medical Sciences- New Delhi, Obstetrics & Gynaecology, New Delhi, India
[3]All India Institute of Medical Sciences- New Delhi- India, Obstetrics & Gynaecology, New Delhi, India
[4]All india Instate of Medical Sciences- New Delhi, Obstetrics & Gynaecology, New delhi, India

Study question: Whether combination of metformin and myoinositol is better as compared to metformin alone in improving clinical pregnancy rate in infertile PCOS women undergoing ovulation induction.

Summary answer: Clinical pregnancy was significantly higher due to synergistic effect of metformin and mho-inositol as compared to metformin alone in infertile PCOS women undergoing ovulation induction.

What is known already: Polycystic ovary syndrome is the most common cause of anovulatory infertility. Metformin has been used for decades as either primary therapy or after failed ovulation induction in infertile PCOS women. Mechanism of action of metformin is through improving peripheral insulin resistance. Recently there is literature on use and function of inositols in PCOS women which have been shown to act at the ovarian level where it improves insulin resistance and improves oocyte quality. Myo-Inositol is the main type required for improving oocyte quality. But there is no consensus on dose, duration and any benefit of combining the two drugs.

Study design, size, duration: A randomised controlled trial was conducted with 120 infertile PCOS women (January 2016 to May 2017). Group I was the intervention group and received Metfromin 500 mg+ Myoinositol 600 mg TDS and Group II (n = 60) received Tab Metformin 500 mg TDS. The therapy was continued for total 6 months and couples were advised to try for natural

conception. Those who didn't conceive after 3 months, were given ovulation induction and intrauterine insemination.

Participants/materials, setting, methods: Baseline clinical and hormonal profile and infertility work up was done and patients were recruited according to inclusion criteria. Clinical and hormonal parameters were repeated at 3 months. Improvement in HOMA-IR was calculated after 3 months of therapy. Primary outcome was clinical pregnancy rate at the end of 6 months. Secondary objective was ovulation rate, ongoing pregnancy rate, OHSS, abortion rate, multiple pregnancy rate and improvement in clinical / metabolic profile of patients.

Main results and the role of chance: Baseline characteristics were comparable in two groups.After 3 months therapy, improvement in clinical and hormonal parameters were comparable in two groups except for improvement in menstrual cycle length and HOMA-IR index, which were significantly better in group I. more patients (14/60; 23.3%) conceived spontaneously in group I as compared to group II (8/60;13.3%), though the difference was not statistically significant($p = 0.15$). Overall conception rate was significantly higher in group I (38/60; 63.3%)) as compared group II (20/60; 33.3%) in Group II with $p = 0.001$. Five patients in group I and 1 patient in group II had multiple pregnancy. one patient in group I had early onset ovarian hyper stimulation syndrome (OHSS) and 4 had late onset OHSS. All late onset OHSS were due to multiple pregnancies. Group II had no case of OHSS. The ongoing pregnancy rate (POG>20 weeks) was 55% (33/60) in Group I and 26.67% (16/60) in Group II which was significantly higher in Group I ($p = 0.002$).

Limitations, reasons for caution: The main limitation was small sample size. Serum progesterone were not done on day 21 of cycles to document ovulation. More data on large sample size is required to document the synergistic effect of metformin and myo-inositol in terms of live birth rate in infertile PCOS women.

Wider implications of the findings: This was the first study to document better efficacy of combined use of metformin and my-inositol over metformin alone in infertile PCOS women. The two can be used to improve clinical pregnancy and ongoing pregnancy rate in infertile PCOS women undergoing ovulation induction cycles.

Trial registration number: CTRI/2017/07/009021

P-636 Convenience and efficacy of treatments for endometrial preparation prior to frozen embryo transfer (FET): a randomised-controlled trial comparing stimulated cycle (SC) vs natural cycle (NC)

A. Lobersztajn[1], M. Pasquier[1], C. Piétin-Vialle[1], C. Villette[1], A.L. Dessapt[1], H. Bry[1], C. Jung[2], M. Brussieux[2], N. Massin[1]

[1]Intercommunal Hospital- University Paris XII, Dpt of Gynecology- Obstetrics and Reproductive Medecine, Creteil, France
[2]Intercommunal Hospital- University Paris XII, Clinical Research Center CRC, Creteil, France

Study question: Can ovarian stimulation with rec-FSH used for endometrial preparation for women undergoing FET be more convenient (number of visits reduced) than natural cycle?

Summary answer: Endometrial preparation with rec-FSH decreases significantly the number of visits needed to schedule the FET, without impairing the ongoing pregnancy rate.

What is known already: Before frozen embryo transfer, it is necessary to ensure that the transfer is carried out at a time when the endometrium is receptive, defined as the "implantation window". Endometrial preparation can be performed by hormone replacement therapy, FSH stimulation, or close monitoring of a natural cycle. The natural cycle may appear more physiological but more burdensome as it needs more monitoring, and reduces flexibility for patients and the organization of centers. To date, no study compares the convenience of FSH stimulation compared to natural cycle for FET.

Study design, size, duration: Prospective open-labeled randomised controlled study in a public IVF center from may 2015 to oct 2017. To demonstrate a decrease of one visit with SC compare to NC, the sample size was calculated as 48 patients per group (two-sided alpha-error 0.05, power 90%), increased by 30% for cancellation rate, ie 62 patients per group and 124 patients in total.

Participants/materials, setting, methods: Women aged 18 to 38 y undergoing their first or second FET (day 2/3 embryos) were randomized to either NC with close monitoring by ultrasound and hormonal measurements beginning at day 12, or stimulation with rec-FSH 75 IU/day from day 6 to 11 and HCG triggering when leading follicle > 17 mm. The study compares number of visits (ultrasound and blood tests), progesterone levels before FET, HCG positive and ongoing pregnancy rates and spontaneous miscarriages.

Main results and the role of chance: 124 women were included, 62 in both groups. Mean age (+SD) 32.8+4.0 vs 33.9+3.3 (p 0.11) for SC and NC respectively, and other baseline characteristics, were comparable. The primary outcome, number of visits, was significantly lower in the SC group (3.7+0.9 vs 4.5+1.1, $p<0.05$). The number of blood tests (2,7+0.9 vs 3.5+1.1, $p<0.05$) as well as the number of ultrasound performed (1.1+0.4 vs 1.4+0.6, $p<0.05$) were also significantly lower in the SC group compared to NC. The number of FET during "non-opening" hours was lower in SC compared to NC but not statistically different (21.1% vs 28.3%, $p = 0.38$). The cancellation rate was also lower in SC compared to NC but not statistically different (8.1% vs 14.5%, p = 0,26). The mean progesterone level was significantly higher in SC 4.2+1.7 vs NC 3.2+1.2 ng/ml ($p<0.05$), measured 72 h before FET. The number of embryo transferred was comparable in SC and NC (1.30+0.5 vs 1.38+0.5, $p = 0.40$). The HCG positive rate and ongoing pregnancy rate per transfer were higher in SC compared to NC but not statistically different (31.6% vs 24.5%, $p = 0.41$ and 22.8% vs 20.7%, $p = 0.79$, respectively). The miscarriage rate was higher in the SC vs NC but not statistically different (21.7% vs 13.3%, $p = 0.51$).

Limitations, reasons for caution: Monitoring cycles with strict criteria in both groups limits the potential bias. The power does not allow us to conclude on pregnancy and cancellation rates. A medico-economic study will be provided as the higher cost with rec-FSH is balanced by the cost and constraints of more visits and cancellation.

Wider implications of the findings: Burden of treatment is a major issue for infertile patients. For women reluctant to have injections, NC is a good option but women must be aware of increased monitoring. SC enables to reduce monitoring and cancellation rates, and offers more flexibility for patients and IVF centers.

Trial registration number: N° EUDRACT: 2015-A00088-41 ClinicalTrials.gov ID: NCT02834117

P-638 Function of Lin28a/Akt/mTOR in regulating premature ovarian failure

J. Chen

the University of Hong Kong, Obestrics & Gynaecology, Hong Kong, Hong Kong

Study question: Does Lin28a play a role in regulating premature ovarian failure?

Summary answer: Overexpression of lin28a in oocyte can enhanced the activity of Akt/mTOR pathway, which may play a role in regulating premature follicle activation.

What is known already: Infertility is a prevalence of disease that besets 15% of couples in childbearing age around the world. Premature ovarian failure (POF), defined as primary ovarian defection and characterized as cessation of menstruation or absent function of ovarian follicles in women under the age of 40, accounts for approximately 1% of infertility disease in women at childbearing age. The study on the specific mechanism of how premature ovarian failure occurs remained further exploration. Lin28a is mRNA binding protein and highly expressed in embryogenesis. Akt/mTOR pathway is also widely reported to be involved in regulating follicologenesis.

Study design, size, duration: Litter size, oocyte number and follicle number of 2-month, 3-month, 4-month and 5-month old Lin28a and wild type mice were counted (n = 6). 100 Oocyte that can be visualized under the microscope was isolated from 3-month (n = 4) and 4-month (n = 4) Lin28a transgenic and wild type mice, and the expression of proteins downstream of the Akt/mTOR pathway including phosphorylated AKT (Ser 473), phosphorylated ribosomal s6 and phosphorylated S6K1 were analyzed by Western blotting and normalized by beta-actin.

Participants/materials, setting, methods: Mice: wild type (ICR), lin28a transgenic mice, female, the age is from 2-month old to 5-month old.

The superovulation result was determined by pregnant mare's serum gonadotropin (PMSG)

Mouse Vasa homologue (Mvh) was used as marker when performing immunohistochemistry to identify oocyte during follicle counting.

western blot was conducted to detect the protein level.

Main results and the role of chance: Lin28a transcripts were found to be highly expressed in the Lin28a mice ovaries. The immunofluorescent staining showed that Lin28a was mainly expressed in the cytoplasm of oocyte. Consistent with the decrease of oocyte number and litter size at 4-month old Lin28a transgenic mice, there was a decrease of primordial follicle and increased primary follicle number of Lin28a transgenic mice from 4-month old compared with wild type control. Expression of downstream molecule of Akt/mTOR pathway-phosphorylated S6 and p-Akt (Ser473) in the oocyte was significantly increased in 3-month and 5-month old Lin28a transgenic mice, which indicated that there may be an interplay of Lin28a/Akt/mTOR in regulating POF.

Limitations, reasons for caution: The technique for in vitro culture of primordial follicle is not available.

The human sample is not easy to be achieved.

Wider implications of the findings: Premature ovarian failure is an important factor that causes women infertility. However, current therapy for POF patient is estrogen treatment. In this study, we explore the functional roles of Lin28a and Akt/mTOR pathway to restore the ovarian reserve and open new treatment strategy to patient who suffered from POF.

Trial registration number: Not applicable.

P-639 Hyperglycemia creates an optimal environment for endometrial cells to exhibit resistance to metformin effects

A. Machado, T. Strowitzki, A. Germeyer

Universitätsfrauenklinik Heidelberg, Abt. für gynäkologische Endokrinologie und Reproduktionsmedizin, Heidelberg, Germany

Study question: Evaluate the antiproliferative effect of therapeutic metformin doses on endometrial cells when exposed to normal and hyperglycemic environment, imitating PCOS and diabetes.

Summary answer: Endometrial cells exposed to high glucose levels exhibit resistance to anti-proliferative metformin effects, an effect potentially related to estrogen receptors expression.

What is known already: Endometrial hyperplasia predisposes for the development of endometrial cancer (EC). Women with PCOS are prone to endometrial hyperplasia due to anovulatory cycles with chronic elevated estrogen serum levels and an increased incidence of adipositas, knowns as an additional risk factor for EC development. Metformin, an insulin-sensitizing agent commonly used in the treatment of type II diabetes, is also used off-label in women with PCOS for ovulation induction. Recently, metformin treatment has been suggested as therapy to inhibit cellular overgrowth and hyperplasia in several tissues, however detail analysis of endometrial tissues under various conditions remain to be examined.

Study design, size, duration: This study is an *in vitro* experimental study using endometrial cell lines treated with metformin under different conditions for 7 days.

Participants/materials, setting, methods: Two different endometrial adenocarcinoma type I human cell lines (Ishikawa and HEC-1A cells) with different estrogen receptors expression were treated long-term (7 days) with low metformin doses (0 mM, 0.01 mM, 0.1 mM, 0.5 mM, 1 mM and 5 mM) cultured in an environment with normal or high glucose concentrations. Moreover, all groups were treated in the presence of 10^{-9} mM estradiol. The proliferation rate and colony formation were performed using crystal violet assay.

Main results and the role of chance: Metformin treatment shows dose-dependent manner effects in the colony formation of both cell lines, decreasing the number and size of colonies independent of the glucose levels present in the medium. Nevertheless, 5 mM metformin treatment showed expressive inhibition effect (demonstrative data). Additionally, in a normal glucose environment 0.5 mM, 1 mM and 5 mM metformin doses decreased the proliferation rate of HEC-1A cells 32% ($P = 0.05$), 38% ($P = 0.02$) and 55% ($P<0.01$), respectively. However, in the presence of high glucose levels, only the highest metformin treatment dose (5 mM) was able to decreased the proliferation rate of this cells (40 %; $P<0.01$), showing significant 15% ($P<0.01$) lower effect when compared to the cells treated in an environment with normal glucose levels. Moreover, this resistance was not observed in Ishikawa cells, where the range between 0.5 mM to 5 mM metformin dose decreased significantly the proliferation rate of this cells in normal (12%; $P<0.01$, 25%; $P = 0.04$ and 55%; $P = 0.02$ respectively) and high (18%; $P<0.01$, 37%; $P<0.01$ and 62%; $P<0.01$) glucose levels. In addition Ishikawa cells did not show different response to metformin effect when compared to cell cultured in normal glucose levels, suggesting that this resistance may be driven by estrogen receptors expression.

Limitations, reasons for caution: These results are regarding to *in vitro* cell line culture, therefore patient viability response are not measured.

Wider implications of the findings: Our data suggest that metformin may be a long-term treatment strategy for anovulatory patients at risk, such as PCOS women, preventing EC development. Furthermore, our results showed the importance of glucose metabolism for the EC treatment response.

Trial registration number: Not applicable.

P-640 The axis and location of male and female pronuclei affect both the determination of first cleavage plane and further development in human embryos

M. Nakaoka, K. Yumoto, K. Iwata, Y. Kai, T. Shimura, Y. Mio

Mio Fertility Clinic, Reproductive Centre, Yonago, Japan

Study question: Are the axis and location of male and female pronuclei involved in both forming the first cleavage plane in human embryos and their further development?

Summary answer: Both the axis and location of male and female pronuclei are involved in determining the first embryonic cleavage plane and affecting further development.

What is known already: Several studies have investigated how the site of the second polar body (2^{nd} PB) might be involved in plane formation in the first cleavage, with suggestions that the 2^{nd} PB position defines the first cleavage plane in human embryos. Thus far, these studies remain controversial. Recently, time-lapse monitoring has been used to monitor and analyze early-stage embryonic development in a clinical setting.

Study design, size, duration: From January to July 2015, we conducted time-lapse imaging (EmbryoScope®) for 40 hours under culture after intracytoplasmic sperm injection (ICSI) of 672 oocytes from couples with severe male factor or fertilization failure. Of the oocytes, 485 were normally fertilized, showing extrusion of the second polar body (2^{nd}PB) with male and female pronuclei (2PN); 361 of these that formed the first cleavage plane and developed to the 2-cell stage were analyzed for this study.

Participants/materials, setting, methods: Oocytes after ICSI were cultured in an EmbryoScope® and images were acquired every 15 minutes for 40 hours to analyze the relationship between axis and location of the cytoplasmic pronuclei and the first cleavage plane. A straight line connecting the pronuclei was defined as the '2PN axis". Based on the direction of first cleavage relative to the 2PN axis, embryos were further classified into two groups, parallel and perpendicular, for evaluation of further development.

Main results and the role of chance: First, we analyzed the relationship between the cytoplasmic 2PN location and the first cleavage plane. Of the 361 fertilized embryos, 208 produced suitable imaging, with 198 (95.2%) forming a cleavage furrow through or close to the 2PN location at first cleavage.

Second, we investigated the relationship between 2PN axis and the first cleavage plane in 315 of the 361 embryos showing suitable images; 275 (87.3%) formed a cleavage furrow parallel to the 2PN axis at the first cleavage, while the remainder ($n = 40$) formed a cleavage furrow perpendicular to the axis.

Third, we analyzed the relationship between 2PN axis and the first cleavage plane in the 24 (6.7%) of 361 embryos with pronuclei located at the cytoplasmic margin. Of those, 20 image sets were suitable for analysis, with 18 (90.0%) forming a cleavage furrow parallel to the 2PN axis at first cleavage.

Finally, the quality of embryos was determined based on the modified Istanbul Consensus. There were significantly more poor-quality embryos in the perpendicular group than in the parallel group (50.0% vs. 25.5%, $P < 0.01$). Furthermore, clinical utility rate was significantly lower in the perpendicular group than in the parallel group (42.5% vs. 69.1%, $P < 0.001$).

Limitations, reasons for caution: Since only ICSI zygotes were analyzed in this study, we could not investigate the influence of fertilization methods on subsequent development. Further studies including molecular biological analyses would help to define the mechanisms underlying determination of the first cleavage plane in human embryos.

Wider implications of the findings: We suggest that both the axis and the location of pronuclei are essential for determining the first cleavage plane and ongoing embryonic development because the 2PN axis might be involved in positioning the mitotic spindle poles.

Trial registration number: Not applicable.

P-641 Comparison of the effect of two combinations of myo-inositol and D-chiro-inositol in women with polycystic ovary syndrome who undergo ICSI

P. Llaneza[1], M. Aragon[2], V. Maldonado[3], J. Lorente[4], M.J. Bravo[5], J. Fonolla[6], M.P. Diaz[6], M. Olivares[6], N. Mendoza[7]

[1]*HUCA, Obstetrics and Gynecology, Oviedo, Spain*
[2]*Torrecardenas Hospital, Obstetrics and Gynecology, Almería, Spain*
[3]*Hospital of Jaén, Obstetrics and Gynecology, Jaén, Spain*
[4]*Reina Sofía Hospital, Obstetrics and Gynecology, Córdoba, Spain*
[5]*El Ángel Hospital, Obstetrics and Gynecology, Málaga, Spain*
[6]*Biosearch Life, Research, Granada, Spain*
[7]*Margen Clinic, Obstetrics and Gynecology, Granada, Spain*

Study question: Do high doses of D-chiro-inositol (DCI) in combination with myo-inositol (MIO) have any effect on pregnacy rate (PR) in women with PCOS who undergo ICSI?

Summary answer: The combination of MIO with high dose of DCI achieved a higher PR in women with PCOS who undergo ICSI.

What is known already: A recent meta-analysis indicates that MIO supplementation is not sufficient to improve oocyte or embryonic quality or the percentage of pregnancies in women with PCOS who undergo ICSI, opening the possibilities to the combination with DCI. On the other hand, the evidence with the use of DCI is scarce and heterogeneous, especially in relation to the dose.

Study design, size, duration: A multicenter controlled, randomized, double-blind, parallel-group study with two MIO-DCI formulations for 12 weeks. Study group (SG): 550 mg MIO + 150 mg DCI (Caronositol®) twice daily; Control group (CG): 550 mg MIO + 13.8 mg DCI 2 times daily.

Participants/materials, setting, methods: Inclusion criteria were: women meeting Rotterdam criteria for PCOS with BMI <30 who undergo ICSI. Sixty women with PCOS were recruited, four women were excluded after randomization and fifty six started the treatment. Three of them did not complete the intervention, two due to personal reasons (one in each group), and one woman in the CG did not complete the study due to an accident. No baseline differences were observed between the two groups.

Main results and the role of chance: At the end of the 12-week study, number of MII oocytes and percentage of good-quality embryos were also similar in both groups. However, the pregnancy and live birth rates were significantly higher in the SG than in the CG (65.5 vs 25.9, $p = 0.003$ and 55.2 vs 14.8, $p = 0.002$). Respect testosterone and insulin sensitivity, a significant improvement was found from baseline to end of the study in both groups.

Limitations, reasons for caution: Results should be taken with caution due to the short sample size.

Wider implications of the findings: A combination of 550 mg MIO + 150 mg DCI twice daily could improve pregnancy and live birth rates in women with PCOS who undergoing ICSI.

Trial registration number: NCT03201601

P-642 All you need to you know about resistant ovary syndrome: a systematic review and foundation for future research

C. Zundel, C.B. Lambalk

VU University Medical Center, Department of Obstetrics and Gynaecology, Amsterdam, The Netherlands

Study question: What is the current standpoint in research and clinical management of resistant ovary syndrome (ROS)?

Summary answer: ROS presents a heterogeneity of etiologies (mutations and antibodies) and phenotypes. Hormonal therapies and in-vitro maturation (IVM) have led to pregnancies resulting in live-births.

What is known already: ROS is a rare disorder characterized by a normal amount of follicles that are arrested in development despite a high level of FSH. Patients thus have a resistance to FSH. This leads to infertility. According to Grynberg (2013), ROS is frequently misdiagnosed as premature menopause. This is because ROS is largely unknown to physicians. Indeed, there are over a hundred papers reporting ROS cases but, remarkably, there is no review on the presentation of ROS and its treatment options. Multiple hypotheses on the etiology of ROS have been made. But an overview of these hypotheses and the evidence found lacks.

Study design, size, duration: We conducted a systematic review of all published articles discussing ROS. We searched for papers on PubMed, Cochrane and Embase. The final search was performed on 26 January 2018. We also identified articles through cross-referencing. We then critically reviewed all the publications found.

Participants/materials, setting, methods: We included all articles ever published concerning women with the characterizing features of ROS, namely oligo- or amenorrhea, post-menopausal FSH level, a normal amount of follicles and an arrest in folliculogenesis. All papers regarding FSH receptor (FSH-R) mutations in women were also included. We excluded cases of subjects with a karyotype other than 46-XX. We also excluded all articles in which neither the abstract nor the text was in English, French, Dutch, Spanish or German.

Main results and the role of chance: From the articles that we found, we drew the typical clinical picture of ROS. Along with the characterizing features of ROS, patients have normal internal and external genitalia. Besides, most patients have normal secondary sex characteristics that developed on time. At the time of diagnosis, patients mostly have either primary or secondary amenorrhea, which is often preceded by oligomenorrhea. Accompanying elevated FSH, LH is often increased and estradiol is usually decreased. Multiple papers reported treatment attempts. Outcomes varied from absence of ovarian response to pregnancies resulting in at-term births of healthy babies. The most promising treatments used were clomiphene, estrogen, hMG with or without hCG, combinations of estrogen and progesterone, and, recently, IVM. ROS could be explained by a mutation in the FSH-R gene or in a molecule regulating the FSH-R or involved in the pathway downstream of FSH-R activation. Another possible cause is antibodies against FSH, against FSH-R or against a molecule involved in its regulation or the downstream pathway. The absence or presence of several of these causative factors, along with the associated cellular disturbances, has been shown in multiple ROS patients. The heterogeneity in causes and phenotypes and in particular the relationship between these two is fascinating.

Limitations, reasons for caution: It is likely that many cases were not published, especially those who did not respond to treatment (Vaitukiatis 1986). Additionally, the search and analyzing work of this review were performed by only one person. Finally, a few articles could not be taken into account due to our language restrictions.

Wider implications of the findings: This study is the only existing review on ROS. It provides a clear view on the current standpoint in clinical management of ROS. It also reports what is known on the etiology of ROS and sets the path for future research, which must aim for treatment improvement.

Trial registration number: not applicable.

P-643 Higher menopausal age but no differences in parity in women with polycystic ovary syndrome as compared to controls

M. Forslund[1], K. Landin-Wilhelmsen[2], J. Schmidt[3], M. Brännström[1], P. Trimpou[2], E. Dahlgren[1]

[1]*Institute of Clinical Sciences, Sahlgrenska Academy, University of Gothenburg*
[2]*Institute of Medicine, Sahlgrenska Academy, University of Gothenburg*
[3]*Institute of Clinical Sciences, Sahlgrenska Academy, University of Gothenburg*

Study question: To study the menopausal age in women with polycystic ovary syndrome (PCOS) as compared to women without PCOS.

Summary answer: Menopause is clearly delayed in women with PCOS and that is also reflected in lower FSH levels.

What is known already: Models with anti-Müllerian hormone predict a later menopause in women with PCOS. A cross-sectional study using questionaires showed a later menopause in women stating that they have PCOS diagnosis.

Study design, size, duration: A prospective cohort study of women with PCOS compared to age-matched, randomly selected controls. Twenty-seven women, diagnosed with PCOS in 1992 were re-examined in 2016. Of the initial cohort of thirty-three, five had died and one declined participation. Controls were recruited from another study, these women were initially examined 1995 and re-examined in 2008. 94 controls were included.

Participants/materials, setting, methods: The PCOS women (mean age 52.4 years, range 42-60 years) were diagnosed 24 years ago. They all met Rotterdam criteria. Age-matching was used to derive a control group from women randomly selected from the same geographic area. PCOS n = 27. Controls n = 94. The women were examined using structured interviews, anthropometric measures, blood pressure, and blood tests.

Main results and the role of chance: Among women with PCOS, 37% stated that they were postmenopausal, compared to 57% of the controls (ns). The mean menopausal age in women with PCOS (53.3 years, n = 7) was significantly ($p<0.01$) higher than in controls (49.3 years n = 52). Serum-FSH levels were significantly ($p = 0.02$) lower in PCOS (31.7 IU/L) than in controls (50.1 IU/L). There was no difference in parity between women with PCOS (1.9 ± 1.3 children) compared to controls (1.7 ± 1.0 children).

Limitations, reasons for caution: The numbers of women that could state their menopausal age were lower in the PCOS group, mainly because a bigger proportion of them had not yet become postmenopausal as compared to controls despite the age-matchning.

Wider implications of the findings: The results supports previous prediction models. The prolonged ovarian hormonal activity might be a protective factor for cardiovascular events later in life in women with PCOS.

Trial registration number: not applicable.

P-645 Comparative analysis of structural differences of Ovaleap and GONAL-f: site-specific glycosylation mapping and cell signaling activation

M. Lispi[1], R. Mastrangeli[2], E. Galano[3], A. Palmese[3], F. Cutillo[2], L. Casarini[4], L. Riccetti[4], S. Longobardi[1], M. Simoni[4]

[1]Merck Serono S.p.A, Fertility Medical Affairs, Roma, Italy
[2]Merck Serono S.p.A, Biotech Development Programme, Roma, Italy
[3]Merck Serono S.p.A, Protein Chemistry, Roma, Italy
[4]University of Modena and Reggio Emilia, Unit of Endocrinology- Dept. Biomedical-Metabolic and Neural Sciences, Modena, Italy

Study question: Could differences in site-specific glycosylation between biosimilar (Ovaleap®) and originator (GONAL-f®) recombinant-human follicle-stimulating hormone (r-hFSH) impact calcium (Ca^{2+})-mediated cell signalling activation with these treatments?

Summary answer: Site-specific glycosylation differences between Ovaleap and GONAL-f, including greater N-glycolylneuraminic acid content with Ovaleap, may impact FSH-mediated intracellular Ca^{2+} increase and the potential for immunogenicity.

What is known already: It is well known that the glycosylation profile of FSH can affect the molecule's receptor-binding efficacy, half-life and clearance, all of which have an effect on the overall biological activity of FSH. In particular, the glycosylation profile at asparagine 52 of the alfa chain (αAsn-52) is known to affect FSH receptor binding and signal transduction. Differences in manufacturing processes can lead to differences in the glycosylation patterns between biosimilar and originator recombinant FSH preparations, including the amount of non-human N-glycolylneuraminic acid that is incorporated, which may have safety implications because N-glycolylneuraminic acid can increase the risk of immunogenicity in humans.

Study design, size, duration: Glycopeptide mapping and Ca^{2+}-mediated cell-signaling activation were assessed in three batches of Ovaleap (S06622, S27266, R38915) and three batches of GONAL-f (199F005, 197F049, 197F051). The Ovaleap batches had 4–11 months until expiry and the GONAL-f batches had 5–7 months until expiry.

Participants/materials, setting, methods: Glycopeptide mapping was performed after chymotryptic digestion and separation with 0.1% TFA in acetonitrile/water on a hydrophilic interaction liquid chromatography column using Acquity UPLC coupled to a Xevo G2-S QTof Mass Spectrometer (Waters, Milford, MA, USA). Intracellular Ca^{2+} increase with 10 nM or 100 nM of the three batches of Ovaleap was compared with the increase with equimolar doses of GONAL-f in FSH receptor-transfected HEK293 cells using a bioluminescence resonance energy transfer assay.

Main results and the role of chance: Site-specific glycosylation mapping revealed differences in glycosylation patterns between Ovaleap and GONAL-f. In particular, the batches of Ovaleap had greater sialylation at all N-glycosylation sites than GONAL-f (Z-number range (Ovaleap vs. GONAL-f): αAsn-52: 178.1–183.8 vs. 173.9–176.0; αAsn-78: 183.7–188.5 vs. 175.6–178.6; βAsn-7: 305.6–311.0 vs. 284.7–290.9; βAsn-24: 211.6–219.5 vs. 184.9–189.2). N-glycolylneuraminic acid content was also higher in batches of Ovaleap, with only trace amounts of N-glycolylneuraminic acid present on GONAL-f (ranges Oveleap vs. GONAL-f: 2.6–4.7% vs. 0.0–0.4%). Differences in the potential for Ca^{2+}-mediated cell-signaling activation were observed between Ovaleap and GONAL-f. Although 10 nM and 100 nM GONAL-F, as well as the positive control thapsigargin, induced a 200–300-fold increase of intracellular Ca^{2+} compared with baseline, equimolar doses of all the three batches of Ovaleap failed to induce an increase in Ca^{2+}. It can be speculated that the differences in Ca^{2+}-mediated cell-signaling activation may be the result of the differences in the glycosylation profiles observed between the FSH preparations.

Limitations, reasons for caution: These analyses were performed *in-vitro*. The potential impact and clinical relevance of the glycosylation differences on efficacy and risk of adverse events cannot be confirmed from these findings.

Wider implications of the findings: Differences in glycosylation among FSH preparations have the potential for profound effects on the efficacy and safety of this treatment and these require further investigation using *in vitro* models and clinical settings.

Trial registration number: Not applicable.

P-646 Further characterization of a newly described hypo-androgenic PCOS-like phenotype based on adrenal and ovarian hormone profiles

N. Gleicher[1], S. Soldin[2], V. Kushnir[1], D. Barad[1], S. Darmon[1], D. Albertini[1], C. Stratakis[3]

[1]Center for Human Reproduction, n/a, New York- NY, U.S.A.
[2]Clinical Center, Department of Laboratory Medicine, Bethesda- MD, U.S.A.
[3]NICHD, Section of Endocrinology and Genetics, Bethesda- MD, U.S.A.

Study question: How do hormone profiles in women with the recently described hypo-androgenic PCOS-like phenotype (H-PCOS) differ from controls?

Summary answer: They differ significantly in almost all hormones of adrenal and ovarian origins.

What is known already: Women with H-PCOS are lean, characterized by excessively high AMH values for age and/or in comparison to FSH levels, by low testosterone (T), low dehydroepiandrosterone-sulfate (DHEAS) and high prevalence of autoimmunity (Gleicher et al; J Steroid Biochem Mol Biol 2017;167:144-152). They at young ages are hyper-androgenic and, likely, demonstrate mild hyper-cortisolism but in late 20 s to early 30 s, suddenly, become hypo-androgenic and, often, show mild hypo-cortisolism (Gleicher et al., Endocrine 2018; doi:10.1007/s12020-017-1498-8).

Study design, size, duration: This was a prospective study involving 7 H-PCOS patients and 9 controls.

Participants/materials, setting, methods: We prospectively investigated 3 young oocyte donors defined as H-PCOS, 4 control donors, 4 older H-PCOS infertility patients undergoing IVF, and 5 control patients in early follicular phase for cortisone, cortisol, corticosterone, 11-deoxycortisol, androstenedione, T, 17-OH-progesterone, progesterone, DHEA and Cyp17(17-0 P/P). Bloods were obtained and frozen at CHR, and transported de-identified and coded to the

NICHD for analyses by ultra-filtration LCMS/MS (Stolze et al., J Steroid Biochem Mol Biol 2016;162:110-116). Statistical analyses were performed at CHR.

Main results and the role of chance: H-PCOS donors and patients were of similar ages as controls (24.0 ± 2.6 vs. 26.8 ± 7.6 and 39.5 ± 7.6 vs.37.8 ± 6.1 years), had significantly higher AMH than controls (8.2 ± 1.9 vs.2.6 ± 07 and 8.1 ± 3.3 vs.1.2 ± 0.9 ng/mL). In non-parametric statistical analyses, H-PCOS donors did not differ from control donors in any of the other hormones. H-PCOS patients, however, demonstrated lower cortisol (P = 0.02), corticosterone (P = 0.04) and 11-deoxicortisol P = 0.04). Comparing H-PCOS donors to older H-PCOS patients no hormonal differences were apparent, while comparing normal control donors and patients, androstenedione was lower in patients than donors (P = 0.02), as was testosterone (P = 0.04) and DHEA (P = 0.04). Adjusting for AMH values, H-PCOS donors had higher corticosterone (P = 0.007), 11-deoxicortisol (P = 0.003), progesterone (P = 0.007 and Cyp17 (P = 0.021), while older H-PCOS patients demonstrated lower cortisol (P = 0.045), corticosterone (P = 0.046) but higher androstenedione (P<0.0001), higher testosterone levels (P = 0.0002) and higher Cyp17 (P = 0.04). Comparing young H-PCOS donors with older H-PCOS patients, donors had higher cortisone (P = 0.03), cortisol (P<0.0001), testosterone (P = 0.01), 17-OHP (P = 0.04) and DHEA (P = 0.02), while among controls, donors had higher cortisone than patients (P = 0.03), cortisol (P<0.0001), androstenedione (P = 0.001), testosterone (P = 0.03) but lower corticosterone (P = 0.03), 11-deoxicortisol (P = 0.04).

Limitations, reasons for caution: Considering the small number of study subjects, the data presented here have to be viewed as preliminary.

Wider implications of the findings: These data reaffirm at all ages significant differences in adrenal and ovarian function between H-PCOS-like phenotypes and controls, supporting a previously reported strong interdependence between adrenal and ovarian steroid hormone secretion (Gleicher et al; J Steroid Biochem Mol Biol 2017;167:144-152; Gleicher et al., Endocrine 2018; doi:10.1007/s12020-017-1498-8).

Trial registration number: not applicable.

P-647 Serum AMH concentration has limited prognostic value for follicle density of primordial and primary follicles questioning AMH as a parameter for the real ovarian reserve

M. Von Wolff[1], M. Roumet[2], J. Reinsberg[3], H. Van der Ven[3], N. Sänger[4], J. Liebenthron[3]

[1]*University of Bern - Inselspital, Department of Endocrinology & Reproductive Medicine, Bern, Switzerland*
[2]*CTU Berne- Institute of Social and Preventive Medicine ISPM, University of Berne, Berne, Switzerland*
[3]*Medical University of Bonn, Department of Gynaecological Endocrinology and Reproductive Medicine, Bonn, Germany*
[4]*Universirty of Frankfurt, Universirty Women's hospital, Frankfurt, Germany*

Study question: What is the prognostic value of Anti mullerian hormone (AMH) to estimate the ovarian density of ovarian primordial and primary follicles?

Summary answer: The prognostic value of AMH to estimate ovarian follicle density is low due to poor correlation of both parameters.

What is known already: AMH is a predictor for ovarian response in IVF therapies. AMH is also used as a marker of ovarian reserve to predict the risk of premature ovarian insufficiency (POI) in gonadotoxic therapies and to estimate the amount of cryopreserved ovarian tissue needed for transplantation.

However, the accuracy of AMH to estimate the ovarian response is limited. Furthermore, the concentration of AMH poorly correlates with the risk of developing POI after gonadotoxic therapies. The reasons for the limited use of AMH as a prognostic factor are poorly understood.

Study design, size, duration: 823 females (29.5 y [23.3; 33.1]) underwent ovarian tissue freezing before gonadotoxic therapy within the network *Ferti*PROTEKT 09/2011 – 08/2016. Based on the analysis and correlation of histologically determined follicle density (three standardized biopsies per ovary, analysed after tissue digestion) and serum AMH concentrations (analysed by the same ELISA assay) the prognostic accuracy of AMH to estimate ovarian follicle density was evaluated.

Participants/materials, setting, methods: Women with ovarian surgery and genetic causes of low ovarian reserve were excluded. First, the crude and adjusted associations between AMH and follicle density were assessed using regression analysis, adjusting for age and disease category. Second, regression models were used to predict follicle density as a function of (i) AMH concentration, (ii) AMH concentration and women age. In order to discuss the accuracy of the derived predictions the 50 and 95% prediction intervals were calculated.

Main results and the role of chance: AMH concentrations and follicular density are significantly correlated (P<0.001). However, the correlation coefficient of 0.26 reveals an only moderate relationship between the two variables. Accordingly, the prediction intervals of follicle density are rather wide.

Regression analysis did not reveal a significant effect of disease category on follicle density whereas a relationship was found between age and follicle density in a quadratic regression analysis. Modelling the follicle density as a function of both AMH and age the predicted follicle density of women aged 10, 20, 30 and 40 y and the associated 50 and 95% prediction intervals were derived:

$$\log10(\text{follicle density}) \sim 1.62 + 0.247 \times \log10(\text{AMH}) - 0.049 \times \text{age}/10 - 0.067 \times (\text{age}/10)^2$$

For instance, in women with an AMH concentration of 2.0 ng/ml, the predicted density was 38.2 per mm^3 at the age of 10 y (50% prediction interval (PI): 18.7;78.1). The density decreased to 21.4 follicles per mm^3 at the age of 20 y (50% PI: 10.6;43.4), to 8.8 at the age of 30 y (50% PI: 4.4;17.9) and to 2.7 at the age of 40 y (50% PI: 1.3;5.4). The large prediction intervals highlight the fact that knowing the patient's age and AMH value is not sufficient to reliably predict the follicle density.

Limitations, reasons for caution: Even though three biopsies were taken from each ovary to increase the accuracy of the analysis, some inaccuracy cannot be excluded.

Wider implications of the findings: As the data provide evidence for the limited prognostic value of AMH for the density of primordial and primary follicles, AMH as a parameter for the real ovarian reserve has to be questioned. Ovarian biopsies might be a better tool to estimate the amount of ovarian tissue needed for transplantation.

Trial registration number: Not applicable.

P-648 Centrosome and spindle organization variations in mouse oocytes matured in vitro under different conditions do not correlate with developmental competence after fertilization

F. Peris[1], S. Alonso[1], J. Santaló[1], M.T. Paramio[2], E. Ibanez[1]

[1]*Universitat Autònoma de Barcelona, Biologia Cel·lular- Fisiologia- Immunologia- Facultat de Biociències, Bellaterra, Spain*
[2]*Universitat Autònoma de Barcelona, Ciència Animal i dels Aliments- Facultat de Veterinaria, Bellaterra, Spain*

Study question: Is maturation, fertilization and development of mouse oocytes differentially affected by addition of follicular fluid from adult (AFF) or prepubertal (PFF) goats to maturation medium?

Summary answer: In vitro maturation conditions resulted in significant variations in centrosome-spindle organization in metaphase-II oocytes, but embryonic development after fertilization was not correlated with these variations.

What is known already: Addition of intraspecific follicular fluid to maturation medium improves both nuclear and cytoplasmic maturation of oocytes in most species, but the effect of interspecific follicular fluid has not been investigated in mouse oocytes. In this species, centrosome and spindle organization has been shown to differ between in vivo and in vitro matured oocytes and among oocytes matured under different in vitro conditions. These variations have been suggested to be related to differences in developmental competence among these oocyte populations. This led to the proposal that centrosome-spindle organization characteristics could be considered as potential biomarkers for oocyte quality.

Study design, size, duration: We analyzed spindle and centrosome organization in metaphase-II mouse oocytes matured in vitro (IVM) for 16-18 h in the presence of 10% fetal bovine serum (FBS, n = 97), AFF (n = 106) or PFF (n =

96), using in vivo ovulated oocytes (IVO) as controls (n = 70). Fertilization and development to the blastocyst stage were also recorded after in vitro fertilization for 3 h and culture for 120 h (IVO n = 123, IVM-FBS n = 114, IVM-AFF n = 96, IVM-PFF n = 114).

Participants/materials, setting, methods: Mouse B6CBAF1 cumulus-oocyte complexes matured in the presence of FBS, AFF or PFF and control IVO oocytes were fixed, immunostained for alpha-tubulin, pericentrin and chromatin, and observed under an epifluorescence microscope to evaluate nuclear maturation status, spindle dimensions and morphology, and number and configuration of cytoplasmic and spindle-pole centrosomes. In a second set of experiments, IVM and IVO oocytes were fertilized in vitro and fertilization and blastocyst rates were determined.

Main results and the role of chance: Nuclear maturation rates were equivalent among IVM groups (70-82%). In contrast to fusiform spindles with pointed poles and solitary pericentrin foci found in IVO oocytes, IVM-FBS and IVM-AFF oocytes exhibited barrel-shaped spindles with wider poles (p<0,0001) and multiple pericentrin foci in 91-96% of them (p<0,0001). IVM-PFF oocytes showed an intermediate phenotype between IVO and the other two groups of IVM oocytes, displaying rhomboid-shaped spindles with an intermediate pole width and multiple pericentrin foci in 70% of them (p<0,0001). Overall, a significant decrease in spindle length (except for IVM-FBS), and a significant increase in spindle width and area (except for IVM-PFF) was evident as a result of IVM. Regarding cytoplasmic centrosomes, IVM oocytes consistently exhibited lower numbers of cytoplasmic pericentrin foci (9-10) than IVO oocytes (15; p<0,001) and a more frequent presence of pericentrin-positive foci in the polar body (22-25% vs 3%; p = 0,0001). Despite the differences in centrosome-spindle organization among the IVM groups and between IVO and IVM oocytes, fertilization rates were equivalent among all of them (90-93%) and blastocyst rates were consistently lower in IVM (41-47%) than in IVO oocytes (90%; p<0,0001). Thus, the differential effect of AFF and PFF in centrosome-spindle organization was not correlated with developmental potential.

Limitations, reasons for caution: Although morphological and morphometrical characteristics of the spindle and spindle-pole centrosomes in IVM-PFF oocytes more closely resembled those of IVO oocytes, compared with IVM-AFF or IVM-FBS oocytes, the spindle-centrosome organization of IVO oocytes was not fully recapitulated. Moreover, other maturation deficiencies may account for their lower developmental potential after fertilization.

Wider implications of the findings: Our data support previous results showing that IVM conditions affect centrosome-spindle organization in mouse oocytes. However, contrary to some of these reports, partial recapitulation of this organization did not translate into an improved development after fertilization. Thus, centrosome-spindle organization characteristics alone may not constitute suitable biomarkers for oocyte quality.

Trial registration number: Not applicable.

P-649 Comparison of oocyte morphology and embryo quality among women with different polycystic ovary syndrome phenotypes

A. UK[1], C. Grysole[2], L. Keller[1], H. Behal[3], C. Decanter[2], D. Dewailly[2], G. Robin[2], A.L. Barbotin[1]

[1]lille university hospital, reproductive biology, Lille, France
[2]Lille university hospital, Department of Endocrine Gynecology and Reproductive Medicine, Lille, France
[3]Lille university hospital, Department of biostatistics, Lille, France

Study question: Does polycystic ovary syndrome (PCOS) phenotype influence oocyte morphology and embryo quality?

Summary answer: Women with different PCOS phenotypes exhibited similar oocyte and embryo quality following controlled ovarian stimulation.

What is known already: In PCOS, phenotype A (or full phenotype combining hyperandrogenism (HA), oligo-anovulation (OA) and polycystic ovarian morphology (PCOM)) and phenotype B (HA+ OA) are considered as the more severe phenotypes. Indeed, these phenotypes are associated with higher risk of comorbidities. Additionally, it has recently been demonstrated that PCOS phenotype A and B are associated with lower clinical pregnancy rate (CPR) as compared to control patients in IVF/ICSI cycles.

Consequently, oocyte quality is suspected to be impaired in cases of combination of OA and HA. However, little is known about oocyte quality and embryo quality among women with different PCOS phenotypes.

Study design, size, duration: In this retrospective study, we have analyzed data collected from women undergoing ICSI cycles between 2006 and 2015. We identified 109 PCOS patients. According to their phenotype, patients were split into 4 subgroups: PCOS A (PCOM + HA + OA, n = 41); PCOS C (PCOM + HA, n = 31); PCOS D (PCOM + OA, n = 37). As only one patient was diagnosed with PCOS phenotype B, therefore the patient was excluded.

Participants/materials, setting, methods: Oocyte quality was the primary outcome and was assessed using morphological criteria. The following abnormalities (fragmented first polar body, abnormal zona pellucida, large perivitelline space, material in perivitelline space, abnormal shape of oocyte, granular cytoplasm and intracytoplasmic vacuoles) were recorded. A total of 602 metaphase II (MII) oocytes for the phenotype A, 462 MII for the phenotype C and 432 MII for the phenotype D were compared. Secondary outcomes included embryo quality and reproductive outcomes.

Main results and the role of chance: After controlling for confounders in logistic regression analysis, our results show that the mean numbers of total and MII oocytes rates did not differ significantly between the three phenotypes. No significant difference was found in the oocyte quality between the three groups. Fertilization rates were similar between PCOS women with phenotype A, C and D (61.8%, 59.1% and 59.2% respectively, p = 0.93). In addition, the percentage of top quality embryos obtained on day 2-3 did not significantly differ regardless of the PCOS phenotype (49.8%, 50.9% and 51.7% respectively, p = 0.86). No difference was found in the implantation rate (31.5%, 28.8% and 32.1% respectively, p = 0.84), CPR (49.1%, 51.3% and 45.5% respectively, p = 0.73) and live birth rate (35.8%, 41.0 and 39.4% respectively, p = 0.51) between the 3 groups. Altogether, our findings suggest that PCOS phenotypes have no impact on the oocyte and embryo quality or the reproductive outcomes following ICSI attempts.

Limitations, reasons for caution: This is a retrospective study with inherent limitations. The main bias is represented by the phenotypic distribution in our study population with only one patient diagnosed with PCOS phenotype B. Indeed, an excessive serum anti-Müllerian hormone level is used as a surrogate for PCOM criterion in our centre.

Wider implications of the findings: In this novel retrospective study, we compared oocyte morphological quality and embryo quality in three different phenotypes of PCOS patients. These findings suggest for the first time that different PCOS phenotypes have no impact on oocyte and embryo quality.

Trial registration number: not applicable.

P-650 Women's perceptions regarding early menopause eHealth resources to facilitate self-care

L. Yeganeh, A.J. Vincent, M. Gibson-Helm, H. Teede, J.A. Boyle

School of Public Health and Preventive Medicine- Monash University, Monash Centre for Health Research and Implementation, Melbourne, Australia

Study question: What are women's needs and perspectives regarding early menopause (EM) eHealth resources?

Summary answer: Most women with EM have access to multiple electronic devices and are supportive of a comprehensive co-designed EM eHealth website or App with multiple features.

What is known already: Provision of evidence based information and resources are integral to high quality collaborative patient centred care, improved patient experience, promotion of best practice and optimal health outcomes. Consumer and health professional knowledge gaps regarding EM exist and potentially contribute to the observed delayed diagnosis, variation in management, dissatisfaction with care, non-compliance with cancer treatment, poor risk perception and poorer outcomes. With continuing increases in digital device ownership, women are seeking electronic resources to

facilitate knowledge access and enhance self-health management, yet current EM related eHealth resources are either lacking or are inadequate for women's needs.

Study design, size, duration: A cross-sectional study of 386 Australian women with EM recruited between May and November 2017. The study was approved by the Monash Health Human Research Ethics Committee.

Participants/materials, setting, methods: Women with a self-reported diagnosis of EM, recruited from hospital clinics or the community, completed an online or paper survey. Exclusion criteria were no formal EM diagnosis or non-Australian residence (n = 123). Data collection included: demographics, medical history, current use of electronic resources to manage health/EM, support for an App, desired features of the ideal App and EM information topics. Data analysis included descriptive statistics (mean ±standard deviation) and logistic regression.

Main results and the role of chance: Of 263 women, the mean age was 53.81(±10.68) with EM diagnosed at age 38.54 (±5.27). Most participants were diagnosed with EM ≥5 years ago (78%), lived in metropolitan areas (55%) and had post-school qualifications (71%). Reported cause of EM was surgical removal of ovaries (30%), unknown (29%), cancer therapy (26%), or autoimmune/genetic/metabolic (14%). Most women had a smartphone (84%) and 98% of those owned multiple electronic devices. Women reported they would prefer a website (59%) to an App (38%) to manage EM with only 37% reporting current App use to manage health and 2% to manage EM. However, 67% women thought an App would be helpful and 45% would be likely to use it. Future menopause App use was less likely with increasing age (OR, 0.96; CI, 0.93-0.99, p = 0.008) but there were no significant associations with residential location, education, time since diagnosis, or cause of EM. Features considered very important/essential to include in an EM App were: evidence-based information (81%), question prompt list (78%), opportunities to ask an expert (76%) and ability to record symptoms/ health measures (67%). EM topics rated very important/essential to include (>80% respondents) were: diagnosis, symptoms, physical/psychological effects, long term implications, hormonal/non-hormonal management and lifestyle changes.

Limitations, reasons for caution: Potential response bias in relation to age/self-reported diagnosis of EM. These findings may be less relevant to non-English speakers, women with lower literacy/ educational attainment and those without internet access.

Wider implications of the findings: The results of this study will help development of high quality eHealth resources aiming to improve self-care and health outcomes. Further research is required to address limitations, and co-develop resources, including user testing and evaluation.

Trial registration number: Not applicable.

P-651 AMH variability and its implications for the number of oocytes retrieved following individualized dosing with follitropin delta

S. Nelson[1], P. Larsson[2], B. Mannaerts[3], A. Nyboe Andersen[4], B.C. Fauser[5]

[1]*University of Glasgow, School of Medicine, Glasgow, United Kingdom*
[2]*Ferring Pharmaceuticals, Biometrics – Global Clinical R&D, Copenhagen, Denmark*
[3]*Ferring Pharmaceuticals, Reproductive Health – Global Clinical R&D, Copenhagen, Denmark*
[4]*Copenhagen University Hospital Rigshospitalet, Fertility Clinic, Copenhagen, Denmark*
[5]*University Medical Center Utrecht, Reproductive Medicine & Gynaecology, Utrecht, The Netherlands*

Study question: Does AMH intra- and inter-menstrual cycle variability influence the number of oocytes retrieved after individualised follitropin delta dosing based on AMH and body weight?

Summary answer: For 95% of women, the implication of AMH variability on ovarian response using individualized follitropin delta dosing is limited to ±1 oocyte.

What is known already: The intra-class correlation coefficient for AMH (age adjusted ICC 0.89, 95%CI 0.84-0.94) was higher when compared to antral follicle count (ICC 0.71, 95%CI 0.63-0.77) when measured across four cycles (Van Disseldorp et al 2010). Within the menstrual cycle AMH exhibits minimal variation. The dose of follitropin delta (Rekovelle®) is based on AMH and body weight where AMH is measured on a random day of the menstrual cycle. Whether variability in AMH across and between menstrual cycles has a clinically relevant impact on the number of oocytes retrieved is unknown.

Study design, size, duration: Cohort study of 1,326 women (aged 18-40 years) participating in a prospective randomised controlled trial undertaken in 11 countries and 37 participating IVF centres, with central AMH measurements (Nyboe Andersen and Nelson et al, 2017).

Participants/materials, setting, methods: Women had serum AMH measured twice: at a random day at screening and at cycle day 2-3 prior to stimulation by centralised laboratory using the Elecsys AMH Plus immunoassay. The variability across the cycle was assessed by analysis of variance with log-transformed AMH ratio. The model underlying the dosing algorithm was used to calculate the predicted number of oocytes based on the doses determined by the AMH values at screening and start of stimulation.

Main results and the role of chance: There was a strong correlation between AMH measured on a random day of the cycle up to 3 months previously (screening AMH) and at the start of stimulation (cycle day 2-3) (r = 0.92). The variation in AMH within-subjects between screening and start of stimulation was limited (coefficient of variation 0.23). This variability was not attributable to measurement on a random day of the menstrual cycle. There was no evidence that AMH varied across the menstrual cycle (p = 0.08). If the dose of follitropin delta had been based on the AMH at start of stimulation instead of AMH at screening this would have had a minor impact on the predicted number of oocytes retrieved. For those women with an anticipated lower response (AMH<15pmol/l) the number of oocytes retrieved would be identical in 97% of women, and for those with an anticipated higher response (AMH≥15pmol/l) the number of oocytes would be at most ± 1 oocyte in 90% of women, with a further 9% attaining ± 2 oocytes. Overall for 95% of women, the implications of AMH variability on ovarian response using individualized follitropin delta dosing is limited to + 1 oocyte.

Limitations, reasons for caution: A centralised AMH measuring laboratory was used which may give rise to reduced AMH variability. AMH measurements were compared with samples taken within 3 months prior to ovarian stimulation, longer time intervals may have shown different variability due to the age-related decline in AMH.

Wider implications of the findings: An AMH measured on a random day of a menstrual cycle prior to commencing ovarian stimulation can be used to individualise the dose of follitropin delta. The variability in AMH within and between menstrual cycles does not have a clinically important impact on the number of oocytes retrieved.

Trial registration number: NCT01956110

P-652 The Bologna criteria patient and dual stimulation for IVF using long-acting FSH - a cohort study

B. Alsbjerg[1,2], T. Hahr[1,2], H.O. Elbaek[1], R. Laursen[1], B.B. Povlsen[1], P. Humaidan[1,2]

[1]*The Fertility Clinic, Skive Regional Hospital, Denmark*
[2]*Health, Aarhus University, Aarhus, Denmark*

Study question: What is the clinical outcome of a patient friendly double stimulation with corifollitropin alfa in a cohort of poor responders, fulfilling the Bologna criteria.

Summary answer: Significantly more oocytes were retrieved during luteal phase stimulation (DuoStim 2) compared to follicular phase stimulation (DuoStim 1).

What is known already: Bologna criteria poor responder patients have a reported live birth rates ranging from 5.5% to 11.7% per cycle started and the crucial parameter is the number of oocytes available. Different combinations of follicular and luteal phase stimulation have been suggested and the overall advantage of the double stimulation is the possibility of retrieving more oocytes within a short period of time having a lower risk of no oocytes retrieved or no embryos available for a consecutive frozen embryo transfer.

Study design, size, duration: In this retrospective cohort study 81 patients were identified in the prospective clinical database from August 2015 to December 2017 planned for DuoStim. Fifty-four patients completed both DuoStim 1 and DuoStim 2 fulfilling the Bologna criteria.

Participants/materials, setting, methods: Patients were treated in a public fertility clinic. Both stimulations were fixed GnRH-antagonist protocol starting on the second or third cycle day using 150 mg corifollipin-α. GnRH-antagonist 0.25 mg daily was introduced on the 5th stimulation day and continued until the day of ovulation trigger. Additional exogenous gonadotropin was added from the 5th or 6th stimulation day and ovulation was triggered with GnRH-agonist followed by "freeze-all". Between the two stimulations there was a four-day pause.

Main results and the role of chance: The average age of the cohort was 36.7 years (SD 3.6; range 24-42) with a mean antral follicle count of 4.4 (SD 1.9). A total of 52 (96%) patients had previously performed at least one oocyte retrieval with less than four oocytes retrieved. Prior to DuoStim 1, patients had a mean number of 2.8 (SD 1.6) failed cycles. Besides the diagnosis of POR, a total of 45 patients (83%) also had a secondary fertility diagnosis.

The mean number of oocytes retrieved in DuoStim 1 and DuoStim 2 was 2.4 (SD 2.1) and 3.7 (SD 2.6) respectively, hence, a total of 1.2 (95% CI 0.46 – 1.96) more eggs were retrieved in DuoStim 2 compared to DuoStim 1, P = 0.002. Neither the number of embryos frozen nor the cancellation rate was significantly different comparing DuoStim 1 to DuoStim 2.

Only 6% (3/54) patients did not have any oocytes retrieved at all. The overall cancellation rate after retrieval was 41% (22/54) meaning that no top-quality embryo was frozen after both stimulations.

A total of 32 patients went through at least one embryo transfer. The overall ongoing pregnancy rate of the cohort was 20 % (11/54). Four patients still have spare embryos in the freezer.

Limitations, reasons for caution: The drawbacks of this study are the retrospective nature, the small number of patients and differences in the additional gonadotrophins and dose. Whether the results can be related to older Bologna criteria patients is uncertain.

Wider implications of the findings: The results of this study corroborate the results of previous studies, showing that dual stimulation might be an alternative treatment concept with more oocytes retrieved within a shorter time; for the first time long-acting FSH was used for stimulation. Collectively this protocol reduces the treatment burden of the Bologna criteria poor responder patient.

Trial registration number: The study was approved by the Regional Ethical Committee. The study carries no Trial registration number due to its retrospective nature.

P-653 Critical role of HOTAIR long non coding RNA as an epigenetically master regulator of HOX loci genes in Cumulus Cells of patients with PCOS

S.Z. Tabatabaei[1,2], P. Eftekharyazdi[3], M. Hafezi[4], S. Zarei Moradi[1], M. Shahhoseini[1,2]

[1]Reproductive Biomedicine Research Centre- Royan Institute for Reproductive Biomedicine- ACECR, Department of Genetics, Tehran, Iran
[2]Faculty of Basic Sciences and Advanced Technologies- University of Science and Culture- ACECR, Department of Genetics, Tehran, Iran
[3]Reproductive Biomedicine Research Centre- Royan Institute for Reproductive Biomedicine- ACECR, Department of Embryology, Tehran, Iran
[4]Reproductive Biomedicine Research Centre- Royan Institute for Reproductive Biomedicine- ACECR, Department of Endocrinology and Female Infertility, Tehran, Iran

Study question: To assess relationship between *HOTAIR* expression associated with *HOXC & HOXD* clusters and determine functional epigenetic marks in women with PCOS.

Summary answer: Aberrant correlative expression of *HOXC & HOXD* clusters and *HOTAIR* gene in alliance with regulatory epigenetic marks of PCOS patients vs. healthy women was observed.

What is known already: Poly Cystic Ovary Syndrome (PCOS) is the most common endocrinal disorder affecting anovulatory infertility. *HOX* family are genes that have altered expression in human reproductive system disorder. Previous researches have shown that long non coding RNAs do epigenetic regulation of gene expression and play important roles in proliferation, apoptosis and metastatic capacity of cancers. Recent studies revealed *HOX* Transcript Antisense Intergenic RNA (HOTAIR) as lncRNA which has estradiol-dependent activation and epigenetically regulatory functions. *HOTAIR* which is located in *HOXC* genes cluster, could bind with histone modifier complexes and direct to specific *HOXD* cluster that prone to cause their expression switching.

Study design, size, duration: Our study consist of 20 patients with PCOS as a case and 20 fertile women with male infertility problems referred to the Royan Institute to get ICSI under GnRH antagonist protocol as a control population. Cumulus cells (CC) were collected from PCOS patients and fertile. Informed consents were obtained from the participants. Thirty six hours after hCG injection, ovaries were punctured and cumulus oocyte complexes were dissected.

Participants/materials, setting, methods: Total RNA was extracted from CCs and cDNA was synthetized by whole transcriptome amplification kit. Quantitative real-time PCR was performed by use of specific primer for target genes. For the epigenetic evaluation, soluble chromatin was extracted from CCs and chromatin immune precipitation (ChIP) coupled with real-time PCR was performed to quantify both activator (H3K27 methylation) and suppressor (H3K4 demethylation) epigenetic histone modification marks on regulatory regions of *HOXD10* gene as a main target of HOTAIR.

Main results and the role of chance: Obtained data showed significant increase of *HOTAIR* ($P<0.05$), *HOXC6* ($P<0.05$), *HOXC9* ($P<0.05$), *HOXC10* ($P<0.05$), *HOXC11* ($P\leq0.01$), *HOXC12* ($P<0.05$), gene expression in PCOS vs. control group but there were no significant changes in PCOS vs. PCOD group. On the other side, there was a significant decrease in expression of *HOXC8* ($P<0.05$), *HOXC13* ($P<0.05$), *HOXD8* ($P<0.05$), *HOXD9* ($P<0.05$), *HOXD10* ($P<0.05$), *HOXD11* ($P<0.05$), *HOXD12* ($P<0.05$). Interestingly there was no significant changes in *HOXD13* ($P<0.05$) contrary to HOTAIR impression on *HOXD* cluster. All above expression profiles was confirmed by epigenetic evaluation in subsequent.

Limitations, reasons for caution: Due to the small number of participant limitation, larger studies should be needed for the confirmation.

Wider implications of the findings: Current study suggest that there is significant correlation between altered expression of HOX family genes, HOTAIR lncRNA as an epigenetic regulator in PCOS disorder. This project provides new insights to understand the pathogenesis of PCOS.

Trial registration number: Not Applicable.

P-654 Role of measuring serum LH levels 12 hours post agonist trigger and administration of rescue HCG trigger

R.G. Patel, V. Mehta, H. Dayma, D.G. Patel

Sunflower Women's Hospital, Reproductive Medicine, Ahmedabad, India

Study question: Does measurement of serum LH levels 12 hours after agonist trigger and administration of rescue HCG trigger(if LH level <50 IU/L) improve oocyte recovery rate and maturity rate?

Summary answer: This kind of approach does not significantly improve oocyte recovery rate and maturity rate.

What is known already: With advent of antagonist protocol in IVF stimulation it has become common to administer agonist trigger for final oocyte maturation to decrease the risk of OHSS. Even though pregnancy rates are lower and miscarriage rates are higher with fresh embryo transfer in agonist triggered cycles, not much has been published about efficacy of agonist trigger in terms of oocyte recovery rate(eggs retrieved/mature size follicles on day of trigger administration) and maturity rate(metaphase II/eggs retrieved). There are few studies reporting lower oocyte recovery rate with agonist trigger if serum LH level < 15IU/L 12 hours post trigger administration.

Study design, size, duration: Retrospective study of 100 patients undergoing IVF-ICSI freeze all cycles with own eggs on flexible antagonist protocol at our centre between April – May 2016 and April- May 2017

Participants/materials, setting, methods: Group 1–50 patients triggered with agonist and serum LH levels not performed (April – May 2016)

Group 2–50 patients triggered with agonist and serum LH levels performed approximately 12 hours after trigger. If levels were below 50 IU/L, injection HCG 2000 units was administered immediately, and ovum pick up was performed 36 hours post agonist trigger. (April- May 2017)

Group 2 A (LH < 15IU/L)
Group 2B (LH 15-30IU/L)
Group 2 C (LH 30-50IU/L)
Group 2D (LH >50IU/L)

Main results and the role of chance: On an average 20 eggs were retrieved per patient in group 1 and 21 eggs were retrieved per patient in group 2(p value – 0.15). There was no significant difference in oocyte recovery rate (oocytes retrieved/follicles > 14 mm on day of trigger administration) between the two groups. (87% in group 1 and 83.9% in group 2, p value- 0.26). There was only one patient with empty follicle syndrome in group 1 and none in group 2. Oocyte maturity rate (metaphase II / eggs retrieved) was also similar between both groups. (Group 1 – 71%, Group 2 – 72.3%, p value- 0.46). No patient had LH levels <15IU/L in our study, 2 patients(4%) had LH level measuring 15-30 IU/L and 10 patients(20%) had LH level measuring 30-50 IU/L. In group 2B(LH <30IU/L), oocyte retrieval rate was lower than remaining 2 groups (Group 2B-59.5%, Group 2C- 90.3%, Group 2D- 90.6%). We had no incidence of OHSS in any of the patients.

Limitations, reasons for caution: Retrospective nature of the study and participants selected over 2 different time spans. Administration of HCG may pose a patient at risk of OHSS. Majority of the participants were hyper-responders undergoing all freeze cycles to avoid risk of OHSS(results cannot be extrapolated to all).

Wider implications of the findings: Measuring LH levels 12 hours post agonist trigger and administration of rescue HCG trigger does not improve oocyte recovery rates even if LH level was<30 IU/L(Incidence 4%). This kind of approach will just add to patient inconvenience, cost and pose them at risk of OHSS.

Trial registration number: not applicable.

P-655 FSH exposure between day 8 and day of hCG administration is an independent predictor of serum progesterone rise

H.M. Fatemi[1], G. Griesinger[2], V. Valerie Teal[3], N.P. Polyzos[4], E. Bosch[5], B. Johnson[6], B. Lawrenz[7], S. Dos Santos Ribeiro[8], J. Garcia Velasco[9], D. Stoop[10]

[1]IVI, Middle east, Abu Dhabi, United Arab Emirates

[4]Dexeus, art, barcelona, Spain
[5]IVI, art, valencia, Spain
[6]MSD, asia pacific, adelaid, Australia
[7]ivi me, art, abu dhabi, United Arab Emirates
[8]uzbrussel, Crg, brussels, Belgium
[9]ivi, art, madrid, Spain
[10]msd, art, brussels, Belgium

Study question: What is the effect of additional recFSH administration after one dose of corifollitropin alfa (CFA) on the progesterone rise on the day of final oocyte maturation?

Summary answer: While little increase in progesterone levels is observed after seven days of CFA stimulation, post-CFA recFSH dosing is the strongest determinant of subsequent progesterone rise.

What is known already: Late-follicular progesterone (LFP) increase is related to both ovarian response and the intensity of FSH exposure during controlled ovarian stimulation (COS). CFA-treated patients who reach the hCG triggering criteria without need for additional daily recFSH (<8days) have a lower incidence of elevated progesterone >1.5 ng/ml when compared to daily recFSH treated controls. This suggests that the pharmacokinetic profile of CFA, with its progressively declining FSH activity, also may reduce the progesterone rise. However, it remains unclear why favourable progesterone levels on the day of hCG administration are not observed in patients who need additional recFSH after CFA (>8days).

Study design, size, duration: A post-hoc subgroup data-analysis of three previously published trials; ENGAGE, ENSURE and PURSUE was performed. All were randomized double-blind trials comparing the efficacy of ovarian stimulation with 150 µg (ENGAGE/PURSUE) or 100 µg (ENSURE) CFA versus a recFSH control group. In both arms, recFSH doses were adjusted according to ovarian response. Cycles with a duration of ovarian stimulation >8 days, which includes all CFA cycles requiring additional recFSH (n = 1234) and their daily recFSH controls (n = 1026), were included.

Participants/materials, setting, methods: The studies included women aged 18–42 years with a regular menstrual cycle (24–35 days), and an indication for ovarian stimulation for IVF/ICSI. All trials were multicentre and multinational involving centres in Europe, North America and Asia. Treatment cycles <8 days were excluded. Progesterone levels were obtained on days 1, 8 and the day of hCG administration. Linear regression analysis was performed to assess the factors contributing to the serum progesterone levels.

Main results and the role of chance: Patient's demographics and baseline characteristics were comparable between groups. Mean progesterone levels on day 8 of stimulation were significantly lower in the CFA group when compared to the recFSH arm (0.6 ± 0.3 ng/ml vs. 0.9 ± 0.4 ng/ml; p<0.001), with a four-fold lower incidence of progesterone levels >1.5 ng/ml (2.2% vs. 8.7%; p<0.001). However, progesterone levels on day of hCG were comparable between groups (1.1 ± 0.7 ng/ml vs. 1.2 ± 0.6 ng/ml; p = 0.18), owing to a significantly sharper increase in progesterone levels between day 8 and the day of hCG administration in CFA-stimulated cycles (0.5 ± 0.5 ng/ml vs. 0.3 ± 0.3 ng/ml; p<0.001). Multivariable linear regression analysis, controlling for age and progesterone on Day 8, showed that the post-CFA progesterone increase was independently associated with the number of days of recFSH stimulation from day 8 onwards (0.10 ng/ml per day; 95% CI 0.08-0.12; p<0.001), the daily dose of post-CFA recFSH (0.08 ng/ml per 50 IU; 95% CI 0.05-0.11; p<0.001) and the number of oocytes retrieved (0.02 ng/ml per oocyte; 95% CI 0.01-0.02; p<0.001).

Limitations, reasons for caution: Although this post-hoc analysis is of importance to generate hypotheses on strategies to minimize progesterone rise, prospective randomized trials are needed to confirm whether reduced post-CFA recFSH dosing could prolong the favourable effect of CFA on progesterone levels without a clinically relevant impact on the ovarian response.

Wider implications of the findings: This study found that CFA treatment has a lower incidence of elevated progesterone during the first week of treatment compared to a daily recFSH regimen. Moreover, it suggests that lower daily recFSH doses following CFA could significantly contribute to maintaining these favourable progesterone levels until the day of hCG.

P-656 The Effect of Alpha Lipoic Acid on expression of IRS-1, GLUT-4, and folliculogenesis in Polycystic Ovary Syndrome with insulin resistance

R. Rusnaidi

Dr. Soetomo General Hospital- Surabaya, Obstetrics & Gynecology, Surabaya, Indonesia

Study question: This study aimed to prove the effect of Alpha Lipoic Acid on expression of IRS-1, GLUT-4 and folliculogenesis of PCOS model rats with insulin resistance.

Summary answer: After administering ALA, expression of IRS-1 and GLUT-4 were higher. There was no difference in folliculogenesis but there was significant difference in de Graff follicles.

What is known already: Polycystic Ovary Syndrome (PCOS) is a frequent endocrine disorder in women of reproductive age where insulin resistance plays an important role. Insulin resistance complicates optimal treatment of infertility. Administration of Alpha Lipoic Acid (ALA) is expected to be an alternative therapy in clomiphene citrate resistant PCOS and in PCOS which has side effects on metformin.

Study design, size, duration: This study used randomized post-test only control group design. The sample size was 30 female rats (rattus norvegicus). This study was conducted in February until May 2017 in Faculty of Veterinary, Universitas Airlangga, Surabaya.

Participants/materials, setting, methods: 30 female rats were given 100 mg/kg B testosterone propionate injection for 28 days to form PCOS model with insulin resistance. Then, they were divided into 3 groups randomly. Group I was negative control, group II got placebo, and group III got ALA. The expression of IRS-1 and GLUT-4 were assessed by Immuno Reactive Score (IRS) on immunohistochemical examination. Folliculogenesis was assessed by counting the number of follicles at each stage through Hematoxylin Eosin (HE).

Main results and the role of chance: The mean expression of IRS-1 in muscle of treatment group (4.28 + 1.05) was significantly higher than placebo (3.02 + 1.03) (p = 0.01). The mean expression of IRS-1 in ovary of treatment group (7.78 + 1.10) was significantly higher than placebo (3.06 + 1.56) (p <0.01). The mean expression of GLUT-4 in muscle of treatment group (4.28 + 0.91) was significantly higher than placebo (3.20 + 1.14) (p = 0.01). The average number of primary follicles in treatment group (58,00 + 13,11) was significantly lower than placebo (66,00 + 19,81) (p = 0,55). The average number of secondary follicles of the treatment group (18.00 + 4.62) was significantly lower than placebo (27.00 + 10.82) (p = 0.10). The average number of tertiary follicles of the treatment group (2.00 + 1.56) was significantly lower than placebo (4.00 + 1.89) (p = 0.13). The average number of de Graff follicles of the treatment group (5.00 + 3.37) was significantly higher than placebo (2.00 + 0.82) (p <0.01). The average number of corpus luteum of the treatment group (9.00 + 3.37) was significantly higher than placebo (6.80 + 3.58) (p = 0.13).

Limitations, reasons for caution: This study has limitation that it did not use normal rats control.

Wider implications of the findings: ALA can be used as an alternative therapy in PCOS patients with clomiphene citrate resistance, especially for women who cannot tolerate the side effects of metformin.

Trial registration number: Not applicable.

P-657 Among Bologna poor responders, does the type of GnRH analogue play any role when corifollitropin alfa is used?

J. Errazuriz[1,2], P. Drakopoulos[1], D. Pening[1,3], A. Racca[1,4], N. De Munck[1], M. De Vos[1], H. Tournaye[1], C. Blockeel[1,5]

[1]*Universitair Ziekenhuis Brussel- Vrije Universiteit Brussel, Center for Reproductive Medicine, Brussels, Belgium*
[2]*Clínica Alemana, Center for Reproductive Medicine, Santiago, Chile*
[3]*Université libre de Bruxelles, Faculté de Médecine, Brussels, Belgium*
[4]*University of Genoa - IRCCS AOU San Martino, Academic Unit of Obstetrics and Gynecology, Genoa, Italy*
[5]*University of Zagreb-School of Medicine, Department of Obstetrics and Gynecology, Zagreb, Croatia*

Study question: Does the type of GnRH analogue in different stimulation protocols affect cumulative live birth rate (CLBR) in Bologna poor responders treated with corifollitropin alfa (CFA)?

Summary answer: CLBR remains similar in different stimulation protocols using corifollitropin alfa in poor responders. However, the GnRH antagonist protocol results in more supernumerary embryos cryopreserved.

What is known already: In normal responders, CFA may increase the number of oocytes retrieved compared to recombinant FSH (rFSH). Preliminary studies using CFA in poor responders have also shown promising results in this poor prognosis population. However, it remains unclear which protocol (GnRH-antagonist, long GnRH-agonist or short GnRH-agonist) represents the ideal therapeutic approach when using CFA in poor responders.

Study design, size, duration: This is a large retrospective analysis including poor responder patients fulfilling the Bologna criteria and undergoing their first ICSI cycle with CFA, between 2011 and 2017. The study population was divided according to the ovarian stimulation protocol into three categories: long GnRH-agonist, short GnRH-agonist and GnRH-antagonist. The starting dose of CFA was 150 µg. CLBR was defined as the delivery of a live born resulting from fresh and all subsequent frozen embryo transfers.

Participants/materials, setting, methods: In the GnRH-antagonist fixed protocol, CFA was started on day2 (D2) of the cycle and GnRH-antagonist was initiated on D6. In the long GnRH-agonist, patients started the agonist from D21 of the previous cycle and CFA was initiated following confirmation of ovarian suppression. For the short protocol, GnRH-agonist was administered from D2 of the cycle and CFA from D3. If necessary, daily injections of hp-HMG (300 IU) were given from D8, until hCG-trigger.

Main results and the role of chance: A total of 757 cycles were divided into 3 groups: group A (antagonist protocol, n = 437), group B (long-agonist protocol, n = 231) and group C (short-agonist protocol, n = 89). There were no differences in baseline characteristics among the groups, including age and ovarian reserve markers. Days of additional hp-HMG following CFA were significantly different between group A, B, and C (3 vs 5 vs 3; *p*=<0.001). There were no differences among the groups in terms of number of mature oocytes, fertilization rate, embryo quality on day 3 and day of embryo transfer. CLBR were 21.0%, 20.8% and 16.9% (*p* = 0.68), respectively, for the three study groups.

Limitations, reasons for caution: The main limitation of our large study is its retrospective design which is inherent to risk of bias.

Wider implications of the findings: This is the largest analysis including Bologna poor responders stimulated with CFA. Based on our results, different CFA protocols do not increase CLBR. However, the antagonist protocol may result in more supplementary frozen embryos.

Trial registration number: not applicable.

P-658 Effect of simvastatin on improvement of polycystic ovary syndrome (PCOS) induced by Dehydroepiandrosterone (DHEA) in rats

M.H. Bahadori[1], E. Mirzajani[2], R. Habibi[2], M. Balani[2]

[1]*Gilan University of Medical Sciences, Cellular and Molecular Research Center, Rasht, Iran*
[2]*Guilan university of medical sciences, Cellular and molecular research center, Rasht, Iran*

Study question: What is the role of simvastatin to protect polycystic ovary syndrome (PCOS) induced with Dehydroepiandrosterone (DHEA)

Summary answer: Its seems simvastatin decrease the damaging influence of Dehydroepiandrosterone (DHEA) on rat polycystic ovary syndrome model.

What is known already: Polycystic ovarian syndrome (PCOS) is the most common endocrine disorders in women and the most common diagnostic criteria are hyperandrogenism, ovulatory dysfunction, and polycystic ovarian morphology. Also Pro-inflammatory cytokines, such as tumor necrosis factor alpha (TNF-α), have been confirmed to be elevated in at least a subcategory of women with PCOS. On the other hand, statins (including simvastatin) not only improve lipid profiles, but also decrease inflammatory markers, ovarian size, and oxidative stress. Moreover, the aim of this study was to investigate the protective effect of simvastatin against polycystic ovarian syndrome (PCOS) induced by Dehydroepiandrosterone (DHEA) in the female rats.

Study design, size, duration: A total of 60 Wistar female rats were randomly distributed into control, DHEA and DHEA + simvastatin (n = 20 per group) groups. The PCOS rat model was developed by the injection of DHEA (6 mg/100 g body weight diluted in 0.4 ml/rat sesame oil) for each animal during 20 days subcutaneously. Control group received only oil. After then each animal daily received simvastatin (10 mg/100 g orally) during 4 weeks or saline solution as control.

Participants/materials, setting, methods: In all groups, ovarian tissue was evaluated by morphological observation and the follicular theca fibrosis was recorded using trichrome Masson staining and morphometric technique. Serum level of anti-Mullerian hormone (AMH) was analyzed by ELISA. Furthermore, tissues were analyzed by immunohistochemistry to detect TNF-alpha and apoptosis. Data were analyzed by one-way ANOVA followed by Tukey's test using SPSS version 16 software. The p<0.05 was considered significant.

Main results and the role of chance: Our result indicated that PCOS group showed a significant increase in serum levels of anti-Mullerian hormone (AMH) compare to control groups (p <0/05). It also increases the follicular theca fibrosis and thickness of theca and decrease body loss in PCOS group significantly (p <0/05). In comparison with the control and PCOS groups, there was a significant increase in the apoptosis index and TNF-α expression (p <0/05). Also Simvastatin (10 mg/100gr) decreases serum anti-Mullerian hormone

(AMH) in the experimental group compare PCOS group significantly (p <0/001). Moreover, compared with the PCOS group, both follicular theca fibrosis and thickness of theca decreased but it's not significant. The apoptosis index was lower (p<0.05) and TNF-α expression was lower (p<0.05) in the simvastatin-treated groups.

Limitations, reasons for caution: It's in only one species and further data are required to better define the polycystic ovarian syndrome.

Wider implications of the findings: We concluded simvastatin could be useful to prevent the harmful effects of PCOS in polycystic ovarian syndrome (PCOS) induced by Dehydroepiandrosterone (DHEA) in the female rats.

Trial registration number: The results of this study indicated that Master of Science thesis in Guilan University of medical sciences with No: 102 and.

P-659 Occurrence and characteristics of recombinant human follicle-stimulating hormone (r-hFSH) dose adjustments during ovarian stimulation in a real-world US database study of 33,962 IVF patient cycles

M. Mahony[1], B. Hayward[2], K. Richter[3], T. D'Hooghe[4]

[1]EMD Serono- Inc., Medical Affairs - Endocrinology/Reproductive Health, Rockland-MA, U.S.A.
[2]EMD Serono- Inc., Global Biostatistics & Epidemiology, Rockland- MA, U.S.A.
[3]Shady Grove Fertility Reproductive Science Center, Research, Rockville, U.S.A.
[4]Merck KGaA, Global Medical Affairs Fertility, Darmstadt, Germany

Study question: What is the real-world occurrence of r-hFSH dose adjustments during IVF cycles and what are the demographics and baseline characteristics of patients with dose adjustments?

Summary answer: Dose adjustments were observed during 40.7% of cycles analysed and there were clinical differences in patients whose dosing was constant versus those with dosing adjustments.

What is known already: Standard practice during individualized ovarian stimulation with r-hFSH is to tailor the starting dose according to a variety of biomarkers (age; BMI; previous ovarian response; ovarian reserve markers like antral follicle count [AFC], anti-Müllerian hormone [AMH], FSH level). In addition, many physicians adjust FSH dose depending on individual ovarian response during ovarian stimulation. Although this is considered common practice, it has been proposed that it is sufficient to maintain the starting dose of FSH without dose adaptation. There is a lack of real-world data documenting the prevalence of dose adjustments and the characteristics and demographics of patients receiving dose alterations.

Study design, size, duration: Non-randomized, observational, retrospective analysis of a large, US, real-world, electronic de-identified medical records database (IntegraMed America, Inc.), including data from >15 ART clinics serving patients from all 50 states. Data for patients receiving any GONAL-f presentation (r-hFSH; EMD Serono, Inc., Rockland, MA, USA) during IVF cycles between Jul 2009 and Dec 2016 were analysed.

Participants/materials, setting, methods: Outcomes evaluated included: overall number of cycles with a constant dose; number with at least one dose adjustment; number with a dose increase; number with a dose decrease; and the subset with both decreases and increases; the mean (standard deviation [SD]) start, end and total r-hFSH (GONAL-f) doses; and patient baseline characteristics according to dosing pattern. Dosing data were evaluated per cycle. The first cycle per patient was evaluated for patient demographics and baseline characteristics.

Main results and the role of chance: A total of 23,582 patients undergoing 33,962 IVF cycles included 13,823 cycles (40.7%) with r-hFSH dose adjustments; 40.0% (5524) of these involved more than one dose change. Among cycles with dose changes, ≥1dose increase was observed in 7939 (57.4%) cycles, ≥1 dose decrease in 8639 (62.5%) cycles and both increases and decreases in 2755 (19.9%) cycles. The mean (SD) starting dose (IU) was higher in cycles with constant dose (292[133.2]) compared with those with dose adjustments (238[122.6], 258[133.3] and 231[149.9] for cycles with ≥1 dose increase, ≥1 decrease and both increases/decreases, respectively; all p<0.0001). The median dose adjustment in all three dose adjustment groups was 75 IU. Patients treated with a constant dose were significantly older (35.9 [4.60] years), had a lower AFC (12.8[7.83]), had a lower AMH (2.2[2.90] ng/mL) and a higher day 3 FSH (8.2[4.81] mIU/mL) compared with cycles with dose adjustments (increases, decreases and both increases/decreases). Patients with constant dosing were more likely to have a diagnosis of diminished ovarian reserve (25.2%) versus those with dose adjustments (20.1%, 15.9% and 14.0%) and were less likely to have ovulatory disorders (10.6% versus 15.2%, 18.3% and 19.2%) for dose increases, decreases and both increases and decreases.

Limitations, reasons for caution: This was a retrospective, observational study of US real-world data, not specifically collected for research purposes, and may not reflect clinical practices in other parts of the world. In addition, diagnostic and drug use information may not always be validated or complete.

Wider implications of the findings: Individualized r-hFSH dose adaptation, depending on ovarian response, is highly prevalent during ovarian stimulation for ART in real world practice in the USA. These dose adjustments are used for all patient types, and more frequently in younger patients with higher ovarian reserve and diagnosis of ovulation disorders/PCOS.

Trial registration number: N/A.

P-660 Long-term health related quality of life (HRQoL), life satisfaction and health status in women with PCOS–a population-based follow-up analysis at ages 31 and 46

S. Karjula[1], L. Morin-Papunen[1], J. Auvinen[2], S. Franks[3], M.R. Järvelin[4], J. Tapanainen[5], J. Jokelainen[6], J. Miettunen[2], T. Piltonen[1]

[2]University of Oulu- Medical Research Center Oulu and Oulu University Hospital, Center for Life Course Health Research, Oulu, Finland
[3]Imperial College, Institute of Reproductive and Developmental Biology, London, United Kingdom
[4]Imperial College, Department of Epidemiology and Biostatistics- Medical Research Council-PHE Public Health England Centre for Environment & Health- School of Public Health, London, United Kingdom
[5]Oulu University Hospital- University of Oulu- Medical Research Center Oulu-PEDEGO Research Unit Oulu- University of Helsinki and Helsinki University Hospital, Obstetrics and Gynecology, Oulu- Helsinki, Finland
[6]University of Oulu, Faculty of Medicine, Oulu, Finland

Study question: Do the health-related quality of life (HRQoL), life satisfaction and self-estimated health status in PCOS change over time between ages 31 and 46 years?

Summary answer: Women with PCOS presented with decreased HRQoL and poor life satisfaction and health status up till age 46 independent of hyperandrogenism and BMI.

What is known already: PCOS is a common syndrome affecting 5-18% of women at reproductive age. The syndrome is mainly characterized as reproductive and metabolic disorders, however, it has become evident that the women also often have psychological problems. Obesity, diabetes, metabolic syndrome, irregular cycles, infertility, psychological distress and aesthetic concerns like acne and hirsutism burden these women, decreasing their HRQoL. As some of the syndrome-related issues and symptoms become untimely (infertility) or they resolve (menstrual irregularities) over time, it would be of interest to assess how HRQoL, life satisfaction and self-estimated health status change over time in these women.

Study design, size, duration: In a prospective, general population-based follow-up birth cohort (n = 5889 females), postal questionnaires were sent at ages 14, 31 and 46 yrs with respective answer rates of 95, 81 and 72%. Questionnaires on PCOS symptoms (31 yrs), 15D HRQoL, life satisfaction and self-estimated health status (31 and 46 yrs) and BMI (14, 31 and 46 yrs) were analyzed. Clinical examination and testosterone measurement were performed at age 31 (3115 women) and 46 (3280 women).

Participants/materials, setting, methods: According to questionnaires, 331 women (11.2%) presented isolated oligoamennorrhea (OA) and 323 (10.9%) isolated hirsutism (H) and 125 (4.2%) presented both symptoms (PCOS), whereas 2188 asymptomatic women where considered as controls. The 15D scores were analysed with Kruskal-Wallis H-test, life satisfaction and

self-estimated health status with chi-square analysis. The risks related to PCOS symptoms were estimated using a logistic regression model.

Main results and the role of chance: In all four study groups HRQoL decreased over time. In women with PCOS and in women with isolated H the HRQoL was decreased both at ages 31 and 46 compared with controls whereas there was no difference in the sum score in women with isolated OA. The individual HRQoL that differed between PCOS and controls were at age 31: vitality, mobility, breathing, sleeping, excretion, discomfort and complaints and at age 46: vitality, mobility, vision, hearing, sleeping, excretion, usual activities, discomfort and complaints and depression. Women with PCOS presented 3.8-fold risk for being in the lowest HRQoL quartile at age 31 and 2.5 –fold risk at age 46. The risk remained significant after adjusting for BMI, testosterone, infertility and marital and socioeconomic status. Women with isolated H or PCOS also associated with risk of low life satisfaction at age 31 (H: OR1.57 95% CI [1.06, 2.34], PCOS: 2.64 [1.59, 4.39]) and PCOS group at age 46 (2.11 [1.59, 3.84]) compared with controls. Moreover, PCOS also associated with risk of poor self-reported health status age 31 (3.60 [1.84, 7.05]) and 46 (3.85 [1.89,7.85]).

Limitations, reasons for caution: The symptoms of PCOS were self-reported and no ultrasound examinations were available. The study population was relatively young for assessing some items included in the 15D tool.

Wider implications of the findings: PCOS and isolated H associates with low HRQoL from fertile age until late reproductive years. As women with PCOS are at risk for reporting poor life satisfaction and health status at age 31 and 46, more studies aiming to improve HRQoL in these women are warranted.

Trial registration number: not applicable.

P-662 Co-administration of GnRH-agonist and a standard dose of hCG (dual trigger) for improving IVF outcome in patients with low proportion of mature oocyte

L. Wang, Y. Wang

Peking University Third Hospital, Department of Obstetrics and Gynecology, Beijing, China

Study question: Whether the Co-administration of GnRH-agonist and standard hCG (dual trigger) can be used for improving IVF outcome in patients with low proportion of mature oocyte?

Summary answer: For patients who have normal ovarian response but low proportion of mature oocytes, dual trigger can help improving their IVF outcome.

What is known already: Oocyte maturation occurs after the luteinizing hormone(LH) surge during the menstrual cycle. As a surrogate LH surge, GnRH-agonist and Human chorionic gonadotropin(hCG) are usually used at the end of controlled ovarian hyperstimulation(COH) to induce final follicular maturation. Patients who have low oocyte maturity or the inability to retrieve mature oocytes have poorer IVF outcomes compared with those who have more mature oocyte obtained. Now it is more frequent to see that normal responding patients with an apparently normal follicular development and E2 levels on the day of HCG injection result in low proportion of mature oocyte.

Study design, size, duration: Retrospective study was preformed to compare the stimulation characteristics of 366 IVF cycles from March 2016 to August 2017. Patients were given combination of Group A (dual trigger group, n = 123), Group B(Group A's patients' previous IVF attempt, triggered with hCG-only, n = 123), Group C (different patients form Group A, triggered with hCG-only, n = 120).

Participants/materials, setting, methods: Patients who were eligible for this study must be normal response and have a prior IVF cycle with low proportion of MII oocytes(<66%) per number oocytes retrieved. During the previous cycle, patients underwent various IVF stimulation protocols and were triggered with hCG only (5,000IU or 10,000IU). For the dual trigger cycle, patients underwent a GnRH antagonist COH protocol and dual trigger(0.2 mg GnRH-agonist plus 250ug rhCG) was preformed 36 hours prior to OPU.

Main results and the role of chance: The basic characteristic date including age, ART indications, duration of infertility, based hormonal level between the three groups were not statistically significant. The number of metaphase-II (MII) oocyte in the dual trigger group is significantly higher than Group B and Group C (6.9vs 3.4vs 4.0, p<0.05). In addition, patients who received dual trigger (group A) had a significantly higher number of top quality embryos (TQE) (1.6vs 0.7vs 0.6, p<0.05), number of embryos transferred(1.1vs 0.5vs 0.5, p<0.05), rate of clinical pregnancy (0%vs 18%vs 2%, p<0.01) while lower rate of cycle cancellation (10.2%vs 28.1%vs 20.3%, p<0.05) than the other two groups.

Limitations, reasons for caution: Our study suggested a higher pregnancy rate in the study group(dual trigger). However, this is biased due to our study design which offered this protocol to patients who had failed their previous IVF attempt. Further multicenter prospective studies are needed to strengthen our current findings.

Wider implications of the findings: This study is based on a large sample of data which may provide some new insights to treat patients who appear to have normal ovarian response and follicular development but low proportion of mature oocyte.

Trial registration number: not applicable.

P-663 Relevance of prednisolone treatment in patients with multipronuclear embryos caused by anticentromere antibodies: improvement of fertilization, blastocyst formation and pregnancy rates

M. Inoue[1], S. Mizuta[1,2], H. Matsubayashi[1,2], T. Takeuchi[2], K. Kitaya[1], T. Ishikawa[1,2]

[1]*Reproduction Clinic Osaka, reproductive medicine, Osaka, Japan*
[2]*Reproduction Clinic Tokyo, reproductive medicine, Tokyo, Japan*

Study question: To investigate whether prednisolone treatment may improve fertilization, blastocyst formation and pregnancy rate in patients with multipronuclear embryos caused by anticentromere antibodies.

Summary answer: We retrospectively confirmed prednisolone significantly improved fertilization, blastocyst formation and pregnancy rate in patients with multipronuclear embryos caused by anticentromere antibodies compared to no prednisolone.

What is known already: Women with anticentromere antibodies have been reported to show impaired oocyte maturation, fertilization, embryo cleavage and pregnancy rates. Sometimes their embryos showed increasing amount of multipronuclear embryos (3 pronuclei or more). Based on mouse studies, injection of anticentromere antibodies interfered with meiosis and mitosis by attachment of anticentromere antibodies to the centromeric region of a chromosome. Those embryos showed impaired oocyte maturation, fertilization, embryo cleavage and blastocyst formation rates as shown in human observations. However, the precise mechanism caused by anticentromere antibodies needs further investigation. To the best of our knowledge, no therapeutic studies have been reported.

Study design, size, duration: A single-center retrospective study was performed. All patients gave written informed consent for this study. Patients who performed in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI) between May 2014 and December 2017 were included in the study. Serum anticentromere antibodies were measured using CLEIA method by a clinical laboratory company, and positive anticentromere antibodies were defined as more than 10 IU/mL. Of 4651 women, 45 women had anticentromere antibodies (0.97%), performing 94 IVF/ICSI cycles.

Participants/materials, setting, methods: The average age of the positive anticentromere antibodies was 38.5 ± 3.6 years. We divided 94 cycles into two groups with or without prednisolone (64 and 30 cycles), and compared fertilization, blastocyst formation and pregnancy rates between two groups. Prednisolone (15 mg/day) was administered orally from the first day of ovarian stimulation to the day before oocyte retrieval. Ovarian stimulation protocols were similar between two groups, because those were set according to patients' age and AMH levels.

Main results and the role of chance: In the ICSI group, two pronuclear (2PN), multipronuclear, cleavage, and blastocyst formation rates with prednisolone group were significantly (P<0.05) better than those without prednisolone (41.2% vs. 20.2%, 28.1% vs. 39.4%, 62.4% vs. 41.4%, 24.1% vs.

0%), respectively. In the IVF group, however, no significant differences were observed between the two groups (20.0% vs. 19.8%, 45.3% vs. 42.3%, 40.0% vs. 29.2%, 31.3% vs. 15.4%), respectively. The titer of the anticentromere antibodies was not related to 2PN or multipronuclear rate. Clinical pregnancies were confirmed in 6 patients from prednisolone group only; 3 patients had live births and 2 patients are ongoing pregnancies. Implantation rate with prednisolone group was significantly (P<0.05) higher than that without prednisolone (7/39 vs. 0/32). Seven patients experienced both cycles with or without prednisolone. In the ICSI group of these patients, 2PN rate with prednisolone (44.3%, 47/106) significantly increased compared with that without prednisolone (20.6%, 13/63). The titer of the anticentromere antibodies in patients who improved fertilization rate with prednisolone was significantly lower than that in patients who did not (P<0.001). Patients who may benefit from prednisolone might be low titer of the anticentromere antibodies.

Limitations, reasons for caution: Since this study is a single center retrospective observational study, multi-center prospective randomized studies are needed to conclude the relevance of prednisolone treatment in patients with multipronuclear embryos caused by anticentromere antibodies. To the best of our knowledge, however, there are no studies for treatment strategies in these patients.

Wider implications of the findings: We, for the first time, revealed relevance of prednisolone treatment in patients with multipronuclear embryos caused by anticentromere antibodies. Oral prednisolone (15 mg/day) successfully improved fertilization, blastocyst formation rates and may improve pregnancy rate in patients with positive anticentromere antibodies in our limited study population.

Trial registration number: N/A.

P-664 The serum ProAMH/totalAMH ratio is linked to metabolic status but not to Polycystic Ovary Syndrome (PCOS) per se

M. Peigné[1,2,3], P. Pigny[4], D. Dewailly[2,3], P. Giacobini[2], S. Catteau-Jonard[2,3]

[3]*CHU Lille, Department of Endocrine Gynecology and Reproductive Medicine- Univ. Lille 2, F-59000 Lille, France*
[4]*CHU Lille, Service de Biochimie et Hormonologie- Centre de Biologie Pathologie-, Lille, France*

Study question: Is the ProAMH/totalAMH ratio decreased in Polycystic Ovary Syndrome or obese women?

Summary answer: Serum ProAMH/totalAMH ratio is not significantly different between PCOS and control women but is decreased in obese women versus controls.

What is known already: Anti Mullerian Hormone (AMH) is known to inhibit initial and cyclic follicular recruitment. Compared to controls, serum AMH level is higher in PCOS women and is supposed to act in the follicular arrest. Different molecular forms of AMH exist: one inactive (proAMH) and two active which can bind the AMHRII receptor and induce AMH specific actions. The active forms are obtained after proAMH cleavage: AMH_C (C-term domain) and $AMH_{N,C}$ (non-covalent association of N-term and C-term domains). In blood, proAMH and $AMH_{N,C}$ are found, whereas the presence of AMH_C is debated. Different AMH molecular forms ratio are described in different populations.

Study design, size, duration: Cross sectional study using 72 biobanked serum samples collected between 2014 and 2017 in one Academic Hospital.

Participants/materials, setting, methods: In a database prospectively constituted from 2014 to 2017, 39 PCOS women according to Rotterdam criteria (21 obese and 18 lean) and 33 controls (14 obese and 19 lean) were selected. Their biobanked serum were tested for total AMH and pro AMH (after desoxycholate treatment) using a Beckman Coulter Dxi automatic analyser. Relative levels of pro AMH were expressed as a proAMH ratio: [proAMH]/[totalAMH]x100.

Main results and the role of chance: PCOS and control women had similar BMI. Total AMH and Pro AMH levels were higher in women with PCOS compared to controls (p<0.001). They were not significantly different between obese and lean women (p = 0.427 and p = 0.96, respectively). ProAMH/totalAMH ratio was not significantly different between control and PCOS women (38.2 % vs 35.9%; p = 0.38). However, it was significantly decreased in obese (PCOS and control) women compared to lean ones (34.7% vs 39.4%; p<0.001). In the subgroups analysis, ProAMH/totalAMH was different between lean and obese women with PCOS (p = 0.001) but not between lean and obese controls (p = 0.15). With univariate analysis, ProAMH/totalAMH was negatively correlated to weight, BMI, waist circumference and fasting insulinemia. No correlation was found with androgens, LH or ovulation disorders.

Limitations, reasons for caution: Small sample size, limiting statistical power in subgroup analysis.

Wider implications of the findings: Metabolic status may have an impact on proAMH cleavage enzymes leading to an increased rate of circulating active AMH forms in obese women (with or without PCOS). Further studies on larger populations are required to study whether they may contribute to ovulation disorders in PCOS women and control obese women.

Trial registration number: Not Applicable.

P-665 Long-Antagonist protocol; single luteal use of long-acting GnRH-antagonist Degarelix can efficiently downregulate LH during ovarian stimulation for IVF. A proof of concept

E. Papanikolaou[1], H. Yarali[2], E. Timotheou[3], P. Tatsi[3], T. Chartomatsidou[3], M. Grynberg[4], O. Zafeiratis[1], C. Vlachou[5], I. Asouchidou[6], H. Tournaye[7], R. Najdecki[1]

[6]*Medical Department, Aristotle University of Thessaloniki, Greece*
[7]*Centre for Reproductive Medicine, Department Gynecology-Fertility, Brussels, Belgium*

Study question: Does a single luteal dose of long-acting GnRH-antagonist efficiently downregulate hypophysis during ovarian stimulation for IVF?

Summary answer: A single dose of long-acting antagonist Degarelix, during luteal phase, down-regulates LH resulting in no LH rise and production of mature oocytes and implantable embryos.

What is known already: Contrary to GnRH-agonist treatment, GnRH-antagonists block GnRH receptors by competitive binding. Therefore, GnRH-antagonist eliminates various disadvantages observed when using GnRH-agonists especially reducing Ovarian Hyperstimulation Syndrome risk (OHSS), without decreasing the likelihood of live birth. Nevertheless, limited flexibility in cycle programming and asynchrony of the follicular cohort are considered drawbacks. Consequently, despite the benefits of antagonist protocols, long-agonist protocol is still the preferred treatment in the majority of IVF clinics. We hypothesized whether a single luteal dose of long-acting antagonist causes prolonged suppression of LH rise allowing thus flexibility in the starting day of gonadotropins later in the follicular phase.

Study design, size, duration: This proof of concept randomized control trial studied the efficacy of a single dose of long-acting antagonist, Degarelix. The study was performed during January-October 2017. Two groups of patients were compared. Group A (control group) consisted of 10 women, who followed a classic fixed day-6 GnRH-antagonist protocol whereas, Group B (study group) involved 10 women undergoing the new long-antagonist protocol. Both groups involved infertile women prepared to undergo IVF treatment in Assisting Nature Centre.

Participants/materials, setting, methods: According to the protocol, in late luteal phase (day-24) a bolus injection of 0,5 ml Degarelix was administrated subcutaneously to control LH surge in the follicular phase. After menses, ovarian stimulation with gonadotropins was initiated from cycle-day-2 to 10. Different gonadotropin starting days were tested to observe LH level and whether ovarian response is affected by the proximity of stimulation initiation to the day of degarelix injection.

Main results and the role of chance: The mean age of participants was not different (32,1 vs. 32,6) among groups. Stimulation ranged from 9-10 days in control group A, whether in the Long Antagonist group ranged from 10-11 days. Similar number of blastocysts produced in both groups (5.8 vs. 7.0). No LH rise was noticed in any groups. Especially, in the Long Antagonist group one patient was triggered with HCG on cycle-day-22. After fresh embryo transfer, pregnancy efficacy and possible negative effect on endometrium receptivity were assessed. All patients (except one who followed Freeze-all strategy) underwent blastocyst transfer. Clinical pregnancy was 40% in classic antagonist (group A) and 50% in the new Long Antagonist (group B).

Limitations, reasons for caution: The limitation of this study is the small size of the groups, however this is a proof of concept trial. Additionally, other doses of Degarelix could be tested to investigate differences in ovarian stimulation.

Wider implications of the findings: This is a pure novel concept for IVF couples combining security and flexibility. This new Long-Antagonist protocol addresses cycle programming that was missing, with antagonist protocols and almost zeros OHSS as it allows also the triggering with GnRH-agonist. However, larger studies are required to confirm the success of this protocol.

Trial registration number: NCT03240159

P-666 Real-life experience with follitropin delta (FD): dosing inconsistencies based on short AMH changes and treatment outcome in patients of the higher AMH spectrum

M. Depenbusch, K. Neumann, A. Schultze-Mosgau, T. Osterholz-Zaleski, G. Griesinger

University Hospital of Schleswig-Holstein- Campus Lübeck, Department of Gynecological Endocrinology and Reproductive Medicine, Lübeck, Germany

Study question: How often will short-term changes of AMH imply a dosage change? What is the ovarian response to an individualized dose in hyper-response risk patients?

Summary answer: Short term AMH (and body weight) changes occur and affect dose choice. The utility of FD in higher AMH level patients needs further study.

What is known already: Dosing of follitropin delta (FD), which was introduced to the market in 2017, is based on body weight and serum AMH levels (measured in one distinct ELISA within 12 months before treatment). In the phase-III trial (ESTHER-1), excessive ovarian response was less frequent in patients receiving individualized FD doses. There is short-term intra-individual variation in body weight and AMH levels, which may lead to inconsistencies between the dose being prescribed at treatment planning (and drug prescription) and the later time point of actual FD utilization. Furthermore, in the ESTHER-1 trial patients with cycle irregularities and BMI >32.0 kg/m^2 were excluded.

Study design, size, duration: Retrospective analysis of all patients undergoing controlled ovarian stimulation with FD for who, at the outset of FD utilization in our center, it had prospectively been decided to repetitively measure body weight and AMH. The target ovarian response was defined as 8-14 COCs (in line with the primary outcome parameter in the ESTHER-1 trial). FD was used according to the posology. Weight and AMH is expressed ±standard deviation (SD). This study is still ongoing.

Participants/materials, setting, methods: For the initial dosing of FD, recent AMH levels and ad-hoc body weight was used. On day of the first follitropin delta injection, AMH and weight was re-assessed and compared. In two cases, AMH was re-assessed later in the follicular phase under ongoing FD administration. The number of COCs in follitropin delta and previous and/or following stimulation cycles using conventional FSH were analysed. AMH assessment was conducted using the Roche Elecsys ELISA AMH assay.

Main results and the role of chance: To date, 20 patients have been included in this analysis. The mean body weight was 71 ± 12 kg on first assessment and 72.6 ± 14.4 kg on second assessment. Mean AMH was 7.1 ± 3.8 ng/ml and 6.0 ± 2.4 ng/ml on first and second assessment, respectively. This change resulted in a dose adjustment in five patients (25%, 95%CI: 11-47%). In the two patients with another AMH value generated during FD administration, the AMH was approximately halved as compared to pre-treatment values. Individual dosing with follitropin delta achieved a target response in COC number in seven patients (35%, 95%CI: 18-57%), whereas 13 (65%, 95%CI: 43-82%) patients responded off-target. Of the off-target patients, two patients with pre-treatment AMH of 8.4 and 7.4 ng/ml showed an aresponse which led to cycle cancellation, the patient with AMH 8.4 having had produced more than 20 COCs in two previous cycles with conventional FSH dosing. A hyperresponse with GNRH-agonist and freeze-all strategy was observed in six patients (30%, 95%CI: 14-52%). A clinical pregnancy was achieved in six patients out of a total of 11 patients undergoing fresh embryo transfer after using follitropin delta for ovarian stimulation.

Limitations, reasons for caution: Short term AMH changes will not necessarily affect dosing in high AMH women, since the minimum dose still remains to be prescribed. Of note, the patient numbers presented herein are still small.

Wider implications of the findings: The implications of short term AMH and body weight changes on the performance of the individualized dosing algorithm needs to be studied further. Furthermore, the performance characteristics of FD may be modulated by AMH, with a risk of underexposure with the minimal dose.

Trial registration number: n.a.

P-667 Rescue protocol and fresh embryo transfer after trigger with analogs of GnRH

F. Cirillo[1], R. De Cesare[1], V. Scolaro[1], P. Persico[1], V. Canevisio[1], V. Immediata[1], E. Morenghi[2], P.E. Levi Setti[1]

[1]Humanitas Research Hospital, Humanitas Fertility Center- Department of Gynecology- Division of Gynecology and Reproductive Medicine, Rozzano Milan, Italy
[2]Humanitas Research Hospital, Biostatistics Unit, Rozzano Milan, Italy

Study question: Do GnRH agonists (GnRHa) trigger and fresh embryo transfer preserve live birth rate in high responder (HR) patients during in vitro fertilization (IVF) cycles?

Summary answer: In HR patients trigger with GnRHa and the rescue protocol seems to reduce the risk of ovarian hyperstimulation syndrome (OHSS) since ensuring excellent pregnancy outcomes.

What is known already: GnRHa trigger is effective in the induction of oocyte maturation and prevention of OHSS during IVF treatment. The trigger with analogue seems to increase the Abortion Rate (AR) and reduce the Live Birth Rate (LBR), due to the supposed luteal phase dysfunction and impaired endometrial receptivity. Some authors affirm that the solution could be the intensive support of the luteal phase; other authors suggest that the best strategy is the "freeze only" policy.

Study design, size, duration: This is a single center retrospective observational study performed in a tertiary care academic Fertility Center. We analyzed a total of 732 antagonist IVF protocols with GnRHa trigger in the period between 1/03/2013 and 31/12/2016. Among these cohort, 271 patients underwent "rescue protocols" and fresh embryo transfer. The rest underwent a freeze only policy.

Participants/materials, setting, methods: In HR patients (AMH> 3.5 ng / ml and more than 18 follicles with diam. ≥ 12 mm) the trigger was obtained with triptorelin 0.2 mg / sc. In patients considered to be at intermediate risk of OHSS (< 18 oocytes retrieved) a rescue protocol has been applied: HCG 1500 IU / sc. at retrieval + estradiol 4 mg + vaginal progesterone 400 mg a day) and fresh embryo transfer on day 3 or 5.

Main results and the role of chance: Patients included in the study were good prognosis women with a mean age of 34.13 ± 4.42 years and good ovarian reserve (FSH mean baseline of 6.29 ± 1.85 and AMH of 4.85 ± 3.34 ng / mL). The retrieved oocytes were 13.71 ± 4.26 with a recovery rate of 75.6 ± 18.84% and a percentage of M2 oocytes of 79.41 ± 15.30%. The percentage of patients with a recovery rate less than 75% was 30.33% and less than 50% of was 6.15%. A total of 548 embryos were transferred, with an implantation rate of 26% and a pregnancy rate of 39.11%. We stratified patients for transfer: 239 women performed the transfer at cleavage stage and 31 on blastocyst stage on day 5. The pregnancy rate were respectively 38% and 48%. Analyzing the evolution of the 106 pregnancies obtained, our results show: 9 abortions in the first trimester and 2 in the second trimester (10.38% abortion rate), 2 therapeutic abortions (1.8%) and 1 ectopic pregnancy (0.9 %). We had 92 deliveries (LBR

39.49%). We observed 8 cases of OHSS (2.95%): 4 cases (1.48%) were admitted to hospital for observation and medical therapy.

Limitations, reasons for caution: Although this is a single center study with an homogenous population, the retrospective nature of the analysis has wide range of biases, and although limited a risk condition for the patients.

Wider implications of the findings: In HR patients with intermediate risk of OHSS, a GnRHa trigger and rescue protocol allows fresh ET with a relative low risk of OHSS, excellent results in terms of LBR and a reduced time to pregnancy compared to a freeze only policy.

Trial registration number: NA.

P-668 The resting metabolic rate in women with polycystic ovary syndrome and its relation to the hormonal milieu, insulin metabolism and body fat distribution

V. Versace[1], D. Romualdi[1], V. Tagliaferri[2], S. De Cicco[1], V. Immediata[1], R. Apa[1], M. Guido[2], A. Lanzone[1]

[1]Università Cattolica del Sacro Cuore, Department of Obstetrics and Gynaecology, Roma, Italy
[2]Ente Ecclesiastico Ospedale Generale Regionale "F. Miulli", Department of Obstetrics and Gynaecology, Acquaviva delle Fonti, Italy

Study question: Is resting metabolic rate (RMR), a major determinant of energy expenditure, altered in women with polycystic ovary syndrome (PCOS) compared with age- and BMI-matched controls?

Summary answer: PCOS women do not seem to have an abnormal basal metabolism, as their RMR resulted comparable to control women.

What is known already: PCOS women have a higher prevalence of obesity compared to the general population, moreover women with PCOS struggle in their attempt to obtain weight loss and encounter more difficulties in weight control compared with the age and BMI-matched general population. Both genetic and environmental factors seem to be involved in this predisposition. Some authors explored the hypothesis that the energy expenditure capacity could be intrinsically reduced in PCOS, but results deriving from studies with indirect calorimetry and Doubly Labeled Water are still inconsistent.

Study design, size, duration: This is a monocentric observational prospective cohort study. It was conducted for two consecutive years from January 2013 to January 2015 and included 138 subjects.

Participants/materials, setting, methods: 107 Caucasian subjects diagnosed with PCOS, according to Rotterdam Consensus diagnostic criteria and 31 healthy, age-BMI matched control women were enrolled in the study. Energy expenditure evaluation, expressed as RMR, was obtained through the SenseWear Armband (SWA), a reliable and validated metabolic holter, never previously used in the PCOS population to this purpose. Hormonal assessment, insulin metabolism evaluated by HOMA-IR and OGTT, anthropometric features (BMI and WHR) were also assessed.

Main results and the role of chance: In accordance with the study design, age and BMI were similar in the two cohorts: median age was 26.0 ± 9.2 years in PCOS women and 25.5 ± 8.5 years in controls (p = 0.524); median BMI 26.4 ± 9.4 kg/m2 in PCOS women and 27.2 ± 12.8 kg/m2 in controls (p = 0.330). Nonetheless, the body fat distribution resulted significantly different between the two groups, suggesting a tendency towards central body fat accumulation in the PCOS population (WHR 0.79 ± 0.10 vs 0.75 ± 0.10; p = 0.020).

Median RMR resulted similar in PCOS and control women: 1520.0 ± 248.00 kcal/day vs 1464.0 ± 332.70 kcal/day (p = 0.472), even after adjusting for obesity, fat distribution, hyperinsulinemia and insulin resistance (respectively p = 0.164, p = 0.317, p = 0.377, p = 0.232). RMR resulted directly correlated with BMI, WHR, estradiol, total cholesterol, triglycerides, basal blood glucose, basal insulin, AUC insulin 240' and HOMA, while inversely with SHBG. In the subgroup of patients with WHR>0,85, PCOS women showed a significantly lower RMR compared with controls.

Limitations, reasons for caution: The relatively small number of controls might unbalance the sample size, even if an appropriate statistic was carried out. WHR is not considered an accurate estimation of body fat distribution.

Wider implications of the findings: Our results strengthen the scientific evidence regarding the normal capacity of consuming energy of women with PCOS. The finding of a significantly lower RMR rate among PCOS women with WHR>0.85 compared with controls requires further investigation about the role of body fat distribution in the metabolic homeostasis of PCOS population.

Trial registration number: clinicaltrials.gov Identifier NCT03132545

P-669 Childhood and adolescence body mass index associates with impaired reproductive function - a prospective, population-based cohort study

[9]Imperial College London, Institute of Reproductive and Developmental Biology, London, United Kingdom
[10]Imperial College London, Department of genomic of complex diseases- School of Public Health, London, United Kingdom

Study question: What is the contribution of the prenatal environment, birth weight, as well as childhood, adolescence and adulthood body mass index (BMI) for reproductive capacity?

Summary answer: Children and adolescent girls with obesity have increased risk of infertility and childlessness in adulthood. The association seems to be partly independent of adult BMI.

What is known already: Previous studies have shown inverted J-shaped relationship between BMI during adolescence and the number of children later in life. Furthermore, obese girls (BMI95thpercentile) display more menstrual irregularities and can be more affected with infertility problems and inability to become pregnant compared to their normal weight (NW, BMI:5-85thpercentile) counterparts. Timing of adiposity peak (AP, maximum infant BMI at around 9 months) and of adiposity rebound (AR, second rise of BMI at 5-7years) is associated with obesity and unfavorable metabolic profile in adulthood. However, follow-up studies through the whole reproductive life span on the relationship between growth patterns and fertility/parity are limited.

Study design, size, duration: We study data from 5889 women born in 1966 and followed-up from gestational week 24 to age 46.

Postal questionnaires at ages 31 and 46 (answer rates 81% and 72%) addressed questions on infertility problems and treatment. The fecundability ratio (FR) was defined as the probability of pregnancy within 12 months of pregnancy attempt. Self-reported infertility at age 46 ('Have you ever had infertility problems?") and/or self-reported infertility treatments at both ages were asked.

Participants/materials, setting, methods: Prenatal and BMI data were collected by trained personnel at all stages. AR and AP were assessed using REED1 model (infancy, N = 2858, and childhood, N = 3471, separately). BMI Z-scores (for 17 time-windows from ages 2 to 31) were used to model developmental trajectories. Four latent BMI categories were identified. Deliveries were collected from the Finnish birth register. All models were adjusted for education level, marital and socioeconomic status, and smoking.

Main results and the role of chance: Mother's BMI or weight gain during pregnancy as well as birthweight, age at AP, AR or menarche were not associated to problems of infertility or number of deliveries. Compared with NW, obesity at adrenarche and menarche was associated with decreased FRs at age 31 (12.5% vs. 20.6%, OR:1.77, 95% CI [1.04-3.02] and 12.8% vs. 20.4%, OR:1.74 [1.07-2.82], respectively). In comparison to NW group, obesity at menarche, but not at adrenarche, positively associated with more self-reported

infertility (15.4% vs. 28.4%, OR:1.48[1.05-2.08]) and nulliparity (18.3% vs. 23.9%, OR:1.47[1.01-2.13]), but not with self-reported infertility treatments. Women with obesity at menarche and at age 31, but not at age 46, had less deliveries than their NW counterparts (1.80 vs. 2.07, p = 0.023; 1.87 vs. 2.06, p = 0.048, respectively). All those results remained statistically significant after adjusting.

The women in the two highest BMI trajectory groups (Group 3: 'slow weight gainers'; 14.0%) Group 4: 'constant high'; 2.3%) exhibited higher risk for low FRs compared to NW control group (Group 4: OR:3.03[1.22-7.56]); Group 3: OR:1.49[0.97-2.31]). They also tend to have increased risk of self-reported infertility (Group 4 OR:1.64[0.79-3.41]; Group 3: OR:1.49[1.02-2.05]) and nulliparity (Group 4:OR:1.90[1.13-3.19]; Group 3:OR:1.40[1.08-1.81]) and had fewer children (Group 4:1.76 (p = 0.056); Group 3:1.84 (p = 0.002) vs. NW:2.09).

Limitations, reasons for caution: Despite high participation rates throughout all collection points, children's growth data was not available for all participants due to delay in digitalization of hand written healthy records.

Wider implications of the findings: This study reveals that girls affected by obesity during childhood and at adolescence might display reduced fertility capacity in adulthood, partly independently of adulthood obesity. These results support the importance of an active prevention and treatment of obesity already in early childhood.

Trial registration number: not applicable.

P-670 Evaluating the impact of ovarian stimulation on endometrial receptivity and reproductive outcome - A sibling oocyte study

D.K. Kumar[1], P. Gopinath[1], N. S[1], R. R[2], B. John[1], G. Kannoly[1]

[1]*Cimar Cochin Hospital, Infertility, Cochin, India*
[2]*cimarcochin hospital, infertility, cochin, India*

Study question: Does " freeze all " policy improve pregnancy rate?

Summary answer: No, fresh transfer has equal or even better results than frozen transfer.

What is known already: Clinical observations that frozen embryo transfer (FET) reduces the risk of ovarian hyper stimulation syndrome and improves endometrial receptivity has been supported by literature. Evidence which has tilted the balance strongly in favor of deferring fresh transfer. Before we make 'freeze all" a norm, it is important to evaluate its effectiveness.

Study design, size, duration: A sibling oocyte study provides a unique window of opportunity to test this hypothesis by comparing outcomes in ESP (Egg Sharing patient) & ERP (Egg Receiving Patient). This is a prospective study conducted at a tertiary level infertility centre during June 2015 - June 2017.the study include 203 ESP and 276 ERP.

Participants/materials, setting, methods: In this study, the data from oocyte sharing of 203 patients (ESP), all stimulated by conventional long protocol (GnRH agonist) and followed by controlled ovarian stimulation with HMG (150IU-300IU) were included. The oocytes were shared among ESP and 276 anonymous recipients (ERP) after endometrial preparation with HRT.

Main results and the role of chance: This study revealed that pregnancy rate was statistically higher (p = 0.0003) in fresh transfer in ESP than fresh transfer in ERP (70.9% vs 53.2%). The pregnancy rate was statistically higher (p = 0.028) in fresh transfer in ESP than frozen transfer in ESP (70.9% vs 55.7%) with no significant difference (p = 0.588) in mean E2 between positive and negative pregnancy rate. It was observed that pregnancy rate was statistically higher (p = 0.03) in frozen ERP than fresh ERP (67.6% vs 53.2%). The pregnancy rate between fresh ESP and fresh transfer deferred ESP (70.9% vs 78.6%) was similar (p = 0.540).The incidence of OHSS in ESP was mild (4.4%), moderate (1.47%) and severe (0.98%).

Limitations, reasons for caution: The study group was small in no. We require larger groups for better comparison. Also other confounding factors in ERP were not taken into account during the study.

Wider implications of the findings: The statistical analysis of this study showed a better pregnancy rate among fresh transfer in ESP than in ERP or with frozen transfers ESP there by disproving the concept of endometrial affliction in cases of stimulated cycles and alleviating the need to freeze all.

Trial registration number: not applicable.

P-671 Random-start Ovarian Stimulation in Egg donors (ROSE trial). A self-controlled randomized pilot study

J.C. Castillo, A. Bernabeu, J. Guerrero, B. Moliner, J. Llacer, R. Bernabeu

Instituto Bernabeu, Reproductive Medicine, Alicante, Spain

Study question: Can we expect a similar oocyte yield after randomly initiating ovarian stimulation during the follicular phase when compared to conventional protocols performed in the same oocyte donors?

Summary answer: The number of total and MII oocytes from random-start protocols initiated during the follicular phase appears similar to conventional ovarian stimulation start protocols in egg-donors.

What is known already: Random-start ovarian stimulation protocols has been well studied in women with cancer for fertility preservation and, more recently, in women who desire 'elective" cryopreservation of oocytes, resulting in optimal outcomes. In the context of an egg donation program, if ovarian stimulation can be initiated irrespective of the phase of the menstrual cycle without adversely impacting oocyte yield or quality, the approach may facilitate schedules.

Study design, size, duration: Single center, prospective, randomized, clinical trial performed in egg donors during year 2017. The study group (15 participants) started ovarian stimulation randomly at different moments throughout the follicular phase, according to a list of random allocation of treatments starting at day 5,7,9,11 or 13 of the menstrual cycle (three participants allocated to each day). Controls: each patient served as her own control comparing previous cycle within 6 months under conventional initiation of stimulation.

Participants/materials, setting, methods: The study group started ovarian stimulation randomly at days 5,7,9,11 or 13 of the cycle. Participants received urinary FSH (Fostipur®) 150-225 IU/d, cetrorelix 0.25 mg/d (Cetrotide®) started five days after ovarian stimulation and triptorelin 0.2 mg (Decapeptyl®) induced the final follicular maturation. Controls: previous cycle by the same egg donor under conventional initiation of stimulation (cycle day 2/3), using the same gonadotrophin and dose. 28 cycles in total were included in the analysis. There was 01 drop-out.

Main results and the role of chance: As a whole, among young egg donors (mean age: 24.8 ± 4.5 y.o.); the results were comparable between study group vs controls with regards to: number of days of stimulation (9.2 ± 1.3 vs 10 ± 1.5 p = 0.2); gonadotrophin (IU) consumption (1898 ± 457 vs 2065 ± 808 p = 0.5); number of collected eggs (19 ± 9.2 vs 21 ± 12.2 p = 0.6) and proportion (%) of mature eggs (82 ± 10 vs 85.8 ± 5.5; p = 0.2) respectively. Additionally, the fertilization rate (ICSI%) was also similar (71 ± 7.8 vs 69.6 ± 8.7 p = 0.3).

Limitations, reasons for caution: Small number of donors included per specific day of started stimulation. These results might be extrapolated to other group of IVF patients (e.g. young women with tubal or male factor infertility) although caution is warranted since laboratory outcomes beyond fertilization were not analyzed. Future trials should address this point.

Wider implications of the findings: As ovarian stimulation can be initiated regardless of the day during the follicular phase of the menstrual cycle without adversely impacting oocyte yield or fertilization rate in egg donors, the approach may facilitate schedules in egg donation programs.

Trial registration number: NCT02821819.

P-672 Validation of a novel ELISA assay for serum AMH determination

A. Schultze - Mosgau[1], K. Neumann[2], M. Depenbusch[2], T. Osterholz-Zaleski[2], G. Griesinger[2]

[1]*University of Schleswig-Holstein- Campus Luebeck, Section of Reproductive Medicine, Lübeck, Germany*
[2]*Section of Gynecologic Endocrinology and Reproductive Medicine, University Hospital of Schleswig-Holstein Campus Luebeck, Lübeck, Germany*

Study question: Validation of the novel Euroimmun MRH/AMH ELISA using the Gen II ELISA by Beckmann Coulter (GenII-BC) as a standard.

Summary answer: The novel EU AMH ELISA achieves adequate performance as compared to established GenII-BC ELISA and is suitable for broader utilization in clinical and research settings.

What is known already: Serum Anti-Mullerian Hormone (AMH) levels correspond to ovarian function and reserve. Clinically, AMH levels are routinely assessed in infertility treatment to estimate the prognosis and risk profile of a given woman.

Different assays have been developed for serum AMH assessments. Several studies demonstrated significant variations of AMH values depending on the ELISA kit used, casting doubts on the validity of AMH measurements in a clinical scenario.

Recently, the company Euroimmun (Luebeck, Germany) developed a novel MRH/AMH ELISA, based on a combination of two highly specific antibodies, different from the antibodies utilized for the GenII-BC

Study design, size, duration: This was a prospective, single-center study. AMH values were generated with/without buffer pre-mixing. Furthermore, different lots of the GenII-BC were tested as reference. The novel Mullerian-duct repression hormone (MRH/AMH) ELISA from Euroimmun (referred to as EU AMH ELISA herein) is based on the combination of two highly specific antibodies. Quantitative measurement is performed at 450 nm wavelength. Results are expressed as nanogrammes per milliliter (ng/ml).

Participants/materials, setting, methods: Frozen serum samples from 121 infertile female patients were analysed by the Euroimmun AMH ELISA and GenII-BC assay, respectively. To study assay agreement, a Passing-Bablok regression model and a Bland-Altman analysis were performed.

Main results and the role of chance: There is no difference between the AMH values generated with or without pre-mixing of probes with assay buffer in either the GenII-BC (Passing-Bablok equation: $y = 1.13 + 0.03\times$, 95% confidence intervals (CI): 1.10. - 1.18, intra class correlation coefficient (ICC) = 0.98, 95% CI: 0.88–0.99, Rc = 0.97, 95% CI: 0.96–0.99; n = 24) or in the EU-AMH ELISA (Passing-Bablok equation: $y = 1.06 + 0.04\times$, 95% CI: 1.03. - 1.10, ICC = 0.99, 95% CI: 0.97–0.99, Rc = 0.99, 95% CI: 0.98–0.99; n = 19).

The Passing-Bablok equation shows adequate performance of the EU-AMH ELISA ($y = 1.17–0.05\times$, 95% CI: 1.12–1.23; n = 121) compared to GenII-BC ELISA. The analysis confirms a linear association (p = 0.51 for non-linear association) and prove adequate correlation of the assays (ICC = 0.96, 95% CI: 0.92–0.98 and Rc = 0.93, 95% CI: 0.90–0.95; n = 121).

Limitations, reasons for caution: It is in the nature of a comparison of two different ELISA assays that an influence of the GenII-BC ELISA on assumed outliers measured by the EU-AMH ELISA cannot be excluded without comparison of these values with those of further ELISA assays.

Wider implications of the findings: The EU-AMH ELISA shows good performance in measuring serum AMH levels. Assessing the intra-assay variation the ELISA revealed a high reproducibility between different standard- and kit-lots. The present study could not reveal an influence of pre-mixing on the reproducibility of measured AMH values which is in contrast to previous investigations.

Trial registration number: not applicable.

P-673 Is there any predictive factor of resistance to clomiphene citrate (CC) for ovulation induction in polycystic ovarian syndrome (PCOS)?

L. Huyghe[1], A. Dumont[2], O. Calistru[3], S. Catteau-Jonard[4], G. Robin[2], D. Dewailly[5]

[1]Medical Gynecology Resident, Endocrine Gynecology and Reproductive Medicine Department- CHRU, LILLE, France
[2]Medical Gynecology Doctor, Endocrine Gynecology and Reproductive Medicine Department- CHRU, Lille, France
[3]Obstetrician Gynecologist Doctor, Obstetrics and Gynecology Department, Lille, France
[4]Medical Gynecology Professor, Endocrine Gynecology and Reproductive Medicine Department- CHRU, Lille, France
[5]Endocrinology Professor, Endocrine Gynecology and Reproductive Medicine Department- CHRU, Lille, France

Study question: To study whether clinical, biological or ultrasonic characteristics of PCOS patients with ovulation disorder can predict total or partial resistance to ovulation induction by CC.

Summary answer: Only BMI was weakly predictive. No other factor could discriminate patients with total or partial resistance to CC from sensitive patients.

What is known already: PCOS is the most common endocrine disorder in women of childbearing age. It can be responsible for ovulation disorder and infertility. The Thessaloniki consensus defines CC as the first-line treatment for ovulation induction in PCOS patients seeking a pregnancy. It is an efficient, easy and low cost treatment. The cumulative pregnancy rate was 70 % after 6 cycles. 20 % of the patients are resistant to CC, either at the starting dose (50 mg) or 100 mg (partial resistance) or at the maximum dose of 150 mg (total resistance). Literature is still conflicting about factor(s) predicting total/partial resistance to CC.

Study design, size, duration: This large retrospective study was conducted between March 1999 and November 2017 in a single academic department of Reproductive Medicine. Patients included were diagnosed with PCOS, as defined by the Rotterdam consensus. Only patients with ovulation disorder (phenotypes A, B, D) and undergoing CC treatment for ovulation induction were included.

Participants/materials, setting, methods: 312 patients were included (1,012 cycles). To determine if the treatment was effective, an ultrasound was performed on D12, looking for a dominant follicle. A progesterone assay was conducted on D24 and ovulation was attested if progesterone was $\geq$ 5 ng/mL. Resistance to CC was defined by absence of ovulation. Four groups were formed according to CC resistance profil: no resistance, resistance to 50 mg, resistance to 100 mg, resistance to 150 mg (total resistance).

Main results and the role of chance: Compared to the group "no resistance" (n = 153), partially and totally CC-resistant patients (n = 249) were more likely to be amenorrheic (p<0.02), and had ranks of higher BMI (p<0.005) and waist circumference (p<0.005). Biologically, in the latter group, baseline serum AMH levels were significantly higher (p<0.02), as well as D4-androstenedione (p<0.02) and fasting insulin levels (p<0.01). SHBG levels were significantly lower (p<0.001). All those parameters increasingly varied between the 3 groups of resistance, although not significantly. By discriminant analysis, only one model including only BMI could significantly (p<0.0001) distinguish between sensitive and resistant patients. By ROC analysis including either BMI, AMH or D4-androstenedione, no discriminating threshold could be obtained to predict CC resistance with satisfactory sensitivity and specificity.

Limitations, reasons for caution: The main limitation of our study was its retrospective design, responsible for bias and missing data. But to our knowledge, this is the largest cohort of PCOS patients monitored for CC in the same hospital, making the evaluation more reliable.

Wider implications of the findings: Our data confirm that no parameter can be used to decide whether skipping or not the step of CC treatment or to choose the starting dose in anovulatory patients with PCOS. However, the association between BMI and CC resistance should encourage the management of obesity before and during treatment.

Trial registration number: Not applicable.

P-674 The ovarian response after follicular versus luteal phase stimulation with a double stimulation strategy

P. Santulli, M. Bourdon, Y. Chen, J. Gonnot, C. Cervantes, V. Blanchet, C. Maignien, K. Pocate-Cheriet, L. Marcellin, C. Chapron

Cochin - Port Royal - Hôpitaux Universitaires Paris Centre-, Service de Gynécologie-obstétrique et médecine de la reproduction II, Paris, France

Study question: Is the ovarian response after stimulation performed during the follicular phase (FP) versus the luteal phase (LP) with a double stimulation strategy equally efficient?

Summary answer: Stimulation during the LP in a double-successive stimulation strategy results in a lower ovarian response as compared to the FP equivalent daily dose stimulation.

What is known already: Double ovarian stimulation is an option for enhancing oocyte recruitment when a single stimulation is not sufficient, or when there is limited time for assisted reproductive technology, such as with fertility preservation. It is also a viable option for dealing with an insufficient ovarian response that can sometimes be encountered with ART, notably in poor responders. Nonetheless, there is still controversy regarding the equivalence and effectiveness of luteal phase controlled ovarian stimulation (COS) as compared to the previous follicular phase stimulation with a double stimulation strategy.

Study design, size, duration: This was an observational cohort study using data collected in a continuous series of patients scheduled for a double stimulation protocol between March 2014 and June 2017 at our institution.

Participants/materials, setting, methods: Women starting a FP (COS1) and a LP stimulation (COS2) in a double-stimulation protocol were enrolled. Both the COS1 and the COS2 used equivalent daily doses of gonadotropins in combination with GnRH-antagonist. Ovulation was triggered using GnRH-agonist. The number of oocytes retrieved, the oocyte maturation rate, the duration of stimulation, the total dose of injected gonadotropin, and the estradiol level at triggering were collected so as to compare the extent of the ovarian response.

Main results and the role of chance: A total of 77 patients were included in the analysis. The number of oocytes retrieved (5.25 ± 3.38 for COS 1 versus 3.83 ± 3.14 for COS 2; p = 0.001), as well as the number of MII oocytes (4.49 ± 3.05 for COS 1 versus 3.25 ± 2.86 for COS 2, p = 0.003) after COS 1 were significantly higher than after the COS 2. There were no significant differences in regard to the oocyte maturation rate between the two stimulations. The duration of the stimulation was significantly shorter (9.71 ± 1.46 days for COS 1 versus 11.25 ± 1.82 days for COS2; p < 0.001), the total dose of injected gonadotropins was significantly lower (2,916.23 ± 439.68 for COS 1 versus 3,374.03 ± 546.62 for COS 2; p < 0.001,) and the estradiol level on the trigger day was significantly higher (1,135.99 ± 824.28 pg/mL for COS 1 versus 661.42 ± 477.74 pg/mL, for COS 2; p < 0.001) with COS 1 as compared to COS 2.

Limitations, reasons for caution: The present study suffers from the limitation of its design involving a retrospective analysis of a prospective cohort. However, in this cohort study, numerous epidemiological variables were collected prospectively through face-to-face interviews before stimulation.

Wider implications of the findings: The two phases (FP and LP) were not equally efficient with a double stimulation strategy. Aside from in an emergency situation, a double stimulation strategy does not appear to be more effective than two separate conventional follicular phase stimulations. Further investigations are required, however, to confirm these findings.

Trial registration number: None.

P-675 A randomized, controlled trial (RCT) of AMH-based individualized ovarian stimulation for in vitro fertilization

J.F. Petersen[1], E.C.L. Løkkegaard[1], L.F. Andersen[1], K. Torp[1], L. Hedegaard[2], D.R. Nysom[2], A.N. Egeberg[2], A.N. Andersen[2]

[1]North Zealand Hospital, Obstetrics and gynecology, HIllerød, Denmark
[2]Rigshospitalet, The Fertility Clinic, Copenhagen, Denmark

Study question: Does an individualized Anti-Müllerian hormone (AMH) based follicle stimulating hormone (FSH) dosing in an antagonist protocol increase the proportion of patients with an optimal number of oocytes?

Summary answer: The AMH-based individualized dosing algorithm did not optimize the number of oocytes mainly due to insufficiency of 100 IU/day of FSH in predicted hyper-responders.

What is known already: Individualizing FSH dosing for ovarian stimulation can theoretically improve the balance between benefits and risks. Current data suggest a reduced risk of ovarian hyperstimulation syndrome (OHSS), but no evidence of increased pregnancy or live birth rates. AMH is known as a good marker of ovarian response, but data are limited on how to implement the use of this predictive factor into clinical practice. Only a few RCTs have used AMH-based algorithms to optimize the FSH dosing in ovarian stimulation.

Study design, size, duration: A dual-center open-label RCT conducted January 2013 – November 2016. Eligibility was assessed in 269 women and 221 were randomized 2:1 between study and control in an antagonist cycle. Women with high AMH (≥25 pmol/L) had minimal stimulation (rFSH 100 IU/day); women with medium AMH (12 – 24 pmol/L) standard stimulation (rFSH 150 IU/day), and low AMH (<12 pmol/L) had maximum stimulation (corifollitropin). The control group had 150 IU/day of FSH irrespective of pretreatment AMH.

Participants/materials, setting, methods: All women had a presumed normal ovulatory menstrual cycle, were aged 25–38 years, weighed <75 kg, had 1st IVF or ICSI with pretreatment AMH ranging from 4–40 pmol/L and had two ovaries accessible to oocyte retrieval. Recruitment was conducted from both participating sites. Women with anovulatory PCOS, endometriosis grade III/IV, hydrosalpings on ultrasound, recurrent miscarriages (≥3) and FSH > 12 IE/L were excluded. All transfers were single blastocyst transfers.

Main results and the role of chance: After randomization 149 women comprised the study group and 72 the control group. The groups had a similar distribution of basal AMH levels. The primary outcome of predefined optimal number of 5-14 oocytes was achieved in 72% of the study and 78% of the controls. This difference was not significant. In the high AMH stratum of the study group given 100 IU rFSH/day 38% had an insufficient (<5) number of oocytes, compared with 6% among the controls given 150 IU rFSH/day (p = 0.03). In the low AMH stratum the study group given corifollitropin had a nonsignificant tendency towards more optimal responses of 73% compared with 53%in the control group. Dose reduction was needed in 2 women (one in each study arm) and cycle cancellation due to insufficient response occurred in 3 (2 in the study and 1 in the control).OHSS was diagnosed in 4 women (2 in each group). Participants answered a daily questionnaire during the luteal phase describing subjective well-being in terms of abdominal distention, abdominal pain, dyspnea and weight. No differences were found between groups. The live birth rates per started cycle were similar (28% and 29%) in the study vs. control group.

Limitations, reasons for caution: This study was powered to determine differences in the distribution of number of oocytes retrieved in the study and control groups, but not to assess possible risk reductions of OHSS as larger data sets would be needed.

Wider implications of the findings: In the high AMH stratum expected to be at risk for excessive responses, 100 IU/day of rFSH seems insufficient when using the antagonist protocol. Further studies should investigate whether 125 IU/day would be better to balance benefits in terms of number of oocytes versus OHSS risk.

Trial registration number: EUDRACT number 2012-004969-40

P-676 Telomere length and telomerase activity in cumulus cells of women with Polycystic Ovarian Syndrome

D.C.C. Pedroso[1], C.L. Miranda-Furtado[1], M.C. Picinato[1], F.S. Donaires[2], R.C. Giorgenon[1], V.P. Santana[1], B.A. Santana[2], D.L. Keefe[3], R.A. Ferriani[1], R.D.T. Calado[2], R.M. Reis[1]

[1]Ribeirao Preto Medical School- University of Sao Paulo, Gynecology and Obstetrics, Ribeirao Preto, Brazil
[2]Ribeirao Preto Medical School- University of Sao Paulo, Internal Medicine, Ribeirao Preto, Brazil
[3]New York University Langone Medical Center, Gynecology and Obstetrics, New York, U.S.A.

Study question: What are the implications of Polycystic Ovarian Syndrome (PCOS) on telomere length and telomerase activity in cumulus cells?

Summary answer: Telomere length in cumulus cells did not differ between PCOS and controls. However, telomerase activity in cumulus cells was higher in the PCOS.

What is known already: Women with PCOS, despite responding well to Assisted Reproduction Treatments (ART), the oocytes usually have low quality and reproductive capacity, which is correlated to oocyte interaction with cumulus cells, in the cumulus-oocyte complex. The low oocyte quality may be related to loss of genomic stability of oocytes, or even cumulus cells, and may lead to a reduction of female fertility. The telomere length and telomerase activity play a fundamental role in maintaining genomic stability, which is considered an important molecular marker of cell viability,

whose alterations are related to apoptosis and/or senescence, maybe also an indicative of oocyte quality.

Study design, size, duration: A prospective case-control study, in which 38 women with PCOS and 61 controls were included from September 2015 to June 2017.

Participants/materials, setting, methods: Age, body mass index (BMI) were measured. Follicle stimulating hormone (FSH), luteinizing hormone (LH), estradiol, prolactin, insulin, androstenedione, testosterone, free androgen index (FAI), c-reactive protein and homocysteine were evaluated. Telomere length in cumulus cells from immature (ICC) and mature (MCC) oocytes, and leukocytes were evaluated by quantitative real-time polymerase chain reaction (qPCR). Telomerase activity from cumulus cells was evaluated by TRAPeze® XL Kit. Statistical analyses were determined by Wilcoxon test and Spearman correlation.

Main results and the role of chance: Age mean was 33.74 (±4.12) in PCOS and 34.33 (±3.63) in controls (p=.509). The variables BMI (p=.001), LH (p=.015), estradiol (p=.004), insulin (p=.002), testosterone (p<.0001), androstenedione (p=.001), FAI (p<.0001) and c-reactive protein (p=.003) was increased in PCOS group. FSH (p=.0002) was smaller in PCOS group. Prolactin and homocysteine were not different between the groups. The telomeres length in ICC did not differ between PCOS and control groups (1.60 ± 0.56 vs 1.58 ± 0.33; p=.649, respectively). The telomeres length in MCC did not differ between PCOS and control groups (1.61 ± 0.47 vs 1.70 ± 0.43; p=.378, respectively). However, in leukocytes reduced telomeres were observed in the PCOS (p=.025), respectively. The telomerase activity in ICC was higher in the PCOS group than in the control group (1.62 ± 1.49 vs 0.30 ± 0.42; p=.003, respectively). The telomerase activity in MCC was higher in the PCOS group than in the control group (1.39 ± 1.63 vs 0.55 ± 0.84; p=.022, respectively). A positive correlation between telomerase activity and telomere length in the ICC was observed in control group (p=.051). PCOS also presented a positive correlation between telomerase activity and telomere length in MCC (p=.048). Telomere length of leukocytes, ICC and MCC were a positive correlated in both groups.

Limitations, reasons for caution: The limited number of cases of the study group. An increase of sample size is recommended to make the data more robust and confirm the results.

Wider implications of the findings: PCOS seems not to affect telomere content in ICC and MCC, only leukocytes telomeres were reduced in this syndrome. On the other hand, higher telomerase activity ICC and MCC may be required for telomere maintenance in the PCOS.

Trial registration number: N/A.

P-677 HECTD1 influences endocytosis of EGFR through APPL1

C. De Geyter[1], X. Wang[2], H. Zhang[2]

[1]University of Basel, Reproductive Medicine and Gyn. Endocrinology RME, Basel, Switzerland
[2]Department of Biomedicine DBM, University Hospital- University of Basel-Switzerland, Basel, Switzerland

Study question: Whether HECTD1, a newly identified E3-ligase, influences endocytosis of membrane-bound hormone receptors (such as the epidermal growth factor-receptor, EGFR) and how is it regulated?

Summary answer: HECTD1 inhibits degradation of EGFR and thereby influences EGF-signalling pathway. It regulates the recycling pathway through APPL1

What is known already: HECTD1, also known as EULIR, denominates a HECT domain containing E3 ubiquitin ligase. HECTD1 interacts with several membrane receptors, including LH-receptor, FSH-receptor and EGFR. APPL1 is a subpopulation of early endosomes, which regulates the endocytosis pathway.

Study design, size, duration: prospective experimental study, lasting 2 years.

Participants/materials, setting, methods: In HeLa cells HECTD1 expression level is downregulated by HECTD1-specific shRNA. The stable cell lines were selected by puromycin. Immunofluorescence and FACS were used to study the receptor trafficking. EGF receptor degradation and EGF signalling pathway activation were examined by Western blot. Immunofluorescence was used to localize APLL1.

Main results and the role of chance: Our studies demonstrated that HECTD1-knockdown inhibits degradation of EGFR and influences signalling of EGF. Activated MAPK signalling pathway is prolonged. APPL1 localizes in the cytoplasm, under the plasma membrane and in the centrosome. HECTD1 co-localizes with APPL1 6 minutes after EGF-stimulation. After HECTD1-knockdown, APPL1 co-localizes with EGF less in cytoplasm but appears close to the plasma membrane.

Limitations, reasons for caution: Basic experimental research results may not be fully appreciated in complete systems.

Wider implications of the findings: Understanding the regulation of endocytosis of membrane-bound receptors through HECTD1 may help to understand local and temporal differences in sensitivity to endocrine regulation.

Trial registration number: None.

P-678 Cumulative live birth rates (CLBR) after in vitro maturation (IVM) of oocytes in patients with polycystic ovary syndrome (PCOS): does PCOS phenotype have an impact?

T. Deckers[1], L. Mostinckx[1], R. Buyl[2], I. Segers[1], E. Anckaert[3], C. Blockeel[1], M. De Vos[1]

[1]Universitair Ziekenhuis Brussel, Centre for Reproductive Medicine, Brussels, Belgium
[2]Vrije Universiteit Brussel, Department of Biostatistics and Medical Informatics-Faculty of Medicine and Pharmacy, Brussels, Belgium
[3]Universitair Ziekenhuis Brussel, Laboratory of Clinical Chemistry and Radioimmunology, Brussels, Belgium

Study question: Which parameters are predictive of CLBR after non-hCG triggered serum-free IVM and is there an impact of the PCOS phenotype?

Summary answer: After IVM, CLBR do not vary significantly between PCOS phenotypes. Calculated free testosterone (FTc) and number of fertilised oocytes are independently correlated with CLBR.

What is known already: In patients with PCOS undergoing conventional assisted reproductive technology (cART), PCOS phenotype is an independent predictor of CLBR. Hyperandrogenic phenotypes of PCOS have significantly poorer cumulative outcomes compared to their normoandrogenic counterparts and compared to patients with polycystic ovarian morphology (PCOM). IVM is a mild-approach, OHSS-free ART alternative and can be offered to patients with polycystic ovaries. Whether clinical outcomes of IVM treatment are influenced by the PCOS phenotype is currently unknown.

Study design, size, duration: Retrospective cohort study of all patients who underwent their first IVM cycle in a university-based tertiary clinic between April 2014 and December 2016. Patients who underwent fertility preservation or preimplantation genetic diagnosis were excluded. In total, 258 cycles were analysed, in 240 of which the cumulative outcome was known.

Participants/materials, setting, methods: Patients with PCOM, PCOS A (hyperandrogenism + ovulatory dysfunction + polycystic ovaries), C (hyperandrogenism + polycystic ovaries) and D (ovulatory dysfunction + polycystic ovaries) between 20-41 years-old underwent non-hCG triggered IVM (30 h) after a short HP-hMG course. Fresh blastocyst transfer was planned if ≥4 good-quality d3-embryos were available. Otherwise, embryos were vitrified at cleavage-stage and transferred in an artificial cycle. Androgens and SHBG levels were measured at intake and cumulative live birth rates were calculated.

Main results and the role of chance: Mean age, body mass index, and antimüllerian hormone concentration were 28.7 ± 3.3 years, 25.0 ± 5.2 kg/m2, and 10.3 ± 6.2 ng/mL, respectively. Mean amount of COCs retrieved, metaphase II oocytes after IVM and 2PN oocytes after ICSI were 20.2 ± 13.0, 9.1 ± 6.4 and 6.0 ± 4.9, respectively. A total of 77 infants were born, all of which were singletons. Overall, CLBR per started cycle was 32.1% (77/240) and CLBR did not vary significantly between PCOS phenotypes, ranging from 23.1% (3/13) in PCOS-C, 31.8% (35/110) in PCOS-D to 37.1% (36/97) in PCOS-A (p = 0.2). In patients with PCOM, CLBR was only 15% (3/20). None of the patients developed OHSS.

Multiple binary logistic regression analysis showed that serum FTc levels and number of 2PN oocytes, with unstandardized coefficients (95% CI) of 0.732 (0.613–0.874) (P = 0.001) and 1.183 (1.076–1.299) (P<0.001), respectively, are strong independent predictors of cumulative live birth.

Limitations, reasons for caution: The relative small sample size of PCOS phenotype C and PCOM may preclude robust conclusions regarding CLBR after IVM in these subpopulations. Other variables, such as needle type, aspiration technique and IVM culture system may also contribute to IVM outcome.

Wider implications of the findings: Cumulative outcomes after HP-hMG primed, non-hCG triggered IVM in selected patients with PCOS are strongly influenced by the endocrine profile of the patient. Whether medical or lifestyle interventions that result in reduced free testosterone levels could improve IVM success rates in hyperandrogenic patients merits further scrutiny.

Trial registration number: not applicable.

P-679 Artificial frozen embryo transfer cycles: how important are the circulating estradiol (E2) levels for live birth rates?

E. Orinx, S. Mackens, S. Santos-Ribeiro, N. De Munck, A. Racca, B. Popovic-Todorovic, H. Tournaye, C. Blockeel, M. De Vos

UZ Brussel, Centre for Reproductive Medicine, Jette, Belgium

Study question: Do artificial frozen embryo transfer (FET) cycles require endocrine monitoring for E2 prior to commencing exogenous P administration?

Summary answer: We found no association between late-proliferative phase serum E2 levels and livebirth rates in artificial FET cycles.

What is known already: The use of FET has progressively increased and the need for endocrine monitoring during the proliferative phase in artificial cycles remains unclear. In several studies, late-proliferative phase serum E2 and luteinizing hormone (LH) levels did not seem to predict outcome, however, others have found elevated proliferative serum E2 may negatively impact live birth rates after artificial FET.

Study design, size, duration: All artificial FETs performed in a tertiary centre between 2010-2015 were included in this retrospective study (n = 1341). The same artificial protocol was performed in all cases and blood sampling with a hormone measurement essay was performed 1 or 2 days before exogenously inducing the luteal phase. These cycles were subdivided into 4 groups according to the 25%, 50% and 75% percentiles for late-proliferative serum E2 levels: ≤190 pg/ml (n = 341), 191-257 pg/ml (n = 331), 258-355 pg/ml (n = 338) and ≥356 pg/ml (n = 331).

Participants/materials, setting, methods: We performed mixed-effects multilevel multivariable regression to assess the potential effect of late-proliferative E2 on livebirth rates while adjusting for the following potential confounders: female age, prior livebirths, IVF/ICSI cycle rank, body mass index (BMI), presence of irregular cycles, number of good quality embryos produced, blastocyst versus cleavage stage transfer, total number of days of E2 supplementation, endometrial thickness, need to step-up the administration of E2, and the late-proliferative serum LH and progesterone levels.

Main results and the role of chance: There were no significant differences between these groups in terms of age (31.9 ± 4.7), IVF/ICSI cycle rank (1.8 ± 1.3), number of oocytes retrieved (15.4 ± 9.2), BMI (25.2 ± 5.2), number of prior livebirths (0.4 ± 0.6), blastocyst vs cleavage stage transfer (65.1% vs 34.9%), total dose of E2 administered (76.1 ± 36.1 mg of estradiol valerate) and endometrial thickness (8.5 ± 2.2 mm). There were, however, statistically significant differences among the 4 study groups in terms of number of embryos produced after the fresh cycle (5.2 ± 2.9, 5.3 ± 3.2, 5.6 ± 3.2, 5.7 ± 2.9, p<0.001), the presence of irregular cycles (59.1%, 61.2%, 53.6%, 50.2%, p = 0.016), the need for a exogenous E2 administration step-up (21.7%, 13%, 14.8%, 19.9%, p0.015) and the total number of days of E2 supplementation (14.4 ± 3.7, 13.8 ± 3.2, 13.7 ± 2.8, 14.2 ± 3.3, p = 0.023). Following both univariable and multivariable regression analysis, the level of late-proliferative circulating E2 showed no significant difference in terms of livebirth rates after FET (15.2%, 16.7%, 18.8% and 16%, p = 0.662).

Limitations, reasons for caution: The interpretation of the findings of this study is limited by the retrospective nature of the analysis and the potential for unmeasured confounding.

Wider implications of the findings: According to this large retrospective dataset, the late-proliferative circulating levels of E2 in artificial FET cycles are not associated with the subsequent livebirth rates and, thus, monitoring these levels and using them to guide clinical decision-making (e.g. medication step-up, cycle prolongation or cancelation) is of questionable value.

Trial registration number: NA.

P-680 Changes in the management of poor-responders patients after internal analysis of IVF outcomes according to the Poseidon criteria

P. Oger[1], L. Delaroche[2], C. Yazbeck[1], N. Kazdar[2], F. Lamazou[1]

[1]*CMC Pierre Cherest, ART Center, neuilly sur seine, France*
[2]*Unilabs-Laboratory, ART Center-CMC Pierre Cherest, Neuilly sur seine, France*

Study question: How did the internal analysis of IVF outcomes in poor-responders patients according to the Poseidon criteria help us to change our management?

Summary answer: Management of poor responders consists to start ovarian stimulation with high-dose of FSH and to cancel the cycle if less than 4 follicles are obtained.

What is known already: The chances of achieving a live birth in the poor responders are low. The definition of poor ovarian responders according to the Bologna criteria is unclear because it mixes different ovarian profiles. That is why the Poseidon group has proposed a new classification defining 4 categories of patients. To our knowledge, no study has reported so far the IVF outcomes according to this new classification.

Study design, size, duration: This is a single-center observational study performed from January 2016 to 2017. 2519 cycles from patients aged between 18 and 42 years old were included. The exclusion criteria were extreme oligoasthenoteratospermia and genetic diseases; classification according to the 4 groups described by the Poseidon classification.

Participants/materials, setting, methods: Ongoing pregnancy (OPR) and miscarriage rates were analyzed according to Poseidon classificationGroup 1 (<35 years, AMH > 2 ng/mL) 498 cycles: 1 A (<4 oocytes) 23 cycles; 1B (4 to 9 oocytes) 165 cycles Group 2 (> 35 years, AMH > 2 ng/mL) 638 cycles: 2 A (<4 oocytes) 64 cycles; 2B (4 to 9 oocytes) 181 cyclesGroup 3 (<35 years, AMH <1.2 ng/mL and AFC<5): 99 cyclesGroup 4 (> 35 years, AMH <1.2 ng/mL and AFC <5): 730 cycles.

Main results and the role of chance: In the good prognosis groups (Group 1 and 2), the pregnancy rate was low in case of few oocytes collected (group 1 A, the OPR is 28.5% (2/7), no miscarriage was reported. In group 2 A, we had no evolutive pregnancy (0/30) and the miscarriage rate was 100% (2/2)). When 4 to 9 oocytes were obtained, the OPR was better in younger group (group 1B, OPR was 28.4% (35/123), miscarriage rate 20.5% (9/44); In group 2B, OPR was 21.4% (28/131), miscarriage rate 39.1% (18/46)). In the worst prognosis groups (Group 3 and 4), regardless of age, OPR was low (group 3, OPR was 7.7% (5/65), miscarriage rate 55% (6/11); group 4, OPR was 16.1% (37/230), miscarriage rate 35.1% (13/37)). in these groups, OPR was not improved by natural cycles compared to high stimulated cycles in the older patients (Group 3: 73 stimulated cycles, OPR was 7.4% (4/54), miscarriage rate 60% (6/10);12 natural cycles, OPR was 25% (1/4), no miscarriage. Group 4: 615 stimulated cycles, 468 pick-up, OPR 16.1% (30/186), miscarriage rate 43.3% (13/30); 115 spontaneous cycles, 96 pick-up, OPR 15.9% (7/44), no miscarriage).

Limitations, reasons for caution: This is an observational retrospective study and the protocols and strategies were specific to each clinician. Some subgroups are too small.

Wider implications of the findings: The Poseidon classification allows to modify medical practice: a maximum number of oocytes is essential because rate of euploid oocytes is constant; the cancellation of a poor cycle allows to propose a stronger appropriate stimulation to recover as many oocytes as possible. Couples can be informed on the expected results.

Trial registration number: not applicable.

P-681 Does the change in needle diameter effect oocyte quality and embryo morphokinetics? A prospective randomized pilot study with sibling oocytes

Y. Atzmon, M. Michaeli, N. Aslih, G. Shrem, O. Ruzov, N. Rotfarb, E. Shoshan-Karchovsky, E. Shalom-Paz

Ruth and Bruce Rappaport School of Medicine- Technion- Haifa- Israel., Hillel Yafe Medical center IVF, Hedera, Israel

Study question: Does the change in needle diameter along the 17-20 G during oocyte collection effect oocyte quality and embryo morphokinetics in compare to 17 G needle?

Summary answer: Beside higher negative value in oocyte score in 17 G needle, no other differences were demonstrated in terms of fertilization, embryo quality or morphokinetics.

What is known already: A smaller diameter needles yielded significant improvement in recovery after ovum pick-up, as well as minimizing bleeding during the procedure and reducing pain afterwards, various needles are available in the field of in vitro fertilization, with the aim of creating a needle that reduces pain without diminishing its stability and ease of operation, a variable diameter 20-17 G needle was introduced to the market (Vitrolife Sweden AB, Goteborg, Sweden). And was found significant decreases in pain and vaginal bleeding compared to the 17 G needle, without affecting the oocyte recovery rate, damaging oocytes or affecting fertilization and clinical pregnancy rates.

Study design, size, duration: Prospective, randomized, blinded pilot study comparing sibling oocytes. 20 patients were prospectively enrolled from August 2016 through January 2017.

Participants/materials, setting, methods: Women undergoing IVF-ICSI, 21 to 39 years old, FSH≤10 IU/l and antral follicular count (AFC) >10 follicles. Comparing oocyte collected with 2 different aspiration needles (17 G/35 mm and 20-17 G/35 mm) in the same patients-Sibling oocytes). Oocyte quality (judged by 5 parameters based on previous publication) and embryo grading including morphology and morpho-kinetics were evaluated. The embryologist was blinded to the needle used for each ovary.

Main results and the role of chance: A total of 256 oocytes were collected, 118 oocytes in the 17 G needle group and 116 in the 20-17 G group. Aspirating with the 17 G needle yielded more oocytes with higher negative score per oocyte compared with the oocytes collected with the 20-17 G needle (2.2 ± 1.39 vs. 1.87 ± 1.69; P = 0.02). Oocytes collected in the cohort with degenerative oocytes (DEG group) immediately after OPU had poorer performance compared to their sibling oocytes from the cohort with no degenerative oocytes(nonDEG group).the DEG group had poorer oocyte scores compared to the nonDEG group(-2.4 ± 1.73 vs. -1.87 ± 1.48; P = 0.02; 95%CI -1.02 to -0.09). Overall fertilization rate was poorer for the DEG group of patients 56.1% versus 70.7% for the nonDEG group (P = 0.05).

However, the amount of good quality embryos were comparable between the DEG vs nonDEG (65.6% vs. 66.4%, respectively).

Furthermore, sub analyzing the cohort with the degenerative oocyte according to the aspiration needle size did not affect fertilization rates or morphokinetic scores (KIDS and alfa ESHRE).

A logistic regression found that the presence of degenerative oocyte in the cohort of sibling oocytes increased the total negative score of the rest of the oocytes in the cohort, ß=-1.3 (95%CI: -1.8 to -0.79); p<0.0001.

Limitations, reasons for caution: Pilot study, small number of participant.

Wider implications of the findings: Our results confirm previous findings that showed no difference in embryo quality and morphokinetics, regardless of the needle used for OPU. This study evaluated embryo quality using morphokinetics parameters after comparing the use of different needle diameters on sibling oocytes.

Trial registration number: NIH number NCT02749773

P-682 Lean PCOS may be a genetically distinct from obese PCOS: lean women with polycystic ovary syndrome and their relatives have no increased risk of T2DM

E. Johnstone[1], L. Cannon-Albright[2], C.M. Peterson[1], K. Allen-Brady[2]

[1]*University of Utah, Obstetrics and Gynecology, Salt Lake City, U.S.A.*
[2]*University of Utah, Genetic Epidemiology, Salt Lake City, U.S.A.*

Study question: Do lean women with polycystic ovary syndrome (PCOS) and their first, second, and third degree relatives have the same risk of type 2 diabetes (T2DM) as obese women with PCOS?

Summary answer: T2DM risk is increased in obese PCOS women and their first, second, and third degree relatives, but not in lean PCOS women or their relatives.

What is known already: PCOS is a strong risk factor for T2DM, with an approximately 2-fold increase in risk. Heritability of PCOS has been demonstrated in numerous studies, but mode of inheritance has not fit a single model. First degree relatives of women with PCOS appear to share the increased risk of T2DM, suggesting shared susceptibility alleles. However, studies of the T2DM and insulin resistance in relatives of women with PCOS have primarily included overweight and obese probands and relatives.

Study design, size, duration: This cohort study used the Utah Population Database (UPDB), which contains demographic and genealogy data, and medical records from the second largest health caresystem in Utah from 1994 through 2015. PCOS and T2DM cases were identified by ICD-9 codes. Body mass index (BMI) was obtained from drivers' licenses. Lean was defined as BMI <25, and obese as BMI ≥ 30. All first, second, and third degree relatives of PCOS probands in the database were identified.

Participants/materials, setting, methods: PCOS cases were diagnosed at ages 10-54, and had least 3 generations of genealogical data in the UPDB. Controls were matched for sex, birth place, birth residence (urban/rural), and 5-year birth cohort. 463 lean PCOS women and their 1369 first degree, 2179 second degree, and 4612 third degree relatives and 367 obese PCOS women and their 1008 first degree, 1760 second degree and 3422 third degree relatives with linked hospital data were included.

Main results and the role of chance: In the lean PCOS cohort, 13 of 463 probands, 36 of 1369 first degree relatives, 150 of 2179 second degree relatives, and 232 of 4612 third degree relatives had T2DM. The relative risks (95% confidence intervals) for T2DM among lean PCOS women were 1.71 (0.91-2.93) for probands, and 0.77 (0.54-1.06), 1.01 (0.86-1.19), and 1.04 (0.91-1.18) for first, second, and third degree relatives, respectively. In the obese PCOS cohort, 50 of 367 probands, 74 of 1008 first degree relatives, 151 of 1760 second degree relatives, and 219 of 3422 third degree relatives had T2DM. The relative risks (95% confidence intervals) for T2DM among obese PCOS women were 6.85 (5.08-9.03) for probands, and 1.72(1.35-2.16), 1.39 (1.18-1.63), and 1.21 (1.05-1.38) for first, second, and third degree relatives, respectively.

Limitations, reasons for caution: This study includes those who received an ICD-9 diagnosis of PCOS and/or T2DM, and thus those with health insurance may be overrepresented. Details of diagnostic criteria are not available, and so there may phenotypic variability between the lean and obese PCOS cohorts beyond BMI.

Wider implications of the findings: This study suggests that the lean PCOS phenotype is genetically distinct from the obese phenotype, and neither lean PCOS probands nor their relatives share the increased risk of T2DM found in obese PCOS families. BMI should be used for stratification in studies of genes associated with PCOS and T2 DM.

Trial registration number: None.

P-683 Estrogen regulates proliferation of mouse female bone marrow-derived stromal cells

Y.J. Kim[1], I.J. Chang[1], Y.Y. Kim[2], S.Y. Ku[2], S.M. Lee[1], J.H. Shin[1], T. Kim[1], J.Y. Hur[1]

[1]*Department of Obstetrics and Gynecology, College of Medicine, Korea University*
[2]*Departments of Obstetrics and Gynecology, College of Medicine, Seoul National University*

Study question: To assess the effects of estradiol on the proliferation of the murine bone marrow-derived stromal cells (BMdSCs) according to its concentration.

Summary answer: Estradiol may have a role in the regulation of proliferation of murine BMdSCs by dose- and time- dependent manners.

What is known already: BMdSCs has been known to demonstrate different responses to sex hormones according to gender difference or reproductive aging. Although estradiol has been known to play a major endocrine role on various cells in vivo to female, dose-dependent effect of estradiol on proliferation of BMdSCs has been rarely known.

Study design, size, duration: Femurs of 6-week-old female C57BL/6 mice (n = 20) were collected and washed using fresh media (DMEM).

Participants/materials, setting, methods: The marrow suspension from collected femurs was filtered through sterile Nitex mesh, and retrieved BMdSCs were cultured in in-vitro-conditioned with estradiol at 10^{-5} to 10^{-7} M and estrogen antagonist (ICI-1640), added for 24, 48, and 72 hours. FACS assay for isolated BMdSCs using markers (CD90 and CD105) and RT-PCR for target gene (FSH receptor and LH receptor) were performed after culture.

Main results and the role of chance: Isolated BMdSCs demonstrated enhanced proliferative activity and positively expressed CD90 and CD105. The expression of FSH receptor and LH receptor genes was increased after estradiol treatment and the peak response was observed at 48 hours. This proliferative effect was slightly suppressed by treatment of estrogen antagonist.

Limitations, reasons for caution: To fully understanding the regulatory roles of hormonal effect on proliferation of BMdSCs, further extended study with androgen and corticosteroids should be necessary.

Wider implications of the findings: This experiment implicates hormonal factors could regulate the cell cycles and regenerative capacity of BMdSC population with dose- and time- dependent manners.

Trial registration number: Not available / This study was supported by grants of Ministry of Education, Republic of Korea (2016R1D1A1A02937287 and 2016R1E1A1A01943455).

P-684 Bax-DUB expression regulated by formaldehyde in ovarian cells

C.Z. Pei[1], S.Y. Kim[1], D.H. Lee[1], K. Lee[2], B.S. Yun[3], K.H. Baek[1]

[1]Department of Biomedical Science, CHA University, Gyeonggi-Do, Korea- South
[2]Department of Obstetrics and Gynecology, Ewha Mokdong Hospital, Seoul, Korea-South
[3]Department of Obstetrics and Gynecology, Gangnam CHA Hospital, Seoul, Korea-South

Study question: Could the role of Bax-DUB on formaldehyde-induced apoptosis be implicated in premature ovarian failure (POF)?

Summary answer: Bax-DUB expression is upregulated by formaldehyde in ovarian cells, and Bax-DUB interacts with Bax, participating in deubiquitination of Bax.

What is known already: It has been known that formaldehyde, a ubiquitous environmental pollutant, has a harmful effect on the ovary and may cause POF. Formaldehyde increases oxidative damage and mitochondrial dysfunction that induces mitochondrial apoptosis. DUBs can reverse protein degradation by cleaving the peptide or isopeptide bond between ubiquitin and its substrate proteins.

Study design, size, duration: The expression levels of Bax-DUB were determined by the treatment of ovarian cells with different concentrations of formaldehyde, and the protein-protein interaction along with biological roles of Bax-DUB in ovarian cells was investigated.

Participants/materials, setting, methods: Ovarian cells were treated with formaldehyde in a dose-dependent manner, and it was found that Bax-DUB was upregulated by formaldehyde. We studied the protein-protein interaction through yeast two-hybrid, GST pull-down, immunoprecipitation, and immunocytochemical assays. Ubiquitination and deubiquitination assays were performed to investigate cellular functions of Bax-DUB in ovarian cells.

Main results and the role of chance: The expression level of Bax-DUB was increased by formaldehyde in ovarian cells. Bax is known as a pro-apoptotic factor to initiate mitochondrial apoptosis and is increased by formaldehyde. Therefore, we investigated relationship between Bax-DUB and Bax, and identified that Bax-DUB binds to Bax directly. Moreover, the ubiquitination level of Bax is decreased by Bax-DUB.

Limitations, reasons for caution: The results of this study were limited by the conduct of a cell line.

Wider implications of the findings: This is the first attempt to explain the pathogenesis of POF in the ubiquitin-proteasome system. The results of this study suggest that Bax-DUB may enhance the effect of mitochondrial mediated apoptosis by regulating the function of Bax, and deplete ovarian cells as early as possible to cause POF.

Trial registration number: not applicable.

P-685 Negative progesterone elevation threhold level on trigger day is different in subclasses of patients

R. De Cesare[1], F. Cirillo[1], P. Persico[1], V. Canevisio[1], V. Immediata[1], E. Morenghi[2], M. Monari[3], P.E. Levi Setti[1]

[1]Humanitas Research Hospital, Humanitas Fertility Center- Department of Gynecology- Division of Gynecology and Reproductive Medicine, Rozzano Milano, Italy
[2]Humanitas Research Hospital, Biostatistic Unit, Rozzano Milano, Italy
[3]Humanitas Research Hospital, Clinical Investigation Laboratory, Rozzano Milano, Italy

Study question: Influence of progesterone elevation (PE) and different progesterone threshold values at trigger day in different groups of fresh cleavage or blastocyst stage embryo transfer.

Summary answer: In good prognosis patients the progesterone impact starts when the serum level is > 1 ng/ml. In other women when it is > 1,75 ng/ml.

What is known already: Endometrial receptivity play a substantial role in implantation and a serum PE measured on the day of human chorionic gonadotrophin (hCG) administration has been associated with a lower pregnancy rate in fresh cycles, although threshold levels and percentage of success reduction are still objects of debate. There is not an optimal PE threshold to predict the IVF cycle outcome, although most studies indicate a value ≥ to 1.5 ng/ml to reduce the pregnancy rate. Several studies indicate that embryo transfer at the blastocyst stage can at least partially reverse the negative impact of high progesterone levels.

Study design, size, duration: This study is a single-center retrospective study, performed in a tertiary care academic Fertility Center. We analyzed all fresh embryo transfer, at cleavage (CS) and blastocyst (BS) stage, performed from January 2012 to December 2015. We, therefore, separately analyzed all the first thawing transfer performed after cancelled transfer cycles for any reason and elevated progesterone values (≥1.5 ng/ml).

Participants/materials, setting, methods: We report of 6,484 fresh embryo transfers performed during the study period: 6,098 cleavage, 386 blastocyst stage transfers and We included 108 thawing cycle. For each cycle, we analyzed serum progesterone level at trigger day. Progesterone assay was performed by a Chemiluminescent Micro particle Immunoassay (CMIA) with an analytical sensitivity ≤ 0.1 ng/mL. The impact of progesterone level on clinical pregnancy rate (CPR) and live birth rate (LBR) were explored using multiple logistic regression.

Main results and the role of chance: After the adjustment for maternal age, number of retrieved oocytes and transferred embryos, in CS transfers CPR shows the first significant decrease at progesterone ≥1 ng/ml (OR 0.83 95%CI 0.69-0.99 P = 0,039). An additional CPR decrease is observed with levels ≥1.75 ng/ml (OR 0.50 95% CI 0.36–0.68 P<0.001). This difference was confirmed by a statistically lower LBR in PE cycles. In good prognosis patients (<38 years and retrieved oocytes >8) the adverse effects of elevate progesterone is already evident when progesterone reaches 1 ng/ml (38.2% vs 30.7%, OR 0.72 95%CI 0.58–0.88 P = 0.001). In patients >38 years or <8 retrieved oocytes the influence of progesterone level become evident only from 1.75 ng/ml (23.1% vs 13.1% OR 0.50 95%CI 0.32–0.78 P = 0.002). In the BS group, only a progesterone level over 1.75 ng/ml halved the CPR (OR 0.43 95%CI 0.19-0.98 P = 0.045) and LBR (OR 0.41 95%CI 0.16-1.05, P = 0.062). In the first frozen embryo transfer after PE freeze only cycles, the CPR (OR 1.19 95%CI 0.78-1.82 p = 0.407) and LBR (0.80 95%CI 0.48-1.34, p = 0.401) appeared not significantly different than in low progesterone level fresh transfers.

Limitations, reasons for caution: This is a retrospective analysis, with all the inherent limitations and bias of such a study. The results of vitrified-warmed freeze only cycles need to be confirmed in a larger sample.

Wider implications of the findings: Our data show that PE at trigger day is significantly inversely related to the fresh cycle outcome in CS and BS transfers, although the PE threshold appear to be higher in BS. Our data confirm that elective freezing strategy rescue the negative effect of PE on cycle outcome.

Trial registration number: N/A.

P-686 Cross-talk between Bcl2l10 and Aurka in regulation of meiotic spindle assembly

S.Y. Lee, E.Y. Kim, K.H. Kim, K.A. Lee

CHA University, Department of Biomedical Science- College of Life Science, Gyeounggi-Do, Korea- South

Study question: How does Bcl2l10 regulate expression and activity of Aurka (Aurora kinase A)?

Summary answer: Bcl2l10 and Aurka regulate each other for their expression and activity via transcription factor of Aurka expression and PP1 (protein phosphatase 1) in mouse oocytes.

What is known already: Previously, we firstly identified the non-apoptotic function of Bcl2l10, a member of Bcl-2 gene family, that Bcl2l10 was expressed in meiotic spindle and RNAi (RNA interference)-based Bcl2l10 silencing caused meiotic arrest at Metaphase-I with abnormal spindle assembly. Aurka is a pivotal kinase that required for centrosome maturation and spindle assembly in mitosis as well as meiosis. Expression of Aurka decreased at transcription and translation levels, whereas phospho-Aurka increased by depletion of Bcl2l10 in mouse oocytes. In addition, activity of Aurka was also reduced by Bcl2l10 RNAi. Consequently, we firstly found that Bcl2l10 is an upstream regulator of Aurka in oocytes.

Study design, size, duration: Phospho-Aurka can be dephosphorylated by PP1. Because Bcl2l10 RNAi increased auto-phosphorylation of Aurka on Threonine 288, we confirmed whether changes in PP1 activity mediated that increase in Aurka phosphorylation after Bcl2l10 RNAi. Oocytes were collected from C57BL/6 mice. Changes in PP1 activity were confirmed by western blot analysis using phospho-PP1 specific antibody. For inhibition or activation of Aurka activity, we treated oocytes with MLN8054 or okadaic acid, respectively.

Participants/materials, setting, methods: Bcl2l10 RNAi-treated MI oocytes were obtained by microinjection of Bcl2l10 double-stranded RNA and non-treated MI-oocytes were used as control. MLN8054 or okadaic acid were added to culture medium and oocytes were incubated for 16 hours. RT-PCR was carried out by using cDNAs equivalent to that of single-oocyte. For western blot analysis, 200 oocytes of each group were used.

Main results and the role of chance: As a result of RT-PCR, transcripts of E4TF1, TRAP220/MED1 and HIF-1α decreased by Bcl2l10 RNAi. In addition, protein expressions of E4TF1 and HIF-1α were decreased whereas TRAP220/MED1 was not detected. Phosphorylation of PP1 at Threonine 320, an inactive form of PP1, increased after Bcl2l10 RNAi treatment indicating that PP1 activity was inhibited by Bcl2l10 RNAi. It suggests that Bcl2l10 regulates the phosphorylation of Aurka through regulation of PP1 activity. By treatment MLN8054 (Aurka inhibitor) or okadaic acid (Aurka activator) during in vitro oocyte maturation, phosphorylation of Aurka at Threonine 228 decreased or increased, respectively. Interestingly, Bcl2l10 expression was enhanced by MLN8054 and was reduced by okadaic acid. Therefore, our data suggests that a novel form of reciprocal regulation exists between Aurka activity and Bcl2l10, forming a feedback loop in mouse oocytes.

Limitations, reasons for caution: This study was performed with mouse oocytes and results need to be validated for human oocytes.

Wider implications of the findings: In the present study, we firstly identified the association between Bcl2l10 and Aurka in meiotic spindle assembly. It is known that defects in spindle assembly are the major contributor to aneuploidy in oocytes. Therefore, this study may provide new theoretical basis about high rates of aneuploidy in human eggs.

Trial registration number: No required.

P-687 Does endometriosis influence the embryo quality and/or development? Insights from a retrospective study

A.M. Sanchez Garcia[1], L. Pagliardini[2], L. Privitera[3], G.C. Cermisoni[3], A. Bartolacci[3], E. Papaleo[3], M. Candiani[3], P. Vigano'[2]

[1]Università Vita-Salute San Raffaele, Reproductive Sciences Laboratory- Division of Genetics and Cell Biology- IRCCS San Raffaele Scientific Institut, Milano, Italy
[2]IRCCS San Raffaele Scientific Institute, Reproductive Sciences Laboratory- Division of Genetics and Cell Biology, Milan, Italy
[3]IRCCS San Raffaele Scientific Institute, Department of Obstetrics and Gynecology, Milan, Italy

Study question: To evaluate the impact of endometriosis on embryo development at cleavage stage.

Summary answer: We did not find differences in the number/quality of day 3 embryos but we detected a lower ongoing pregnancy rate in women with endometriosis.

What is known already: The impact of endometriosis on fecundity and IVF outcomes is still controversial. Some studies suggested that endometriosis could influence IVF outcomes since oocytes may be more difficult to be retrieved and fewer embryos could be obtained compared to women without endometriosis. Poor oocyte and embryo quality has been as well postulated. Moreover, endometriosis has been not consistently associated with lower implantation rates and lower pregnancy rates. Nevertheless, the reasons to explain the suboptimal performance of IVF in endometriosis patients are poorly understood and can only be hypothesized.

Study design, size, duration: This is a retrospective study including patients undergoing IVF at the San Raffaele Hospital from 2013 to 2017. Endometriosis were laparoscopically diagnosed in all patients before IVF treatment.

A total of 430 cycles from women with endometriosis were studied and matched with cycles of women without the disease (n = 854) according to age, number of oocytes retrieved and time period of the treatment. A total of 3818 embryos at cleavage stage (day 3) have been analyzed.

Participants/materials, setting, methods: Embryo quality at day 3 in terms of number of cells, cell fragmentation and symmetry was evaluated. Principal components summarizing baselines variables (age, BMI, seminal parameters, number of oocytes retrieved, number of oocytes available) were used as covariates. Student's test, Mann-Whitney U test and logistic regression model were used as appropriate. All the results are presented as mean ± SD, OR (95% CI) or median (interquartile range)

Main results and the role of chance: The number of oocytes retrieved in both groups were similar (5.8 ± 4.4 controls vs 5.8 ± 4.6 endometriosis, p = 0.84). We did not find as well any statistically differences in the percentage of MII oocytes [80% (56-100%) controls vs 75% (50-100%) endometriosis patients, p = 0.25] and in fertilization rate [80% (57-100%) controls vs 80% (61-100%) endometriosis patients, p = 0.29]. Overall, in cycles from endometriosis women we did not find any difference regarding the number of embryos obtained at cleavage stage (3.5 ± 2.6 controls vs 3.7 ± 2.6 endometriosis patients, p = 0.47). In addition, the percentage of top/good quality embryos was as well similar [56% (25-100%) controls vs 50% (17-88%) endometriosis patients, p = 0.20]. Besides, we did not find any difference in the blastulation rate, excluding cycles in which transfers were performed or embryos were frozen in day 3. Despite similar fertilization rate and number/quality of embryos obtained, we found a reduction in ongoing pregnancy rate in women with endometriosis compared with the control group (24.2% in controls vs 17.7% in endometriosis group, corrected OR = 0.60; 95% CI 0.40-0.90, p = 0.014) after adjusting for the number and quality of transferred embryos, the day of transfer (cleavage or blastocyst stage) and principal components.

Limitations, reasons for caution: The main limitation of our study is its retrospective design; however, no clinical decision/intervention has been done between the time of fertilization and day 3 so that this study may be comparable to a prospective one. In both groups, the effect of other causes of infertility cannot be excluded.

Wider implications of the findings: These results indicate that women with endometriosis undergoing IVF treatments may expect a similar embryo quality than women without the disease. The results of this study could help in understanding whether embryo or endometrial factor represents the main cause for the poor success in ART in patients with moderate/severe endometriosis.

Trial registration number: not applicable.

P-688 GnRH antagonist administration in the luteal phase for the prevention and management of severe OHSS: a systematic review and meta-analysis

T.G. Lainas[1], G. Lainas[1], I. Sfontouris[1], A. Prodromidou[1], C. Venetis[2], I. Zorzovilis[1], B. Tarlatzis[3], E. Kolibianakis[3]

[1]EUGONIA, Dept. of IVF, Athens, Greece
[2]University of New South Wales, School of Women's and Children's Health UNSW Medicine, Sydney, Australia

[3]*Aristotle University of Thessaloniki Medical School, Unit for Human Reproduction - 1st Dept of Obstetrics and Gynecology, Thessaloniki, Greece*

Study question: Is luteal GnRH antagonist administration effective for the prevention and management of severe OHSS?

Summary answer: Luteal GnRH-antagonist administration is not effective for the prevention of severe OHSS, while appropriate trials evaluating its use for outpatient management of OHSS are lacking.

What is known already: Despite the increasing use of GnRH agonist trigger in high risk for OHSS patients, hCG administration remains the most popular triggering option, and as a result a significant proportion of high-risk women (9-38%) will still develop severe OHSS. Luteal GnRH-antagonist administration has been used as a method of OHSS prevention, as well as tertiary management of established severe OHSS at an outpatient level via a luteolytic mechanism.

Study design, size, duration: Medline, Scopus, Google Scholar, Cochrane and Clinicaltrials.gov databases were systematically searched for articles published up to December 2017, along with the references of all articles that were retrieved in full text. Trials referring to prevention or treatment of OHSS by administering GnRH antagonists in the luteal phase of women undergoing ART who were either at risk for developing OHSS or were diagnosed with severe OHSS were considered eligible for inclusion.

Participants/materials, setting, methods: Fourteen studies with a total 1029 patients were considered eligible for inclusion. Pooled odds ratios (OR) and 95% confidence intervals (CI) were calculated using random effects model due to significant heterogeneity in the methodological characteristics of the included studies. Higgin's I^2 was utilized for statistical heterogeneity assessment. Statistical meta-analysis was performed using RevMan 5.3.

Main results and the role of chance: Prevention of early OHSS: Four eligible studies (1 RCT, 1 case-control, 2 retrospective) with 409 high-risk patients (GnRH-antagonist n = 197 versus control n = 212) were included in the meta-analysis. GnRH-antagonist was administered from Day 0 or Day 1 for 3-5 days. The incidence of OHSS was not affected by GnRH-antagonist administration (Mild OHSS: OR = 1.58%, 95% CI:0.49-5.15, p = 0.44, I^2 = 79%; Moderate OHSS: OR = 0.92%, 95% CI:0.41-2.05, p = 0.84, I^2 = 56%; Severe OHSS: OR = 0.39%, 95% CI:0.05-3.16, p = 0.37, I^2 = 54%). Clinical pregnancy rates were similar (229 patients; OR 1.33 95% CI 0.71 to 2.51, p = 0.37; I^2=%, p = 0.56) in GnRH-antagonist and control group.

Management of established early severe OHSS (tertiary management): Ten studies: 3 prospective observational, 2 retrospective and 5 case-series; 620 patients) were considered eligible. GnRH-antagonist was administered from the day of severe OHSS diagnosis for 2-4 days. The studies used different methodology and inclusion criteria, rendering a meta-analysis not feasible. In the systematic review conducted, the majority of studies supported that luteal GnRH-antagonist administration prevented patient hospitalization and resulted in rapid regression of established severe OHSS. OHSS resolution was demonstrated by a significant decline of ovarian volume, ascites, haematocrit, white blood cell count, serum oestradiol and progesterone, making patient management on an outpatient basis feasible.

Limitations, reasons for caution: The retrospective nature of most of the included studies, their high heterogeneity and low quality, as well as the limited number of patients treated constitute significant limitations. Furthermore, the definition of OHSS and the therapeutic protocol of GnRH- antagonist administration varied both for prevention and for treatment of OHSS studies.

Wider implications of the findings: Although available evidence is insufficient, luteal GnRH-antagonist administration does not appear to be effective for the the prevention of severe OHSS. On the other hand, GnRH-antagonist appears to result in rapid regression of established severe OHSS, but appropriate trials evaluating its use for outpatient management of OHSS are lacking.

Trial registration number: Not applicable.

P-689 Follicular flushing is associated with a significantly higher oocyte recovery rate compared to no flushing: a randomized controlled trial

G. Lainas[1], I. Sfontouris[2], T. Lainas[2], A. Makris[2], C. Venetis[3], I. Zorzovilis[2], G. Petsas[2], B. Tarlatzis[4], E. Kolibianakis[4]

[1]*Barts and The London NHS Trust - Royal London Hospital, Obstetrics and Gynaecology, London, United Kingdom*
[2]*EUGONIA, Eugonia Unit of Assisted Reproduction, Athens, Greece*
[3]*University of New South Wales, School of Women's and Children's Health UNSW Medicine, Sydney, Australia*
[4]*Aristotle University of Thessaloniki Medical School, Unit for Human Reproduction - 1st Dept of Obstetrics and Gynecology, Thessaloniki, Greece*

Study question: Is follicular flushing associated with a higher oocyte recovery rate compared to no flushing?

Summary answer: Follicular flushing is associated with significantly higher oocyte recovery rates compared to no flushing.

What is known already: There is an ongoing debate regarding the effectiveness of follicular flushing during oocyte retrieval. Current evidence suggests that follicular flushing does not seem to improve live birth rate, clinical pregnancy rate or the number of oocytes retrieved, but to significantly increase the duration of oocyte retrieval compared to no flushing. Nevertheless, follicular flushing continues to be a routine procedure in many IVF centres.

Study design, size, duration: In this randomized controlled trial, conducted from November 2017 until January 2018, the right and left ovary from each patient were randomized (with a computer-generated randomization list) to be aspirated using either follicular flushing or no flushing. The primary outcome was oocyte recovery rate defined as the number of oocytes retrieved/number of follicles aspirated (>11 mm). Assuming a 10% difference in recovery rate, a sample size of eighteen patients was required to yield 80% power.

Participants/materials, setting, methods: Patients aged <42 years, with intact ovaries, each containing at least four follicles > 11 mm on the day of hCG administration were included in the study. Patients with endometriotic cysts were excluded. Oocyte retrieval was performed 35–36 h after hCG by transvaginal ultrasound-guided aspiration using the same double lumen needle (16 G, Casmed International Ltd, UK) and the same digitally adjusted aspiration vacuum for both ovaries. Outcomes were analyzed using paired t-test.

Main results and the role of chance: A total 20 patients were included in the study. Baseline characteristics, expressed as mean (SD), were: age 34.6 years (4.7), BMI 24.1 kg/m^2 (5.2), duration of infertility 4.1 years (3.0), number of previous attempts 1.0 (1.1), AFC 8.8 (5.8), AMH 3.1 (2.7), basal FSH 7.2 (1.9), basal LH 5.1 (1.9), basal oestradiol 43.8 (13.8) and basal progesterone 0.7 (0.6).

Oocyte recovery rates [mean (95% CI)] [74.2% (65.0-83.4) versus [42.7% (30.0-55.5), p<0.0001], number of COC retrieved [7.7 (5.1-10.2) versus 4.1 (1.7-6.5), p<0.0001], number of metaphase-II oocytes [6.8 (4.6-8.9) versus 4.0 (1.7-6.3), p<0.0001] and number of fertilised oocytes [4.1 (2.9-5.4) versus 2.2 (1.2-3.1), p = 0.001] were significantly higher using follicular flushing compared to no flushing. Maturation rates [90.2% (82.5-97.9) versus 87.8% (75.6-99.9)], fertilization rates [64.5% (53.4-75.6) versus 65.3% (45.5-85.1)], proportion of embryos transferred [34.1% (6.4-61.9) versus 25.8% (-3.4 – 55.1)] were similar in the flushing and no flushing groups. There were no cases of bleeding in either group of the present study.

Limitations, reasons for caution: A double-lumen needle was used in both "flushing" and "no-flushing" groups. The use of a single-lumen aspiration needle in the non-flushing group might have altered the results obtained, although this is not supported by the published literature. The current study was powered to compare retrieval rates but not pregnancy achievement.

Wider implications of the findings: Follicular flushing was associated with a significantly higher oocyte recovery rate, number of COCs retrieved, number of metaphase-II oocytes, number of 2PNs but with similar oocyte maturation, fertilization rates and proportion of embryos transferred compared to no flushing in normal/high responders.

Trial registration number: NCT03354858

P-690 The acceleration of reproductive aging in MMTV-TGF-alpha mice

T. Önel[1], E. Yildirim[2], S. Dogan[3], A. Yaba Ucar[2]

[1]*Yeditepe University Institute of Health Science, Histology and Embryology, İstanbul, Turkey*
[2]*Yeditepe University School of Medicine, Histology and Embryology, İstanbul, Turkey*
[3]*Yeditepe University School of Medicine, Medical Biology, İstanbul, Turkey*

Study question: Does MMTV-TGF-alpha mice present diminished ovarian reserve during reproductive lifespan and does TGF-alpha gene interfere with mTOR signal pathway during ovarian aging?

Summary answer: Protein and mRNA expression levels of mTOR and P-mTOR were gradually decreased from 10 to 18 week, but increased at 50 week in MMTV-TGF-alpha ovary.

What is known already: TGF-alpha is an important growth factor regulating follicle development and tumorigenesis. TGF-alpha detected in granulosa cells of developing follicles, atretic follicles and theca-lutein cells. mTOR is a key regulator for proliferation, growth, differentiation, and apoptosis. Previously, we have shown that mTOR has regulatory role during follicular development and inhibition of mTOR induced a reduction in granulosa cell proliferation and follicle growth. mTOR signaling also plays a major regulatory role in aging since suppression of this pathway extends lifespan in model organisms.

Study design, size, duration: Total of 24 MMTV-TGF-alpha female mice which overexpreses TGF-alpha were used. Animals were ad-libitum fed and sacrificed and then, ovaries were removed at 10, 18, 50 and 82 weeks of mouse age.

Participants/materials, setting, methods: Ovaries of 10, 18, 50 and 82 week old MMTV-TGF-alpha mice were dissected and fixed in 4% paraformaldehyde and embedded in paraffin. 5 µm slides were taken from paraffin blocks and stained with hematoxylin and eosin staining in order to examine the morphological changes in ovaries. mTOR and P-mTOR protein and mRNA expression levels were detected using western blot and q-RT-PCR,respectively, for each experimental group.

Main results and the role of chance: 10 week old MMTV-TGF-alpha mouse ovary presented numerous developing follicles from different follicular developmental stage. However, compared to the usual healthy mouse ovary, MMTV-TGF-alpha ovary had smaller antrum spaces in secondary follicles and did not exhibit a healthy follicular structure. The number of infiltration of luteinized cells were higher, while the number of developing follicles were lower at 18 week old ovaries. Compared to the other groups (10, 18, and 82 week), 50 week old ovary had decreased number of developing follicle and increased number of atretic follicles. In addition, diminished number of developing follicules and increased number of atretic follicles were detected in 82 week old mouse ovary. Protein and mRNA expression levels of m-TOR and P-mTOR were gradually decreased from week 10 to 18 week, but they were increased at 50 week. Then, expression levels were decreased again towards to week 82 of mouse age. Therefore we suggest that TGF-alpha may have relation with mTOR signal pathway during ovarian aging and over-expression of TGF-alpha may cause acceleration of diminished ovarian reserve and premature ovarian failure.

Limitations, reasons for caution: The best way to explain interaction between TGF-alpha and mTOR signal pathway might be use TGF-alpha homozygote/heterozygote knock-out mouse ovary.

Wider implications of the findings: TGF-alpha and/or mTOR might be targets for developments of drug which could be used in infertility.

Trial registration number: Embryology/(female (in) fertility)

P-691 Altered endometrial receptivity in infertile females with polycystic ovarian syndrome (PCOS) as compared to fertile counterparts: analogy of protein expression profiles

N. Rashid[1], A. Nigam[2], S.K. Jain[3], S. Wajid[1]

[1]*Jamia Hamdard, Biotechnology, Delhi, India*
[2]*Hamdard Institute of Medical Sciences and Research, Gynecology and Obstetrics, Delhi, India*
[3]*Hamdard Institute of Medical Sciences and Research, Biochemistry, Delhi, India*

Study question: To unravel the proteins involved in compromising the receptivity and hampering the decidualization process in the endometrium of females with polycystic ovarian syndrome.

Summary answer: Proteins involved in cell proliferation, differentiation, development, signaling, mitochondrial metabolism, DNA repair, apoptosis and post-transcriptional modification may play key roles in endometrial programming for receptivity.

What is known already: Various expression studies have revealed the profiles of genes underlying unique cellular and molecular mechanisms involved in endometrial shedding, repair, regeneration and remodelling. Endometrium in PCOS females is known to be compromised for receptivity due to progesterone resistance with elevated levels of androgens and/or insulin. However dysregulation of specific downstream pathways and involved proteins need to be elucidated in detail for the development of biomarkers related to infertility and pregnancy disorders in PCOS women.

Study design, size, duration: 12 infertile PCOS and 12 healthy fertile subjects within reproductive age group (24–36 years) were recruited from Gynecology and Obstetrics OPD of HAH Centenary Hospital, Jamia Hamdard, during the period (june 2015 to august 2016) after approval of JHIEC for clinical studies. Endometrial biopsies were collected during secretory phase in oligo-ovulatory PCOS, anovulatory PCOS (progesterone withdrawal bleeding) and normal subjects after written informed consent was taken from all subjects enrolled in the study.

Participants/materials, setting, methods: Tissue was lysed and protein profiles were generated though two-dimensional gel electrophoresis (GE Lifesciences) and analyzed with PD-QUEST analysis software (Bio-Rad). Differential protein spots were identified through MALDI-TOF MS protein mass fingerprinting (Ultraflex III instrument). This was followed by RNA isolation (MiniSure Spin total RNA isolation kit, Nucleopore) and cDNA synthesis using RevertAid^{TM} H Minus first strand cDNA synthesis kit (Thermo Fisher Scientific). Relative expression analysis was performed using real time-PCR (Light cycler 480, Roche)

Main results and the role of chance: Relative expression of 13 genes was calculated with reference to GAPDH (reference gene). Altered expression in genes UCHL1, MYO3A, TGM1, CCNB1, AR6P1, PARP6, CRBB2, PIGX, DUS2L, THIL, ZNHI1, RAM and P2YP12 was found to be associated with infertile endometrial grounds in PCOS females. Besides basic cellular processes like proliferation, differentiation and development; cell cycle regulatory, DNA repair and apoptotic processes seemed to be involved in decreased endometrial receptivity in case of PCOS females. Mitochondrial metabolism, cell signaling and cellular transport were some other key affected processes. Regulation at post transcriptional level also seem to control many important downstream processes. The observed differences in gene expression profiles provide a roadmap into the intricacies involves in endometrial remodelling and receptivity.

Limitations, reasons for caution: Small sample size and unicentric nature of the study are the main limitations.

Wider implications of the findings: These findings have important diagnostic and prognostic implications in case of infertile PCOS females. Moreover the study also provide insights into endometrial cancer risk in infertile PCOS subjects. Further studies are required to establish the role of these proteins in the regulation of pathways associated with endometrial programming and remodeling.

Trial registration number: None.

P-692 Increased apoptosis and inflammation are key factors in endometrial dysfunction of PCOS patients

N. Daei-farshbaf[1], F. Amjadi[1], Z. Zandieh[1], M. Mehdizadeh[2], M. Ashrafi[3], R. Aflatoonian[4]

[1]*School of medicine- Iran university of medical science, Department of Anatomy, Tehran, Iran*
[2]*School of medicine- Iran university of medical science, Cellular and Molecular Research Center and Department of Anatomy, Tehran, Iran*
[3]*School of medicine- Iran university of medical science, Obstetrics and Gynecology Department, Tehran, Iran*
[4]*Royan Institute for Reproductive Biomedicine- ACECR, Department of Endocrinology and Female Infertility at Reproductive Biomedicine Research Center, Tehran, Iran*

Study question: Which phenomena could result in impaired endometrial function in women with PCOS?

Summary answer: Apoptosis and inflammation pathways play important roles in endometrial dysfunction of PCOS patients.

What is known already: Increased cytokine expression and inflammatory responses due to intense leukocyte immigration could impede endometrial

preparation and manifest implantation failure and recurrent miscarriage. Besides, overexpression of p53-dependant apoptosis genes demonstrated excess cell death in endometrial cell in PCOS patients which could be caused by higher inflammation and following ROS production. Generally, it seems that reduced implantation rate in PCOS might be due to insufficient endometrial preparation caused by more intense inflammation and apoptosis than normal proliferative phase endometrium.

Study design, size, duration: This study was genomic analysis that 10 human endometrial biopsies taken from pcos patients and 10 from healthy fertile women in the proliferative phase. All participants are in reproductive age with normal menstrual cycles.

Participants/materials, setting, methods: Total mRNA were extracted from endometrial tissues from pcos patients (n = 10) and healthy fertile individuals (n = 10) during proliferative phase. The expression profile of female infertility was investigated using qRT-PCR array.Informed consent was obtained from patients. All measurements were performed in triplicates on independent biological replicates.

Main results and the role of chance: Data of PCR array demonstrated high expression of apoptosis inducing factors such as IL1B, TNF and TNFRSF and apoptosis promoting factors like TP53, BAX and Bcl2 in PCOS group, while the expression of CASP3 was not different significantly in both groups. Beside apoptosis genes, cytokine genes expression was higher in PCOS group. overexpression of inflammatory factors like CCL5, CXCL12, CLDN4 and ICAM1 confirmed leukocyte immigration in endometrial tissue and inflammation. In inflammation, TNF, IL6 and IL1 activate NF-kB which could enhance DNA hypermethylation and chromosomal instability. Following DNA hypermethylation, epigenetic inactivation of tumour suppressors and overexpression of Bcl2 which suppresses DNA repair might reduce endometrial cell quality and impair its function in implantation.

Limitations, reasons for caution: The main limitation of this study is a low number of human endometrial samples for array analysis.

Wider implications of the findings: This study provide novel data about impeded endometrium preparation in proliferative phase of PCOS patients as compared to normal women which might affect endometrial receptivity in women with PCOS.

Trial registration number: N/A.

P-693 Effect of maternal separation stress and use of antidepressants on rat ovarian reserve

H.K. Parlaktaş[1], E. Yıldırım[1], T. Onel[1], H. Zortul[2], F. Arıcıoğlu[2], A. Yaba Ucar[1]

[1]Yeditepe University School of Medicine, Histology And Embryology, İstanbul, Turkey
[2]Marmara University, Department of Pharmacy, İstanbul, Turkey

Study question: does maternal separation and consequent antidepressant use effect ovarian reserve in rat ovaries?

Summary answer: Maternal separation may cause diminish of ovarian reserve. Afterwards antidepressants use have different effects on ovary depending on Agmatine treatment or Imipramine treatment.

What is known already: Premature ovarian insufficiency (POI) occurs when primordial follicle pool of a female is depleted early in her reproductive life leading to the cease of menstrual cycle and fertility. The premature activation of primordial follicles can occur due to many reasons such as genetic background, diseases, drug use or exposure to harmful materials. There might be a relationship between the use of antidepressants and the premature depletion of ovarian reserve in female rats using a depression model. Therefore, we aimed to determine the follicle reserve of the ovaries in the depression model created by maternal separation in rats with antidepressants used.

Study design, size, duration: Totaly 20 pups were used in this study. Pups separated from their mother on their second postnatal day for 4 hours every day for 15 days and when they were grown to 60 days old they were given antidepressants Agmatine and Imipramine for 15 days until dissection. Dissected ovaries were processed, embedded in paraffin and sectioned using microtome. The sections were then stained with hematoxylin and eosin for morphological analyzes and imaged using light microscope.

Participants/materials, setting, methods: Dissected ovary tissues were processed and sectioned at 5 µm. Sections were stained using hematoxylin and eosin for morphological analyzes and follicle counting. Afterwards mTOR and P-mTOR expression were detected in serial sections using immunofluorescence staining.

Main results and the role of chance: Morphological results presented that maternal separation may cause diminish of ovarian reserve. Rats were separated from their mother as pups but not treated with antidepressants later in life would have smaller ovaries and more corpus luteum then control ovaries that were kept together with mother. Afterwards antidepressants use have different effects on ovary depending on Agmatine treatment or Imipramine treatment. Agmatine treatment helps decrease corpus luteum numbers so may maintain follicles from reserve in each ovarian cycle in rats. In addition to that decreased number of Graafian follicle numbers in Agmatine treated group could indicate that, activation of oocytes decrease along with their full maturation therefore number of Graafian follicles decrease and ovarian reserve is maintained. mTOR expression was detected in oocyte and granulosa cells in rat ovary from each experimental group. P-mTOR expression observed specifically in oocyte nucleus and in mitotic dividing granulosa cells in rat ovaries. Even though no significant change is observed in mTOR and P-mTOR levels in immunofluorescence staining, Imipramine has detrimental effects on ovarian reserve as it increases corpus luteum numbers. Therefore, further functional studies will provide an insight into whether mTOR signal pathway have relation with Agmatine and Imipramine treatment in model of depression.

Limitations, reasons for caution: Anti-mullerian hormone level might show as indicator of diminished ovarian reserve. We will confirm mTOR and P-mTOR expression results with western blot and qRT-PCR.

Wider implications of the findings: Tricyclic antidepressant Imipramine has more severe effects that Agmatine on ovarian reserve.

Trial registration number: not applicable.

P-694 Does early respons on ovarian stimulation using corifollitropin alfa versus hp-hMG influence live-birth rates in a GnRH antagonist protocol?

S. De Rijdt[1], J. Errazuriz[1,2], S. Santos-Ribeiro[1], P. Drakopoulos[1], A. Racca[1], A. Galvao[1,3], N. De Munck[1], M. Camus[1], H. Tournaye[1], C. Blockeel[1]

[1]Universitair Ziekenhuis Brussel, Center for Reproductive Medicine, Brussels, Belgium
[2]Clinica Alemana, Center for Reproductive Medicine, Santiago, Chile
[3]Centro Materno Infantil do Norte - Centro Hospitalar do Porto, Department of Obstetrics and Gynecology, Porto, Portugal

Study question: Does early respons on ovarian stimulation using either corifollitropin alfa (CFA) or highly purified human postmenopausal gonadotrophin (hp-hMG) in an antagonist protocol influence live-birth rates?

Summary answer: No statistically significant difference in terms of clinical outcomes between early versus normal responders after ovarian stimulation with CFA or hp-hMG was found.

What is known already: A single injection of CFA for the first 7 days of ovarian stimulation provides similar clinical outcomes when compared to daily injections of rFSH, namely with respect to the number of oocytes and live-birth rates. A retrospective analysis has also shown that early responders (women who fulfill the final maturation hCG trigger criteria prior to or on stimulation day 8) have comparable number and size of pre-ovulatory follicles, oocytes, good-quality embryos and ongoing pregnancy rates, when compared to those who perform stimulation for >8 days. However, comparative information between early and late responders following CFA versus hp-hMG is lacking.

Study design, size, duration: This is a retrospective analysis of a cohort of fresh IVF/ICSI cycles in GnRH antagonist protocol performed in a single tertiary IVF center, during the period comprised between January 2011 and January 2017.

Participants/materials, setting, methods: Patients (aged ≥35 to ≤42 years) received either a single dose of 150 µg CFA or daily 300IU of hp-HMG for the first 7 days of stimulation. From day 8 on, treatment continued with a daily dose of hp-hMG (300IU/d) until the day of trigger. We categorized patients as "early responders" if they reached at least three follicles ≥17 mm

before day 8 of stimulation and as "normal responders" those that reached the criteria after 8 days.

Main results and the role of chance: A total of 916 cycles were divided in 4 groups: group A (CFA early responders, n = 116), group B (CFA normal responders, n = 344), group C (hp-hMG early responders, n = 127) and group D (hp-hMG normal responders, n = 309). There were no differences in demographic characteristics among the groups regarding age, AFC and BMI. Patients who needed 8 or more stimulation days needed on average 3 extra days until triggering in both groups (CFA-group 10.1 total days vs hp-hMG-group 9.5 total days; p = 0.2). There were no differences among the four groups in terms of total number of retrieved oocytes (6.0 ± 5.3, 5.7 ± 3.3, 5.6 ± 4.9, 5.7 ± 3.7, p = 0.9), number of mature oocytes (4.4 ± 4.3, 4.7 ± 2.7, 4.0 ± 3.0, 4.4 ± 3.2; p = 0.22), and number of embryos transferred (1.5 ± 0.8, 1.6 ± 0.6, 1.5 ± 1.0, 1.5 ± 0.9; p = 0.3). Live-birth rates were 22.4%, 20.4%, 17.3% and 15.6% (p = 0.28) respectively, for the four study groups.

Limitations, reasons for caution: We acknowledge that this is a retrospective data analysis. Although a large dataset was analyzed, prospective studies are needed to confirm these results.

Wider implications of the findings: The duration of ovarian stimulation to reach the criteria for triggering final oocyte maturation did not seem relevant for the clinical outcome.

Trial registration number: not applicable.

P-695 NLRP3 expression is upregulated in ovarian granulosa cells in a mouse model of polycystic ovary syndrome

B. Wang[1], P. Hong[2], G. Yuping[1], L. Bin[1]

[1]*Xinhua Hospital- School of Medicine- Shanghai Jiaotong University, Department of Reproductive Medicine, Shanghai, China*
[2]*The International Peace Maternity and Child Health Hospital- School of Medicine- Shanghai Jiao Tong University, reproduction center, Shanghai, China*

Study question: TLR3 and NLRP3 inflammasome contribute to the pathogenesis of Type 2 diabetes in functioning as sensors for metabolic stress. Whether TLR3 and/or NLRP3 are involved in the pathogenesis of PCOS.

Summary answer: By immunohistochemical analysis, expressions of TLR3 and NLRP3 are increased in granulosa cells in the PCOS mice.

What is known already: Elevated TLR3 is involved in dysfunction of pancreatic β-cells. NLRP3 inflammasome activation is upregulated in type 2 diabetes. TLR3 activation is one of the most important signals that can activate NLRP3 inflammasome. Most PCOS women are suffering from insulin resistance. High fat diet (HFD) and letrozole (LET) treatment have successfully induced reproductive and metabolic phenotype of PCOS in mice.

Study design, size, duration: Four week-old, C57BL/6 N female mice were implanted subcutaneously with a placebo or 3 mg LET pellet with or without HFD (60% calories from fat) feeding (n = 8 for control and HFD group, n = 6 for LET and LET plus HFD group). Seven weeks after treatment, the mice were anesthetized with chloral hydrate, blood was collected via retro-orbital bleeding, the parovarian fat pad, the ovaries were dissected, fixed in 4% paraformaldehyde.

Participants/materials, setting, methods: The mice were weighed weekly. A glucose tolerance test was performed on the mice 3 weeks after the treatment. Blood triglyceride, total cholesterol were measured. Paraffin-embedded fats and ovaries were sectioned and stained with hematoxylin and eosin. Expression of TLR3 and NLRP3 in the ovaries were evaluated by immunohistochemical staining. Numbers of follicle and corpus luteal in each ovary were recorded, and diameters of fat cells were measured by using the CellSens software.

Main results and the role of chance: From 3 weeks after treatment, the LET + HFD and LET mice exhibited significantly more weight gain than control and HFD mice (P < 0.05). LET + HFD and LET mice contained more large antral follicles than HFD and control mice. The number of corpora lutea was significantly lower in LET and LET + HFD mice than in control and HFD mice (P < 0.01). Fasting glucose levels in LET and LET + HFD mice were significantly higher than control mice (P < 0.05). LET + HFD mice resulted in markedly increased serum glucose levels at 60, 120 and 180 min after administration of glucose compared with control and LET mice (P < 0.01). LET + HFD mice exhibited significantly higher serum triglyceride and total cholesterol levels than control, HFD, and LET mice (P < 0.05). The average diameter of adipocytes was significantly larger in LET + HFD mice than control and LET mice (P < 0.01). Integral optical density (IOD) of TLR3 in ovary section of LET and LET + HFD mice was higher than HFD and control (P > 0.05). IOD of NLRP3 in LET and LET + HFD mice was significantly higher than control (P < 0.05).

Limitations, reasons for caution: In this study, expression of TLR3 and NLRP3 in the ovary was shown only in mouse species evaluated by immunohistochemistry. Further study needs to be carried out in human beings. Whether increased NLRP3 correlates with activation of caspase-1 then results in pyroptosis of granulosa cell still need to be clarified.

Wider implications of the findings: The significant body weight gain, dyslipidemia and ovarian morphology change in mice is caused mainly by LET. TLR3 and NLRP3 mediated inflammation might involved in the pathogenesis and etiology of PCOS. NLRP3 might be used as potential therapeutic target in this disease.

Trial registration number: basic research, no trial registration number.

P-696 Dual trigger with gonadotropin-releasing hormone agonist (GnRHa) and standard dose of human chorionic gonadotropin (hCG) to improve oocyte maturation rate (MR)

I. Elkouhen[1], C. Herbemont[1], A. Brax[2], M. Comtet[2], S. Sarandi[1], A. Seroka[2], B. Dagher-Hayeck[2], J. Boujenah[3], C. Vinolas[2], M. Grynberg[2], I. Cedrin-Durnerin[2], C. Sifer[1]

[1]*Hôpital Jean Verdier, Histologie-Embryologie-Cytogenetique-CECOS, Bondy, France*
[2]*Hôpital Jean Verdier, Medecine de la Reproduction, Bondy, France*
[3]*Hôpital Jean Verdier, Gynecologie-Obstetrique, Bondy, France*

Study question: Does dual trigger with GnRHa and standard dose of hCG in IVF/ICSI cycles increase MR in patients with a history of >25% of immature oocytes?

Summary answer: The proportion of mature oocytes retrieved was significantly higher after a dual trigger in comparison with the patient's previous cycle.

What is known already: Oocyte maturation for IVF/ICSI cycles is commonly induced by hCG to mimic natural luteinizing hormone (LH) surge. After controlled ovarian hyperstimulation (COH), few oocytes are arrested at immature stages. If >25% of retrieved oocytes are immature, affected patients have poorer IVF outcomes than those with <25%. GnRHa has been explored in many clinical scenarios, primarily to prevent ovarian hyperstimulation syndrome. One advantage of using GnRHa to trigger oocyte maturation is the induction of a more physiological release of LH/FSH (Follicle-Stimulating-Hormone). Recently, a dual trigger has been proposed as a potential treatment in patients with a history of immature oocytes retrieved.

Study design, size, duration: This is a retrospective, case-control study performed between December 2008 and December 2017. A total of 70 patients, who experienced high oocyte immaturity rate (>25%) during their first IVF/ICSI cycle (analyzed as control group) and received a dual trigger for their subsequent cycle (dual trigger group), were involved in the study. Only patients with at least one oocyte retrieved were included.

Participants/materials, setting, methods: Initial COH cycle was performed using agonist/antagonist protocols, and ovulation was triggered with hCG. During the subsequent cycle, patients received antagonist protocol and dual trigger using triptorelin 0.2 mg and hCG. Primary endpoint was MR (number of metaphase-2 (M2) oocytes/ retrieved oocytes). Secondary endpoints were (i) fertilization (ii) D2-top-quality-embryo (D2-TQE: 4 blastomeres, <20% cytoplasmic fragmentation) and (iii) cumulative clinical pregnancy rates (including fresh and frozen-thawed transfers during the study period). Outcomes were compared using paired-sample analysis.

Main results and the role of chance: Briefly, patients' mean age was 32.9 (control group) versus (vs.) 34.3 years (dual trigger group) (p<0.0001). A mean of 11.3 and 12.3 oocytes were retrieved in control and case groups, respectively (p = 0.26). A significant increase in number of M2 oocytes and consequently MR was achieved in case of dual trigger (8.9; 73.0%) when compared to control group (6.0; 50.3%: p<0.0001). Hence, numbers of fertilized oocytes (6.2 vs. 3.8; p<0.0001) and D2-TQE (2.2 vs. 1.6; p = 0.015) were significantly higher after dual trigger. However, fertilization (61.3 vs. 68.0%; p = 0.19) and

D2-TQE rates (33.5 vs. 36.7%, p = 0.4) per mature oocyte were statistically similar when compared between control and dual trigger groups, respectively. During the study period, cumulative clinical pregnancy rate yielded 50% (35/70) in control group vs. 64.3% (45/70) in dual trigger group (p = 0.08).

Limitations, reasons for caution: Cases of high oocyte immaturity rate are rare, explaining the long inclusion period in this retrospective study. Besides, baseline characteristics of patients were heterogeneous; especially antagonist and agonist protocols were included in control group. Only randomized studies, analyzing both biological and clinical outcomes, would confirm the efficiency of this strategy.

Wider implications of the findings: Dual trigger seems efficient for managing patients with high oocyte immaturity rate. Moreover, oocyte ability to be fertilized and develop into TQE might not be impaired by this treatment. If these results were confirmed, dual trigger, permitting to obtain more M2-oocytes, might optimize the chances of pregnancy in such patients.

Trial registration number: Not applicacable.

P-697 Oocyte quality in patients with polycystic ovary syndrome (PCOS): impact on the extended culture and live birth rates

L. Delaroche[1], C. Dupont[2], N. Kazdar[3], F.X. Aubriot[4], P. Oger[4], F. Lamazou[4], C. Yazbeck[4]

[1]Laboratoire d'AMP Eylau Unilabs de la clinique Pierre Cherest, AMP, Neuilly sur seine, France
[2]University Hospital Tenon, Reproductive Medecine, Paris, France
[3]Laboratoire d'AMP Eylau Unilabs de la clinique Pierre Cherest, Reproductive Medecine, Neuilly sur seine, France
[4]CMC Pierre Cherest, Reproductive Medecine, Neuilly sur Seine, France

Study question: Does the oocyte quality in patients with PCOS affect the extended culture and live birth rates?

Summary answer: PCOS does not seem to affect the rate of useful blastocysts when compared to normo-ovulatory patients.

What is known already: PCOS and its subsequent fertility disorders cause difficulties in the management of the assisted reproductive technologies. Some authors have hypothesized that PCOS patients have a lower oocyte and embryo quality due to modifications of intra- and extra-ovarian factors. Nonetheless, few studies have investigated the biological parameters in PCOS patients after IVF attempts and specifically the extended culture.

Study design, size, duration: This is a single-center cohort study performed from October 2015 to December 2017. Patients with PCOS (Rotterdam criteria) and control normo-ovulatory patients (defined as patients presenting tubal, male or idiopathic infertility, with regular cycles and AMH basal level between 2 and 4 ng/ml), who underwent IVF with extended culture to day 6 were included. Were exclude: woman's age > 37 years, severe endometriosis, cycle rank > 3 and severe male factor (<1 million/mL).

Participants/materials, setting, methods: 59 PCOS and 114 control patients were included. The main endpoint was the rate of useful blastocysts obtained (transferred and/or frozen) and secondaries were the oocyte maturity rate and the cumulative live birth rate per ovum pick up.

Results were compared using chi-square test and Student t-test. Confounding factors were evaluated by a logistic regression model. The P value was considered significant when <0.05. The results were expressed by mean ± standard deviation or percentage.

Main results and the role of chance: The mean age of the patients was 31.5 ± 3.1 and 32.4 ± 3.0 years old, respectively, for the PCOS and the control groups (p = 0.06). While the total dose of FSH administered and the number of days of stimulation were similar, the average number of oocytes retrieved was significantly higher in the PCOS group compared with controls (15.7 ± 7.3 versus 12.9 ± 7.1, p = 0.02). The oocyte maturity rate was statistically lower in the PCOS group compared to controls (74.3% versus 83.1%, p = 0.005). The rate of useful blastocysts was similar between the PCOS and the control groups (50.1% versus 53.6%, p = 0.62). The cumulative live birth rates per ovum pick up were not statistically different (31.7% in the PCOS group versus 37.2% in the control group, p = 0.50; Odds Ratio = 0.78; 95% Confidence Interval [0.38; 1.59]).

Limitations, reasons for caution: This preliminary results need to be confirmed by larger studies and prospective randomized controlled trials.

Wider implications of the findings: Our study confirms that PCOS patients have significantly more retrieved oocytes but a lower maturity rate thus leading to a similar number of mature oocytes compared to normo-ovulatory patients and the chances of obtaining useful blastocysts were similar. Pregnancy and birth rates were comparable to those of the normo-ovulatory patients.

Trial registration number: I certify that there is with any financial organization regarding the material discussed in the study.

P-698 To compare clinical and metabolic effects of metformin versus combined therapy with metformin and myoinositol and D- chiro-inositol in PCOS women: A randomized control trial

A. Bahadur, H. Arora, J. Chaturvedi, A. Raj, L. Chawla, A. Gaurav, K. Khoiwal, R. Kuncham, O. Kumari, N. Bhattacharya, A. Yadav, S. Kumari

All India Institute of Medical Sciences, Obstetrics & Gynaecology, Rishikesh, India

Study question: Does addition of Inositols have a role in improving clinical and metabolic parameters in women with PCOS?

Summary answer: Inositols have shown to reduce insulin resistance, it improves insulin sensitivity of target tissues and positively affects clinical and metabolic parameters in women with PCOS.

What is known already: PCOS is one of the most common endocrine disorders (6-10%) affecting women of reproductive age. Insulin resistance plays a pivotal role in etiopathogenesis of PCOS. To prevent long term health consequences of PCOS, besides life style modifications, use of insulin sensitizers has been proposed. Metformin has been commonly used. Recently, inositols-Myoinositol (MI) and D-chiro-inositol (DCI) have shown to be an efficient and safe alternative in PCOS management.

Study design, size, duration: This randomized controlled trial was conducted in Gynae OPD at All India Institute of Medical Sciences, Rishikesh from January 2017 till December 2017. Patients with PCOS were randomized into two groups, 30 in group I (Metformin) and 32 in group II (Metformin and MI and DCI).

Participants/materials, setting, methods: Group I received Metformin 500 mg twice a day for 3 months & in Group 2 received metformin with Myoinositol 550 mg + D-chiro-inositol 150 mg twice daily for 3 months. Clinical parameters like menstrual cycle regularity, acne, hirsutism, BMI, waist & hip circumference were compared at baseline and after 3 months of therapy. Similarly fasting blood sugar, fasting insulin levels and HOMA-IR index was compared at baseline and after 3 months of therapy.

Main results and the role of chance: Baseline characteristics were similar in two groups. Mean age was 28.35 +/- 2.74 & 27.12 +/- 3.34 years in Group I and II respectively. Mean BMI was 27.71 +/- 3.60 & 27.38 +/- 3.92 kg/m2 in Group I and II respectively. There was no improvement in acne score. However, after receiving treatment for 3 months statistically significant improvement was seen in Group 2 (metformin + MI +DCI) in their clinical parameters like weight (p < 0.02), waist circumference (p < 0.0155) & hip ratio (p < 0.00045). A significant improvement was seen in menstrual cycle length and bleeding days in Group II (p < 0.01). HOMA-IR index also showed a statistically significant improvement after 3 months of therapy in Group II (2.83 +/- 1.29 vs 1.62 +/- 0.59, p < 0.03).

Limitations, reasons for caution: Main limitation of this study is small sample size. Large randomized control trials are required to explore above hypothesis.

Wider implications of the findings: Using a comprehensive, detailed assessment of clinical parameters our study has shown a beneficial effect of Metformin in combination with MI + DCI in women with PCOS & insulin resistance. Combined therapy may have a role in PCOS patients.

Trial registration number: Applied for.

P-699 Impaired follicular development and ovulation in PCOS mouse model can rescued by rapamycin treatment

A. Yaba[1], M.Ş. Aydin[2], S. Agus[3], E. Gunalan[3], E. Yildirim[1], B. Yilmaz[3]

[1]*Yeditepe University School of Medicine, Histology and Embryology, Istanbul, Turkey*
[2]*İstanbul Medipol University School of Medicine, Histology and Embryology, İstanbul, Turkey*
[3]*Yeditepe University School of Medicine, Physiology, Istanbul, Turkey*

Study question: Does Rapamycin (Inhibitor of mTOR) treatment suppress proliferation of granulosa cells and decrease LH level in treatment of PCOS?

Summary answer: Rapamycin may have important role in treatment of PCOS.

What is known already: Polycystic ovary syndrome (PCOS) is a complex reproductive and endocrine disorder. The target of rapamycin (TOR) gene product has been implicated in the control of cell growth and proliferation, protein synthesis, and autophagy. mTOR consist of 2 different protein complex as TOR complex 1 (mTORC1) and TOR complex 2 (mTORC2). Rapamycin is an inhibitor of mechanistic target of rapamycin pathway. Phosphorylation of serine residue 2448 in mTOR has been shown to correlate with the activation status of mTOR and proliferation of granulosa cells, and mTOR has functional role in granulosa cells during successful folliculogenesis and ovary with PCOS.

Study design, size, duration: 5 groups were mainly designed: Control (no treatment), PCOS (injection of DHEA (6 mg/100 g BW in 0.1 ml of sesame oil) (s.c) for 20 consecutive days), Vehicle (daily (s.c) sesame oil alone injection), Rapamycin (5 mg/kg in DMSO), Rapamycin Vehicle (daily (s.c) DMSO alone injection).

Participants/materials, setting, methods: We used hematoxylin-eosin staining for morphological eveluation to show the effect of Rapamycin treatment on PCOS mouse ovary. 17-Beta estradiol, progesterone and Luteinizing hormone levels detected by using ELISA. Additionally TUNEL and follicle counting methods were used for determine of follicle reserve in each experimental groups. mTOR signal pathway proteins and genes were presented with western blot and quantitative Real Time PCR, respectively.

Main results and the role of chance: it is the first time mTOR pathway (TORC1 ve TORC2) and activation products are presented at protein and mRNA levels in Rapamycin treated-PCOS mouse model. We detected that Rapamycin treatment can improve follicular development, decreased LH level and provide ovulation, and corpus luteum structure can occur again in PCOS mouse ovary ($p<0.05$). Additionally, we detected decrease number of atretic follicle and save primordial follicle reserve ($p<0.05$) after Rapamycin treatment. Therefore Rapamycin may be use as a potential therapeutic strategy for the treatment of PCOS.

Limitations, reasons for caution: Different treatment dosages might use for treatment model of POCS.

Wider implications of the findings: We suggested that Rapamycin may have a new approach to PCOS treatment and understanding the mechanism of dominant follicle selection and anovulatory female infertility.

Trial registration number: not applicable.

P-700 Cumulative live birth rates in women with low ovarian reserve are higher with conventional IVF stimulation than after repeated natural cycle IVF attempts

M. Gaudoin[1], P. Sim[2], H. Smith[3], R. Fleming[1], L. Zujovic[3], N. Raine-Fenning[3]

[1]*GCRM- Glasgow Centre For Reproductive Medicine, IVF Unit, Glasgow, United Kingdom*
[2]*University of Glasgow, Medical School, Glasgow, United Kingdom*
[3]*Nurture, IVF Unit, Nottingham, United Kingdom*

Study question: To determine the comparative efficacy of stimulated IVF (stimIVF) versus natural cycle IVF (ncIVF) in women with predicted poor ovarian reserve (POR).

Summary answer: The stimIVF group had fewer visits, fewer cycles cancelled and higher egg yield (all $P<0.001$) and higher cumulative live birth rate (18.2% vs. 10.3%, $P<0.03$).

What is known already: The conveyor belt of follicle recruitment in POR, and how many follicles might develop in any one treatment cycle, is unpredictable and variable. Such women have a poor prognosis and clinics are often reluctant to treat them because of the perceived effect on the clinic's success rates. In the UK, ncIVF is not counted in a clinic's pregnancy results so it offers an alternative, also avoiding expensive FSH injections and the possibility of back-to-back treatment cycles if a cycle is unsuccessful. However, a maximum of 2 oocytes is achievable.

Study design, size, duration: Simultaneous, parallel 2-centre cohort study in cycles from January 2015 – December 2016.

501 women underwent 699 stimIVF cycles (flare protocol with Gonal-F) at GCRM (Glasgow), and 55 women underwent 116 ncIVF cycles at Nurture (Nottingham).

The number of visits required, the cycle cancellation rate, the egg yields, live birth rates (LBR) per fresh cycle and cumulative LBR were determined.

Participants/materials, setting, methods: Both centres are private IVF units but take a different approach to treatment of poor ovarian responders. GCRM (Glasgow) favours conventional stimulation flare protocol with Gonal-F (225 IU/day if weight < 80Kg, 300 IU/day if weight > 80Kg). Nurture (Nottingham) favours ncIVF with no FSH but starting Cetrotide and daily ultrasound scans when the lead follicle is greater than 13 mm diameter. Both trigger using Ovitrelle and oocyte retrieval is performed 35-37 hours post-trigger.

Main results and the role of chance: There was no difference in BMI between the groups but the stimIVF patients were one year younger ($P<0.01$). They had a higher AMH level ($P < 0.001$) but were more likely to smoke ($P<0.001$).

The stimIVF group had fewer treatment cycles per patient (1.4 vs. 2.1, $P < 0.01$). Furthermore, they had fewer scans (and hence fewer clinic visits), fewer cycles cancelled, higher egg yields per egg retrieval (3.6 ± 2.7 vs. 0.9 ± 0.5) with more embryos available for transfer (all $P<0.001$). Only 4% of the stimIVF patients retrieved no eggs compared to 18% in the ncIVF group although this was not statistically significant ($P = 0.11$).

The fresh live birth rate (LBR) per cycle start was not different (16.6% v. 10.3%, $P = 0.09$). However, the stimIVF group had a greater chance of having frozen embryos and when subsequent frozen embryo transfers were taken into account, the cumulative LBR was higher (18.2% vs. 10.3%, $P<0.03$).

Limitations, reasons for caution: This was neither a matched nor randomised study. The stimIVF group were more likely to smoke but had a higher AMH. However, the difference in AMH does not account for the difference in the egg yields between the groups.

Wider implications of the findings: This is a poor prognosis group and both approaches have their merits. The avoidance of FSH injections in ncIVF must be balanced against the need for more scans (the increased burden of more clinic visits), the psychological impact of greater likelihood of cycle cancellation and the lower cumulative LBR.

Trial registration number: N/A.

P-701 Optimal number of oocytes need to complete family per retrieval

R.A. Gupta, K.D. Nayar, G. Kant, N. Sharma, M. Singh, D. Nayar, Kapil Dev Nayar

Akanksha IVF centre, Mata Chanan Devi Hospital, New Delhi, India

Study question: To determine the optimal number of oocytes per retrieval needed to obtain at least two live births while practicing safe and effective stimulation.

Summary answer: Retrieving12-16 oocytes per cycle is optimal for completing family without wastage of surplus embryos as compared to retrieving more than16 or less than 8 oocytes.

What is known already: The practice is globally shifting to mild stimulation and elective single embryo transfer claiming to attain pregnancy rates similar to conventional stimulation and embryo transfer, but the desire to complete family and need for multiple retrieval cannot be overlooked. Aggressive stimulation to obtain too many oocytes, is associated with risk of OHSS, diminished receptivity because of high estradiol levels. On the other hand mild stimulation with multiple stimulation cycles, associated surgical and anaesthetic risks, financial and emotional burden.Too many cryopreserved embryos burden the lab and

couples financially. Generally they are written off by couples after achieving two live births.

Study design, size, duration: A prospective cohort study conducted in an IVF centre of tertiary hospital. All women less that 36 years with primary infertility undergoing IVF between 1st January 2016 and 31st December 2016.

Participants/materials, setting, methods: Women were stimulated with conventional antagonist protocol. All the participants meeting the inclusion criteria were divided in 3 groups Group A: 8-12, Group B: 12–16 and Group C with ≥ 16 oocytes. Women with < 8 retrieved oocytes or with single embryo transfer were excluded. The primary outcomes cumulative pregnancy rate (CPR) and family completion rate (≥ 2 live births) were calculated for each group. Statistics done using chi square test.

Main results and the role of chance: A total of 782 women meeting the inclusion criteria were divided in Group A (N = 186) Group B (N = 308) Group C (N = 288) based on number of oocytes as described. The number of fresh cycles were least in Group C (39%) due to elective freezing to prevent OHSS. The family completion rate was comparable in group B and Group C which was significantly more than that in Group A (23%, 26%, 13% respectively p = 0.0005,0.0007, 0.34). There would be significantly more number of patients with unused embryos in group C compared to Group B (15% vs 9% p = 0.03).

N = 782	Group A 8-12 N = 186 (%)	Group B 12-16 N = 308(%)	Group C > = 16 N = 288 (%)
Fresh ET cases	162 (87%)	211 (89%)	112 (39%)
Retrievals leading to a 1 Live Birth	87(47%)	179 (58%)	184 (64%)
Retrievals leading to 2 Live Birth	20(11%)	52 (17%)	55(19%)
Patients with 1 live birth with frozen embryos remaining	14 (8%)	74 (24%)	83 (29%)
Patients with 2 live birth with frozen embryos remaining	3 (2%)	29 (9%)	43(15%)
Expected no. patients to achieve a 2nd child from their remaining frozen embryos	4(2%)	18 (6%)	20 (7%)
Family Completion Achieved	24(13%)	70(23%)	75(26%)

Limitations, reasons for caution: A better design would be comparison of multiple stimulation cycles in women with low oocyte yield. Small sample size and short follow up too are limitations.

Wider implications of the findings: Stimulate mildly to retrieve 12-16 oocytes as LBR are better in fresh cycles with just sufficient number of frozen embryos needed for family completion compared to too many oocytes posing risk of OHSS and high cost of unused cryopreservation embryos without any increase in number of women with completed family.

Trial registration number: Trial registration number: MCDH/2015/58

P-702 The impact of polycystic ovary syndrome (PCOS) on early- and late-morphokinetic parameters: a retrospective analysis of 3938 time-lapse (TL) monitored embryos

G. Christou[1], I. Dimitriadis[2], C.R. Sacha[2], J.B. Bakkensen[2], K.A. Dickinson[1], C. Veiga[1], A. Blanchard[1], C.L. Bormann[3], I. Souter[3]

[1]*MGH Fertility Center, Obstetrics and Gynecology, Boston- MA, U.S.A.*
[2]*Massachussets General Hospital, Obstetrics and Gynecology, Boston- MA, U.S.A.*
[3]*Massachussets General Hospital/Harvard Medical School, Obstetrics and Gynecology, Boston- MA, U.S.A.*

Study question: Is there an effect of PCOS on either early- and/or late-morphokinetic parameters obtained during embryonic culture to blastocyst stage in a TL-monitored incubator?

Summary answer: When comparing embryos derived from PCOS patients with those from other diagnoses no significant effect of PCOS on either early- and/or late-morphokinetic parameters was noted.

What is known already: PCOS contributes to both anovulation and poor embryonic quality, as well as an increased risk for early pregnancy loss. Emerging TL studies have raised suspicions that PCOS may influence certain TL-morphokinetic parameters, such as the duration of the 4th cleavage division and the time to reach the morula stage. Whether PCOS affects the timing of additional early- and/or late-morphokinetic parameters thought to predict blastocyst formation and implantation remains unclear.

Study design, size, duration: Data from 3938 embryos, derived from 579 IVF cycles taking place at a major academic center between 9/2013 and 9/2016, were retrospectively reviewed. All embryos were cultured to the blastocyst in a TL-monitored incubator. Embryos derived from PCOS were compared to i) those from patients with all other diagnoses (225 and 3713 embryos, respectively), and ii) in a sub-analysis to those with either idiopathic or tubal factor infertility (TFI), in regards to certain morphokinetic parameters.

Participants/materials, setting, methods: Groups were compared in regards to the following TL-morphokinetic parameters: time-period from i) pronuclei fading (tPN*f*) to 1st-cytokinesis (P_1), ii) 2- to 3-cells (P2), iii) 3- to 4-cells (P3), iv) 4- to 5-cells (P4), v) tPN*f* to early-blastulation (P_{SB}).

Mann-Whitney *U*-, χ^2-tests, and multilevel mixed-effects regression models [adjusted for potential confounders: age, body mass index (BMI), basal-FSH, fertilization method] were used to assess mean differences [AMD (95% CI)] between groups. P<0.05 was considered significant.

Main results and the role of chance: Median (interquartile range) age, BMI, basal-FSH were 33.1(31.6-36.6) vs. 35.6(32.9-38.8) years, p = 0.01; 24.5(22.3-28.1) vs. 23.1(21.2-26.5) kg/m^2, p = 0.06; 5.4(5.0-6.5) vs. 7.0(5.9-8.3) IU/L, p<0.01 for PCOS vs. non-PCOS diagnosis, respectively. When all embryos were included in the analysis, no difference was noted in any of the morphokinetic parameters between the groups [AMD (95% CI) in hours: 0.1 (-0.2-0.3), p = 0.54; -0.3(-1.3-0.7), p = 0.53; -0.4(-1.4-0.6), p = 0.46; -0.3 (-1.8-1.1), p = 0.66; 1.3(-1.6-4.3); p = 0.38; for P_1, P_2, P_3, P_4 and P_{SB}, respectively]. Furthermore, when usable (selected for either transfer or cryopreservation) were analyzed separately from discarded embryos, the results did not change.

Similarly, in a sub-analysis comparing PCOS-embryos to those derived from couples with idiopathic infertility, no significant differences were noted in any of the studied morphokinetic parameters [AMD (95% CI) in hours: 0.10(-0.18-0.38), p = 0.48; -0.3(-1.3-0.7), p = 0.53; -0.4(-1.4-0.6), p = 0.46; -0.3(-1.8-1.1), p = 0.66; 1.3(-1.6-4.3), p = 0.38; for P_1, P_2, P_3, P_4 and P_{SB}, respectively]. However, when comparing PCOS to TFI-embryos (no oocyte factor infertility), P_1 duration was significantly longer and P_2 significantly shorter in the former subgroup [AMD (95%CI): 0.36(0.07-0.66) hours, p = 0.02; 1.25(0.44-2.06) hours, p<0.01, respectively]. Differences persisted for the most part, even when analyzing usable embryos separately from discarded ones. All other morphokinetic parameters did not differ between PCOS and TFI groups.

Limitations, reasons for caution: Limitations include mainly the retrospective design of the study and the inclusion of only those morphokinetic parameters thought to predict blastocyst development. Furthermore, insulin resistance and/or metformin treatment were not taken into consideration. Time periods were normalized to tPN*f* to account further for fertilization method, as needed.

Wider implications of the findings: No obvious effect of PCOS was noted on either early- or late-morphokinetic parameters assessed by TL-microscopy, except when PCOS embryos were compared to a subgroup with no obvious contributing oocyte factor, a finding suggestive of a subtle impact of PCOS on oocyte quality.

Trial registration number: Not applicable.

P-703 Impact of serum progesterone on embryo quality and cumulative live birth rate in oocyte donation cycles

C. Blockeel[1], A. Racca[1], N. De Munck[1], S. Santos-Ribeiro[1], J. Errazuriz Valenzuela[1], P. Drakopoulos[2], A. Galvao[1], S. Mackens[1], M. De Vos[1], H. Tournaye[1]

[1]*Universitair Ziekenhuis Brussel, Centre for Reproductive Medicine, Jette- Brussels, Belgium*
[2]*University of Liège, Department of Reproductive Medicine, Liège, Belgium*

Study question: Does late follicular elevated serum-progesterone (LFEP) during ovarian stimulation for oocyte donation have an impact on embryo quality (EQ) and cumulative live birth rates (CLBRs)?

Summary answer: LFEP does not have an influence on embryo quality and CLBR in oocyte donation cycles.

What is known already: Ovarian stimulation promotes the production of progesterone (P) which has been demonstrated to have deleterious effect on IVF outcomes when elevated during the follicular phase. While there is robust evidence that this elevation results in (epi)genetic changes impairing endometrial receptivity, the impact on EQ remains a matter of debate. The oocyte-donation model is the best tool to assess the effects of LFEP on EQ from those on endometrium receptivity separately. Previous studies in oocyte donation cycles investigating the influence of elevated P on pregnancy outcomes in oocyte recipients gave conflicting results.

Study design, size, duration: This was a retrospective analysis including all GnRH antagonist down-regulated cycles for fresh oocyte donation that took place in a tertiary referral university hospital between 2010-2017. A total of 397 donor-acceptor cycles were included. Each donor was included only once in the analysis and could be associated to a single acceptor.

Participants/materials, setting, methods: The sample was stratified according to the following serum P levels on the day of ovulation triggering: ≤1.5 ng/mL and >1.5 ng/mL. The primary outcome parameter was the top-quality embryo rate on day 3 and the secondary outcome was CLBR defined as a live-born delivery after 24 weeks.

Main results and the role of chance: 397 fresh oocyte donation cycles were included in the analysis, of which 314 (79%) had a serum P ≤ 1.5 ng/ml and 83 (20.9%) had a serum P>1.5 ng/ml. The average age of the two oocyte donor groups was 31.4 ± 4.7 and 30 ± 4.6 years, respectively. The mean number of oocytes retrieved was significantly higher in the elevated P group with 16.6 ± 10.6 vs 11.5 ± 6.7 in the P ≤ 1.5 group (p<0.001). Maturation rate, fertilization rate and mean age of the acceptors did not vary significantly between the two study groups (p = 0.622; p = 0.767; p = 0.889, respectively). The total number of good quality embryos on day 3 was significantly higher in the elevated P group with 6.1 ± 4.4 vs 8.7 ± 6.3, p<0.001); however, the good quality embryo rate and the utilization rate (defined as the number of transferred or cryopreserved embryos to the number of fertilized oocytes) were similar between the two arms (p = 0.386 and p = 0.098, respectively). Furthermore, multivariable regression analysis accounting for donor age and number of oocytes retrieved as potential confounders showed that CLBR was not negatively influenced by LFEP (60.7% for P ≤ 1.5 ng/ml and 71.2% for P>1.5 ng/ml, p = 0.115).

Limitations, reasons for caution: This is an observational study based on a retrospective data analysis. Better extrapolation of the results could be validated by performing a prospective analysis.

Wider implications of the findings: This is the first study providing evidence that LFEP in oocyte donation programs does not influence embryo quality neither cumulative live birth rates in the oocyte recipient.

Trial registration number: not applicable.

P-704 Effects of progesterone on the regulation of luteinising hormone surge in adult female rat

W. He[1,2], X.F. Li[2], K.T. O'Byrne[2], Y.P. Kuang[1]

[1]*Assisted Reproduction Department, Shanghai Ninth People's Hospital, Shanghai Jiaotong University School of Medicine, China*
[2]*Division of Women's Health, King's College London, United Kingdom*

Study question: Our clinical studies have shown that progesterone acts as an effective alternative for blocking premature LH surges in COH. What is the underlying mechanisms of progesterone blocking LH surge?

Summary answer: Our results indicate progesterone prevents premature LH surges during superovulation in women and rats. The hypothalamic AVPV and ARC nuclei may be targeted for this.

What is known already: Premature LH surges are a major cause for cycle cancellation during controlled ovarian stimulation (COH) in women undergoing IVF. Efforts to minimize the occurrence of premature LH surges have mainly relied on the use of GnRH agonist/antagonist, which exert greater risk of side effects. Our clinical studies have shown that progesterone acts as an effective alternative for blocking premature LH surges in COH. Early studies indicate the hypothalamus mediates the feedback effect of progesterone on regulation of LH level. However, the underlying mechanisms remain unknown, which exert difficult for clinical doctors to use this protocol.

Study design, size, duration: This study included a total of 64 adult female Sprague-Dawley rats, who were given a single intraperitoneal injection of pregnant mare serum gonadotropin to induce ovarian hyperstimulation followed by either progesterone or oil injection for 2 days.

Participants/materials, setting, methods: The collected data considered the LH surge and pulse, progesterone and estradiol dynamic during hyerovulation. Also, the follicle development and embryological result were examined. We tested the hypothesis:1, progesterone can prevent premature LH surge during superovulation without affecting oocyte quality in rat model; 2, Progesterone may prevent premature LH surges via progesterone receptors in the hypothalamic arcuate (ARC) and/or anteroventral periventricular (AVPV) nuclei; loci known to be involved in LH pulse and LH surge generation.

Main results and the role of chance: Our results indicated that progesterone prevents premature LH surges during superovulation in rats,without affect the number of oocyte retrieved and further embryonic development, These results coincide with our clinical observation. Meanwhile, progesterone administration prolonged the estrous cycle (P<0.05) in SD rats. Onset of the LH surge was significantly delayed when progesterone was administrated with PMSG(P<0.05). Furthermore, bilateral microinjections of anti-progestin RU486 (5 ng/μl, 0.8 μl) into the AVPV and ARC influence LH levels. Therefore, The hypothalamic AVPV and ARC nuclei may be targeted for progesterone regulation of LH surges in the rat.

Limitations, reasons for caution: Transferability of our findings is challenged by the possible variation of hypothalamus nuclei corodinates, but positively affected by our intra-nuclei injection technique and observation on microscopic histological inspection of stained brain sections to eliminate animals with inappropriate bilateral cannulae placement.

Wider implications of the findings: Our present study enhances the current understanding of the roles of progesterone in the regulation of the GnRH/LH surge:1) progesterone can effectively blocking LH surges during superovulation while maintaining normal follicle development ;2.The hypothalamic AVPV and ARC nuclei may be targeted for progesterone blockade of LH surge in rats.

Trial registration number: Not applicable.

P-705 Retrospective analysis of DuoStim cycles shows similar overall performance and oocyte quality between follicular and luteal phase stimulation

G. Cecchino, M. Cerrillo, M. Cruz, J.A. Garcia-Velasco

IVI-RMA Global, Reproductive Endocrinology and Infertility, Madrid, Spain

Study question: Is there any difference in the overall performance of follicular and luteal phase stimulation among patients undergoing double ovarian stimulation (DuoStim)?

Summary answer: DuoStim shows similar results with respect to the number of retrieved oocytes, fertilization and blastocyst formation rates in both the follicular and luteal phase stimulation.

What is known already: Previous studies have demonstrated that several waves of cyclic development of antral follicles may coexist within the same menstrual cycle. Moreover, it has been shown that follicles formed during the luteal phase have a similar ovulation potential. Often, physicians are compelled to perform several stimulation cycles to obtain more eggs. Thus, the DuoStim

protocol could be an attractive alternative to obtain a higher number of oocytes in a shorter period, declining the time-to-pregnancy. It also emerges as an interesting option for emergency fertility preservation in oncologic patients. However, more studies are needed to validate its feasibility.

Study design, size, duration: Retrospective analysis of DuoStim cycles performed over the past year in IVI-RMA Global clinic, Madrid, Spain. We aimed to evaluate the potential usefulness of the DuoStim protocol by comparing oocyte quality and overall performance between follicular and luteal phase stimulation within the same menstrual cycle.

Participants/materials, setting, methods: We included 25 women who underwent a total of 30 cycles using the DuoStim protocol in 2017 at IVI-RMA Global clinic, Madrid, Spain. Data containing baseline and demographic characteristics along with the variables of interest from both the follicular and the luteal stimulation were exported from our institutional repository software platform. Statistical analysis included ANOVA test for variables with normal distribution and Mann-Whitney U test whenever the distribution was not normal.

Main results and the role of chance: Baseline characteristics revealed that the median values of age, AMH, AFC and IMC were 39.2 years, 1.34, 5.88 and 20.8 kg/m^2, respectively. Thus, our study population was mainly composed of women with advanced age and low ovarian reserve. In fact, all patients presented with very poor reproductive prognosis and multiple IVF failures. Variables of interest presented a normal distribution, except for the blastocyst formation rate. ANOVA test demonstrated no significant differences between the follicular and luteal stimulation, respectively, regarding the median of: days of stimulation (10.53 vs. 11.83; $p = 0.077$), amount of gonadotropin administered (2059.26 UI vs. 2603.45 UI; $p = 0.061$), retrieved oocytes (4.83 vs. 5.17; $p = 0.737$), MII oocytes (3.93 vs. 4.20; $p = 0.741$) and fertilization rate (60.75% vs. 62.76%; $p = 0.830$). Likewise, Mann-Whitney U test did not show any difference with respect to the blastocyst formation rate (20.78% vs. 26.62%; $p = 0.260$). There was a trend to use greater amounts of gonadotropin during the luteal phase, although not statistically significant. In conclusion, the use of the DuoStim protocol exhibited encouraging results irrespective of age and ovarian reserve. Similar findings were reported by other few studies comprising patients with a distinct clinical profile. Randomized clinical trials are needed to legitimize its use in daily practice.

Limitations, reasons for caution: Unequivocal limitations are essentially related to the retrospective design. Therefore, the study is prone to sources of error due to confounding factors. Nevertheless, considering the scarcity of prospective data in literature, our results provide important insights on the effectiveness of the DuoStim.

Wider implications of the findings: This work contributes to confirm the efficiency of the DuoStim protocol. It may be especially convenient for oncologic patients or those with a poor reproductive prognosis pursuing infertility treatments. Not only it reduces the time to obtain a higher number of eggs, but it also attenuates the couple´s anxiety.

Trial registration number: Not clinical trial.

P-706 Primary subfertility is significantly associated with higher levels of Thyroid Stimulating Hormone within the normal range preceding In Vitro Fertilization

C. Delprat[1], E. Van Dam[2], P. Van de Ven[3], K. Aissa[4], M. Ter Haar[4], Y. Feenstra[4], A. De Roos[4], G. Beelen[4], R. Schats[4], C. Lambalk[4]

[1]*VUMC, IVF, Amsterdam, The Netherlands*
[2]*VUMC, Internal Medicine, Amsterdam, The Netherlands*
[3]*VUMC, Epidemiology and Biostatistics, Amsterdam, The Netherlands*
[4]*VUMC, Obstetrics- Gynaecology and Reproductive Medicine, Amsterdam, The Netherlands*

Study question: Is the distribution of Thyroid Stimulating Hormone (TSH) levels within the normal range different in primary or secondary subfertile women without thyroid hormone substitution?

Summary answer: In women with primary subfertility preceding In Vitro Fertilization (IVF) the prevalence of higher TSH values is significantly increased compared to secondary subfertile women.

What is known already: Among healthy fecund women, TSH levels ≥ 2.5 mIU/L were not associated with fecundity, pregnancy loss, or live birth (Plowden, et al., 2016). While in subfertile women the prevalence of TSH levels 2.5 mIU/L -4.5 mIU/L is much higher (20%) than in the general population (5 %) we don't know the influence of primary or secondary subfertility on this distribution. In the context of the discussion whether the cut-off level for TSH for subfertile women should be 2.5 mIU/L or 4.5 mIU/L we should fill this gap of knowledge and precise predicting factors for and define individual thyroid (dys) function.

Study design, size, duration: In a cohort study in women starting In Vitro Fertilization (n = 858) or Intra Cytoplasmatic Sperm Injection (n = 843) between the first of January 2008 and the first of March 2012 the distribution of TSH levels (0.3-2.49 and 2.50-4.5 mIU/L) was compared in primary and secondary subfertility women.

Participants/materials, setting, methods: Women aged 22-45 years with TSH 0.3–4.5 mIU/L without thyroid hormone substitution were included at VU University Medical Center, Amsterdam, the Netherlands, an Iodine-sufficient area. Chi-square tests were used to compare groups of patients based on TSH values using 2.5 mIU/l as a cut-off, and primary or secondary subfertility.

Main results and the role of chance: In primary subfertile women TSH is significantly increased preceding IVF compared to secondary subfertile women ($p = 0.006$): of the primary subfertile women 23.4 % has TSH levels in the higher reference range, while of the secondary subfertile women 16 % has TSH levels in the higher reference range.

Limitations, reasons for caution: Unknown values of free thyroxine and thyroid peroxidase antibodies limit the clinical interpretability.

Wider implications of the findings: Increased prevalence of higher TSH levels in primary subfertile women preceding IVF corresponds with Plowdens data that increased TSH values are of less importance in previous pregnant women. In primary subfertile women preceding IVF on the other hand these increased TSH values might disclose thyroid dysfunction.

Trial registration number: not applicable.

P-707 Caenorhabditis elegans, a model for polycystic ovary syndrome

M. Muñoz[1], C. Viera[2], C. Lopez[2], S.G.H. Viso[2], M. Artal[2], J.A. Horcarjadas[2], A.M. Brokate-Llanos[2], A. Garzón[2], J. Vioque[3], J. Girón[3], M.S. Alaiz[3]

[1]*Universidad Pablo de Olavide, Genética, Sevilla, Spain*
[2]*Andalusian Center for Developmental Biology-, Consejo Superior de Investigaciones Científicas/Junta de Andalucía/Universidad Pablo de Olavide, Seville, Spain*
[3]*Instituto de la grasa - CSIC, Componentes bioactivos y funcionales de productos vegetales, Sevilla, Spain*

Study question: Can C. elegans be used as a model for POCS suitable for drug screening and gene target identification?

Summary answer: We have found drugs, natural extracts and genes that when inactivated reduce the infertility of a C. elegans POCS model.

What is known already: PCOS is the most common endocrine and metabolic disorder affecting women in reproductive age. Although the ethology is complex, in most cases this syndrome is related to the insulin signalling pathway. In fact, two-thirds of adult women with PCOS suffer from insulin resistance and hyperinsulinemia. Reduction of the insulin signalling pathway reduce fertility in all biomedical model organism, including invertebrate like Drosophila and the nematode Caenorhabditis elegans. C. elegans is a simple model organism that allow easily to search in high through put scale for genes, drugs and natural extracts that suppresses the reduction of fertility.

Study design, size, duration: We have selected C. elegans strains affected in the insulin pathway which generate a strong reduction of the fertility. Specifically, a mutant in the homologue gene to the insulin receptor and a mutant in the phosphatidylinositol-3-kinases.

By using high through put RNAi screening we have tested reduction of activity in 16.000 genes in the PCOS models and observed if the infertility is reduced. Furthermore, we have treated with 250 edible plant extracts and 50 purified compounds.

Participants/materials, setting, methods: C. elegans allows high through put screening of plant extracts and purified compounds. Plant extracts were collected by our group and hydrophilic and hydrophobic extract were generated of each extract.

RNAi screening were performed, feeding C. elegans with bacteria that produce double strand RNAi of target genes.

In each case more than 10 individuals were treated and in three days all the brood size was counted.

Main results and the role of chance: From 16.000 RNAi assays we have found that inactivation of 42 genes suppress the infertility of the PCOS model. We are currently analyzing those genes that are involved in different biological processes among them oxidative stress and cell cycle control.

Some of those genes are targeted of already identified drugs, which we are now testing for suppression of the infertility.

Two extracts form edible plants have also demonstrated a suppression of the infertility of the PCOS models. We are now purifying the active principle.

Limitations, reasons for caution: C. elegans model is a very suitable to perform high through put screening of drugs, compounds or RNAi; However; results needs to be validates in a mammal model.

Wider implications of the findings: Gen identification of suppressor of the infertility of the C. elegans model for PCOS will allow to better understand the nature of the reduction of fertility.

Identification of compounds or extracts can be of interest for future treatment of the disease.

Trial registration number: Not application.

P-708 Could polymorphisms of some hormonal receptor genes, involved in folliculogenesis help in predicting patient response to controlled ovarian stimulation?

E. Prasnikar[1], Čuš[1], K. Repnik[2], V. Vlaisavljević[3], U. Potočnik[2], B. Kovačič[4]

[1]University medical centre Maribor, Department of reproductive medicine and gynecological endocrinology, Maribor, Slovenia
[2]Medical faculty Maribor- University of Maribor, Centre for human molecular genetics and pharmacogenomics, Maribor, Slovenia
[3]Biomedical Research Institute BRIS, Bris, Ljubljana, Slovenia
[4]University medical centre Maribor, Department of reproductive medicine and gynecological endocrinology, Maribor, Slovenia

Study question: Are single-nucleotide polymorphisms (SNPs) in genes involved in folliculogenesis associated with serum hormonal levels and recombinant FSH (rFSH) dose used in controlled ovarian stimulation (COS)?

Summary answer: FSHR rs1394205 was only SNP that was positively associated with serum AMH level and used rFSH dose per retrieved oocyte.

What is known already: Despite of development in diagnostics, unexpected ovarian response in patients undergoing COS could still occur. For COS in an in vitro fertilization (IVF) programme, exogenous gonadotrophins are administered to patients. Numerous studies were focused on genetics of ovarian hormonal receptors but the results are contradictory. It is suggested that specific SNPs of hormonal receptor genes from granulosa cells influence foliculogenesis, oocyte development and maturation. Ovarian response to COS is usually determined by the number of growing antral follicles and consequently by the number of retrieved oocytes and is characterized as low, normal, or high.

Study design, size, duration: In a cross-sectional study (March–July 2015) 60 IVF patients were treated by GnRH antagonist and rFSH. Patients of advance age (>39 years), PCOS, or endometriosis were excluded from the study. Oocyte were retrieved from follicles >16 mm in diameter. Patients were normal- (7–15 oocytes)(n = 26), poor- (according to Bologna criteria)(n = 17) and hyper (>15 oocytes)(n = 17) responders according to the oocyte number. Blood samples were collected for basal FSH and AMH measurements and SNPs genotyping.

Participants/materials, setting, methods: Genotyping SNPs (AMH rs10407022, AMHR rs3741664, FSHR rs1394205, FSHR rs6166, and ESR1 rs2234693) was performed using high resolution melting (HRM) method. After follicle puncture the number of retrieved oocyte was counted and the dose of used rFSH per oocyte was calculated. Main outcomes measures were prevalence of genotypes among patient subgroups and associations between specific genotypes and clinical parameters (serum FSH and AMH, rFSH dose administered and number of oocytes retrieved).

Main results and the role of chance: AMHR rs3741664, FSHR rs1394205 and rs6166 and ESR1 rs2234693 were positively associated with serum AMH, FSH and rFSH dose used, whereas AMH rs10407022 was not. Selected SNPs do not show any association with oocyte number.

Patients with GG genotype of FSHR rs1394205 had lower measured serum AMH level, compared to women with heterozygotes and AA homozygotes in one group (AA+AG) ($p = 0.016$). No association with basal AMH level and other SNPs were detected. Patients with GG genotype of FSHR rs1394205 also required lower rFSH dose per oocyte than patients with AA+AG genotypes ($p = 0.036$). When compared genotype and allele frequencies between groups, we found higher frequency of GG genotype in poor- (76.5%) than in hyper-responders (37.5%, $p = 0.002$). Distribution of other SNPs between patient groups was not statistically significant.

Patients with AA genotype of FSHR rs6166 had higher level of measured basal serum FSH compared to those with AG+GG genotypes ($p = 0.043$). In other genotypes, hormonal levels were not different.

Women with GG genotype of AMHR rs3741664 required higher rFSH dose in COS in comparison with patients carrying genotypes AA+AG ($p = 0.028$).

Limitations, reasons for caution: Our results may be confounded by a small sample size; further investigations including more patients are needed to confirm our findings. Gene analysis on granulosa cells could confirm the impact of SNPs to the level of specific hormonal receptor expression.

Wider implications of the findings: Based on our results, genotyping of hormonal receptor SNPs from patient blood sample is not yet reliable diagnostic method for prediction of patient's ovarian response to rFSH therapy.

Trial registration number: Study was approved by Slovenian Medical Ethics Committee (012-347/2015-8). It is a part of research projects P3-0327 and J3-7177 funded by the Slovenian Research Agency.

P-709 Does the phenotype of polycystic ovary syndrome influence the ovarian response to controlled ovarian hyperstimulation for IVF?

G. Robin[1], C. Grysole[1], A. Uk[2], A.L. Barbotin[2], C. Decanter[1], D. Dewailly[1]

[1]CHRU de Lille, Service d'Assistance Médicale à la Procréation et préservation de la fertilité, Lille, France
[2]CHRU de Lille, Service de Biologie de la Reproduction, Lille, France

Study question: The aim of this study was to compare the ovarian response pattern to controlled ovarian stimulation (HOC) for IVF between different PCOS phenotypes.

Summary answer: Phenotype A seems to be the PCOS phenotype with the higher cancellation rate and the longer duration of stimulation.

What is known already: PCOS phenotypes do not have the same endocrine and metabolic profiles. But few studies have evaluated the impact of PCOS phenotype in IVF.

Study design, size, duration: This is a retrospective cohort study, in which 178 PCOS patients completed 376 IVF +/- ICSI cycles, between January 2009 and Marsh 2016, at the University Hospital of Lille.

Participants/materials, setting, methods: This PCOS population was divided into 4 phenotypes, defined by the modified Rotterdam classification, according to the presence of oligo-anovulation (OA), hyperandrogenism (HA) and polycystic ovarian morphology (PCOM) (on ultrasound and/or excessive serum AMH level). Phenotype B (OA+HA, without PCOM) was excluded because of its small size (n = 1). The response to HOC protocol was compared between the 3 phenotypes.

Main results and the role of chance: The PCOS phenotypes were defined as A (OA+HA+PCOM, n = 194 cycles), C (HA+PCOM, n = 82 cycles) and D (OA+PCOM, n = 100 cycles).

Full phenotype A had significantly higher LH and AMH levels than phenotypes C and D.

The number of canceled cycles was significantly higher in phenotype A compared to phenotypes C and D (22.7%, 13.4% and 12.0%, respectively, p = 0.038). The majority of cycle's cancellations in the phenotype A seemed to be due to a poor ovarian response, but there was no significant difference between the groups. Patients with phenotype A had significantly longer ovarian stimulation than those with phenotype D.

Furthermore, doses of gonadotropins used were not significantly different between the phenotypes.

Thus, a resistance to exogenous FSH could explain the higher cancellation rate for phenotype A, and could be associated with high AMH levels.

The hyperstimulation syndrome (OHSS) rates and clinico-biological outcomes between the 3 phenotypes were not significantly different.

Limitations, reasons for caution: The main limitation of this study is the retrospective design. However, the high number of cycles adds strong value to our study.

Wider implications of the findings: Our study suggests that patients with phenotype A seem more difficult to stimulate. A recent study showed that phenotype A may be at greater risk of OHSS. A prospective study could confirm the need to increase gonadotropin doses for phenotype A, with GnRH agonist trigger to limit OHSS.

Trial registration number: non applicable.

P-710 Multiple consecutive stimulation cycles as a method to shorten duration of infertility treatment

K. Łukaszuk[1], J. Palaszewski[2], M. Jakubow[3], A. Lukaszuk[1], M. Kunicki[2]

[1]Invicta Sp. z o.o., Fertility Clinic, Gdansk, Poland
[2]Invicta Sp. z o.o., Fertility Clinic, Warsaw, Poland
[3]Invicta Sp. z o.o., Fertility Clinic, Wroclaw, Poland

Study question: Can a multiple consecutive stimulation protocol help in shortening duration of infertility treatment?

Summary answer: Multiple consecutive stimulation protocol has potential to shorten IVF treatment duration.

What is known already: In infertility treatment there are many cases when patients need to accumulate oocytes or embryos for fertility preservation, for planned preimplantation genetic testing, or due to low ovarian reserve (patients would benefit from shortening duration of their treatment).

Study design, size, duration: Our objective in the this study is to develop an effective multiple stimulation protocol (Gdansk protocol) that would allow patients to safely undergo consecutive stimulations. This would enable them to collect the desired number of oocytes or embryos in a short period of time.

Study included women aged over 37 who in previous attempts obtained few or no transferrable embryos.

Participants/materials, setting, methods: The preliminary stage of the study included 16 patients that underwent 2 (14 patients) or 4 (2 patients) consecutive stimulations. Mean age: 40.4 yo (SD 2.1) & mean basal AMH level: 1.78 ng/ml (SD 0.87 ng/ml).

Main results and the role of chance: Initial stimulation was performed with contraception priming and gonadotropin dosage was based on patients basal AMH level. As per standard procedure luteinizing hormone (LH), estradiol (E2) and progesterone (PRG) levels were monitored and on day 7 decision was made about extending the stimulation. Ovulation was triggered with triptorelin 34 hours prior to scheduled oocyte retrieval (OR).

Retrieved oocytes were fertilized using ICSI procedure and cultured for 5-6 days. Number of top quality embryos obtained was evaluated and based on that the decision to start the consecutive stimulation cycle was made.

Hormonal parameters were assessed at the start of cycle 2. Gonadotropin dosage was again based on patient's AMH level. Patients did not receive any medication to block premature LH surge due to the level of endogenous progesterone up to day 12 from the previous OR.

The reminder of the second cycle was managed as in the first one. If needed, again based on the number of embryos obtained, the decision was made to either complete the protocol or continue with another consecutive stimulation.

Mean number of blastocysts were 1.6 and 1.4 in 1st and 2nd cycle, COC – 9.0 & 8.9, MII - 6,6 & 7,1 respectively.

Limitations, reasons for caution: This is a preliminary stage of the study with a limited number of patients.

Wider implications of the findings: This appears to be a promising method of shortening duration of treatment for patients who need to accumulate embryos or face the pressure of time in their attempts to start a family. We are continuing this study and working on optimizing the protocol.

Trial registration number: Not applicable.

P-711 Effect of resveratrol and metformin on ovarian reserve and ultrastructure in PCOS: An experimental study

S. Furat Rencber[1], S. Kurnaz Ozbek[1], E. Guzel Meydanli[2], C. Eraldemir[3], Z. Sezer[2], S. Ceylan[1]

[1]Kocaeli University Faculty of Medicine, Department of Histology and Embryology, Kocaeli, Turkey
[2]Istanbul University Cerrahpasa Faculty of Medicine, Department of Histology and Embryology, Istanbul, Turkey
[3]Kocaeli University Faculty of Medicine, Department of Biochemistry, Kocaeli, Turkey

Study question: Can resveratrol be used instead of metformin or combination with metformin on PCOS treatment via SIRT1 and AMPK activation?

Summary answer: Resveratrol can be used in combination with metformin to ameliorate PCOS symptoms such as impaired cell architecture, imbalanced hormone profile, oxydative stress, and inflammation.

What is known already: Polycystic ovary syndrome (PCOS) is a reproductive hormonal abnormality and a metabolic disorder. It is frequently associated with hyperandrogenism, chronic inflammation, and oxidative stress (OS), though the pathogenesis mechanism has not been well defined. Resveratrol (3,5,4-trihydroxystilbene) is a natural polyphenol synthesized by several plants as a phytoalexin. This agent may have beneficial effects such as antioxidant and anti-inflammatory actions. Metformin (1,1-dimethylbiguanide hydrochloride) is an oral antihyperglycemic drug widely used for the treatment of type 2 diabetes and can cause reductions in body weight, restore ovulation and increase the rate of pregnancy.

Study design, size, duration: 63 female Wistar albino rats (three weeks-old) were initially divided into control (n = 9) and experimental(PCOS) groups (n = 54). After DHEA administration, PCOS group (n = 54) were randomly divided into 6 groups (n = 9) as follows. Group 1 (PCOS; no treatment), Group 2 (Resveratrol; 20 mg/kg), Group 3 (Ethanol; resveratrol solvent), Group 4 (Metformin; 300 mg/kg), Group 5 (Salin; metformin solvent) and Group 6 (Metformin+Resveratrol). The daily treatments of both groups lasted for up to 28 days.

Participants/materials, setting, methods: Estrous cyclicity was monitored by vaginal smears. At the end of the treatment, body and ovary weights were measured. Right and left ovaries were processed for electron and light microscopic examination, respectively. For immunohistochemical examination, sections were performed anti-SIRT1 and AMPK antibodies. Apoptosis was evaluated by TUNEL assay. Serum FSH, LH and Testosterone levels were analysed with bio-otoanalyzer, while plazma and tissue AMH and TNF-α were determined by ELISA. Serum MDA levels were also measured.

Main results and the role of chance: Metformin and combined treatment groups reduced the body and organ weights compared to the PCOS group ($p<0.05$ and $p<0.001$, respectively). Serum testosterone levels were significantly higher in the PCOS group than in the control group($p<0.001$) and this was reduced when PCOS was treated especially with resveratrol($p<0.001$). Higher plasma AMH level in the PCOS group was decreased in the resveratrol group($p<0.05$). TNF-α levels were significantly increased in the PCOS group compared to the control group($p<0.05$) however, in all the treatment groups, TNF-α levels were significantly decreased compared to those in the PCOS group($p<0.05$). Serum MDA levels in the PCOS group significantly increased when compared to the control group($p<0.05$) but resveratrol and combined treatment reduced this oxidative stress marker levels compared to the PCOS group($p<0.05$). Primordial follicle pool was significantly diminished in the PCOS group($p<0.001$) whereas primary follicle count remained unchanged. Secondary, cystic and atretic follicles were increased in the ovarian sections of

PCOS group($p<0.001$) which were ameliorated in the treatment groups supported by light and electron microscopic findings($p<0.001$). Increased number of TUNEL(+) granulosa cells in the PCOS group were reduced significantly in the treatment groups($p<0.001$). SIRT1 and AMPK immunreactivity in the combined treatment groups were significantly increased compared to the PCOS group($p<0.001$).

Limitations, reasons for caution: Because of financial limitations, serum hormone levels were measured by otoanalyser instead of ELISA which gives more sensitive results.

Wider implications of the findings: According to our findings, resveratrol may act through its antioxidant and anti-inflammatory effects via SIRT1 and AMPK activation. However, using with metformin therapy gives better results to solve the disease. But these results should be supported by further clinical trials using different doses of these therapeutic agents.

Trial registration number: Not applicable.

POSTER VIEWING

Reproductive epidemiology, socio-cultural aspects and health economy

P-712 Fertility preservation procedures for female and male patients facing gonadotoxic treatment - a micro-costing and diagnostic related group payment comparison analysis

J. Olofsson[1], L. Fajutrao[2], J.W. Phoon[3], K. Rodriguez-Wallberg[4]

[1]Karolinska Institutet, Division of Obstetrics and Gynecology- Department of Women's and Children's Health, Stockholm, Sweden
[2]Merck AB, Health Economics, Stockholm, Sweden
[3]KK Women's & Children's Hospital, Reproductive Medicine Department, Singapore, Singapore Rep. of
[4]Karolinska University Hospital and Karolinska Institutet, Department of Reproductive Medicine and Department of Oncology-Pathology, Stockholm, Sweden

Study question: What is the actual cost for fertility preservation (FP) within a large established clinical program in Sweden and its relation to Diagnosis-Related Groups (DRGs) tariffs?

Summary answer: Micro-costing analysis revealed a relative budget deficit of -27.1 % (total net value loss of €-250732) for all FP services performed in one year.

What is known already: The DRG system of payment was designed to encourage hospitals to operate efficiently and minimize overtreatment of patients. However, this may be challenging to needs for individualization and quality of services, as access to care risks being limited to selected patient groups. Despite the recognized importance of FP to cancer patients, high costs of the procedures and economic concerns are reported as main barriers limiting access to FP, especially for female patients. Until now, the actual costs of procedures involved in performing FP for both female and male patients have not yet been reported.

Study design, size, duration: A micro-costing analysis was done to accurately assess the costs of all FP-related procedures performed within one year in our clinical program, specifically oocyte cryopreservation, oocyte-embryo cryopreservation combined, ovarian tissue cryopreservation, sperm cryopreservation by semen banking and surgical sperm retrieval by testicular extraction. The costing exercise included all patients seen (n = 267) and all procedures directly related to gamete or gonadal tissue cryopreservation. Published hospital DRG prices were used for comparisons.

Participants/materials, setting, methods: Single-center study conducted at Karolinska University Hospital, which provides FP healthcare to the Stockholm region (population 2.2 million). Main health resource use categories for each procedure were identified (personnel, equipment, pharmaceuticals, laboratory related, single-use consumables and overhead charges), measured and valued using 2015 as the reference year (data for 2017 are under way). The bottom-up model included staff interviews and detailed real-life observations to accurately estimate the intensity of resource use.

Main results and the role of chance: Excluding cost of pharmaceuticals for ovarian stimulation, which are reimbursed directly to patients under the national pharmaceutical benefit scheme, the total cost of oocyte cryopreservation per patient (n = 38) was €2227, €3077 for oocyte-embryo cryopreservation (n = 50), €5990 for ovarian tissue cryopreservation (n = 28), €1356 for semen banking (n = 368), and €1981 for cryopreservation of sperm obtained by testicular biopsy (n = 10). Compared to the published DRG tariffs, the actual costs found and hence payments that the hospital received, were lower in all procedures evaluated (-14.4%, -38.0%, -8.7%, -32.1% and -27.8%, respectively). Multiplied by the number of procedures performed this translated into a net loss of €-250732 or in relative terms, a budget deficit of -27.1% for the year 2015 for FP services.

Limitations, reasons for caution: All FP procedures in Sweden are offered to the eligible population under the tax-funded health care services in academic centers only. The derived costs may not be generalizable to other FP centers.

Wider implications of the findings: An increasing demand of FP urges the complete evaluation of patient procedure costs to guide health care service for delivery and future planning. These results may increase awareness of national, regional and local health policy administrators to economic aspects of FP in planning for appropriate allocation of health services' budgets.

Trial registration number: Not applicable.

P-713 Knowledge of pregnancy and its danger signs among Indonesian women not improved by Maternal and Child Health Handbook

K. Tjandraprawira, I. Ghozali

Rumah Sakit Umum Daerah Majalengka, Emergency Department, Majalengka, Indonesia

Study question: What is the efficacy of the Indonesian Maternal and Child Health Handbook in improving the knowledge of various stages of pregnancy and its danger signs?

Summary answer: The Indonesian Maternal and Child Health handbook did not exert a significant influence in improving maternal knowledge around pregnancy and the associated obstetric danger signs.

What is known already: The first Maternal and Child Health handbook was introduced by Japan in the final decade of the 20th century and it was championed for empowering women in pregnancy, parturition and early childcare, as well as the pressing obstetric danger signs.

Study design, size, duration: This is a primary cross-sectional study conducted at Majalengka General District Hospital on recently delivering postpartum women between August – September 2017. 127 women were recruited, later divided into two separate groups according to their self-admission on the degree they had read the Maternal and Child Health handbook (50% and <50%).

Participants/materials, setting, methods: All the participating women were administered a pre-validated questionnaire to assess their knowledge around pregnancy and its danger signs.

Main results and the role of chance: It was discovered that our population had had high knowledge around pregnancy and its danger signs and the Maternal and Child Health handbook did not hold a significant role in effecting this finding (**p-value 0.295**). Furthermore, various socio demographic factors (age, maternal and paternal educational backgrounds, family welfare status, distance from healthcare center, parity and number of antenatal care visits) also did not exert a statistically significant influence on the level of knowledge in our population (**p-values 0.579, 0.521, 0.617, 0.908, 0.342, 0.618 and 0.939** respectively).

Limitations, reasons for caution: The relatively small sample size; selection bias as only a single population of patients (from Majalengka General District Hospital) was chosen; response bias in assessing the degree the handbook had been read and from answering the questionnaire; possible confounders, e.g. mass media and knowledge passed from relatives.

Wider implications of the findings: Our study revealed a satisfactorily high level of knowledge about pregnancy and the associated obstetric danger signs

among Indonesian women, but contrary to other studies, the use of Maternal and Child Health Handbook was not significantly responsible for such finding.

Trial registration number: not applicable.

P-714 Introducing Value Based Health Care as a new concept in treating fertility patients

M. Curfs, C. Van Bavel, B. Cohlen

Isala Clinics, Isala Fertility Center, Zwolle, The Netherlands

Study question: Can we increase value for fertility patients by either raising patient relevant outcomes resulting in the best possible health gain and/or by decreasing costs?

Summary answer: Value Based Health Care provides us an all-encompassing and powerful concept to provide better service for our patients against equal or even lower costs.

What is known already: Health care costs rise dramatically and society has major challenges to keep health care affordable for all. In The Netherlands the costs rose from 10% of the gross domestic product in 2000 to 14% in 2015. To turn the tide, a new concept in health care economics, Value Based Health Care (VBHC), was introduced by Michael Porter (2006). There are numerous examples where VBHC was successfully implemented (such as the UCLA Medical Center, USA, for kidney transplantation and the Martini Klinik, Germany, for the treatment of prostate cancer) but to our knowledge not yet for the treatment of fertility patients.

Study design, size, duration: Representatives of all professionals involved in fertility care were brought into a project team and during several sessions defined the necessary building blocks in close collaboration with actively involved patients. During these sessions truly relevant clinical outcome measures in relation to initial patient conditions and case mix variables were defined. Besides these, patient reported outcome measures (PROMS) and experience measures (PREMS) and the different care pathways were defined and described in detail.

Participants/materials, setting, methods: Professionals, such as physicians, clinical embryologists, nurses, technicians but also psychologists and social workers along with patients participated in defining relevant clinical outcome measures, PROMS, PREMS and the analysis of treatment pathways. Clinical outcome measures and treatment pathways are analyzed by means of a query from the electronic patient file. PROMS were linked to validated questionnaires and the PREMS to a tool measuring patient satisfaction. All these blocks are brought together into a management dashboard.

Main results and the role of chance: The most important clinical outcome measure is the cumulative live birth rate per patient journey, starting with referral to our center and ending with discharge from our center. A journey may consist of one or more treatment pathways, which in turn may consist of multiple treatment cycles. A first analysis in the pathway intrauterine insemination (IUI) with donor sperm, has revealed that a plateau is reached several treatment cycles before the maximum number of cycles that local and professional national guidelines propose. This knowledge can be shared with the patient and through shared decision making might result in more patient value. Less treatment cycles will be performed (and as a result a more rapid transition to a more invasive treatment) resulting in a more efficient treatment against lower costs and a shorter time to pregnancy.

The registration of initial patient conditions and case mix variables related to outcome measures enables us to a more individual approach, again increasing patient value.

The registration of PROMS and PREMS helps us to detect and take necessary measures for patients at risk for e.g depression and anxiety, sexual problems, but also for quality of life in general, both during treatment and in the long term.

Limitations, reasons for caution: The implementation of VBHC can be concerned as a prospective cohort study where results are systematically evaluated over a long period of time.

Currently fertility centers are paid as a fee per service. To prevent that treatments are offered which do not increase value, bundled payment arrangements should be made.

Wider implications of the findings: VBHC increases value for patients by increasing outcomes and/or by reducing costs. The implementation of an internationally accepted standard makes it possible to compare fertility centers corrected for initial patient conditions and case mix variables. Patient can then choose for the best value for their money.

Trial registration number: Not applicable.

P-715 The effect of religious background on the attitude toward sex selection

A. Salame[1], J. Nassif[2], J. Awwad[3], E. Moubarak[4], A. Hannoun[3], A. Abu Musa[3]

[1]*American University of Beirut Medical Center, OBGYN/ REI, Beirut, Lebanon*
[2]*AUBMC, Obstetrics and Gynecology, Beirut, Lebanon*
[3]*AUBMC, Obstetrics and Gynecology/ REI, Beirut, Lebanon*
[4]*MLH, Obstetrics and Gynecology/ REI, Beirut, Lebanon*

Study question: Does the difference in religious background affect the attitude towards sex selection using pre-implantation genetic diagnosis (PGD)?

Summary answer: The study showed a negative attitude towards sex selection for non-medical reasons through PGD. Religious beliefs are the most important factors affecting such decisions.

What is known already: Surveys of the general population regarding sex selection using PGD are limited and were mainly conducted in the United States and Northern Europe. In those Western societies, surveys have shown that people's interest in using sex selection techniques is driven solely by the desire for a sexually balanced family, consisting of both sons and daughters. It is important to determine attitudes towards sex selection in a wider range of countries especially that cultural differences exists among countries.

Study design, size, duration: A questionnaire-based cross-sectional study regarding attitudes towards sex selection for non-medical reasons was designed. The population size targeted was 1500 participants. The surveys were distributed during the period extending from January 2016 to September 2017.

Participants/materials, setting, methods: 1500 participants of the reproductive age group presenting to the Women s Health Center at the American University of Beirut Medical Center (AUBMC) were offered to complete the survey. The questionnaire included demographic details, obstetric and infertility history, opinions regarding sex selection, personal interest in expanding the family, and personal interest in choosing the sex of a future child. Out of the 1500 patients approached, 1300 agreed to fill the questionnaire.

Main results and the role of chance: The calculated response rate was 86.6%. Eighty six per cent of the respondents were females and 19.4 % were males. Sixty three per cent of the respondents were Muslim, 26.2% were Christian and 8.7 % were Druze. Seventy two percent of the participants were fertile and 58.5% already had children. Nineteen per cent of the respondents considered it strictly prohibited, 38.8% considered the technique's acceptable only if medically indicated while 33.4 % believed that it should be available to all those who request it. Of those who opposed sex selection for non-medical reasons, 40 % considered the intervention as playing God while 34 % reasoned that the child is a gift that deserves to be loved irrespective of his/her sex. Only 20.1% of the respondents stated that they would use if the procedure was prohibited by their religion. When asked about the gender preference of their first child, 71.5% said they didn't care. Men and women equally stated that sex selection should be available for medically indicated conditions. Forty nine percent of Christians accepted the procedure when it was medically indicated while 35.5 % of Muslims considered it to be acceptable if medically indicated.

Limitations, reasons for caution: Despite the large sample size, all the participants were visitors of one clinic located in the center of the capital. Thus the population that we had might not actually reflect the total population living in the peripheral areas.

Wider implications of the findings: The knowledge of the factors that affect decision making in reproductive issues will improve couple counseling in this part of the world were religion plays an important role in decision making. This is imperative especially in debated situations such as sex selection for medical and non-medical reasons.

Trial registration number: not applicable.

P-716 Socioeconomic deprivation and pregnancy rates in IVF

R. Imrie, S. Ghosh, K. Vigneswaren, N. Narvekar, M. Savvas

King's College University Hospital, Assisted Conception Unit, London, United Kingdom

Study question: Are higher levels of socioeconomic deprivation associated with reduced success in IVF and ICSI cycles in terms of pregnancy and live birth rate?

Summary answer: Our study suggests that there is a statistically significant correlation between socioeconomic deprivation and successful IVF/ICSI treatment as an independent factor.

What is known already: Socioeconomic deprivation has been correlated with poorer access to health care and health outcomes and this has been particularly studied in the diabetic and mental heath care populations. There is a well reported 'postcode lottery' of access to assisted conception treatment in England but as yet there have been no studies looking into whether socioeconomic deprivation based on patient postcode is an independent variable influencing IVF /ICSI success rates.

Study design, size, duration: This was a retrospective cohort analysis. All patients undergoing a fresh IVF or ICSI cycle from the point of egg collection onwards between 1st January 2015 and 31st December 2016 were identified. All patients undergoing an elective freeze-all cycle (e.g. fertility preservation) were excluded. A total of 1661 patients were included in the study. Data was collected using both electronic and paper patient records.

Participants/materials, setting, methods: Patients undergoing IVF/ICSI at three south London hospitals were included, all using the King's College Hospital Assisted Conception Unit laboratory. Patient postcode, age at start of treatment, number of eggs retrieved and pregnancy outcomes were collected. The UK Index of Multiple Deprivation was used to assess deprivation based on patient postcode. Logistical regression analysis was performed to determine the effect of deprivation on pregnancy outcomes whilst controlling for patient age and number of eggs collected.

Main results and the role of chance: Using the UK Index of Multiple Deprivation, patients were categorised into deprivation quintiles (highest deprivation = quintile 1, lowest deprivation = quintile 5). Compared with patients undergoing IVF and ICSI in the lowest quintile of depravation, those in the highest quintile showed a statistically significant increase in both pregnancy and live birth/ongoing clinical pregnancy rates when controlled for age and number of eggs collected. The odds ratio for patients in the least deprived quintile relative to the most deprived quintile for pregnancy rates was 1.8290 (95% CI 1.251 to 2.675, $p = 0.002$). For live births and ongoing clinical pregnancy rates the odds ratio was 1.984 (95% CI 1.291 to 3.049, $p = 0.002$). There was a threshold level of deprivation (patients at deprivation quintile 3 or above) beyond which further decreases in deprivation had no further statistical impact for both pregnancy and live birth/ongoing pregnancy rates. Of note, there were increasingly more patients undergoing IVF/ICSI treatment as deprivation levels reduced (174 patients in deprivation quintile one compared to 410 in deprivation quintile 5).

Limitations, reasons for caution: This study included patients receiving treatment from three south London hospitals and, whilst this is a socioeconomically diverse part of England, it is not necessarily reflective of the wider IVF community. Inclusion of further co-variables such as duration of infertility and BMI would help improve statistical analysis.

Wider implications of the findings: By identifying socioeconomic deprivation as an independent variable affecting IVF/ICSI outcome, we may be able to provide more accurate individual predictions of treatment success. Future studies would be needed to determine which aspects of patient deprivation are most influential and whether there are any modifiable changes that can be made.

Trial registration number: not applicable.

P-717 Fertility awareness and knowledge among Indian women attending infertility clinic: A cross-sectional study

M. Gupta[1], R. Mahey[2], S. Kandpal[2], N. Malhotra[3], P. Vanamail[2], N. Singh[4], A. Kriplani[2]

[1]Senior Resident, Obstetrics and Gynecology Department of Assisted Reproduction, NEW DELHI, India
[2]All India Institute of Medical Sciences, Obstetrics Gynecology, New Delhi, India
[3]All India Institute of Medical Sciences, Obstetrics and Gynecology, New Delhi, India
[4]All Institute of Medical Sciences, Obstetrics Gynecology, New Delhi, India

Study question: How good is the knowledge and awareness of infertile Indian females regarding fertility in relation to age and menstrual cycle and need of assisted reproductive technique?

Summary answer: The study population had poor knowledge of fertility and reproduction and the knowledge regarding assisted reproduction varied according to socioeconomic status.

What is known already: Worldwide studies have shown that people are unaware of biological aspects of conception, have poor knowledge about most fertile period in the menstrual cycle, chances of getting pregnant in one cycle and about steep decline in fertility potential after age of 34-35 years. Also both men and women lack knowledge about effect of smoking, alcohol, job stress and other life style factors on fertility potential. There is generalized lack of fertility awareness irrespective of gender.

Study design, size, duration: Cross-sectional study of 205 infertile women seeking fertility treatment at assisted reproductive unit between March 2017 to August 2017.

Participants/materials, setting, methods: Total 205 infertile female patients in the age group of 21 to 44 years were interviewed with the help of nine item questionnaire designed after reviewing previous papers on fertility awareness and modified according to patient population and level of understanding in an Indian set up. The study population was divided into four socioeconomic classes according to modified Kuppuswamy scale. The answers were stratified according to socioeconomic status.

Main results and the role of chance: Majority of women (59%) belonged to the age group of 20-30 years indicating a young age group in need of infertility evaluation. More than half (63%) of the patients were from the middle socioeconomic strata. Even so, knowledge about fertility and reproduction was low: 85% missed the ovulatory period in the menstrual cycle, only 8% considered age more than 35 years as the most significant risk factor for infertility, approximately 60-80% were not aware when to seek treatment for infertility after trying for pregnancy. Almost 97% participants associated past intake of combined oral contraceptive pills with infertility. Participants in the upper SES scale had better knowledge (39% indicated need of donor oocytes in aged females) regarding ART treatment options. Terms like surrogacy, were significantly ($p = 0.002$) better known to participants in upper SES category (more than 50% correctly answered) than in the lower category (24%).

Limitations, reasons for caution: Studies with larger study population and a control group of fertile female patients will enable a better understanding of need of fertility education.

Wider implications of the findings: There is a significant lack of awareness regarding effect of age on fertility among women belonging to all types of social sections in India. There is need of educational interventions emphasizing on ideal age of fertility, factors affecting fertility potential and fertility options available for sub-fertile couples.

Trial registration number: Not applicable.

P-718 Randomized trial of a home pregnancy test intervention to improve cohort retention and detection of miscarriage

L.A. Wise[1], K. Rothman[1,2], A. Wesselink[1], E. Mikkelsen[3], S. Willis[1], E. Hatch[1]

[1]Boston University School of Public Health, Department of Epidemiology, Boston, U.S.A.
[2]RTI International, RTI Health Solutions, Research Triangle Park, U.S.A.
[3]Aarhus University Hospital, Department of Clinical Epidemiology, Aarhus, Denmark

Study question: In a cohort study of female pregnancy planners, does offering 12 home pregnancy tests (HPT) at enrollment improve cohort retention and detection of spontaneous abortion (SAB)?

Summary answer: Offering HPTs to female participants in a preconception cohort study appears to increase cohort retention and SAB detection.

What is known already: In prospective cohort studies of time-to-pregnancy (TTP), incorporating daily urinary human chorionic gonadotropin (hCG) testing

to detect implantation is ideal because it increases identification of early pregnancy loss, allows for examination of early vs. late pregnancy losses, and reduces misclassification of TTP. However, use of daily hCG testing is expensive and time-intensive, and is not practical for most population-based epidemiologic studies. No prospective cohort study of TTP has assessed the extent to which offering HPTs to female pregnancy planners improves cohort retention, increases detection of SAB and advances the timing of SAB detection.

Study design, size, duration: Pregnancy Study Online (PRESTO) is a web-based prospective preconception cohort study of ≥7,000 female pregnancy planners residing in the U.S.A. and Canada (2013 to present).

Participants/materials, setting, methods: Participants were aged 21-45 years, not using fertility treatment, and attempting to conceive for ≤6 cycles at study entry. Women completed baseline and bimonthly follow-up questionnaires. After enrollment, 401 U.S. participants were 1:1 randomized to receive 12 Clearblue HPTs, with guidance to test the day after a missed menstrual period (N = 198), or the standard protocol (N = 203). On follow-up questionnaires, women reported incident pregnancies, including SABs, and gestational weeks at SAB. We performed an intent-to-treat analysis.

Main results and the role of chance: After a median of 32 weeks of follow-up, cohort retention was higher among women randomized to receive HPTs (N = 166; 83.8%) relative to the standard protocol (N = 139; 68.5%) (mean difference = 15.4%, 95%CI = 7.1%-23.6%). Conception was reported by 62.7% in the HPT arm and 53.3% in the standard protocol arm. Among women who conceived, SAB was reported by 22 (21.2%) in the HPT arm (gestational weeks at SAB: median = 5.0, range: 4-10) and 13 (17.8%) in the standard protocol arm (gestational weeks at SAB: median = 5.0, range = 4-9). The number of SABs reported at <8 weeks' gestation was higher in the HPT arm (N = 18) than in the standard protocol arm (N = 11).

Limitations, reasons for caution: Numbers were small and results were imprecise. Participants were not followed for the full 12 months of follow-up, thus cohort retention will likely be higher than what we report above. Because the study relies on self-reported data, some SABs may have been missed.

Wider implications of the findings: Preconception cohort studies might benefit from offering 12 HPTs to participants at study enrollment as a means of increasing cohort retention and SAB detection.

Trial registration number: Not applicable.

P-719 The impact of night shift work on menstruation among nurses - a multi-center epidemiological investigation

Y.M. Lin[1], B.Y. Miao[2], J.P. Shu[3], F.H. Liu[4], M.F. Deng[2], S.Z. Cheng[5], N. Zhou[4], M.Q. Xie[1], Y.W. Xu[2], Y.J. Fan[6]

[1]*Sun Yat-sen Memorial Hospital, General Gynecology, Guangzhou, China*
[2]*The First Affiliated Hospital of Sun Yat-sen University, Reproductive center, Guangzhou, China*
[3]*Chinese PLA General Hospital, Department of Obstetrics and Gynecology, Beijing, China*
[4]*GuangDong Women and Children Hospital, Department of Obstetrics and Gynecology, Guangzhou, China*
[5]*The First Affiliated Hospital of Sun Yat-sen University, Department of Obstetrics and Gynecology, Guangzhou, China*
[6]*China CDC, National Center for Women and Children's Health, Beijing, China*

Study question: To explore the impact of night shiftonmenstruation among nurses.

Summary answer: Night shift might increase the likelihood of irregular menstrual cycle and aggravated dysmenorrhoea among nurses.Menstruation status alteration increased with the frequency of night shift increasing.

What is known already: Menstruation status was considered a symbolic of female fertility. Irregular menstrual cycle, including shorter or longer cycles were related to infertility. Some studies illuminated that stress was an important influence to menstruation,besides other factors including age,weight, tumor, imflammation or genetic factors.

Study design, size, duration: By questionnaires, a retrospective cohort study was conducted among 702 married female nurses who were at childbearing age and currently working at The First Affiliated Hospital of Sun Yat-Sen University, GuangDong Women and Children Hospital or Chinese PLA General Hospital from November 2014 to December 2014.

Participants/materials, setting, methods: By questionnaires, a retrospective cohort study was conducted among 702 married female nurses who were at childbearing age and currently working at The First Affiliated Hospital of Sun Yat-Sen University, GuangDong Women and Children Hospital or Chinese PLA General Hospital.

Main results and the role of chance: A total of702 nurses were investigated, among which 597nursesgave valid questionnaires, with an effective rate of 85.04%.Potential confounding factors were adjusted. 134nurses(22.45%) had a trend of irregular menstrual cycles, with apparent difference($P<0.05$) if they worked late night shift twice a week or more. 162nurses(27.14%) suffered aggravated dysmenorrhea, especially when nurses worked no less than thrice per week for late night shift ($P<0.05$). Corresponding OR values of late night shift were larger than those of early night shift. After adjustment for sleeping condition,OR values of both early and late night shifts on menstrual cycle and dysmenorrhea decreasedin certain degree, suggesting that sleeping condition may be the intermediaters.

Limitations, reasons for caution: Firstly, nurses without night shifts or unmarried nurses weren't included. Secondly, night shift workload and working hours weren't standardized.Thirdly, recalling bias and reporting bias was indelible in this retrospective cohort study.

Wider implications of the findings: Late night working may be the key to biological rhythm alteration. Further study on the machanism and among factors to the change of menstruastion of nurses with night-shifts

should be conducted, to better understand reproductive impairment of night shift work.

Trial registration number: not applicable

P-720 Mobile app utilization and fecundity in a north american preconception cohort

J. Stanford[1], S. Willis[2], E. Hatch[2], K. Rothman[2], L. Wise[2]

[1]*Office of Cooperative Reproductive Health, Family and Preventive Medicine- Univ Utah, Salt Lake City, U.S.A.*
[2]*Boston University School of Public Health, Epidemiology, Boston, U.S.A.*

Study question: Do women trying to conceive who utilize fertility apps have increased fecundability (shorter time to pregnancy) than women who use no apps?

Summary answer: Individuals who utilized any fertility app in comparison to no app had increased fecundability. Several apps designated *a priori* were associated with higher fecundability.

What is known already: Many women who are trying to conceive use a menstrual cycle or fertility app to identify the "fertile window," or the days of the menstrual cycle when intercourse is most likely to result in pregnancy. Prior studies have found that some apps are more accurate than others to identify the fertile window.

Study design, size, duration: Pregnancy Study Online (PRESTO) is an internet-based prospective cohort study of women trying to conceive, ongoing since 2013 in the U.S.A. and Canada. Women included in this analysis were enrolled through October 2017, were aged 21-45, in a stable relationship with a male partner, not utilizing contraception or fertility treatment, and had been attempting to conceive for < = 6 months. A total of 4345 women were included in this analysis.

Participants/materials, setting, methods: Female participants complete a baseline questionnaire providing demographic, lifestyle, medical and reproductive histories. They completed bimonthly follow-up questionnaires in English until conception or up to 12 months after study entry. Each baseline and follow-up questionnaire asked about specific menstrual cycle or fertility apps used, and any occurrence of pregnancy. A proportional probabilities model was used to estimate fecundability ratios (FR) and 95% confidence intervals (CI). Higher FR indicate higher fecundability (reduced time to pregnancy).

Main results and the role of chance: Among 4345 participants, 2527 pregnancies were recorded within 17,185 observed cycles (14.7% crude fecundability). Of participants, 72% used an app to record and possibly also interpret menstrual cycle data and/or fertility signs. The total number of apps used was 78, with 31% using one of a group of likely "advanced" apps specified *a priori*

because they can track multiple biomarkers of ovulation: Fertility Friend, Kindara, Glow, Clue, or Ovia. At baseline and adjusting for woman's age, gravidity, body-mass index, education, smoking, prior hormonal contraception, cycle regularity, and sleep quality, relative to using no app, the FR for individuals who used one of the *a priori* advanced apps, or any other app was 1.13 (CI: 1.03-1.23) and 1.07 (CI: 0.97-1.18), respectively. Results were similar in time-varying analyses based on responses from follow-up questionnaires, but varied somewhat when stratified based on duration of time attempting pregnancy. Strengths of the study include the prospective reporting of app use.

Limitations, reasons for caution: Fertility app use was self-reported, with no specific data on how intensively the app was used. Time to pregnancy was also self-reported. We cannot rule out bias due to differential loss-to-follow-up or residual confounding by subfertility history or attempt time at study entry.

Wider implications of the findings: A majority of women trying to conceive are likely to use a fertility or menstrual cycle app. Such app use may reduce time to pregnancy. Apps that track multiple biomarkers of fertility appear to be more effective than others to reduce time to pregnancy.

Trial registration number: NA.

P-721 Impact of patient's socioeconomic status on the outcome of IVF cycles in India

K.D. Nayar, P. Nayar, N. Agarwal, M. Singh, M. Gupta, G. Kant, R. Gahlot, D. Nayar

Aakansha IVF Centre - Mata Chanan Devi Hospital, Reproductive Medicine, New Delhi, India

Study question: Does patient's socioeconomic status like income, education level and occupation affect IVF outcome?

Summary answer: Patients undergoing IVF treatment in India have different success rates based on variables like income, occupation and education due to disparity in awareness and affordability.

What is known already: Apart from medical problem infertility is also a social problem affected by various factors like accessibility, availability and knowledge. In India, Infertility is not insurance covered so service seeking is comparatively difficult for lower socioeconomic class. Women working in male dominated occupational environment faces more work stress and time constraint in pursuing treatment. On the other hand, women working as teachers, dealing in public relations and housewives feel free to discuss their problems and are more comfortable in completing cycles. Education helps to counter the various negative beliefs related to Assisted Reproductive Technology.

Study design, size, duration: Longitudinal study was performed at fertility centre in Delhi, India where 800 patients were interviewed during the year January 2017 to December 2017. Data were analyzed using SPSS software version 20.

Participants/materials, setting, methods: The study included 800 patients who consented to participate. Data were analyzed using logistic regression model for the number of cycles undergone and clinical pregnancy rate on the basis of monthly income (80 Indian Rupees, INR = 1 €) {< INR 25000 (n = 256), ≥25000–100,000 (n = 400), >100,000 (n = 144)}, education {≤12thstd (n = 167), Graduate (n = 344), Postgraduate (n = 288)}, Occupation {women working in male dominated areas (n = 287), working in non male dominated areas (n = 304), housewives (n = 208)}.

Main results and the role of chance: A logistic regression was performed to ascertain the affects of income and number of cycles of IVF on the likelihood that participants achieved pregnancy. The logistic regression model was statistically significant, $\chi2(5) = 19.746$, $p < .0001$. The model explained 37.5% (Nagelkerke R2) of the variance in pregnancy and correctly classified 80.0% of cases. Patients with monthly income > INR 1,00,000 group were associated with an increased likelihood of pregnancy.

Similarly to ascertain the effects of education level on number of cycles of IVF so that participants achieved pregnancy. The logistic regression model was statistically significant, $\chi2(5) = 83.615$, $p < .0001$, model explained 30% (Nagelkerke R2) of the variance in pregnancy and correctly classified 78.0% of cases.

Logistic regression model for area of occupation was statistically significant, $\chi2(5) = 98.748$, $p < .0001$, model explained 30.7% (Nagelkerke R2) of the variance in pregnancy and correctly classified 77.0% of cases respectively.

As income, education level of patient increases and women working in non male dominant fields were associated with an increased likelihood of pregnancy. In the entire above model of logistic regression increasing number IVF cycle were associated with an increased likelihood of pregnancy although demographic features were comparable.

Limitations, reasons for caution: Although it is prospective study, it has limitation of small sample size.

Wider implications of the findings: People with low education level and limited knowledge about infertility may delay efficient interventions. Jobs that put stress on women may also negatively affect results. Income status compromises the affordability for repeated cycles of IVF. Clinicians may keep these in mind while counselling the patients and discussing about their prognosis.

Trial registration number: MCDH/2017/5

P-722 The role of ovarian hormones in generating options for social contact: Women scoring high on neuroticism show significant menstrual cycle fluctuations

S. Schweizer[1], K. Schmalenberger[1], T. Eisenlohr-Moul[2], B. Ditzen[1]

[1]*Heidelberg University, Medical Faculty- Institute of Medical Psychology, Heidelberg, Germany*

[2]*University of Chicago, Medical Faculty- Department of Psychiatry, Chicago, U.S.A.*

Study question: This study investigates whether the process of generating options for social decision-making is associated with ovarian hormone fluctuations during the menstrual cycle and women's personality structures.

Summary answer: The study revealed quantitative and qualitative differences in option generation between the ovulatory and the menstrual phases moderated by women's personality structures.

What is known already: Before making a decision, agents in less structured environments generate a set of options. There is a recently accumulating body of evidence on the affective, motivational, and cognitive effects of the menstrual cycle. It was argued that the pre-ovulatory rise of estrogen and dopamine may increase the quantity of options generated in everyday decision-making. There are findings on qualitative changes in the creativity of options as associated with situational effects, such as the familiarity of the situation. Individual and biological factors such as personality and endocrinology as well as the *social quality* of option generation have been neglected so far.

Study design, size, duration: An observational study with repeated measures was conducted to compare the *quantity and quality* of generated options in the ovulatory and the premenstrual phase of one menstrual cycle. In both the ovulatory and the menstrual session, naturally cycling women (N = 21) with a regular cycle (26-35 days) performed parallel versions of an *option generation task*. Session dates were individually fixed by ovulation test. The social quality of the options was independently rated by two trained raters.

Participants/materials, setting, methods: Female psychology students (mean age = 24) completed an option generation task consisting of vignettes of everyday decision making scenarios followed by the question "What could you do?" Personality was assessed using the NEO-FFI. Social option quality was rated on the dimensions *Social contact quality* (whether and what kind of person is involved) and *Social affiliative quality (*degree to which an option satisfies the human need for affiliation). We performed a multi-level analysis using SAS.

Main results and the role of chance: Concerning the quality of the generated options our analyses revealed that *Social affiliative quality* varies significantly across the cycle when Neuroticism and Extraversion are used as moderators: Significantly lower affiliative quality of generated options was found at ovulation compared to premenstrual testing in women scoring high on Neuroticism ($p<.05$). Elevated E2 levels could be associated to more self-reliance, self-sufficiency, confidence and independence, and hence less tend and befriend at ovulation. Also, women with a low extraversion score generated options with significantly higher affiliative quality at menstruation compared to ovulation ($p<.05$). This could imply that even women with low Extraversion may have increased needs for social connectedness in the pre-menstruum that is often experienced as more difficult than the ovulatory phase. *Social contact quality* never varies significantly as a function of the cycle, no matter which of the five personality scales is used as a moderator. Concerning the *quantity* of the generated options women scoring low on agreeableness as well as women scoring

low on Conscientiousness and also those scoring high on the Openness to experience dimension generated significantly more options at ovulation (p<.001), whereas women with a low openness score generated more options at menstruation (p<.01). Interrater reliability was excellent.

Limitations, reasons for caution: Limitations of the study are the rather small number of participants and no counterbalancing of order of sessions.

Wider implications of the findings: This study provides first empirical insights into the mechanisms of how ovarian hormones could be associated with social decision-making in different personalities. It also brings up more specific issues, for instance that strong social-cognitive fluctuations during the menstrual cycle may be less beneficial to relationship stability in highly neurotic women.

Trial registration number: Not applicable.

P-723 IVF outcome in Chinese versus Caucasian women

R. Pasin[1], L. Perego[2], M. Leonardi[2], M.G. Corbucci[2], V. Caccavari[2], D.R. Diaferia[2], C. Colasante[2], P. Boldi Cotti[2], B. Lombardi[2], L. De Lauretis[2]

[1]*ICCS, Centro fertilità, Milan, Italy*
[2]*ICCS, Centro PMA, Milan, Italy*

Study question: Is there any difference between Chinese and Caucasian women concerning IVF outcomes?

Summary answer: There is a higher abortion rate in Chinese than in Caucasian women.

What is known already: Ethnicity is a common prognostic factor in medicine, but there is little data on the relationship between ethnicity and IVF outcome. It has been showed a reduced chance of live birth and clinical pregnancy rate in South Asian population compared to White women despite the similar choice of achieving pregnancy.

Study design, size, duration: In this retrospective cohort study, we investigate differences in terms of background and IVF outcomes between Chinese and Caucasian women underwent reproductive technologies in our Center from January 2014 till July 2017.

Chinese women were 3% of the total population (48 Chinese women versus 1451 Caucasian women).

Participants/materials, setting, methods: We matched some epidemiological characteristics and some outcomes of the two different groups (Chinese and Caucasian): age, infertility etiology, results of the ART in terms of pregnancy rate, miscarriage, serum estradiol values at the end of stimulation, number of eggs recovered.

We used *Chi-quadro* and *t-student* tests to match our results.

Main results and the role of chance: Differences were observed between age average, being significantly lower in Chinese than in Caucasian women (34,7 ± 4.8 *vs* 37.4 ± 4.1; P<0.01). The proportion of Tubal factor in Chinese was significantly higher in Chinese than in Caucasians (75% *vs* 18%; P<0.01), and it was found to be the most common infertility factor of Chinese women afferent to our Center.

We also observed significantly higher serum estradiol values average at triggering in Chinese than Caucasian women (2063.9 ± 1412.2 *vs* 1718.7 ± 1044.2; P<0.05) despite a similar oocyte recovery average (5.8 ± 3.3 *vs* 6.3 ± 4.6; ns)

Concerning IVF outcomes, we observe similar results in terms of pregnancy rate for transfer, but with a higher abortion rate in Chinese than in Caucasian women (27.0% *vs* 28.0% and 40.0% *vs* 18%; ns).

Limitations, reasons for caution: Further investigation and randomizations are needed in order to improve patient number and better understand the possible mechanisms involved in poorer IVF results in Chinese than in Caucasian women (systemic components, metabolic components, Other factors)

Wider implications of the findings: Our data confirm a reduced chance of live birth and clinical pregnancy rate in South Asian population compared to White women.

Trial registration number: Not applicable.

P-724 Infertility in the Middle East and North Africa region: a systematic review with meta-analysis of prevalence surveys

A. Eldib[1], O. Tashani[2]

[1]*Leeds Beckett University - Leeds UK., School of Clinical & Applied Sciences, BRADFORD, United Kingdom*
[2]*Leeds Beckett University, School of Clinical & Applied Sciences, Leeds, United Kingdom*

Study question: What are the overall estimate of the different indicators of infertility in the Middle East and North African (MENA) region?

Summary answer: The overall clinical primary and total infertility rate in the MENA region are (3.8%, 95% CI = 1.7-8.4) and (17.2%, 95% CI = 10.6-26.7) respectively.

What is known already: Statistics on the birth rates in different regions of the world including the developing countries suggested that there is a decrease in the number of children per couple but there is limited epidemiological research on direct estimates of infertility in the developing countries.

Study design, size, duration: A systematic review with meta-analysis of infertility rates according to the clinical and demographic definitions was conducted. Relevant publications providing data from MENA region were retrieved from Science direct, Web of knowledge, Medline, Embase, Cinahl, google and WHO website with no language or date restriction on July 2017. Data of prevalence, risk factors and causes of infertility were extracted and meta-analysed to produce the overall effect sizes of the infertility estimates.

Participants/materials, setting, methods: Eight cross-sectional studies surveyed 35274 women to estimate infertility according to the clinical and epidemiological definitions, and one WHO report contained prevalence data from 4 MENA countries (35494 women between the ages of 15 to 49 years) were included in this study. Studies estimated clinical primary and total infertility were pooled in a forest plot using comprehensive meta- analysis software. In addition, the four estimates according to the demographic definition was also pooled together.

Main results and the role of chance: Research areas of studies were Iran (7 surveys) and Saudi Arabia (one survey) in the peer reviewed journal and demographic surveys on Egypt, Morocco, Jordan and Yemen which were reported by the WHO DHS program. The clinical primary infertility defined as "*.the failure to become pregnant after 12 months or more of continuous and unprotected sexual intercourse*" was estimated in 5 surveys as 3.8% (95% CI = 1.7-8.4, effect size = -7.564, p = 0.0001), with the total clinical infertility, both primary and secondary infertility, estimate was 17.2% (95% CI = 10.6-26.7, effect size = -5.5, p = 0.0001). However, this only represents studies from two countries; Iran and Saudi Arabia. *Percentage of women who have been married for the past five years, who have ever had sexual intercourse, who have not used contraception during the past five years, and who have not had any births*" was used to produce the demographic estimate of infertility in surveys by a WHO programme. Demographic primary infertility was 22.6% (95% CI = 13.4-35.5. effect size = -3.8, p = 0.0001) and demographic total infertility rate was 38.5% (95% CI = 28.8-49.2, effect size = -2.11, p = 0.035).

Limitations, reasons for caution: There was more research in Iran than on all other countries combined in MENA region which makes any overall pooling of data biased. There are also two different definitions of infertility. Infertility estimates in demographic surveys is extremely high possibly because of inclusion of many unmarried women.

Wider implications of the findings: Data suggested that infertility in the MENA region is low when it is defined clinically and high when it is defined demographically suggesting the need for standardizing infertility indicators to inform future health and social policy. There is limited information on causes of infertility. More robust epidemiological research is needed.

Trial registration number: Not Applicable.

P-725 Follicular fluid concentrations of phthalate metabolites and early reproductive outcomes among women undergoing in vitro fertilization

Y. Du[1], N. Guo[1], T. Deng[1], X. Hua[1], Y. Yao[1], Y. Wang[2], X. Teng[1], Y. Li[1]

[1]*Tongji Hospital- Tongji Medical College- Huazhong University of Science and Technology, Reproductive Medicine Center, Wuhan- Hubei, China*

[2]Tongji Medical College- Huazhong University of Science and Technology, Department of Occupational and Environmental Health- School of Public Health, Wuhan- Hubei, China

Study question: Are follicular fluid (FF) concentrations of phthalate metabolites associated with impaired oocyte development and embryo quality among women from a fertility center?

Summary answer: Higher FF concentrations of certain phthalate metabolites were associated with lower mature and fertilized oocyte count, and declined embryo quality.

What is known already: Phthalates, a group of synthetic industrial chemicals, has led to widespread exposure across the world. Evidence from toxicological studies has established a role for phthalates in disrupting folliculogenesis, oocyte maturation and embryonic development. However, whether phthalates measured in the most biologically relevant matrix of the ovary (i.e. FF) can affect the developmental competence of in vivo exposed oocytes and result in impaired embryo quality is unclear.

Study design, size, duration: In this prospective cohort study, we recruited 636 women seeking infertility treatment at the Reproductive Medicine Center of Tongji Hospital, Wuhan, China, between 2014 and 2016.

Participants/materials, setting, methods: We measured eight phthalate metabolites in FF samples collected at oocyte retrieval. Data on early in vitro fertilization (IVF) outcomes, including total and mature oocyte count, number of fertilized oocytes and high-quality cleavage stage embryos, and proportion of high-quality blastocysts were obtained from electronic medical charts. Generalized linear models were performed to estimate the associations of FF phthalates and IVF outcomes. All models were adjusted for age, body mass index, smoking status and infertility diagnosis.

Main results and the role of chance: Most phthalate metabolites were highly detected in FF samples. The detection rates ranged from low (37.1%) for mono-n-octyl phthalate to high (77.2-98.6%) for the other seven metabolites. Mono(2-ethylhexyl) phthalate (MEHP) was the most abundant metabolite found in FF, with a median level of 1.65 ng/mL, followed by monobutyl phthalate (MBP) and mono(2-ethyl-5-hydroxyhexyl) phthalate (MEHHP). A borderline statistically significant relationship was observed for higher quartiles of FF MEHHP and lower oocyted yield (P-trend = 0.05). We found a negative dose-response association between FF monobenzyl phthalate (MBzP) and MEHHP relative to decreased mature and normal fertilized oocyte count, as well as number of cleavage embryos (all P-trend <0.05). Moreover, MEHHP was inversely associated with decreased number of high-quality cleavage stage embryos (P-trend = 0.01). Women in the second to fourth quartiles of MEHHP had a significant decrease of -11.49 (95% CI: -19.51, -2.66), -12.45 (95% CI: -20.55, -3.54) and -12.37 (95% CI: -20.31, -3.63), respectively, in high-quality Day 3 embryos compared with the first quartile. At the blastocyst stage, there was a significant trend toward lower proportion of high-quality blastocysts with increasing MBP, MBzP, MEHP, MEHHP and ∑DEHP [molar sum of three di (2-ethylhexyl) phthalate (DEHP) metabolites] quartiles (all P-trend <0.05).

Limitations, reasons for caution: The single measurement of FF may lead to misclassification of phthalate exposure owing to their short half-life and variability in individual behaviors. Our findings drawn from women undergoing IVF may not extrapolate to the general population, and the possibility of bias from uncontrolled confounding may also exist.

Wider implications of the findings: Our findings indicated that the intra-ovarian environment of women undergoing IVF has been pervasively exposed to most studied phthalates. Despite the low concentrations, certain FF metabolites were associated with adverse IVF outcomes, which raise concerns over exposure assessment at target organ and low-dose effect of phthalates on female reproduction.

Trial registration number: NA.

P-726 Donor recruitment for heterologous art in italy; still an uphill path

V. Carotenuto[1], L. Parmegiani[1], A. De Dominicis[2], A. Arnone[1], E. Troilo[1], A. Maccarini[1], S. Amicucci[1], S. Taraborrelli[1], W. Ciampaglia[1], F. Infante[1], G. Cognigni[1], M. Filicori[1]

[1]Gynepro, Reproduction Unit, Bologna, Italy

[2]University of L'Aquila - San Salvatore Hospital, Division of Obstetrics and Gynecology, L'Aquila, Italy

Study question: Can spontaneous and altruistic donation alone enable setting up gamete donation programs for infertile couples?

Summary answer: Scarce heterologous oocyte supply in Italy four years after legalization underlines difficulties to secure local availability; establishment of sperm banks appears more easily achievable.

What is known already: In April 2014 the Italian Supreme Court legitimized heterologous ART. Gamete donation cannot be remunerated. The issue of reimbursement of expenses met by donors (e.g. absence from work, transportation) has not been clarified. As a result, a large majority of heterologous ART in Italy is based on gamete or embryo shipment from abroad.

Study design, size, duration: A total of 356 heterologous ART cycles were performed from January 2015 to January 2018. Gametes were obtained from donors recruited by our Center in Italy or shipped from abroad.

Participants/materials, setting, methods: Donors (314) were divided in 4 groups: 6 sperm internal donors (SID), 41 sperm external donors (SED), 3 oocyte internal donors (OID) and 258 oocyte external donors (OED). Number of treatments, mean donor age and number of cycles for each donor class were analyzed. Statistical significance of results was tested by Student's t-test for continuous variables, and by the χ^2 test for nominal data. $P < 0.05$ was considered statistically significant.

Main results and the role of chance: In the study period we obtained 15 local donations, 12 SID (6 excluded due to sperm or screening test abnormalities) and 3 OID. All OID were eligible. A total of 101 heterologous sperm IVF cycles were performed: 53 cycles (52.5%) with SID and 48 cycles (47.5%) with SED. A total of 275 heterologous oocyte IVF cycles were performed: 6 cycles (2.2%) with OID and 269 cycles (97.8%) with OED. The difference between the number of treatments performed with SID vs. OID was statistically significant (P<0.0001). The SID mean (±SD) age was 29.2 ± 1.5 years, whereas in SED it was 26.2 ± 4.2 (P = 0.003). The OID age was 28.3 ± 5.5 years vs. 24.7 ± 3.3 in OED (P=NS). The number of cycles for each donor group was 8.8 ± 4.8 with SID vs. 1.2 ± 0.4 with SED (P<0.05); and 2.0 ± 1.0 in OID vs. 1.1 ± 0.2 in OED (P=NS).

Limitations, reasons for caution: The number of local oocyte donors (OID) was very low, due to the logistics of donor recruitment.

Wider implications of the findings: Local sperm donor recruitment allowed to perform numerous procedures internally; the vast majority of oocyte donations required external supply. In Italy, a local donor program is possible for sperm, but still unfeasible for oocytes. It would be desirable that Italian governmental institutions provide clarifications regarding the economic treatment of donors.

Trial registration number: not applicable.

P-727 Cost-effectiveness of diagnostic investigation of infertility and subfertility: a systematic review

S. Kiatpongsan, A.A. Amornpetchsathaporn, R. Pawa, L. Udomsrisumran

Chulalongkorn University, Dept. of Obstetrics and Gynecology, Bangkok, Thailand

Study question: Is diagnostic investigation of infertility and subfertility cost-effective?

Summary answer: Diagnostic tests shown to be cost-effective were laparoscopy, hysteroscopy and chlamydia antibody testing.

What is known already: There have been many studies on cost and cost-effectiveness of treatment for infertility and subfertility. Studies on cost and cost-effectiveness of diagnostic investigation of infertility and subfertility were quite limited and diverse in scope and methodology.

Study design, size, duration: Systematic review was conducted by two independent reviewers. English language, peer-reviewed journal articles from January 1997 to December 2016 were screened with key search terms: cost-effectiveness, infertility, subfertility and names of each diagnostic test (for both female and male infertility/subfertility). Database search was done through PubMed, Medline, Scopus and cross-references.

Participants/materials, setting, methods: Inclusion criteria

- Diagnostic tests for infertility and subfertility in male and/or in female patients.
- Cost-effectiveness analysis was performed with reporting of cost and effectiveness data.
- Published between January 1997 and December 2016
- English language.
- Exclusion criteria.
- Ongoing study.
- Review and systematic review articles.
- Therapeutic investigation.

Main results and the role of chance: 7 of 33 identified articles presented actual cost and effectiveness data.

7 studies were reported from Canada (1), Italy (1), The Netherlands (3), Turkey (1), and USA (1). None of the studies was conducted under the context of a developing country. The identified studies exclusively focused on diagnostic investigation of infertility in female patients. Investigations evaluated were laparoscopy, hysterosalpingography, hysteroscopy, sonohysterosalpingography, transvaginal hydrolaparoscopy and Chlamydia antibody testing.

5 studies used modeling models while 2 studies were a part of clinical trials. Effectiveness was reported as expected live births and probability of pregnancy. Cost was reported as mean cost per live birth, total direct procedural costs (healthcare perspective) and total or average cost of care per patient. 4 out of 7 studies reported cost-effectiveness in term of incremental cost-effectiveness ratio (ICER). Only one study used a societal perspective approach while most studies used a healthcare perspective approach.

Diagnostic tests determined to be cost-effective were laparoscopy, hysteroscopy and chlamydia antibody testing. Influential factors in sensitivity analyses were female age and dropout rate.

Limitations, reasons for caution: There were a limited number of studies on cost-effectiveness of diagnostic tests for infertility and subfertility. Measurement of cost and effectiveness varied across studies.

Wider implications of the findings: Our systematic review shows that there is a limited number of studies on cost-effectiveness of diagnostic tests for infertility and subfertility especially in developing countries or in low-resource settings. More studies should be conducted for new diagnostic tests and in low-resource settings.

Trial registration number: not applicable.

P-728 The younger the better: the case for continuing use of IUI as a first-line infertility treatment in a Ghanaian population

M.B. Yakass[1], B. Woodward[2], M.A. Otoo[1], J. Adoboe[1], E.K. Hiadzi[1]

[1]*Lister Hospital and Fertility Centre, Fertility Unit, Accra, Ghana*
[2]*X & Y Fertility, Assisted Conception Unit, Leicester, United Kingdom*

Study question: In low-income countries, can performing lower technology treatments such as intrauterine insemination (IUI), offer simple and less costly fertility treatment with effective pregnancy rates?

Summary answer: IUI is an effective first-line fertility treatment for unexplained and mild male factor infertility, particularly in younger women.

What is known already: Infertility in sub-Saharan Africa can be traumatic, especially for the woman. Primary and secondary infertility is higher in younger African women (<37 years). Mostly, younger couples are in low to middle-income brackets without good economic standing. To the best of our knowledge, no African country offer medical insurance covering fertility treatments, pushing young infertile couples to seek loans at high-interest rates (over 30%) for fertility treatments. Guidance from the National Institute for Clinical Excellence in the UK advises against IUI as a first-line fertility treatment. However, in our setting, IUI offers a low-cost, low-tech option, providing effective results.

Study design, size, duration: This is a retrospective study involving 859 couples who were treated with IUI in a fertility clinic in sub-Saharan West Africa between March 2012 and December 2017. Female participants were age-stratified into three groups; ≤30 years, 31 – 36 years and ≥37 years. Sperm count and motility data were collected and presented as mean ± SEM. Pregnancy rates were reported as percentages. ANOVA was performed to determine inter-group differences.

Participants/materials, setting, methods: All participants received IUI in a stimulated cycle using clomiphene citrate for 5 days followed by FSH (150IU) every other day for 3-5 times. HCG (10,000IU) was administered when leading follicle was ≥16 mm and the first insemination performed 36 hours post-HCG administration. A second insemination was performed 60 hours post HCG (24 hours after the first insemination). Ejaculated semen was prepared using density gradient centrifugation and the prepared semen warmed to 37°C some 30 minutes prior to insemination.

Main results and the role of chance: Enrolled participants had at least one patent Fallopian tube, with IUI only taking place if ovulation matched the side of patency. The main causes of infertility were anovulation, mild male factor and unexplained infertility. Approximately half of the female participants were in the age group 31 – 36 years (49.7%), with the remaining quarters in the age groups ≤30 (25.7%) and ≥37 years (24.6%) respectively. There was no significant difference in sperm count and percentage motility across age groups; [sperm count (million/ml): 18.3 ± 1.50, 19.3 ± 1.88 and 13.6 ± 2.20, p = 0.1296], [Motility (%): 34.1 ± 2.12, 31.8 ± 1.92 and 26.1 ± 2.91, p = 0.0697] respectively. There was a significant difference in pregnancy rates across the three age categories: 14.9%, 9.1% and 4.7%, p = 0.0142 for women ≤30, 31 – 36 and ≥37 years respectively.

Limitations, reasons for caution: A poorer pregnancy rate from IUI in women ≥37 years does not preclude such women from undertaking IUI treatments.

Wider implications of the findings: In resource-limited countries where medical insurance does not cover fertility treatments, younger women (≤30 years) could perform a less costly procedure like IUI with respectable pregnancy rates.

Trial registration number: N/A.

P-729 Expert consensus for primary management of reproductive health: a Delphi study

D. Orozco-Beltran[1], A. Bernabeu[1,2], C. Carratala-Munuera[1], J. Llacer[1,2], A. Lopez-Pineda[3], F. Sellers[1,2], J. Quesada[1], V. Gil-Guillen[1], R. Bernabeu[1,2]

[1]*Miguel Hernandez University, Chair of community medicine and reproductive health, San Juan de Alicante, Spain*
[2]*Instituto Bernabeu, Assisted reproduction department, Alicante, Spain*
[3]*Miguel Hernandez University, Cátedra de Medicina Comunitaria y Salud Reproductiva, San Juan de Alicante, Spain*

Study question: To identify barriers and enablers to appropriate primary management of the reproductive health by healthcare professionals.

Summary answer: A good consensus was achieved by experts to identify barriers and enablers to appropriate primary management of reproductive health.

What is known already: Infertility affects more than 80 million people worldwide. Fertility problems may be caused by genetic abnormalities, infectious or environmental agents, and certain life styles. There are modifiable factors contribute to the burden of infertility. In addition to psychosocial problems that may cause the infertility, the treatment of infertility contributes to increasing the cost of healthcare. For many causes of infertility, primary prevention is feasible. Thus, an appropriate management of reproductive health from the very beginning might reduce the prevalence of infertility and improve health and quality of life.

Study design, size, duration: This observational study was carried out from September 10, 2017 to January 20, 2018 using the modified Delphi technique. The coordinating project group selected the expert panel and defined the items of the questionnaire. The questionnaire was distributed online on November 2017 through a web page.

Participants/materials, setting, methods: 40 gynecologists from private and public assisted reproduction clinics and from different Spanish regions were selected randomly and were invited to participate as a panel member. Individual and anonymous opinions were asked by answering a 58-items questionnaire via e-mail (two rounds were done). Level of agreement was assessed using measures of central tendency and dispersion. Consensus was reached on an item when more than 65% of level agreement or disagreement was achieved.

Main results and the role of chance: Response rate: 60%. After the first round, consensus items were 42 (72.4%): of which 35 in agreement and 7 in disagreement. Eight items were modified in the questionnaire of second round according to expert requests. All the items reaching consensus by experts will be presented. Some examples of items with agreement are: 'General population have not enough information about vitrification' (100%) or 'Oncologic patients are not the only patients where vitrification could be indicated' (100%), 'General gynecologists must be more implicated in reproductive health' (100%), 'Family planning must include information about reproduction probabilities and not be centered only on anticonception' (100%).

Limitations, reasons for caution: The inherent limitations of Delphi study. A further possible limitation was the use of a structured questionnaire but free text responses were allowed in the first-round questionnaire that were incorporated into the questionnaire used in the second round.

Wider implications of the findings: Consensus was reached between assisted reproduction specialists on the most important concepts, which can provide the basis for primary management of reproductive health in Spain.

Trial registration number: Not applicable.

P-730 The association between the number of oocytes retrieved for IVF, perinatal outcomes and obstetric complications

Å. Magnusson[1], U.B. Wennerholm[2], K. Källén[3], M. Petzold[4], A. Thurin-Kjellberg[5], C. Bergh[6]

[1]Sahlgrenska University Hospital, Department of Gynecology and Reproductive Medicine, Göteborg, Sweden

[3]Department of Reproduction Epidemiology- Tornblad Institute- Department of Clinical Sciences- Lund University- SE-223 62 Lund- Sweden, Department of Reproduction Epidemiology, Lund, Sweden
[4]The Sahlgrenska Academy- Gothenburg University- SE-405 30 Gothenburg- Sweden, Health Metrics Unit, Gothenburg, Sweden
[5]Department of Obstetrics and Gynaecology- Institute of Clinical Sciences- Sahlgrenska Academy- Gothenburg University- Reproductive Medicine- Sahlgrenska University Hospital- SE-413 45 Gothenburg- Sweden, Department of Obstetrics and Gynaecology, Gothe
[6]Institute of Clinical Sciences- Sahlgrenska Academy- Gothenburg University- Reproductive Medicine- Sahlgrenska University Hospital- SE-413 45 Gothenburg- Sweden, Department of Obstetrics and Gynaecology-, Gothenburg, Sweden

Study question: Is there an association between the number of oocytes retrieved for IVF and perinatal and obstetric outcomes?

Summary answer: No significant association was found between the number of oocytes retrieved and perinatal outcomes, while an association was found for placenta praevia and male gender.

What is known already: Previous studies have shown that 8-15 oocytes retrieved at oocyte pick up (OPU) are optimal for live birth in fresh cycles. We showed in a recent study that cumulative live birth rate, including fresh and all cryo cycles following one OPU, increases by the number of oocytes retrieved up to around 20 oocytes, however also with an increase in serious side effects such as severe ovarian hyperstimulation syndrome (OHSS). Few studies with contradicting results have investigated if the number of oocytes retrieved also might be associated with negative obstetric and perinatal outcomes.

Study design, size, duration: Retrospective population-based registry study including all singleton deliveries after fresh IVF cycles performed in Sweden during the years 2002-2015 (n = 27,359). Treatment characteristics from The Swedish National Quality Registries of Assisted Reproduction including the number of oocytes retrieved, fertilization method, date of embryo transfer, number of embryos transferred, embryo stage and number of sonographically visible gestational sacs at gestational weeks 7-8 were cross-linked to the Medical Birth Registry (MBR) and the National Patient Register (NPR).

Participants/materials, setting, methods: Main perinatal outcomes were preterm birth (PTB), small for gestational age (SGA), and peri/neonatal death. Main obstetric outcomes were gestational hypertension/preeclampsia and placenta praevia. Multivariate analyses.were used to explore the association between the number of oocytes retrieved and outcome variables. Adjustments were performed for maternal age, parity, smoking, BMI, cause of infertility, years of infertility, chronic diseases, paternal age, treatment period, embryo stage and vanishing twin.

Main results and the role of chance: The number of oocytes retrieved were categorized in <10, 10-14, 15-19 and >20 oocytes and 4-9 oocytes was used as a reference. SET was performed in 76.4% of the cycles. Blastocyst transfer was performed in 12.7% and cleavage stage embryo transfer was performed in 87.3% of the cycles. No significant association was observed between the number of oocytes retrieved and PTB (OR 1.004, 95% CI 0.996 to 1.013), SGA (OR 0.999, 95% CI 0.998 to 1.009) or peri/neonatal death (OR 0.992, 95% CI 0.960 to 1.025). A significant association was detected between the number of oocytes retrieved and gender distribution, with a higher rate of males after > 20 versus 4-9 oocytes (AOR 1.121, 95% CI 1.042 to 1.206). Concerning obstetric outcomes a significant association was found for placenta praevia (AOR 1.016, 95% CI 1.001 to 1.032) while no association was found for preeclampsia after adjustment for confounders.

Limitations, reasons for caution: Some of the OPUs performed in 2015 have resulted in births in 2016, thus the obstetric and perinatal outcomes are not yet available in the registry for these treatment cycles.

Wider implications of the findings: These results are assuring concerning children outcome with no indication of an adverse effect of a high number of oocytes retrieved. The association between the number of oocytes and placenta praevia was significant, however weak. The new finding of an association with gender should be interpreted with caution.

Trial registration number: 2018:0201

P-731 Dizygotic multiple pregnancy, Dutch trends over two decades from 1995 through 2015

T. Konig[1], C. Hukkelhoven[2], C.B. Lambalk[1]

[1]VU University medical center VUmc, Department of Obstetrics and Gynaecology- division of Reproductive Medicine, Amsterdam, The Netherlands
[2]Perined, Epidemiology, Utrecht, The Netherlands

Study question: To identify the contribution of natural conception, in vitro fertilization (IVF), intra uterine insemination (IUI) and ovulation induction (OI) to the occurrence of dizygotic twinning over time.

Summary answer: Twinning increased until 2001 and declined thereafter, related to maternal age only in case of natural conception and not with IVF/ICSI.

What is known already: Over the past decades there has been a strong increase followed by a decline of multiples in the Netherlands, similar to many other developed countries. The increase has been associated with the introduction of artificial reproductive therapies (ART). Multiple pregnancies are often seen as a complication rather than a success, because of the association with pregnancy complications endangering mothers health as well as the foetus health. It is important to keep closely tracking trends regarding multiple pregnancy rates in relation to the various conception modes, including the natural way.

Study design, size, duration: Data from the national obstetric registration (PRN) for a period of 20 years were analysed. The data represent all hospitals in the Netherlands, as all twins are born in hospitals.

Participants/materials, setting, methods: The PRN data contains information on all primiparous and multiparous twins from an amenorrhoea of ≥16 weeks classified by mode of conception and information about gender. The number of opposite sex twins is multiplied by two to estimate the total dizygotic twins (Weinberg rule). Data of the Dutch Central Bureau for Statistics on total number of deliveries over the examined years was used in order to calculate prevalence of twin births.

Main results and the role of chance: From 1995 to 2001 there was a strong increase of twin births together with a gradually increase of the maternal age. Both naturally conceived and IVF/ICSI twins accounted for this strong increase, although the largest increase came from natural conception. Between 2001 and 2006 the number of dizygotic twin births was stable, both in the naturally conceived group as in the IVF/ICSI group. From 2006 onwards a

continuous decrease of naturally conceived dizygotic twins is seen, together with a decrease of maternal age in twin mothers.

Remarkably on average, maternal age of all delivering women over that period remained just over 31 years, whereas age of primiparous mothers continued to increase. The number of IVF/ICSI conceived dizygotic twin pregnancies declines from 2006 onwards. With a strong accelerated decline as of 2012 associated with a strong increase of the maternal age. Furthermore, since 2014 the number of dizygotic twin pregnancies after OI and IUI is larger than after IVF/ICSI in the Netherlands.

Limitations, reasons for caution: A limitation of this study that we have to rely on accurate recordkeeping in all registering hospitals. The way of recording information has not changed over the last years, therefore these data do provide accurate insight into valuable trends.

Wider implications of the findings: The decline of natural twinning from 2006 onwards in association with lower maternal age demonstrates decline of age related twinning which could reflect that family completion takes place earlier. This is supported by the ever increasing maternal age of primipara and the stable maternal age for all deliveries.

Trial registration number: not applicable.

P-732 The sex ratio in twins and the influence of gender mix in twins on gestational age, birth weight and perinatal mortality

B. Decommer, M. Verstraeten, O. Degomme, I. Dehaene, C. Derom, C. Roelens

UGent, ICRH, Ghent, Belgium

Study question: Is the sex ratio in twins different from singletons? And does the gender mix of a twin influence gestational age, birth weight and perinatal mortality?

Summary answer: The sex ratio in twins is lower compared to singletons. There is evidence for gender effect in twins on gestational age and perinatal mortality.

What is known already: The sex ratio in singletons is generally male-biased, and decreases in twins and triplets. This means that there are proportionally more girls in twins than in singletons.

De gender of one fetus of the twin can have an influence on perinatal factors of the other fetus of the twin, such as birth weight, gestational age and perinatal mortality. This influence is known as gender effect. For example, the gestational age in opposite gender twins is significantly longer that the gestational age in male same sex-twins.

Study design, size, duration: Our study group included 9563 twin pairs (9591 boys and 9535 girls) of the East Flanders Prospective Twin Survey (EFPTS). To study the sex ratio, the use of assisted reproductive techniques (ART), the zygosity, chorionicity and amnionicity were also taken into consideration. The sex ratio of singletons was based on the general register of East Flanders. Statistical analyses were performed using IBM SPSS Statistics 24.

Participants/materials, setting, methods: We performed statistical analyses on 9563 twin pairs of the East Flanders Prospective Twin Survey (EFPTS), which has been registering all multiple births of East Flanders since 1964. Perinatal factors were obtained from the obstetric records. To evaluate differences in sex ratio, we used Wilson score intervals and binary logistic regressions. To examine whether gender has an influence on perinatal factors, multiple linear regressions and multiple logistic regressions were used ($\alpha = 0,05$).

Main results and the role of chance: The sex ratio in twins is lower than in singletons ($p<0,05$). No significant results were found comparing the sex ratio between spontaneously conceived twins and twins conceived by ART, although there was a trend towards a decreasing sex ratio for dizygotic twins conceived through IVF+GIFT+ZIFT compared to spontaneously conceived dizygotic twins (OR = 0,929; p = 0,093). There is also a trend towards an increasing sex ratio for dizygotic twins compared to monozygotic twins (OR = 1,073; p = 0,087). We found a significant difference in sex ratio of dichorionic-diamniotic twins compared to monochorionic-monoamniotic twins (OR = 2,794; $p<0,001$), and of monochorionic-diamniotic twins compared to monochorionic-monoamniotic twins (OR = 2,760; $p<0,001$). This shows that the chance for girls is much higher in monochorionic-monoamniotic twins (in our dataset nearly 75% were girls).

There is an association between gender mix and gestational age, where the gestational age for girls with a twin brother is approximately one day shorter compared to female same-sex twins (p = 0,072), and approximately one day longer for boys with a twin sister compared to male same-sex twins (p = 0,088). No direct association between gender mix and birth weight was found. Comparing perinatal mortality, boys with a twin sister have a lower chance to die than boys with a twin brother (OR = 0,680; p = 0,022).

Limitations, reasons for caution: One important limitation of this study is that many confounding variables could have an influence on the results of gender effect (like smoking, infections during the pregnancy…), which were unknown in our database.

Wider implications of the findings: As our dataset is based on the Caucasian population in East Flanders, extrapolation to other populations is impossible. Although the effects are too small to be clinically significant, the findings do have a theoretical significance to help understand underlying mechanisms of twins.

Trial registration number: None.

P-733 Assessing the impact of obstetrics ultrasound on maternal and perinatal health outcomes in African rural or low-income settings

O.P. Shehu[1], A. D'Angelo[2]

[1]*Sheffield Teaching Hospital NHS Trust, Medical Imaging, Manchester, United Kingdom*

[2]*Cardiff University, School of Medicine, Cardiff, United Kingdom*

Study question: Is there a direct association between obstetric ultrasound and reduction of maternal and perinatal mortality in African rural or low-income settings?

Summary answer: Use of obstetric ultrasound in African rural settings showed significant benefits with potential to reduce maternal and perinatal mortality rates.

What is known already: A disproportionate disparity exists in maternal and neonatal mortality rates between developed and developing countries of the world, with 99% of all maternal deaths occurring in developing countries.

Innovative and ground-breaking use of ultrasound in addressing disease burdens is a feature of healthcare systems in developed countries. The evidence base for routine use of ultrasound in antenatal care was mainly derived from the developed world, where other factors may account for the low maternal mortality rates.

Research done to establish a direct association between access to routine obstetric and reduction in maternal/perinatal mortality rates in African rural settings is sparse.

Study design, size, duration: Systematic review of journal articles on the use of ultrasound by appropriately trained persons, in resource-poor, African rural communities, as a diagnostic tool in obstetric care. 20 articles published between 2000-2017 which met the inclusion criteria were selected for the review.

Participants/materials, setting, methods: Electronic databases search (PubMed/Medline, Cochrane library, CINAHL, google scholar) were conducted using MeSH (Medical Subject Heading) keywords 'Ultrasonography', 'Maternal mortality and foetal mortality', 'Africa AND rural communities OR Low-income populations OR rural populations' to extract relevant articles which were screened for appropriateness and data extraction accuracy by a second reviewer. The Quality Assessment of Diagnostic Accuracy Studies -2 (QUADAS-2) tool for assessing the quality of diagnostic studies for systematic reviews was used for this review.

Main results and the role of chance: Results of this review should be interpreted with caution owing to the low quality of evidence supporting the assumptions of the authors, However, findings from the reviewed studies indicate increased rate of diagnosis of conditions associated with maternal and perinatal morbidity which has significantly informed change in clinical management decisions and early referral to specialist care. The power of ultrasound as a pull-factor to attract pregnant women and their spouses was demonstrated through increased attendance at antenatal care offered at health facilities. Opportunities for role extension through focused ultrasound training for rural healthcare workers was reported.

Though there is dearth of quality data for robust analysis to validate these observations, this review highlights the need for randomized controlled trials (RCT's)to evaluate the clinical and economic effectiveness of introducing ultrasound in African rural settings. Conceptual and methodological limitations of the currently published findings on this question should be fully considered by researchers, so that future trials will be rigorous in design and implementation to ensure conclusive findings.

Limitations, reasons for caution: Due to paucity of quality research on the study topic, the disparate nature of studies design/implementation and lack of study control groups, performing a risk of bias and applicability analysis was difficult, resulting in high likelihood of bias and limitation to the generalizability of the report's conclusions.

Wider implications of the findings: Obstetric ultrasound in African rural settings changes management of otherwise undetected high risk maternal conditions, enables early referral and increases attendance to and uptake of other beneficial interventions at health facilities. Opportunities for further research to generate the necessary evidence for use of ultrasound in antenatal care in rural Africa.

Trial registration number: not applicable

P-734 Clinical analysis of gonads with ectopic adrenal tissue in disorders of sex development patients

Q. Tian

Peking Union Medical College Hospital, OB/GYN, Beijing, China

Study question: To summaries the characteristics, diagnosis and management of gonads with ectopic adrenal tissue in disorders of sex development(DSD) patients.

Summary answer: Removal of ectopic adrenal tissue does not affect the prognosis and may have some benefits in CAH treatment.

What is known already: The risk of dysplasia gonad with ectopic adrenal tissue in DSD patients is rare. Diagnosis relies on pathology, and hardly could be found pre-surgery.

Study design, size, duration: A total of 139 patients of DSD underwent surgery in Peking Union Medical College Hospital from Aug 2007 to Aug 2017. Among them, 5 patients were complicated with ectopic adrenal tissue and their clinical and pathology manifestation were analyzed.

Participants/materials, setting, methods: 5 patients, complicated with ectopic adrenal tissue and their clinical and pathology manifestation, were analyzed.

Main results and the role of chance: The ectopic adrenal tissue risk of DSD was 3.60% (5/139). All the 5 patients were female phenotype with Y chromosome or SRY gene. One patient was 45,XO, SRY(+) with dysgerminoma, the rest four patients were 46,XY, among which 3 were diagnosed with 17-alpha-hydroxylase(17-OHD),1 was partial gonadal dysgenesis (PGD). All the clinical manifestation and images before or in the surgery didn't show any sign but were testified of ectopic adrenal tissue in the resected gonad by pathology. 2 patients with 17-OHD received lower dosage of glucocorticoid after the surgery in the follow up. Hormone replacement therapy was given to maintain growth and development, and 2 patients obtained regular period.

Limitations, reasons for caution: Non-RCT study, only 5 patients were analyzed.

Wider implications of the findings: Current understanding of characteristics, diagnosis and management of dysplasia gonad with ectopic adrenal tissue in disorders of sex development(DSD) patients is limited. This study provided more data and evidence to learn about them.

Trial registration number: No.

P-735 Hemodynamic parameters and ICSI outcome in patients undergoing anesthesia for oocyte retrieval using alfentanil, fentanyl and remifentanil: a randomized clinical trial

F. Farzi[1], M. Mehrafza[2], A. Mirmansouri[1], Z. Zahiri[1], Z. Atrkar Roushan[1], A. Raoufi[2], R. Shalkohi[2], S. Samadnia[2], A. Hosseni[2]

[1]Anesthesia Research Center- Department of anesthesiology- Alzahra Hospital- School of Medicine- Guilan University of Medical Science- Rasht- Iran, Department of anesthesiology, Rasht, Iran

[2]Mehr Medical Institute, Fertility research center, Rasht, Iran

Study question: What is the effect of alfentanil, fentanyl and remifentanil on hemodynamic parameters and intracytoplasmic sperm injection (ICSI) outcome in patients undergoing general anesthesia for transvaginal oocyte retrieval?

Summary answer: All opioids lead to similar hemodynamic characteristics and pregnancy rate.

What is known already: In general anesthesia, there are some concerns about impacts of anesthetics on ICSI outcome. No study has been found to compare the effects of these three opioids in patients undergoing general anesthesia for oocyte retrieval and express the superiority of one opioid over others.

Study design, size, duration: In the present double-blinded clinical trial, 340 patients were assessed for eligibility and randomized for transvaginal oocyte retrieval following general anesthesia and 105 were lost to follow up. Data were collected from December 2014 to May 2017. Participants were randomized using block randomization method.

Participants/materials, setting, methods: Two hundred thirty five women ≤ 40 years old, with normal ovarian reserve tests and fresh embryo transfer were completed trial and divided among three groups: A (1.5 μg/kg, n = 78), F (1.5 μg/kg, n = 77) and R (15 μg/kg, n = 80). Patients with ≥ 2 unsuccessful ICSI cycle, history of cardiovascular disease, chronic opioid use and allergy to anesthetic agents did not include. All patients underwent pituitary suppression using long acting gonadotropin releasing hormone agonists.

Main results and the role of chance: There was no significant difference among groups with respect to demographic characteristics. Pre-induction and post-induction systolic and diastolic blood pressure and heart rate were not significantly different among the three groups. Time of respond to verbal command (A: 1.99 ± 1.64, F: 2.56 ± 1.72, R: 1.78 ± 1.34, P = 0.014), terminal systolic (101.61 ± 9.15, 105.29 ± 12.61, 102 ± 12.91, P = 0.01) and diastolic (A: 59.97 ± 9, F: 65.63 ± 9.13, R: 63.69 ± 11.01, P = 0.003) blood pressure and opioid induce cough (A: 21.8%, F: 11.7%, R: 31.3%, P = 0.021) was significantly different among groups.

No statistically significant difference were found among groups with respect to progesterone and estradiol level on human chorionic gonadotropin (hCG) day, total number of retrieved and metaphase II oocytes and endometrial thickness. The ratio two pronuclei (2PN) to total number of retrieved oocyte was significantly higher in remifentanil group than other groups (A: 51.6%, F: 54.4%, R: 62.2%, P = 0.018). There was no significant difference among groups with regards to implantation rate (P = 0.814), chemical (P = 0.922) and clinical (P = 0.925) pregnancy rate.

Limitations, reasons for caution: Due to high plasma level of estradiol or progesterone on hCG day in some patients and need to delay their embryo transfer, they were excluded, so sampling and data collection were taken long time.

Wider implications of the findings: Secondary endpoints revealed superiority of remifentanil due to shorter recovery time and higher ratio of 2PN to total number of retrieved oocyte compared to fentanyl and alfentanil.

Trial registration number: IRCT201410258677N4

P-736 Complicated clinical course and poor reproductive outcomes of women with tuboovarian abscess following fertility treatments

Y. Fouks[1], Y. Cohen[2], L. Ishai[3], B. Almog[3], A. Cohen[3]

[1]Lis Maternity Hospital- Department of Obstetrics and Gynecology- Sourasky Medical Center. Affiliated to the Sackler School of Medicine- Tel Aviv University Address: 6 Weizmann Street- Tel Aviv- Zip code 64239- Israel., Obstetrics and Gynecology-, Tel A

[2]Department of Obstetrics and Gynecology- McGill University- Montreal- Quebec- Canada- Department of Obstetrics and Gynecology- Lis Maternity Hospital- Tel-Aviv Sourasky Medical Center- Sackler Faculty of Medicine, Department of Obstetrics and Gynecology
[3]Lis Maternity Hospital- Department of Obstetrics and Gynecology- Sourasky Medical Center. Affiliated to the Sackler School of Medicine- Tel Aviv University Address: 6 Weizmann Street- Tel Aviv- Zip code 64239- Israel., Lis Maternity Hospital- Department

Study question: To assess the clinical course, treatment and reproductive outcome of women with tuboovarian abscess (TOA) following fertility treatment.

Summary answer: TOA following fertility treatment has a substantial effect on the clinical course, surgical and fertility outcome.

What is known already: There is limited data regarding the clinical course, treatment and reproductive outcome of women with (TOA) following fertility treatment.

Study design, size, duration: Retrospective cohort study over 10 consecutive years.

Participants/materials, setting, methods: The study was performed in a tertiary university-affiliated hospital. Electronic medical records were used to identify patients who were diagnosed with fertility treatment associated TOA. Fertility unit charts and phone survey were used to assess patient clinical course, surgical and reproductive outcomes.

Main results and the role of chance: Thirty-seven women who were diagnosed with TOA following fertility treatments (in-vitro fertilization and intrauterine insemination) were compared with 313 women who were diagnosed with TOA not associated with fertility treatments during the same time period. Women with TOA following fertility treatments had significantly higher inflammatory markers upon admission as compared to the non-fertility treatment group (mean WBC 16.1 ×1000/mm3 (SD± 4.3) vs. 13.8 ×1000/mm3 (SD± 6.3), p = 0.001, respectively and mean CRP 149 mg/L (SD± 78.3) vs. 78.2 mg/L (SD± 68.5), p = 0.001, respectively). In addition, women with TOA following fertility treatments were associated with significantly higher surgical intervention rate and a more complicated clinical course as was shown by shorter time interval from admission to surgery (2.1 days vs. 3.2 days, p = 0.01), higher rates of antibiotic failure, higher conversion rate from laparoscopy to laparotomy (14.2% vs. 3.2%, p = 0.005), increased perioperative complications rate (25.0% vs. 3.8%, p = 0.0001) and a longer hospitalization period (7.2 days vs. 4.8 days, p = 0.01). Clinical pregnancy rate per cycle in women with TOA following fertility treatments was 9%. one case of live births was recorded.

Limitations, reasons for caution: Retrospective cohort analysis, based on medical records.

Wider implications of the findings: Prophylactic treatment and embryo transfer cancellation should be considered in patients that are at risk for infection.

Trial registration number: 'not applicable'.

P-737 Impact of laparoscopic myomectomy on reproductive and obstetric outcomes in patients with intramural myomas

M. Sato, S. Hara, F. Suyama, W. Beck, Y. Mukoda, K. Sekigawa, K. Sasaki, H. Okubo, H. Tajima, H. Asada, Y. Yoshimura, S. Ikuta, R. Tokutomi, A. Jinno, S. Akimoto

Shin-Yurigaoka General Hospital, Obstetrics and Gynecology, Kawasaki-shi, Japan

Study question: Does removal of intramural myomas improve reproductive outcomes?

Summary answer: Laparoscopic myomectomy (LM) may contribute to success infertility treatment in patients with intramural myomas.

What is known already: Uterine myomas are the most common benign tumors in women of reproductive age. Submucosal myomas have been shown to lower fertility rates, and their removal improves reproductive outcomes. However, the benefit of LM in subserosal or intramural myomas has not been clearly established.

Study design, size, duration: We performed a retrospective analysis at Shin-Yurigaoka General Hospital between 2012 and 2016. Of 766 patients who underwent LM during this time period, 81 infertile women with intramural myomas alone or both intramural and subserosal myomas were examined. Patients with submucosal myomas or those who discontinued infertility treatment at our hospital were excluded.

Participants/materials, setting, methods: Medical records were retrospectively reviewed to analyse reproductive outcomes and obstetric complications. We collected data pertaining to age, the largest myoma diameter, the number and total weight of the removed myomas, and distortion of the uterine cavity. The pregnant and non-pregnant groups were compared. The rate of pregnancy among 16 infertile patients who underwent resection of submucosal myomas by hysteroscopy during the same period was also evaluated as part of a secondary analysis.

Main results and the role of chance: Patient age in the pregnant and non-pregnant groups was 36.3 ± 4.2 and 38.2 ± 3.7years (p = 0.04), respectively. The number of intramural myomas (5.6 ± 4.6 vs 5.4 ± 3.7), the largest diameter (7.5 ± 2.4 and 6.9 ± 2.2 cm), and the total weight of myomas removed (225 ± 222 vs 169 ± 151 g) were not significantly different between the pregnant and non-pregnant groups. The rate of cavity distortion was also not significantly different between groups (55.8% vs 48.3%). The pregnancy rate among patients with intramural myomas who underwent LM was 64.2% (52/81), which is comparable to that in patients who underwent submucosal myomas resection by hysteroscopy (68.8%, 11/16). Overall, 52 patients had 63 pregnancies via ART (assisted reproductive technology) (n = 47) or non-ART (n = 16). The mean time period between LM and the first pregnancy was 12.3 months (range, 3-39 months; median, 10.5 months). The rate of miscarriages and live birth were 36.5% and 37.0%, respectively. Overall, 23 babies were born to 20 patients at our hospital by Caesarean section. All deliveries were after 37 weeks of gestation. No case of uterine rupture or placental abnormalities was observed. We did not observe any detrimental effect on reproductive and obstetric outcomes.

Limitations, reasons for caution: Our study is limited by its retrospective design and small sample size. Additionally, the lack of a control group does not allow for definitive conclusions.

Wider implications of the findings: Larger well-designed prospective randomized trials are needed to further evaluate the effect of LM on reproductive outcomes in patients with intramural myomas. LM may be offered to patients who do not become pregnant after infertility treatment. Management should be individualized considering age and infertility factors other than myomas.

Trial registration number: We did not receive a trial registration number.

P-738 Vaginoplasty and concomitant oocyte retrieval in Rokitansky syndrome

V.S. Vanni[1], D. Delprato[1], M. Candiani[1], A. Bartolacci[1], V. Gervasio[1], G. Cermisoni[1], L. Fedele[2], E. Alleva[1], E. Papaleo[1]

[1]IRCCS San Raffaele Hospital, Obstetrics and Gynecology, Milano, Italy
[2]Ospedale Policlinico Ca' Granda, Obstetrics and Gynecology, Milan, Italy

Study question: Can invasiveness in the treatment of Mayer-Rokitansky-Küster-Hauser (MRKH) patients be minimized by performing concomitant laparoscopic oocyte retrieval and vaginoplasty?

Summary answer: We report the first three MRKH cases in which laparoscopic vaginoplasty and oocyte retrieval were efficiently combined and oocytes cryopreserved for future use.

What is known already: MRKH syndrome diagnosis is based on congenital aplasia of the upper vagina and uterus, and affects approximately 1/4,500 women. Patients experience the early distress of lack of sexual activity and infertility: thus, the main medical interests in this syndrome are to enable intercourse through vaginoplasty and genetic motherhood through oocyte retrieval and surrogacy or - more recently - uterus transplantation. Oocyte retrieval is not standardized in MRKH patients: due to reduced vaginal length or to adhesions resulting from previous surgical vaginoplasty,the routine transvaginal technique can be challenging and a laparoscopic or percutaneous approach can be needed.

Study design, size, duration: MRKH patients undergoing laparoscopic vaginoplasty between august 2017 and december 2017 at the IRCCS San

Raffaele Hospital (Milan, Italy) who expressed a desire for future motherhood were offered concomitant controlled ovarian stimulation and laparoscopic oocyte retrieval.

Participants/materials, setting, methods: After psychological and medical counselling, three patients aged 17, 17 and 21 gave informed consent and underwent controlled ovarian stimulation according to a GnRH-antagonist protocol. Final follicular maturation was induced with Gn-RH analogue to avoid the risk of ovarian hyperstimulation and combined surgery was scheduled 36 hours after. A standard 19 G ovum aspiration needle (Cook, USA) was inserted through the laparoscopic ports for oocyte retrieval and subsequent Davydov's laparoscopic vaginoplasty was performed.

Main results and the role of chance: In the first, second and third case n = 12, n = 14 and n = 18 oocytes were retrieved and cryopreserved. Subsequent steps were unchanged compared to the Davydov's laparoscopic vaginoplasty, without any additional technical difficulty. Postoperative care was also unchanged and no complications occurred. Compared to delaying oocyte retrieval, our concomitant approach abolishes the risks of ovarian aspiration in the presence of post-surgical adhesions as well as the anesthesiologic risks of a second procedure. Hence, referral to centers with expertise in vaginoplasty but also in reproductive medicine should be considered in all MRKH patients,and clinicians involved should contemplate this novel strategy for those MRKH patients with an indication to laparoscopic vaginoplasty and a desire for future motherhood.

Limitations, reasons for caution: Further evaluation of the safety of this novel approach will be of ineterest.

Wider implications of the findings: Because the doctor-patient relationship is crucial in MRKH syndrome, we envisage that simultaneous treatment of both the sexual and reproductive functions by a single team will also enhance patients' emotional ease and compliance with cares.

Trial registration number: Not applicable.

P-739 A retrospective analysis of the effect of salpingectomy for hydrosalpinx on in vitro fertilization – embryo transfer

Y. Mizusawa, N. Hayashi, E. Enatsju, K. Katayama, Y. Tokura, E. Okamoto, S. Yamada, Y. Matsumoto, S. Kokeguchi, M. Shiotani

Hanabusa Women's Clinic, reproductive health, Kobe, Japan

Study question: What is the indication of salpingectomy for hydrosalpinx in the patient undergoing in vitro fertilization and embryo transfer?

Summary answer: Salpingectomy is not effective for the pregnancy after the embryo transfer in patients older 41 years old.

What is known already: It has been demonstrated that, in patients with hydrosalpinx, the overall success of in vitro fertilization and embryo transfer (IVF-ET) is lower than expected due to implantation failure, miscarriage and ectopic pregnancy and it is generally recognized that removal of a hydrosalpinx can increase the implantation rate of IVF –ET. However, whether salpingectomy affects ovarian reserve is uncertain and the indication of salpingectomy is not clear as well.

Study design, size, duration: In this study, we compared the result of oocyte numbers and embryo genesis in 46 and 209 oocyte retrieval cycles in 124 patients after and without salpingectomy for hydrosalpinx between January 2014 and December 2016. Also, we compared the result of 52 and 189 embryo transfer cycles in 124 patients after and without salpingectomy.

Participants/materials, setting, methods: We compared the number of oocyte retrieval, fertilization rate and the rate of developing to the blastocyst in 27 patients after salpingectomy and 97 patients without salpingectomy for hydrosalpinx. Secondary, we compared the pregnancy rate, miscarriage rate and the live birth rate after the embryo transfer cycles in 29 patients after salpingectomy and 95 without salpingectomy. For the analysis of the significance, we used chi-square test and t-test and defined the significance as $P<0.05$.

Main results and the role of chance: In this study, the patients at age 23 to 45 years old were included. There was no significant difference in the number of oocyte retrieval, fertilization rate, and embryogenesis in the patients after salpingectomy and the patients without salpingectomy. Re the results after embryo transfer, the pregnancy rate was significantly higher in patients after salpingectomy than that of patients without salpingectomy (55.8% versus 39.2%, P = 0.03). The live birth rate was significantly higher in the patients after salpingectomy than that of the patients without salpingectomy (40.4% versus 18.5%, P = 0.0009).The miscarriage rate was lower in patients after salpingectomy than that of patients without salpingectomy (27.6% versus 48.6%, P = 0.07). Analysis by age showed that, in patients younger than 40 years old, the pregnancy rate and live birth rate for embryo transfer were higher in the patients after salpingectomy than that of the patients without salpingectomy. The all result in patients older than 41 years old were similar between the two groups.

Limitations, reasons for caution: The number of the patients who had salpingectomy for hydrosalpinx was smaller than that who didn't, and it means that we need to pay attention to not only the rate of the result but the numbers of oocyte retrieval and embryo transfer cycles.

Wider implications of the findings: Salpingectomy for hydrosalpinx is associated with better result in embryo transfer, but no effect on retrieval oocyte number or embryo genesis for the patients younger than 40. This means that we need to consider carefully for the suggestion of salpingectomy before the embryo transfer to the patients over 41.

Trial registration number: not applicable.

P-740 Effect of vitamin C on tissue damage and oxidative stress following tunica vaginalis flap coverage after testicular torsion

M. Shokoohi[1], A.A. Khaki[1], M. Moghimian[2], H. Shoorei[3], M. Soltani[4], H. Abtahi[5]

[1]*Tabriz University of Medical Sciences, Anatomical sciences, Tabriz, Iran*
[2]*Gonabad University of Medical Sciences, Physiology, Gonabad, Iran*
[3]*Tabriz University of Medical Sciences, Anatomical sciences, Tehran, Iran*
[4]*Gonabad University of Medical Sciences, Anatomy and Histolgy, Gonabad, Iran*
[5]*Gonabad University of Medical Sciences, Clinical Biochemistry, Gonabad, Iran*

Study question: Are the removal of compression syndrome by flap method and the use of vitamin C can lead to the reduction of testicular tissue damages induced by testicular torsion/detorsion?

Summary answer: Eliminating the pressure caused by compartment syndrome and using vitamin C decreased injuries induced by reperfusion in long-time testicular torsion.

What is known already: Tunica vaginalis flap coverage may decrease oxidative stress and tissue damage by reducing pressure on the testicles. It was found that flap coverage reduced tissue damage and oxidative stress as the duration of ischemia increased. A tunica albuginea incision with a tunica vaginalis flap can increase oxidative stress after short-term (1 h) ischemia. This may be the result of the surgical intervention; for this reason, the technique is useful only after long-term (9 h) ischemia.

Study design, size, duration: This experimental study was performed on 70 adult male Wistar rats weighing 250–300 g. Rats were randomly divided into two experimental groups: Group 1: testicular torsion for 5 h (T5) with 5 subgroups, including, TD5h, TDF5, TDVit.C5, TDFVit.C5, Sham 5h; Group 2: testicular torsion for 9 h (T9) with 5 subgroups, including, TD9h, TDF9, TDVit.C9, TDFVit.C9, Sham9.

Participants/materials, setting, methods: Torsion/detorsion, in 28 adults Wistar rats, was created by 720° counterclockwise rotation of the left testis. Also, in the same number of rats, testicular torsion was maintained for 5 or 9h followed by detorsion with tunica vaginalis flap coverage. After blood sampling, left testis was removed. Then, The Johnsen score, assessment of seminiferous tubules, and serum's oxidative stress markers were examined. The dates analyzed using SPSS 20 and ANOVA test applied for comparing the means.

Main results and the role of chance: The Johnsen score, the diameter of seminiferous tubules, and thickness of the seminiferous tubule epithelium significantly increased in the 5 h testicular torsion group receiving treatment with vitamin C and tunica vaginalis flap coverage compared with the group receiving tunica vaginalis flap alone ($p\leq0.05$). The level of testosterone decreased significantly in all groups except for the 5 h testicular torsion group receiving treatment with vitamin C and tunica vaginalis flap coverage. The MDA level also decreased in the group receiving treatment with vitamin C and tunica vaginalis flap coverage compared with the group receiving tunica vaginalis flap coverage

alone. The levels of SOD and GPx were significantly lower in the group receiving treatment with vitamin C and tunica vaginalis flap coverage than sham group.

Limitations, reasons for caution: Although this experimental study showed that flap method could prevent the reduction of spermatogenesis-related to testicular tissue damages, there are still unknown potential errors and lack of knowledge about possible side-effects of this method on this condition in the human's body; therefore, it can not use in clinical trials.

Wider implications of the findings: Testicular decompression after testicular torsion by tunica vaginalis flap technique can provide a protective effect against tissue damage and oxidative stress after prolonged ischemia and that such effects were not observed for short-term ischemia. Other studies also showed the same effect.

Trial registration number: The ethical considerations were based on the guidelines for laboratory animals from the Research and Technology Deputy of Gonabad University of Medical Sciences, Gonabad, Iran.

P-741 What is the optimal skin closure technique for 5 mm laparoscopic port-site? – a systematic review and meta-analysis

N. Mohd Zulkifli[1], M. Hamdan[1], S.Z. Omar[1], W.A.H. Wan Ghazali[2]

[1]*University Malaya Medical Centre, Department of Obstetrics & Gynaecology, Kuala Lumpur, Malaysia*

[2]*Putrajaya Hospital, Department of Obstetrics & Gynaecology, Putrajaya, Malaysia*

Study question: What is the outcome differences between sutured [subcuticular (SC) or transcutaneous (TC)] and sutureless [Adhesive Skin Tape (ST) or Tissue Adhesive (TA)] 5 mm laparoscopic port-site skin closure technique?

Summary answer: Sutured and sutureless techniques have comparable cosmetic outcome. In sutured group, TC is better than SC while ST is better than TA in sutureless group.

What is known already: As laparoscopy has become the access of choice even in complex abdomino-pelvic surgery cases and more abdominal access ports have been used to assist with the surgery, the concern has now diverted into the cosmetic outcome of the skin closure. There are various techniques available, but it is mainly based on the surgeon's preference and ultimately patients' satisfaction and to date, there is no "gold standard" on the technique particularly in small 5 mm laparoscopic port-site.

Study design, size, duration: Systematic review and Meta-Analysis

Participants/materials, setting, methods: A total of 1053 papers were identified through electronic search and after screening, 5 studies (all RCT) were included for data synthesis. The PRISMA guidelines for randomised controlled trials were used to examine the quality of the studies. All suitable data were extracted and analysed using Review Manager 5.3 software.

Main results and the role of chance: We found a total of five studies comparing sutured (n = 367) with sutureless (n = 266) techniques. No studies compared closure with non-closure methods. From the studies using sutures, TC has better cosmetic outcome than SC (MD -0.79 [-1.45, -0.13], n = 104) & (OR 1.93 [1.29, 2.99], n = 118). In sutureless group, ST has comparable cosmesis with TA (OR 0.68 [0.28, 1.64], n = 88) but less reported pain (OR 5.75 [1.14, 28.88], n = 88). Compared with TC, TA has comparable cosmetic outcome (MD -0.8, [-4.44 to 2.84], n = 112) and no infection or complication such as hernia were observed in both techniques. Compared with both TC and SC, ST has comparable cosmetic outcome (MD 0.25 [-0.48, 0.98]), n = 75) and (MD -0.54 [-1.13, 0.05]), n = 75) respectively. Similarly no infection or complication were observed in these methods. Closure time were comparable between sutured group and TA (MD 8.4 [-1.27, 18.07]), n = 89) but slightly longer than ST (MD 9.7 [0.9, 18.5]), n = 89).

Limitations, reasons for caution: Despite the nature of the randomised included studies, the results of this study are still subjected to confounders relating to clinical and statistical heterogeneity. The studies reported the outcomes differently.

Wider implications of the findings: Conventional suturing – TC is still an optimal 5 mm laparoscopic skin closure technique. However, sutureless methods – TA and ST are able to eliminate risk of needle stick injury. The material cost of TA is higher than sutures or ST. Further trials should be conducted to evaluate total cost effectiveness.

Trial registration number: not applicable.

P-742 Robot-assisted myomectomy may improve pregnancy rates after surgery

S. Huberlant, J. Lenot, V. Letouzey, F. Masia, R. DeTayrac, S. Warembourg

University Hospital of Caremeau-, Department of Obstetrics and Gynecology and ART, Nimes, France

Study question: Is robot-assisted myomectomy is efficient for the management of myoma?

Summary answer: Among the patients having a desire of pregnancy, more than half obtained a pregnancy after myomectomy by surgery robot assisted, mainly spontaneously.

What is known already: Uterine myoma affects 25% of women worldwide. Conservative surgery for uterine myoma could be proposed in case of infertility, whatever the size and the number of myomas. Long terms benefits and obstetrical outcomes were not very evaluated with the robotic assistance myomectomy. The purpose of the study was to evaluate the outcomes of robot-assisted myomectomy in terms of pregnancy rates (spontaneous and with assistance reproductive technology).

Study design, size, duration: It is a monocentric retrospective study conduced between 2009 July and 2006 April in a French department of gynecology surgery and assistance reproductive center. 82 patients were referred in the center for the management of at least one uterine myoma. A robot-assisted myomectomy was realized by an experimented surgeon. An office hysteroscopy was prescribed 3 months after the surgery.

Participants/materials, setting, methods: 82 patients were included and 36 patients suffering from infertility. with a main time 2,5 years. Inclusion criteria were the indication of myomectomy (whatever the number) for patient suffering from infertility or abdominal pain. Age, BMI, time de conceive, number and size of uterin myoma were reported. The details of surgery were reported as the operative time and the surgical complications. The main objective was to evaluated the clinical pregnancy rate.

Main results and the role of chance: The mean age of patients was 36 years old (± 6). 45% of the patients suffered from an overweight.

The mean number of myoma was 2 (± 1.5) with a mean size of 65.9 mm (± 20.3) and a middleweight of 150 g (± 137) for the most voluminous myoma. The opening of the uterine cavity was noticed in 15.8% of the cases investigated.

Post operative hysteroscopy was performed 3 months after the surgery for 31 patients (85%). 2 cases of intra uterine adhesions were diagnosed and treated during the office hysteroscopy. 4 hysteroscopy resections for secondary myoma and one septum resection were also reported.

The clinical pregnancy rate was 32.8% (25 patients) which 51% of the infertile patients. The mean time to conceive was 18 months after surgery (±12.9). 8 pregnancies were obtained after assistance reproductive technology (28.6%). Among clinical pregnancy, 4 (14.3%) miscarriages were diagnosed and 2 cases of fœtal death (7,1%) and one pre term delivery (3,6%) were reported. Overall, the live birth rate was 37 % (22 cases).

Caesarean was performed in 17 cases (70.8%). No case of uterine rupture has been reported.

Limitations, reasons for caution: The main limitation was the absence of comparison between robotic-assisted and conventional laparoscopy. These encouraging results in favour of the robotic assisted myomectomy must be confirmed by randomized studies comparing to results with conventional laparoscopy.

Wider implications of the findings: Our results suggest a benefit to perform myomectomy with robotic assistance in agreement with the data of literature. The reduction of the opening uterine cavity could reduce the intra uterine adhesions and improve the pregnancy rate.

Trial registration number: This study received the agreement of the Ethics Committee of the university hospital (Institutional review board n°17.02.01)

P-743 T-shape uterus in the 21st century (post DES era) - we need to know more!

A. Sood[1], M. Akhtar[2]

[1]Senior Clinical Fellow, Reproductive Medicine, Manchester, United Kingdom
[2]Consultant- St. Mary's Hospital, Reproductive Medicine, Manchester, United Kingdom

Study question: Is T-shaped uterus prevalent in sub-fertile women in post DES era? What is the effect of hysteroscopic metroplasty on pregnancy rate, miscarriage rate and live birth rate for these women?

Summary answer: Surprisingly, the prevalence of T shaped uterus is significant even today. Hysteroscopic metroplasty is a simple procedure which can potentially improve outcomes in sub-fertile women.

What is known already: T-Shaped uterus is a rare uterine malformation, and has classically been associated with "in-utero" exposure of DES (diethylstilbestrol). It can be seen as a congenital variant or post infection synechiae rarely. The reproductive population of today's date constitute all women who were born well after the use of DES was completely stopped. The diagnosis of T shaped uterus can be made with HSG and 2D USS; and today with increasing use of 3D USS in Reproductive medicine, the detection rates have increased. The diagnostic criteria, investigation of choice, reproductive outcomes and treatment options are not well defined for these women.

Study design, size, duration: Systematic review and meta-analysis of literature.

Participants/materials, setting, methods:

- History of subfertility or poor reproductive outcomes.
- Diagnosis of T shaped uterus on HSG, USS or 3D scan.
- Hysteroscopic metroplasty done.
- Outcomes- pregnancy, miscarriage and live birth rates.

Total no of studies- 16 (7 published and 9 conference abstracts). There is scarce data on reproductive outcomes after intervention. There is no randomised controlled trial done, the only studies that are available are 9 retrospective analysis and 7 prospective case intervention studies.

Main results and the role of chance: Systematic review showed potential benefit from surgical intervention in the form of hysteroscopic metroplasty. It is reported to improve pregnancy rates and live birth rates and concurrently decrease miscarriage rates. It was difficult to derive meaningful measure of improvement due to potential differences and bias in reporting.

Meta-analysis of the data could not be done, because of following reasons:

- No randomised controlled trials.
- Heterogeneous study data – patient population, diagnostic modality and procedure details.
- Only number of pregnancies achieved mentioned in most of the studies, it is not clear if the same patient achieved multiple pregnancies subsequently.
- The interval between surgery and pregnancy is not clearly defined and it is difficult to comment if the intervention in the form of hysteroscopic surgery was the reason for improved outcome.

Limitations, reasons for caution: Scarce data and reporting bias.

Wider implications of the findings: There is a need for centralized database for registration of women with T shaped uterine anomalies which can be either a national or European registry database. This will help in defining clear diagnostic criteria, surgical indication & technique, and follow up of reproductive outcomes after the procedure.

Trial registration number: Not applicable.

P-744 Two cases of successful pregnancy after treatment for uterine cervical pregnancy by transcervical removing pregnancy contents and hysteroscopic cauterization following laparoscopic temporally uterine artery ligation

Y. Fukushi, S. Wada, Y. Ohara, T. Fujino

Teine Keijinkai Hospital, Obstetrics and Gynecology, Sapporo, Japan

Study question: Whether the case of uterine cervical pregnancy after treatment of our surgical methods achieve successful pregnancy and have uneventful delivery?

Summary answer: Two of the seven cases after treatment of our surgical methods for uterine cervical pregnancy were achieved pregnancy and had uneventful delivery.

What is known already: There were reports of treatment for uterine cervical pregnancy, for example MTX and/or KCL local injection, uterine artery embolization, Foley catheter balloon tamponade and hysterectomy, but our surgical methods: Transcervical removing cervical pregnancy contents and hysteroscopic cauterization following laparoscopic temporally bilateral uterine arteries ligation for uterine cervical pregnancy, has not been described.

Study design, size, duration: Study design: cohort study.

Size: Seven cases of uterine cervical pregnancy.

Duration: between 2003 and 2017.

Participants/materials, setting, methods: materials: Seven cases of uterine cervical pregnancy treated at our hospital.

methods: We examined seven cases of uterine cervical pregnancy from the medical records.

surgical methods: Transcervical removing cervical pregnancy contents and hysteroscopic cauterization following laparoscopic temporally bilateral uterine arteries ligation.

Main results and the role of chance: Two of the seven cases after treatment for uterine cervical pregnancy were achieved pregnancy and had uneventful delivery.

Four patients had a history of previous abortion with uterine cervical dilatation and curettage, two patients had also a history of previous cesarean section. Median age was 35 years-old(range 29-30), median operative times was 69.5 min(range 54-97), median estimated blood loss was 35 ml(range 10-200) and median postoperative hospital stay was 2days(range 2-3). All patients had no conversion to hysterectomy and intra- or postoperative complications.

Limitations, reasons for caution: Limitations: Our experienced cases are too small numbers but a uterine cervical pregnancy is an extremely rare ectopic pregnancy, the incidence ranging between 1 in 8000 to 18,000 pregnancies, and uterine cervical pregnancy represents about 0.15% of all ectopic pregnancies.

Wider implications of the findings: We experienced seven cases of uterine cervical pregnancy successfully treated with our surgical methods and two of the seven cases after treatment were achieved pregnancy and had uneventful delivery. This method may be an effective option in treatment of uterine cervical pregnancy.

Trial registration number: non-clinical trials.

P-745 Clinical pregnancy outcome of secondary infertility treated by transvaginal repair of previous cesarean scar defect

X. Liu[1], W. Liu[1], W. Deng[1], H. Zhao[1], K. Deng[2], C. Wu[1], J. Wang[1]

[1]Shenzhen IVF Maternity Hospital, obstetric and gynecology, Shenzhen, China
[2]Foshan women and children hospital, Obstetrics and Gynecology, Foshan, China

Study question: The clinical pregnancy outcome of secondary infertility treated by transvaginal repair of previous cesarean scar defect (PCSD) is still unknown.

Summary answer: Transvaginal repair of previous cesarean scar defect (PCSD) can effectively improve the clinical symptoms of PCSD and treatment of secondary infertility.

What is known already: Transvaginal repair of previous cesarean scar defect (PCSD) is simple and time-saving, however, its effect on symptoms improvement and pregnancy outcome is not totally understood.

Study design, size, duration: Observation study.

Sample size is 56.

Follow-up duration is 12 months.

Participants/materials, setting, methods: 56 cases of patients with previous cesarean scar defect in our hospital were selected for transvaginal repair from Aug, 2015 to Aug,2016. The average age was 35 ± 4.2 years old. The infertility period is 2-8 years with abnormal uterine bleeding or pubis pelvic pain. All cases were treated with standard transvaginal repair.Histological

examination were perfromed after surgery and the size, location, the thickness of the uterine myometrium were confirmed by ultrasonic examination after 3 months.

Main results and the role of chance: All the operations were successful. Histology showed fibrous scar and lymphocytic infiltration. Abnormal uterine bleeding or the pain of the pubis pelvis was obviously improved after operation. Natural pregnancy was obtained in 55 cases after 1 year follow-up, of which 49 were given live birth (89.09%). 6 cases (10.9%) were aborted, and the patients with abortion were re-examined by B-ultrasound without diverticulum.

Limitations, reasons for caution: The sample size needs further expande. In this study, infertility was observed as the only complaint and exclused other male or female-factor infertility. All cases have had a health child.

Wider implications of the findings: Transvaginal repair of previous cesarean scar defect(PCSD) is desreved to popularization for treating second infertility due to PCSD.

Trial registration number: not applicable.

P-746 Skilled reproductive surgeons may ensure better outcomes in infertile patients

V. Vargiu[1], V. Versace[1], V. Tagliaferri[2], A.L. Astorri[3], P.A. Margariti[1], A. Lanzone[1], G. Scambia[1], D. Romualdi[1]

[1]Policlinico A. Gemelli" Foundation, Department of Obstetrics and Gynecologic, Rome, Italy
[2]Ospedale Generale Regionale Ente Ecclesiastico F.Miulli, Department of Obstetrics and Gynaecology, Acquaviva delle Fonti, Italy
[3]International Scientific Institute "Paolo VI"- Catholic University of the Sacred Heart, Department of Obstetrics and Gynecologic, Rome, Italy

Study question: Can a skilled reproductive surgeon improve the pregnancy rate (PR) in patients who undergo laparoscopy for infertility?

Summary answer: A skilled reproductive surgeon can significantly ameliorate pregnancy rate in infertile patients undergoing surgery when a putative cause is identified and treated intraoperatively.

What is known already: Unexplained infertility (UI) affects 1/3 of subfertile couples. The use of laparoscopy in the work-up of these patients is still a subject of debate, although laparoscopy remains the gold standard for diagnosis and treatment of several pelvic pathologies. Actually, a high proportion of women with unexplained infertility or minor abnormalities treated at the time of laparoscopy, conceive spontaneously. In other fields of gynecological surgery, such as oncology, the surgeon's expertise plays a pivotal role in determining the outcomes. Few data are to date available on this matter in the field of reproductive surgery.

Study design, size, duration: This retrospective observational study included 83 infertile patients, who underwent surgery (diagnostic/operative laparoscopy and diagnostic/operative hysteroscopy) at our Institution between January 2015 and June 2017. The study population was divided in: group 1 (59 patients) operated by reproductive surgeons, and group 2 (24 patients) operated by non-specifically skilled surgeons. 9 patients were lost at follow-up. A questionnaire was administrated in January 2018, in order to establish the PR of the operated patients.

Participants/materials, setting, methods: The clinical records of women undergoing laparoscopy for infertility were retrieved from a computerized database. Exclusion criteria were: infertility male factor, overt metabolic or endocrine disorders, age >43 years. We analyzed the rate of spontaneous or ART-induced pregnancies in the two groups after dividing patients on the basis of the performed surgery (diagnostic-only vs operative). The analysis was conducted with the Mann-Whitney, Fisher-Exact and Chi-square tests. A p value ≤ 0.05 was considered statistically significant.

Main results and the role of chance: The two groups did not differ in median age (36,0 vs 37,0) and BMI (21.5 vs 23). The PR in group 1 was 40% (20/50) while in group 2 was 29.16% (7/24) with a p-value of 0.44. Afterwards, we analyzed the percentage of spontaneous and ART-induced pregnancy in each group and we found no statistical difference (12/20 vs 7/24, p-value: 0.068). Even in the subgroups of spontaneous pregnancy, the two populations did not differ in terms of age and BMI. As a secondary outcome we found out that 34/83 patients had pathologic findings at laparoscopy (40.9%): peritoneal adhesions, minimal-mild endometriosis and hydatid cysts. 4 of them were lost at FU. Patients were divided into two subgroups: patients who underwent *1*: diagnostic laparoscopy (real UI) (44/74) and *2*: operative laparoscopy (30/74). The overall PR did not differ between subgroups (p-value 0.80). Within subgroup 1, the PR was 38.6%, and no statistical difference between patients operated by skilled or non-skilled surgeon was found (34.2% vs 55.5 %, p-value 0.24). Interestingly, in subgroup 2 the PR of patients operated by a reproductive surgeon was significantly higher of one of patients operated by a non-skilled surgeon (53.3% vs 13.3%) with a p-value of 0.020

Limitations, reasons for caution: This was a retrospective observational analysis with a relatively small population. A further limitation is the use of data obtained by telephone surveys, which implies the risk of under- and misreporting.

Wider implications of the findings: Our findings suggest that skilled reproductive surgeons may ensure better outcomes in infertile patients where putative causes for infertility are identified. Based on this contention, infertile couples should be addressed to specialized Centers in order to maximize their chance to conceive. Further randomized studies are needed to confirm our hypothesis.

Trial registration number: Not applicable.

P-747 Who is at risk of endometrial cavity breach at laparoscopic myomectomy?

K. Rajah, Kriedt K., N. Balanchandren, M. Moghazy, E. Burt, D. Mavrelos

Reproductive Medicine Unit, University College London Hospitals, London, United Kingdom

Study question: To examine whether fibroid ultrasound characteristics are predictive of endometrial cavity breach at laparoscopic myomectomy.

Summary answer: The minimum distance of the fibroid edge from the endometrial cavity is the best predictor of endometrial cavity breach at laparoscopic myomectomy.

What is known already: It is accepted that submucous fibroids reduce the chance of spontaneous conception. Intramural fibroids larger than 3 cm have also recently been shown to affect the chance of conception after embryo transfer. Submucous fibroids mostly in the myometrium can be removed laparoscopically. One of the risks of surgery is breaching the endometrial cavity and associated risk of endometrial adhesions. Caesarean Section is often advised as the mode of delivery for women who have had their endometrial cavity opened at myomectomy.

Study design, size, duration: This is a retrospective cohort study of women who underwent a laparoscopic myomectomy from December 2014 to November 2017. Ultrasound images and operation notes were reviewed. The size, position and minimum distance of the fibroid from the endometrial cavity in the longitudinal plane were determined from ultrasound images (negative distance was scored when the fibroid protruded into the cavity). Endometrial cavity breaches at the time of surgery were identified from the operation notes.

Participants/materials, setting, methods: This study was carried out at a central London university teaching hospital. All women who underwent a laparoscopic myomectomy were initially included in the study. Women who did not have a pre-operative ultrasound and those who had more than two fibroids removed were excluded. Cases with incomplete ultrasound data were also excluded.

Main results and the role of chance: During the study period 74 women who had laparoscopic myomectomy and a pre-operative ultrasound were identified. The median age was 36.0 (IQR 33 – 39.8) and the median fibroid diameter was 68.2 mm (IQR 47.7 – 80.6). 10/74 (13.5%, 95% CI 5.7 – 21.3) had a breach of the endometrial cavity at laparoscopic myomectomy. Women who suffered a breach had a fibroid that was close to or within the endometrial cavity (distance from cavity -9.9 vs. 8.9 mm, p = 0.001, degree of protrusion 17% vs. 0.0% and intracavitary surface area 1463mm^2 vs. 0.0). A logistic regression model with cavity breach as independent variable and ultrasonic variables as predictors selected minimum distance from cavity as the best predictor of cavity breach (OR 0.79, 95% CI 0.73 – 0.92). 10/19 (52.6%, 95% CI 30.2 – 15.1) of women with a submucosal component to their fibroid did not have a cavity

breach. No women with a fibroid further than 5.2 mm from the endometrial cavity had a breach identified at surgery.

Limitations, reasons for caution: This is a retrospective study which could have led to selection bias. The ultrasound parameters were identified from saved ultrasound images and this confers a degree of subjectivity and bias. There is also possibility that an endometrial cavity breach may not have been identified intra-operatively.

Wider implications of the findings: There has been no previous study reporting the risk of endometrial cavity breach at laparoscopic myomectomy. Identifying patients who are at increased risk based on ultrasound facilitates appropriate pre-operative counselling regarding the risk of intrauterine adhesions and the need for Caesarean Section and more vigilant intra-operative endometrial cavity assessment.

Trial registration number: Not applicable.

Safety and quality of ART therapies

P-748 Fertility care: patient journey's modelling through invoice data

M. Pasquier[1], N. Salaun-Penquer[2], B. Haddad[3], C. Piétin-Vialle[1], L. Vienet-Légue[1], J. Labrosse[1], M. Ortala[4], H. Bry[1], N. Massin[1]

[1]*Intercommunal Hospital- University Paris XII, Department of reproductive medicine, Creteil, France*
[2]*Kaduceo SAS, Data department, Toulouse, France*
[3]*Intercommunal Hospital- University Paris XII, Department of gynecology and obstetrics, Creteil, France*
[4]*Kaduceo SAS, Board, Toulouse, France*

Study question: The objective of this study was to build a model of the fertility care journey based solely on administrative data collected from invoices.

Summary answer: Analysis based on billing data alone is sufficient to build quick, reliable and usable model in fertility care which is a huge source of information.

What is known already: Time in fertility care is the most important prognosis factor, whether considered as the patient's age or duration of treatment. Mastering it is a way to improve the global success rate and the patient's experience. One way to tackle this issue is to take a look at the global patient journey and try to identify pitfalls that could lead to delays in care and impact the patient's experience and chances of positive outcome.

Study design, size, duration: It is a longitudinal retrospective study. Invoicing data usually used for economic purposes were collected and gathered on a 7 year period and focused on our department of reproductive medicine. Over 2.4 M patient files from January 2010 to December 2016 were studied. After extraction, analyses were conducted on data related to all activities of the center. We rebuilt each patient's billing history, gathering specific information including medical acts, medical units and date of provided care.

Participants/materials, setting, methods: Inspired by customer's modelling and decision tree, we applied 'big data" statistical approach to create a model displaying in a universally readable format the overall patient journey. We identified key steps, and calculated statistics to show time estimation and proportion of patients between each steps. In order to verify the quality and reliability of this model we conducted the same analysis, enriched with medical data extracted from MediFirst, software specialized in medically assisted reproduction field.

Main results and the role of chance: We defined a patient journey by detecting its beginning (first appointment) and its end (delivery). 45% of the patients having a first appointment pursue a treatment, 39% with intra-uterine insemination (IUI) and 61% with embryo transfer (ET). The first attempt occurs after 7 months (median) from the first appointment, faster for IUI than for ET (5 vs 6 months). We observed that 2 appointments were sufficient for 80% of the women to begin the IUI process but 3 or 4 were required for ET. Time for delivery is shorter for ET than for IUI (17 vs 22 months). After // a 3-year follow-up period the success rates are similar for IUI and ET: 64% of pregnancies and 50% of deliveries. Comparison of the two models showed that there were less than a 5% differences for each proportion tested. In conclusion, analysis based on billing data alone is sufficient to build quick, reliable and usable models in fertility care. This model is a huge source of information for the patients and the practitioners. The immediate results and concrete use of this study were a drastic reorganization in our facility practices, leading to reduced waiting time before beginning fertility treatment.

Limitations, reasons for caution: The reliability of the results depends on the quality of track keepind and encoding by medical staff.

Wider implications of the findings: The model has the potential to not only inform the patient about the overall process awaiting him, but also give a clear picture of the organization of an healthcare unit and areas to be improved. The strength of this model is to be transposable to virtually any medical unit.

Trial registration number: not applicable.

P-749 Risk evaluation for pronuclear transfer using for preventing the transmisson of mitochondrial disease: a mouse model

L. Tianjie[1], Y. Yang[2], Q. Jie[2]

[1]*peking university third hospital, OB/GYN, Beijing, China*
[2]*Peking University Third Hospital, Reproductive Center- OB/GYN, Beijing, China*

Study question: Is it safe to prevent transmission of mitochondrial disease using pronuclear transfer as a mitochondrial replacement technology?

Summary answer: There is a potential risk in pronuclear transfer offspring in metabolism.

What is known already: Pathogenic mitochondria DNA (mtDNA) mutation is closely linked with many mitochondria diseases that usually lead to fatal results such as premature death. MtDNA is transmitted maternally within oocyte cytoplasm. Management of mitochondrial disease is limited due to its characteristic inheritance. Pronuclear transfer is considered to be effective in preventing the transmission of pathogenic mtDNA from mother to offspring.

Study design, size, duration: Pronuclear transfer technology were performed between zygotes of CD-1 mice to obtain constructed zygotes and offspring. We preformed 263 zygotes to assess embyoes development and 40 PNT offsprings to evaluate risk of PNT procedure.

Participants/materials, setting, methods: The constructed zygotes produced by PNT was fused by electrofusion. By testing mitochondria DNA copy number, the ratio of donor mitochondria was calculated. The cell number of balstocyst was counted and gene expression profiling was identified by NGS technique. Then PNT blastocyst were transferd to pesodu-pregnant mice. For PNT offspring, the body weight, ratio of fat/weight and energy expenditure were measured. The reproductive function was also assessed both in female and male PNT offspring.

Main results and the role of chance: The development efficiency was significantly decreased in PNT embryos compared with normal control embryos. Compared with normal fertilized embryos, total cell numbers of the blastocysts from PNT technology were decreased significantly, and a large amount of genes showed the abnormal expression levels. But there were no significant differences between neonatal body weight and plancenta weight. the ratio of donor mitochondria was no more than five percent. However, the quality of PNT blastocysts was declined. Compared with control blastocysts, implantation rate and birthrate in PNT blastocysts were all impaired.

For PNT offspring, compared to the controls, the body weight, ratio of fat/weight, energy expenditure, blood pressure and glucose tolerance showed no difference both in female and male pronuclear transfer mice. Estrous cycle, histogical analysis of ovary and fertility were normal in female pronuclear transfer mice, so were the testicular morphology, sperm concentration and fertility in male pronuclear transfer mice. However, a considerable of genes were differentially expressed between pronuclear mice and control group.In tissues where mebabolism were more vigorous like brain, heart, liver and muscle, an abundant of genes showed the abnormal expression levels. Differentially expressed genes were highly related in metabolism, which suggest a potential risk of pronuclear transfer offspring.

Limitations, reasons for caution: The ratio of donor mitochondria was not assessed in all tissues of PNT offspring during the whole life cycle. In addition, the F2 mice of PNT mice were not evaluated throughout the whole life.

Wider implications of the findings: The result not only emphasize the potential risk associated with metabolism of PNT procedure using to prevent transmission of mitochondrial disease but also facilitate a better understand of the effects of PNT procedure on development of offspring and enhancing the awareness of improving the outcome of PNT procedure.

Trial registration number: Not applicable.

P-750 To flush or not to flush: A retrospective analysis of follicle flushing during oocyte retrieval in Wales

A. D'Angelo[1], A. Mohd Azmil[2], A. Ibrahim[3,4], Z. Shehadeh[5], G. Kalra[5]

[1]*University Hospital of Wales- Wales Fertility Institute - Cardiff University-, Wales Fertility Institute, South Glamorgan- Cardiff, United Kingdom*
[2]*Cardiff University, Wales Fertility Institute, Cardiff, United Kingdom*
[3]*University Hospital of Wales, Wales Fertility Institute, Cardiff, United Kingdom*
[4]*Cairo University, Obstetrics and Gynaecology, Cairo, Egypt*
[5]*Neath Port Talbot, Wales Fertility Institute, Neath Port Talbot, United Kingdom*

Study question: Is follicular flushing during transvaginal ultrasound guided eggs collection useful to improve outcomes in women undergoing IVF/ICSI treatment for sub/infertility?

Summary answer: Lower n. of oocytes, mature oocytes, fertilised oocytes in the flushing, compared to the direct aspiration group. Fertilisation, clinical pregnancy rates were not different.

What is known already: The practice of follicle flushing has been a topic of discussion since ultrasound-guided transvaginal oocyte retrieval was introduced in 1981. Theoretically, flushing would allow for the retrieval of more oocytes, and consequently result in greater fertilisation and pregnancy rates. However, many studies have found no significant increase. National Institute of Clinical Excellence (NICE) guidelines suggest that follicle flushing for women with 3 follicles prior to oocyte retrieval should not be offered, as it increases the length of the process, the pain experienced without the added benefit of greater numbers of oocytes retrieved or higher pregnancy rates.

Study design, size, duration: Data from 221 women who underwent oocyte retrieval at the University Hospital between May 2016 to April 2017 were retrospectively evaluated. 162 women were included in this study, as 59 had to be excluded due to inadequate information available. 39 women (24.1%) were noted to have undergone oocyte retrieval with direct aspiration only, while the remaining 123 (75.9%) had undergone oocyte retrieval with follicle flushing.

Participants/materials, setting, methods: Procedures at the centre were performed using 16 gauge double lumen needles. Flushing medium used was from Origio.Chi square tests performed with $P < 0.05$ considered statistically significant. To determine a cut off value for the number of follicles needed to be present at the point of HCG administration, a Receiver Operating Characteristic (ROC) curve was plotted and the Area under the Curve (AUC) was calculated.SPSS version 24 was used.

Main results and the role of chance: The total number of oocytes (13.6 ± 6.5 vs 7.7 ± 5.2), the number of mature oocytes (11.7 ± 6.4 vs 6.3 ± 4.6), the number of fertilised oocytes (7.5 ± 5.3 vs 4.4 ± 3.6), the duration of procedure (21.8 ± 7.3 mins vs 20.2 ± 5.6 mins) as well as maturation (84.7% vs 83.7%) and clinical pregnancy rates (30.8% vs 22.8%) were found to be higher in the direct aspiration only group compared to the flushing group. The chi square test [χ^2 (degree of freedom)] indicated that all of the above, except the duration of procedure and clinical pregnancy rate, were statistically significant.On the contrary, the flushing group demonstrated higher fertilisation rates (57.8% vs 54.7%) when compared to the direct aspiration only group. However, these rates were not statistically significant.The area under this curve was measured to be 0.080 with 95% confidence interval (0.000, 0.181). This area unfortunately, being <0.5, implies that the cut off value of roughly 9 follicles at the point of HCG administration, below which follicle flushing would be recommended to obtain at least 3 mature oocytes, may not be accurate.

Limitations, reasons for caution: The suggested cut off value of roughly 9 follicles at the point of HCG administration, below which follicle flushing would be recommended to obtain at least 3 mature oocytes, derived from the ROC curve may not be accurate due to a small AUC of 0.080.

Wider implications of the findings: These findings, coupled with the first principles of surgery, which dictate that shorter and simpler procedures with minimal tissue handling can result in fewer complications, form the basis of our recommendation that follicle flushing should not be routinely performed during oocyte retrieval.

Trial registration number: None.

P-751 Monozygotic twin gestations after embryo biopsy in blastocyst stage

F. Sellers[1], J. Ten[2], J. Ortiz[3], J.C. Castillo[1], B. Moliner[1], R. Sellers[2], R. Bernabeu[1]

Study question: Check if the incidence of monozygotic pregnancies increases after the transfer of embryos biopsied at the blastocyst stage.

Summary answer: The risk of monozygotic pregnancy is double after the transfer of embryo biopsied in blastocyst stage.

What is known already: Monozygotic twin pregnancies are associated with a high number of perinatal complications. It has been demonstrated that the use of Assisted Reproduction Techniques (ART), with the manipulation of gametes, especially of the oocyte: intracytoplasmic sperm injection (ICSI), assisted hatching and blastocyst biopsy, can increase the incidence of this type of pregnancies.

However, there are no published studies on these monoclonal pregnancies after biopsied embryos in the blastocyst stage.

Study design, size, duration: Retrospective study carried out from 2014 to 2016, to collect the cases of monozygotic twin gestation after single embryo transfer with biopsy of the trophoectoderm of blastocysts, compared with a control group of pregnancies obtained with single embryo transfer cycles without biopsying the blastocysts always having carried out ICSI.

Participants/materials, setting, methods: In the study group we obtained 190 pregnancies after transfer of biopsied blastocysts, 107 were with fresh embryo transfer and 83 were after cryotransfer of thawed embryos; 102 cases were with own oocyte and 88 with donated oocyte.

In the control group we obtained 454 pregnancies after the transfer of non-biopsied blastocysts, 330 were in fresh cycle and 124 after cryotransfer; 101 cases were with own oocyte and 353 with donated oocyte.

Main results and the role of chance: There were 6 monozygotic pregnancies in the group of biopsied blastocysts, and 7 monozygotic pregnancies in the control group.

The overall analysis shows a frequency of occurrence of monozygotic twin pregnancies of 1.59% in gestation after transfer of non-biopsied embryos, compared to 3.16% after transfers of biopsied blastocysts, with an ODR: 2.08 (95% CI: 0.69-6.28) ($p = 0.18$).

In the individual analysis according to the type of treatment, an increased risk of monozygotic pregnancies is always observed, except in the case of cryotransfer with own oocyte, but without reaching any statistical significance:

– Own oocyte fresh cycle: ODR: 3.1 (95% CI: 0.27-35.32%)
– Own oocyte and cryotransfer: ODR: 0.63 (95% CI: 0.04-10.33)
– Donated oocyte fresh cycle: ODR: 1.38 (95% CI: 0.14-13.43)
– Donated oocyte and cryotransfer: ODR: 4 (95% CI: 0.53-30.08)

Limitations, reasons for caution: Although the risk of monozygotic pregnancy is double after blastocyst biopsy, this increase does not become statistically significant due to the few cases collected to date.

Wider implications of the findings: It is advisable to continue collecting cases in order to increase the total number of cases to find out if this tendency can achieve any statistically significant differences.

Trial registration number: NO.

P-752 United States rates of elective single embryo transfer tightly coincide with clinician preferences and approaches to patient education

J. Anderson

FertilityIQ, Editorial Staff, San Francisco, U.S.A.

Study question: Do United States patients receive pressure from, or are influenced by, their clinicians to have elective Single Embryo Transfer (eSET) or elective Multiple Embryo Transfer (eMET) performed?

Summary answer: Clinician opinion, and the extent to which they educate patients, strongly coincides with how many embryos a patient receives upon first transfer.

What is known already: Patients in the United States receive eSET in a distinct minority of cases. Elective single embryo transfer is pivotal in minimizes the risks to both mother/carrier and offspring.

Study design, size, duration: Patient survey and retrospective analysis of 499 verified United States IVF patients treated after 2015.

Participants/materials, setting, methods: 499 IVF patients treated in the United States and eligible for single or multiple embryo transfer were surveyed on the ways in which they were educated by their clinician, the influence the clinician had, and the number of embryos they had transferred. Results were tabulated and characterized using multi-variate analysis using a 95% confidence interval isolating for variables pertaining to patient age when treated, year treated, use of PGS and ultimate treatment decision.

Main results and the role of chance: 91% of patients reported their doctor made a clear recommendation on the number of embryos to transfer with nearly-two thirds (65%) of patients believing their clinician had an "equal or greater say" in the decision than they did. Ultimately, patients complied with their doctor's specific recommendation to a significant degree (72% for eSET, 82% for eMET, p <.01).

24% of patients reported no discussion transpired on the risks of multiple embryo transfer to the mother and 39% reported no discussion on the risks to offspring. Those patients who were educated on the risks to mother or offspring appear more likely (p = .07) to ultimately have eSET performed.

We noted patients who underwent eSET (p=.05) and PGS (P <.01) believe they were given more time to make a decision and with each passing year more patients felt their opinion influenced the decision more than their doctor's (p = .06). We noted younger women (under age 37) were more likely to be educated by their clinician on the risks of multiple embryo transfer (p = .01) and older women on the benefit it confers (p=.02), in this case, higher rates of success upon first transfer.

Limitations, reasons for caution: Retrospective analysis without randomization.

Wider implications of the findings: eSET rates in the United States are notoriously low with clinicians claiming patients ask for this and prefer it. This data suggests otherwise and that clinician practice and educational procedures may have a meaningful influence. eSET is effective in helping avoid perinatal and post-natal medical and financial deleterious effects.

Trial registration number: Not applicable.

P-753 No differences found of Small for Gestational Age (SGA) between Fresh Embryo Transfer (ET) babies and Spontaneously Conceived (SC) ones

P. Boyer[1], A. Beltran Anzola[2], V. Pauly[3], R. Sambuc[2,3], O. Riviere[4], F. Venditelli[4], M.J. Gervoise Boyer[1]

[1]*Hôpital Saint-Joseph, Laboratoire de Biologie de la Reproduction, Marseille Cedex 08, France*

[2]*Aix-Marseille Université - Faculté de médecine, Département de Santé Publique et Maladies Chroniques- Unité de recherche EA 3279, Marseille, France*

[3]*Assistance Publique Hôpitaux de Marseille, Service d'information médicale, Marseille, France*

[4]*Université Claude Bernard Lyon 1, AUDIPOG Association des Utilisateurs de Dossiers informatisés en Pédiatrie- Obstétrique et Gynécologie-, Lyon, France*

Study question: Are babies born after Fresh Embryo Transfer more exposed to a risk of being SGA rather than babies born after SC as previously published?

Summary answer: The incidence of SGA in babies conceived after fresh embryo transfer (6.9%) is not higher than in babies born after a SC (6.8%).

What is known already: The literature has shown that singletons born after a fresh Embryo Transfer (ET) conceived after In Vitro Fertilization (IVF) either with or without micromanipulation IntraCytoplasmic Sperm Injection (ICSI) have an increased risk of low birth weight under 2500 g, preterm birth before 37 gestational weeks, congenital anomalies and SGA, compared to singletons born after SC. Several studies suggested that the increase for SGA in babies born after fresh ET could be due to the ovarian stimulation.

Study design, size, duration: The study design was a historical exposed and unexposed cohort of singletons conceived after Fresh ET (exposed group) matched to singletons conceived after a SC (unexposed group). The exposed group involved 1961 singletons conceived after IVF or ICSI between 1995 and 2015. The unexposed group involved 5883 singletons issued from French AUDIPOG sentinel network, and born in the same period.

Participants/materials, setting, methods: The study involved 7844 singletons (>22 weeks or >500 g).Three babies born after a SC were matched on the year of birth, maternal age, parity, and sex. SGA was defined as a birth weight below the 5th percentile. A univariate analysis using Generalized Estimating Equations (GEE) for correlated data was performed to compare maternal background, obstetric parameters and perinatal outcomes. To analyse the factors influencing the incidence of SGA a multivariate analysis using GEE were performed.

Main results and the role of chance: In univariate analyses, SGA incidence was similar between babies born after fresh ET 135 (6.9%) and babies born after a SC 399 (6.8%) (p = 0.856) while the incidence of low birth weight (8.6%) was higher in the exposed group in comparison to SC babies (7.0%) (p = 0.021).

In the multivariate analysis, the transfer of fresh embryos did not affect the incidence of SGA (aOR 1.0 [95%CI 0.8-1.3]). This result contrasts with previous reports and may be partially due to the day of embryo transfer. Indeed, in our exposed group, we have a considerable rate of transfer in D5 (47.6%). A transfer at D5 is nearest to the physiology of implantation which may favour the Single ET at this stage and increases the birth weight. In addition, selected matching criteria could be also explaining this absence of SGA risk. In fact, these factors are already known to be related to higher rates of SGA.

The significant factors influencing the SGA incidence were a low rate of multiparity (aOR 0.5 [95%CI 0.3-0.7]), an advanced maternal age (aOR 1.0 [95%CI 1.0-1.0]), maternal underweight (aOR 1.5 [95%CI 1.1-2.1]), maternal smoking behaviour (aOR 1.9 [95%CI 1.4-2.4]), and high blood pressure induced by pregnancy (aOR 2.4 [95%CI 1.8-3.4]).

Limitations, reasons for caution: The 5th percentile was used to define SGA instead of 10th percentile used by most studies. In fact, this definition varies across studies with conflicting results. We wanted to use thresholds which may represent the more possible situations involving specific medical conditions.

Wider implications of the findings: Fresh ET was often related to SGA. However, our results suggested that it is rather maternal factors which influence SGA incidence. Furthermore, a higher rate of D5 (47.6% vs 27.0% at national level) could decrease this incidence, as suggested in a recent study.

Trial registration number: not applicable.

P-754 Obstetric outcome of women with in vitro fertilization pregnancies hospitalized for ovarian hyperstimulation syndrome: a retrospective cohort study

L. Hu[1], R. Xie[1], M. Wang[1], Z. Bu[1], W. Dai[1], C. Wang[2], Y. Sun[1]

[1]*First Affiliated Hospital of Zhengzhou University, Center for Reproductive Medicine, zhengzhou, China*

[2]*College of Public Health- Zhengzhou University, 100 Kexue Avenue, Zhengzhou, China*

Study question: The aim of this study was to investigate the effects of late moderate-to-critical OHSS on pregnancy and neonatal outcomes.

Summary answer: OHSS was associated with higher rates of Venous thrombosis(VT) and Gestational diabetes mellitu (GDM).

What is known already: Earlier studies have shown that the pregnancy and abortion rates increase significantly among OHSS patients and that these patients are more likely to develop adverse pregnancy outcomes such as abortion, growth restriction, PIH, GDM and low neonatal birth weight (LBW).

Study design, size, duration: This is a retrospective cohort study of 9143 eligible patients diagnosed with clinical pregnancy after IVF/ICSI-assisted conception and fresh ET from June 2012 to July 2016. All patients were registered in our data management system, which was used to save all medical information of patients trying to conceive through ART.

Participants/materials, setting, methods: All eligible subjects were determined based on the established inclusion and exclusion criteria, then, a propensity score matching analysis was performed with matching of nine maternal baseline covariates and the number of multiple gestations. 385 patients (4.9%) were hospitalized for late moderate-to-critical OHSS and compared to a matched control group of 1540 patients. The primary outcomes were live birth rate, preterm delivery rate, miscarriage rate, gestational age at birth (weeks), obstetric complications and neonatal complications.

Main results and the role of chance: The primary strength of the present study is elimination of multiple pregnancy impact on obstetric complications and neonatal complications. Live birth and neonatal complication rates did not significantly differ. The obstetric complications of Venous thrombosis and Gestational diabetes mellitus (GDM) were significantly higher in the OHSS group (0.5% vs. 0%, OR 0.995 (95% CI 0.988-1.002; P = 0.04); 1.8% vs. 0.6%, OR 3.150 (95% CI 1.166-8.513; P = 0.017), respectively).The duration of gestation was significantly higher in the matched non-OHSS group than in the OHSS group (38.0 ± 2.2 vs. 38.4 ± 2.2 (P = 0.011), OR 0.100, 95% CI 0.6-0.08). During hospitalization, 147 (38.2%) OHSS patients underwent paracentesis and/or multifetal pregnancy reduction (MFPR), and the mean hospitalization duration was 12.7 ± 6.9 days. Hospital duration, obstetric complication rate, preterm delivery rate, and HCT and WBC values were significantly higher in the severe and critical OHSS group.

Limitations, reasons for caution: Our study has a limitation, because our center began measuring AMH from 2016, it was not included in the results of AMH.

Wider implications of the findings: OHSS was associated with higher rates of Venous thrombosis(VT) and Gestational diabetes mellitu (GDM). The surgical treatment group had increased hospitalization durations and neonatal complications and decreased obstetric complications. OHSS severity increased the incidences of obstetrical complications and preterm labor but had no effect on neonatal complications.

Trial registration number: Not applicable.

P-755 Freeze-only versus fresh embryo transfer in full-term singleton birth: a retrospective cohort study

J. Zhang, L. Sun, M. Du, Z. Li, J. Hu, Y. Feng, B. Zhao, L. Wang

Third Affiliated Hospital of Zhengzhou University, Third Affiliated Hospital of Zhengzhou University, Zhengzhou, China

Study question: Investigate whether freeze-only embryo transfer is preferred than fresh embryo transfer in the full-term singleton low birth weight (LBW) and small for gestational age (SGA).

Summary answer: Our study suggested that freeze-only embryo transfer was associated with statistically significantly lower rate of LBW and SGA.

What is known already: Improvement in the technology of vitrification and increase of single embryo transfer, frozen embryo transfer(FET) cycles have rapidly increased. Meanwhile, some evidence suggested that FET may increase the pregnancy rate and perinatal outcomes were less affected by the FET. But whether freeze-only proposal is preferred than fresh embryo transfer in LBW and SGA of full-term singleton birth remains controversy.

Study design, size, duration: Retrospective cohort study of none pregnancy-related complications patients, undergoing freeze-only embryo transfer (n = 2053) and fresh embryo transfer cycles (n = 2059) resulting in full-term singletons births between July 2008 and September 2016 at the Center for Reproductive Medicine of the Third Affiliated Hospital of Zhengzhou University.

Participants/materials, setting, methods: The singleton full-term births via IVF/ICSI were included. Cycles with pregnancy-related complications, donor oocytes, PGD/PGS, vanishing twins or incomplete records were excluded. Primary outcome measures were full-term LBW (birthweight <2500 g) and SGA (<10th percentile for gestational age). Secondary outcome measures were neonatal birthweight, LGA (>90th percentile for gestational age) and macrosomia (birthweight ≥4000 g). And we used logistic regression to adjust for the baseline characteristics between two groups to minimize the potential confounding factors.

Main results and the role of chance: Neonatal birthweight in singleton born after freeze-only embryo transfer was higher compared with singleton born after fresh embryo transfer (3468.7 ± 475.3 vs. 3386.7 ± 448.1; p<0.001). The frequency of full term singleton LBW and SGA after freeze-only embryo transfer was significantly lower than that after fresh ET (1.7 % vs. 3%; 4.4 % vs. 6.7 %), for the adjusted rate ratio of 0.59(95% CI, 0.37 to 0.98; p = 0.026); 0.73(95% CI, 0.55 to 0.99; p = 0.041). While freeze-only embryo transfer resulted in a higher frequency of macrosomia (15.1% vs 10.2%) than fresh ET, for the adjusted rate ratio of 1.43(95% CI, 1.16 to 1.75; p = 0.001). Furthermore, the incidence of LGA was significantly higher in the freeze-only embryo transfer than in the fresh-embryo group (22.8% vs. 17.5%), for a rate ratio of 1.26 (95% CI, 1.07 to 1.49; P = 0.007).

Limitations, reasons for caution: The current study is a retrospective cohort study, prospective studies are required to validate the freeze-only protocol is preferred than fresh embryo transfer in LBW and SGA. Furthermore, the pathogenesis of LBW in IVF/ICSI remains unclear, this study did not explore other relevant mechanisms.

Wider implications of the findings: Our study suggested freeze-only protocol was preferred than fresh embryo transfer of LBW and SGA. FET is an important supplement for fresh embryo transfer, while whether freeze-only can be the first choice requires further clinical and fundamental research.

Trial registration number: N/A.

P-756 A survey on standardization of practice in Ultrasound in ART, gynaecology and early pregnancy

A. Urazbayeva[1], A. Horne[2], N. Vermeulen[3], E. Kirk[4], A. D'Angelo[5]

[1]Pilgrim Hospital, United Lincolnshire Trust, Boston, United Kingdom
[2]MRC Centre for Reproductive Health- University of Edinburgh, Centre for Reproductive Health, Edinburgh, United Kingdom
[3]ESHRE, Central Office, Grimbergen, Belgium
[4]Royal Free Hospital, Obstetrics and Gynaecology, London, United Kingdom
[5]University Hospital of Wales- Cardiff University, Wales Fertility Institute, Cardiff, United Kingdom

Study question: Is there a need for standardization of practice in Ultrasound in ART, gynaecology and early pregnancy?

Summary answer: The results of this survey support the development of good practice recommendations on the use of ultrasound in ART, for gynaecological pathology and early pregnancy.

What is known already: Ultrasound practise is essential in ART, as many every day activities in the fertility units are ultrasound-based. However, there seems to be a large variation in the way ultrasound is performed, both in individual approach and between different countries. Only a small proportion of countries have national guidance on ultrasound, although are not necessarily focussed on fertility and early pregnancy. In other countries, ESHRE, RCOG, NICE, ASRM and ISUOG guidelines are used instead.

Study design, size, duration: Between November 2016 and February 2017 a survey to explore these differences was carried out. The survey included 14 questions, aiming to explore whether there is a role for collating the different recommendations or guidelines from other societies and for developing standards in ultrasound in ART and Early pregnancy that could be implemented in Europe and beyond. The survey was disseminated via mailings and social media.

Participants/materials, setting, methods: This online survey was conducted among ESHRE members and 333 responses were collected. Most of the responders (63%) were based in Europe, 20% in Asia, and the remaining 17% in Africa, America and Australia. Regarding occupation, a majority of responders (84.9%) was medically qualified, the remaining included embryologists, nurses, midwifes, counsellors and managers. Given that experts' views were extremely valuable for drawing the conclusion, responders were felt to be with appropriate level of knowledge/experience.

Main results and the role of chance: Regarding the fertility treatment, two-thirds of the responders (68.4%), mainly from European countries, stated there is a national body regulating fertility treatments in their country of residence. Half of the responders from Asia, and approximately 80% of the South American and African, responded that they do not have guidelines for ART in their country. Interestingly, but not surprising, in countries with no national guidelines for ART, ESHRE, ASRM and NICE were the most followed ones. Regarding guidelines on Ultrasound, only a quarter of the responders stated that there is a national guideline for ART, gynaecological pathology and early pregnancy. Most of the responders (85%) stated there is a need for standardized guidelines regulating USS in ART, gynaecological pathology and early pregnancy. Notably a number of responders (181) suggested these topics to be covered in a potential guideline. Finally, a two third of the responders showed initiative to be included into a guideline development group and a half of the total number of responders provided their email addresses to be contacted.

Limitations, reasons for caution: Limitations are an absence of experts interviews and different answers from the same country of residence on national guidelines.

Wider implications of the findings: The strength of this survey results are number of responses, targeted users included and broad views on different clinical topics collected. The results of this survey will support the proposal of developing recommendations for standardised practice in USS in different aspects of ART, gynaecological pathologies and early pregnancy.

Trial registration number: none.

P-757 Comparison of pregnancy and perinatal outcomes after frozen and fresh embryo transfer

S. Lijun, Z. Li, J. Hu, J. Zhang, B. Zhao, Y. Feng

reproductive center of the third affiliated Hospital of Zhengzhou University, Zhengzhou University, Zhengzhou, China

Study question: Does frozen embryo transfer (FET) have better pregnancy and perinatal outcomes than fresh embryo transfer?

Summary answer: We found no significant improvement regarding pregnancy and perinatal outcomes in FET compared with fresh embryo transfer.

What is known already: FET has been progressively used during the past few decades and it becomes an essential part of assisted reproductive technology (ART). Extra good quality embryos are preserved in FET for women with good response to ovarian stimulation, improving cumulative pregnancy rate, increasing single embryo transfer, decreasing risk of multiple pregnancy and hyperstimulation syndrome. However, whether FET can improve pregnancy and perinatal outcomes is uncertain.

Study design, size, duration: A retrospective cohort study was performed consisting of 8370 FET cycles and 8573 fresh embryo transfer cycles between January 2008 and September 2016 at our reproductive center.

Participants/materials, setting, methods: Women who underwent FET and fresh embryo transfer are divided into two groups: FET group (8370 patients) and fresh embryo transfer group (8573 patients). To compare the rates of implantation, biochemical pregnancy, clinical pregnancy, first-trimester abortion and multiple pregnancy. The incidence of preterm delivery, live delivery,ectopic pregnancy, pregnancy-induced hypertension, gestational diabetes mellitus, mean birthweight, low birth weight and congenital malformation were evaluated.

Main results and the role of chance: After adjusting for confounding factors, no differences were observed in implantation [adjusted odd ratio (aOR) 0.98, 95% confidence interval (CI) 0.97-1.13], biochemical pregnancy (aOR 0.88 ,95%CI 0.76-1.13), clinical pregnancy (aOR 0.94, 95%CI 0.89-1.02), multiple pregnancy (aOR 1.12 ,95%CI 0.96-1.27), gestational diabetes mellitus (aOR 0.82 ,95%CI 0.62-1.12) and congenital malformation (aOR 0.94 ,95%CI 0.57-1.36) rates of the two groups. Live birth rate (aOR 1.23 ,95%CI 1.15-1.32) after FET was significantly elevated compared with fresh embryo transfer. And FET showed decreased risks of ectopic pregnancy(aOR 0.83 ,95%CI 0.60-0.98) and low birth weight (aOR 0.83 ,95%CI 0.82-0.96). Mean birthweight was higher in the FET versus the fresh embryo transfer (P<0.001). The significantly increased risks of preterm delivery(aOR 1.28 ,95%CI 1.10-1.50), first-trimester abortion(aOR 1.11 ,95%CI 1.07-1.25) and pregnancy-induced hypertension (aOR 1.63 ,95%CI 1.29-2.12) in FET compared with fresh embryo transfer were found.

Limitations, reasons for caution: As in all observational studies, the possible role of residual confounding factors and bias should be considered. In this study, we were not able to control for confounding factors, such as smoking, parity and child's sex.

Wider implications of the findings: The study suggest that FET do not present significant benefit in pregnancy and perinatal outcomes compared with fresh embryo transfer. As a consequence, a comprehensive consideration should be given when selecting a transplantation program.

Trial registration number: N/A.

P-758 The effect of the underlying type of infertility on placental-mediated adverse outcomes for patients that used IVF: a population-level study

A. Lanes[1,2], A. Sprague[2], A. Leader[3], B. Potter[4], M. Walker[1,2,5]

[1]*Ottawa Hospital Research Institute, OMNI Research Group, Ottawa- Ontario, Canada*
[2]*Children's Hospital of Eastern Ontario, BORN Ontario, Ottawa- Ontario, Canada*
[3]*Ottawa Fertility Centre, Ottawa Fertility Centre, Ottawa, Canada*
[4]*University of Ottawa, Epidemiology and Public Health, Ottawa, Canada*
[5]*The Ottawa Hospital, Obstetrics- Gynecology and Newborn Care, Ottawa, Canada*

Study question: To investigate associations between type of infertility and placental-mediated adverse outcomes among women that used in vitro fertilization (IVF) to conceive compared to spontaneous conception.

Summary answer: There was a statistically significant increased association found among births using IVF; specifically among cases where female factor infertility was the underlying cause of infertility.

What is known already: Previous studies have found associations between fertility treatment and stillbirth, and preeclampsia. Additionally, a recent meta-analysis found an association between fertility treatment and gestational hypertension and placental abruption. Multiple pregnancies among women who used fertility treatments to conceive have been found to be associated with an increased risk of preeclampsia. However, it is important to consider the role of multiple gestations in driving the increased associated risk. Conversely, there have been studies that found no significant association between fertility treatment and preeclampsia once they adjusted for maternal age and parity.

Study design, size, duration: This was a population-level retrospective cohort study of 200,469 live births and stillbirths in Ontario, Canada from May 2013 through October 2014. This study used fertility treatment data from CARTR (Canadian Assisted Reproductive Technologies Register) Plus, and pregnancy and birth outcomes data from BORN (Better Outcomes Registry & Network) Ontario and the Canadian Institute for Health Information. This study included all documented births in Ontario, Canada during this period of time.

Participants/materials, setting, methods: The exposed group included live births and stillbirths from women that used IVF, frozen embryo transfer, frozen oocyte IVF to conceive and a control group of births from spontaneous conceptions during the same time period. Unadjusted logistic regression models were performed using generalized estimating equations, as well as models adjusted for maternal age, neighbourhood income level and smoking were generated for the composite outcome (preeclampsia (PE), placental abruption, stillbirth, small-for-gestational-age), and all individual outcomes.

Main results and the role of chance: Significant differences were found for maternal age, hospital level-of-care and pre-existing maternal health conditions for births that used IVF to conceive. However, there were no significant

differences among the infertility groups with respect to characteristics of fertility treatment except for method of insemination.

Births resulting from IVF conceptions were found to be statistically significantly associated with an increased risk of the composite outcome (RR: 1.15, 95%CI: 1.01-1.31), as well as PE (RR: 1.74, 95%CI: 1.28-2.35) and placental abruption (RR: 1.65, 95%CI: 1.12-2.44), as compared to births from spontaneous conception. Similarly, female factor infertility was significantly associated with an increased risk of the composite outcome (RR: 1.21, 95%CI: 1.01-1.46), as well as PE (RR: 2.01, 95%CI: 1.34-3.00). The results remained significant after adjusting for potential confounders.

IVF was associated with a higher risk of preterm birth (<37 weeks) and very preterm birth (<32 weeks), relative to spontaneous conception, adjusted RRs, 1.64 (95%CI: 1.40-1.93) and 1.74 (95%CI: 1.19-2.56), respectively. When type of infertility was investigated we found IVF for female factor infertility was most strongly associated with a higher risk preterm birth: adjusted RRs, 1.77 (95%CI: 1.42-2.20) and 2.40 (95%CI: 1.52-3.80) for <37 weeks and <32 weeks, respectively, compared to spontaneous conceptions.

Limitations, reasons for caution: This study used comprehensive administrative data; nevertheless this study was potentially affected by misclassification of the exposure and/or outcome variables, a data quality issue that plagues studies that use administrative data.

Wider implications of the findings: The hormonal and/or structural factors associated with female factor infertility may have affected the implantation and development of the placenta, leading to an increased associated risk of the study outcomes. The increased risk among this group should be appropriately considered and accounted for when delivering IVF conceptions.

Trial registration number: not applicable.

P-759 In Freeze-all strategy Cumulative Live Birth Rate (CLBR) is increasing according to the number of blastocysts formed in women <40 undergoing IntracytoplasmIc Sperm Injection (ICSI)

T. Chartomatsidou[1], E. Timotheou[1], P. Tatsi[1], E. Katsoula[2], O. Zafeiratis[3], R. Najdecki[3], E. Papanikolaou[3]

[1]*Assisting Nature- IVF Centre- Thessaloniki- Greece, Embryology Lab, Thessaloniki, Greece*

[2]*Assisting Nature- IVF Centre- Thessaloniki- Greece, Midwifery Department, Thessaloniki, Greece*

[3]*Assisting Nature- IVF Centre- Thessaloniki- Greece, Clinician, Thessaloniki, Greece*

Study question: Does the number of the formed and vitrified blastocysts affect Cumulative Live Birth Rate in women undergoing Freeze-all strategy?

Summary answer: CLBR after three frozen/ thawed embryo transfers (ETs) is increasing respectively according to the number of vitrified blastocysts.

What is known already: Elective freezing of all embryos, followed by frozen/ thawed ET cycles emerged to prevent risk of Ovarian Hyperstimulation Syndrome and to allow endometrium recovery after Controlled Ovarian Stimulation. The efficacy of embryo vitrification allowed Freeze-all policy to gain popularity. Freeze-all policy, however, should preferentially be performed on day 5 of embryo culture, in order to minimize the number of abnormal embryos and consequently to decrease failed ETs and emotional cost. Previous studies reported better In vitro Fertilization (IVF) outcomes after adopting the Freeze-all policy, instead of fresh ET. Nevertheless, efficacy in terms of CLBR has not been studied yet.

Study design, size, duration: This prospective observational cohort study was performed in 156 women undergoing ICSI with antagonist protocol, without fresh ET. CLBR was compared in three groups of women according to the number of blastocysts formed and cryopreserved; group A: 1-4 blastocysts (n = 38), group B: 5-7 blastocysts (n = 66) and group C: ≥8 blastocysts (n = 52). The CLBR was estimated separately for each group, after completing 3 cycles of frozen/thawed ETs (two women still have blastocysts frozen for transfer).

Participants/materials, setting, methods: Study was performed from January 2014 until March 2017 in Assisting Nature IVF Centre, Thessaloniki, Greece. All cases concerned couples with a female age range of 21-39 years, with fresh ejaculated sperm. Patients underwent estrogen preparation of endometrium and were divided in three groups according to the number of the blastocysts vitrified. CLBR was calculated following blastocyst Freeze-all strategy when three thawed cycles had been finalised.

Main results and the role of chance: There was no difference in the mean age of each group (34 vs 33 vs 31). The mean blastulation rate was above 50% of the number of 2 pronuclei (2PN) embryos in each group ($p>0.05$). Cumulative Live Birth Rate was 31.51% in group A (1-4 blastocysts), 75.75% in group B (5-7 blastocysts) and 84.61% in group C (≥8 blastocysts). The above difference was statistically significant ($p<0.05$) among the three groups.

Limitations, reasons for caution: No sperm quality was taken into account and no natural cycles were used for endometrium preparation.

Wider implications of the findings: Adopting Freeze-all strategy after blastocyst culture can contribute to improve delivery outcome after IVF in terms of Cumulative Live Birth Rate. The number of the total cryopreserved blastocysts produced might reflect the quality of the oocyte and can successfully predict the pregnancy outcome.

Trial registration number: not applicable.

P-760 Hospitalization before pregnancy in infertile women treated with ART, non-ART, or no fertility therapy compared with fertile women

J.E. Stern[1], C.L. Liu[2], H.J. Cabal[3], D. Gopal[3], L. Harvey[4], C.C. Coddington[5], S.A. Missmer[6], H. Diop[2]

[5]*Mayo Clinic, Obstetrics & Gynecology, Rochester- MN, U.S.A.*

[6]*Michigan State University, Obstetrics- Gynecology- and Reproductive Biology, Grand Rapids- MI, U.S.A.*

Study question: Do diagnoses during pre-pregnancy hospitalizations in ART-treated women, women using non-ART medically assisted reproduction(MAR), or untreated infertile women, differ from hospitalization diagnoses for fertile women?

Summary answer: Diagnoses during hospitalizations prior to pregnancy for women who have ART, MAR, or untreated infertility all differ from pre-pregnancy diagnoses for fertile women.

What is known already: Compared with fertile women, women who have been treated with ART or MAR, and those who have unassisted pregnancies but indicators of infertility, have a greater risk of adverse delivery outcomes such as low birthweight and prematurity. Prior studies have shown that infertility-related diagnoses may contribute to these adverse outcomes, but whether adverse outcomes are most attributed to underlying disease or to infertility treatment is unknown. One potential indicator of underlying disease that can shed light on this issue is hospitalization prior to pregnancy and the reasons associated with that hospitalization.

Study design, size, duration: We included 125,206 first live-birth deliveries between 2004 and 2010 to women ≥18 years of age with private health insurance from the Massachusetts Outcome Study for Assisted Reproductive Technology (MOSART) and evaluated hospital stays for the 5 years prior to pregnancy. MOSART links ART deliveries from the Society for Assisted Reproductive Technology Clinic Outcome Reporting System (SART CORS) to birth certificates and hospital discharges in the Pregnancy to Early Life Longitudinal (PELL) data system.

Participants/materials, setting, methods: The study included 7,080 ART and 1,834 non-ART-MAR deliveries, 1,036 deliveries to women with infertility diagnosis but no fertility treatment (infertile), and 115,256 deliveries with no indicators of infertility or treatment (fertile). Demographics, gestational age and birthweight were obtained from birth certificates. Diagnoses from PELL were evaluated for prevalence in each group and then compared among all groups. Multivariable logistic regression models with fertile group as reference were adjusted for maternal age, race and education.

Main results and the role of chance: ART, MAR and infertile deliveries differed from fertile in adjusted odds of low birthweight (<2,500 gms: adjusted odds

ratio [AOR], 95% confidence interval [CI] 2.8, 2.6-3.0, ART; 2.2, 1.9-2.6, MAR; 1.9, 1.6-2.3 infertile) and prematurity (< 37 weeks gestational age: AOR, 95% CI: 2.9, 2.7-3.2 ART; 2.1, 1.8-2.4, MAR; 1.8, 1.5-2.2 infertile). Common diagnoses at hospitalization in the ART, MAR and infertile groups included higher adjusted odds than fertile women of endometriosis (AOR, 95% CI: 12.4, 9.4-16.3 ART; 6.0, 3.5-10.6 MAR; 22.3, 14.7-33.7 Infertile), reproductive organ disease (AOR, 95% CI: 6.5, 5.5-7.8 ART; 2.1, 1.3-3.4 MAR; 8.1, 5.7-11.4 Infertile), ectopic pregnancy and miscarriage (AOR, 95% CI: 5.5, 4.4-6.8 ART; 2.8, 1.7-4.6 MAR, 4.7, 2.9-7.6 Infertile), and disorders of menstruation, ovulation, and genital tract (AOR, 95% CI: 3.8, 2.8-5.2 ART, 4.2 2.5-7.0 MAR, 7.3, 4.5-12.0 Infertile). Diagnoses of disorders of fluid and electrolyte imbalance, psychiatric disorders, and misuse of drugs, which were most common in the fertile group, did not differ between the groups. Odds of overweight and obesity diagnosed during hospitalization did not differ among the fertile, ART, and infertile groups but were significantly higher in the MAR group (AOR, 95% CI 2.2, 1.4-3.6).

Limitations, reasons for caution: The time from pre-pregnancy diagnoses to first pregnancy was not evaluated and diagnoses out of hospital are not included. ART and non-ART-MAR women may have greater access to care and thus greater likelihood of hospitalization compared to untreated infertile or fertile women. The population is from a single U.S. state.

Wider implications of the findings: Women treated with ART and non-ART-MAR and who are infertile with no treatment, all have elevated odds of pre-pregnancy hospitalizations for reproductive disorders. The data have implications for the health of deliveries to these women and suggest that underlying disease plays a role in outcome in these populations.

Trial registration number: not applicable.

P-761 Single and double embryo transfer provide similar live birth rates in frozen cycles

A. Racca[1,2], P. Drakopoulus[1], L. Van Landuyt[1], C. WIllem[1], S. Santos-Ribeiro[1,3], H. Tournaye[1], C. Blockeel[1,4], N. Polyzos[1,5,6]

[1]UZ Brussel, UZ Brussel Fertility clinic -CRG-, Brussels, Belgium
[2]University of Genoa- IRCCS AOU San Martino, Academic Unit of Obstetrics and Gynecology, Genova, Italy
[3]Santa Maria University Hospital, Department of Obstetrics- Gynecology and Reproductive Medicine, Lisbon, Portugal
[4]School of Medicine of the University of Zagreb, Department of Obstetrics and Gynecology, Zagreb, Croatia
[5]Dexeus University Hospital, Department of Reproductive medicine, Barcelona, Spain
[6]Faculty of Health University of Aarhus, Department of Clinical Medicine, Aarhus, Denmark

Study question: Do live birth rates (LBRs) differ in frozen cycles of women who received single versus double embryo transfer?

Summary answer: LBRs are similar in women undergoing frozen embryo transfer (FET) with one or two embryos.

What is known already: FET has become an intricate part of IVF treatment and is no longer viewed as a mere supplement to fresh embryo transfer. Although the policy in many IVF centers tends towards single embryo transfer (SET) in case of a fresh embryo transfer, frozen cycles do not seem to follow the same pattern since they are still frequently considered as a means to counterbalance a previous failed fresh attempt.

Study design, size, duration: This was a large retrospective cohort study including all consecutive women who underwent their first FET in a tertiary referral University Hospital between January 2009 and December 2014. Each patient was included only once in the analysis.

Participants/materials, setting, methods: All eligible patients had vitrification as the cryopreservation method and underwent single (SET) or double (DET) FET with either cleavage or blastocyst stage embryos. Our primary outcome was LBR. Secondary endpoints included biochemical/clinical/miscarriage and multiple birth rates.

Main results and the role of chance: In total, 3601 patients were included in the analysis with 1936 (53.8%) having a SET and 1665 (46.2%) having a DET. Overall, 657/3601 (18.24%) had a live birth. LBR were similar between SET and DET either for cleavage [100/757 (13.1%) versus 153/1032 (14.8%), p = 0.33] or blastocyst stage FET [256/1179 (21.7%) versus 148/633 (23.4%), p = 0.4). Similarly, ongoing pregnancy rates were comparable between DET and SET [316/1665 (18.9%) versus 359/1936 (18.5%)]. However, biochemical pregnancy rates were significantly higher in DET, suggesting a higher risk for early pregnancy loss in case of DET compared to SET [326/1665 (19.6%) versus 308/1936 (15.9%) p = 0.004]. Multiple delivery rates were significantly higher in women with DET compared to SET [53/316 (16.7%) versus 7/359 (1.9%), p<0.001]. Multivariate logistic regression analysis allowing adjustment for relevant confounders showed that the number of embryos transferred in the frozen cycle is not related to LBR.

Limitations, reasons for caution: This is an observational study based on retrospective data collection. Despite our robust methodological approach, the presence of biases related to the retrospective design cannot be excluded.

Wider implications of the findings: This is the largest study providing evidence that both SET and DET may result in similar LBR, albeit multiple pregnancy rates are significantly lower in case of SET. Therefore, SET should be the main strategy in women undergoing FET. The higher miscarriage rates in women with DET warrant further evaluation.

Trial registration number: not applicable.

P-762 Cumulative live birth rate following freeze-only versus conventional fresh transfer cycles: a population-based cohort study

Z. Li[1,2], A. Wang[1], M. Bowman[2], K. Hammarberg[3,4], C. Farquhar[5], L. Johnson[3], N. Safi[1], E. Sullivan[1]

[1]University of Technology Sydney, Faculty of Health, Sydney, Australia
[2]The University of Sydney, Sydney Medical School, Sydney, Australia
[3]Victorian Assisted Reproductive Treatment Authority, Victorian Assisted Reproductive Treatment Authority, Melbourne, Australia
[4]Monash University, School of Public Health and Preventive Medicine, Melbourne, Australia
[5]University of Auckland, Department of Obstetrics and Gynaecology, Auckland, New Zealand

Study question: What is the cumulative live birth rate following a 'freeze-only' strategy compared with a 'fresh transfer' strategy?

Summary answer: Compared with 'fresh transfer' strategy, 'freeze-only' strategy resulted in a similar cumulative live birth rate among high responders but significantly lower rate among normal/suboptimal responders.

What is known already: Frozen-thawed embryo transfer is associated with decreased risk of adverse obstetric and perinatal outcomes compared with fresh embryo transfer. It is unclear whether 'freeze-only' strategy should be offered to all women undergoing assisted reproductive technology (ART) treatment.

Study design, size, duration: A population-based retrospective cohort study. This study included 14331 women undergoing their first stimulated ART cycle with at least one oocyte fertilized between 1 Jul 2009 and 30 Jun 2014 in Victoria, Australia. ART treatment and resulting pregnancy and birth outcomes were recorded for the stimulated cycle and associated thaw cycles until 30 June 2016, or until a live birth was achieved, or until all embryos from the stimulated cycle had been used.

Participants/materials, setting, methods: Women were grouped by whether they had undergone the 'freeze-only' strategy (n = 1028) where all embryos were cryopreserved for future transfer, or the 'fresh transfer' strategy (n = 13303) where the best embryo(s) were transferred in the stimulated fresh cycle and remaining embryo(s) were cryopreserved for future use. A Cox proportional hazard model was used to evaluate the cumulative live birth rate following 'freeze-only' and 'fresh transfer' strategy.

Main results and the role of chance: A total of 1028 women undergoing 'freeze-only' strategy and 13303 women undergoing 'fresh transfer' strategy who had 1788 and 22334 embryo transfer cycles resulting in 452 and 5126 live births respectively. The majority of women (61.3%) in the 'freeze-only' group had more than 15 oocytes retrieved in the stimulated fresh cycle compared with less than one fifth (18.1%) of women in the 'fresh transfer' group (p<0.001). The overall cumulative live birth rate was 44.0% in the 'freeze-only' group and 38.5% in the 'fresh transfer' group. For high responders (>15 oocytes), the adjusted likelihood of live birth in the 'freeze-only' group was

similar to the 'fresh transfer' group (Adjusted hazard ratio (AHR) 0.96, 95% confidence interval (CI) 0.85–1.09). However, the likelihood of live birth was lower in the 'freeze-only' group compared with the 'fresh transfer' group among normal responders (10-15 oocytes) (AHR 0.71, 95% CI 0.54–0.93) and suboptimal responders (<10 oocytes) (AHR 0.72, 95% CI 0.49–1.04).

Limitations, reasons for caution: A limitation of this population-based study is the lack of information available on clinic-specific protocols for the 'freeze-only' strategy and the potential impact on outcomes. Data were not available on whether the 'freeze-only' strategy was used to prevent ovarian hyperstimulation syndrome.

Wider implications of the findings: This study presents population-based evidence on clinical efficacy associated with a 'freeze-only' and 'fresh transfer' strategy. The 'freeze-only' strategy may benefit some subgroups of patients, including women who are high responders and those who are at risk of OHSS, but should not be offered universally.

Trial registration number: not applicable.

P-763 Double oocyte pick-up (OPU) for the patients with diminished ovarian reserve (AHM less than 1.0 ng/ml) and showing unsynchronized follicle growth during ART treatment

R. Sugiyama, K. Nakagawa, A. Moriyama, R. Sugiyama, K. Nakao, T. Horikawa, K. Kuroda, S. Takamizawa

Sugiyama Clinic Shinjuku, Reproductive Medicine Center, Tokyo, Japan

Study question: Dose double OPU result in more oocytes available for patients with diminished ovarian reserve (DOR) and who have shown unsynchronized follicular growth during ART treatment?

Summary answer: For patients with DOR, double OPU could increase the number of oocytes and usable embryos for embryo transfer in one treatment cycle.

What is known already: In order to achieve pregnancy, ART treatment can provide many oocytes in one OPU procedure, which could improve the chances of selecting the best embryo or blastocyst for embryo transfer. It is difficult, however, for DOR patients to obtain a plurality of oocytes in one OPU. On the other hand, clinicians sometimes observe unsynchronized follicle growth during ovarian stimulation. In those cases, the dominant follicle size is a crucial maturation trigger, and, subsequently, inadequately developed follicles are removed at a target of OPU, despite their value to DOR patients.

Study design, size, duration: This is an observational study of 13 women with DOR (AMH level <1.0 ng/ml) who were recruited between January and December in 2017. All patients were stimulated with clomiphene citrate (CC) with or without gonadotropins for ART treatment. When the follicles had reached ≥17 mm in diameter, this provide a maturation trigger and either human chorionic gonadotropin (hCG) or gonadotropin-releasing hormone agonist (GnRH-a) was then administered 35 hours before OPU (first OPU).

Participants/materials, setting, methods: During the first OPU, smaller follicles (≤12 mm in diameter) were not punctured. After OPU, ovarian stimulation was restarted with CC with or without gonadotropins to develop the missed follicles. When these follicles then reached 17 mm in diameter, a maturation trigger using hCG or GnRH-a was administered, and 35 hours later a second round of OPU was performed. The number of retrieved and developed oocytes was evaluated. The cleaved embryos were cryopreserved.

Main results and the role of chance: The average age of the patients was 41.6 years, and the average AMH and FSH values on day 3 were 0.47 ng/ml and 15.1 IU/L, respectively. For the first round of OPU, the average progesterone concentration was 0.6 ng/ml with no recorded incidences of elevated progesterone concentration. During the first OPU session, at least one oocyte was collected from 12 of the patients.

During the second OPU session, all patients were stimulated by CC with or without gonadotropins. The average progesterone level at the time of the second maturation trigger was 15.6 ng/ml. During the second round of OPU, at least one oocyte was collected from 10 of the patients.

The mean numbers of collected oocytes (/patient) from the first and second rounds OPU were 1.3 and 1.2, respectively, and the total number of the collected oocytes (/patient) was 2.5. During the first and second rounds of OPU, the total numbers of usable embryos for cryopreservation were 10 and 5, respectively, and as a consequence 12 of the patients were able to obtain cryopreserved embryos. Of these 12 patients, 4 were not able to obtain cryopreserved embryos without a second round of OPU.

Limitations, reasons for caution: This study was limited by a small sample size. Moreover, only 6 patients received thawed embryo transfer, and 2 of these achieved pregnancy.

Wider implications of the findings: Progesterone elevation did not decrease the pregnancy rate when a fresh embryo transfer was avoided, and it did not affect the embryo development rate. Furthermore, a random start was reported for ovarian stimulation. This indicated that the start of ovarian stimulation was not related to the menstrual cycles.

Trial registration number: This study has no RCT status, and, therefore, a trial registration number was not assigned.

P-764 Assessment of preimplantation genetic testing for embryo aneuploidies: a SWOT analysis

A. Alteri[1], L. Corti[1], E. Rabellotti[1], L. Privitera[1], D. Del Prato[1], E. Papaleo[2], P. Vigano'[2]

[1]IRCCS San Raffaele Scientific Institute, Obstetrics and Gynecology Department, Milan, Italy

[2]IRCCS San Raffaele Scientific Institute, Reproductive Sciences Laboratory- Division of Genetics and Cell Biology, Milan, Italy

Study question: Can a SWOT analysis provide a comprehensive and objective perspective to judge preimplantation genetic testing for embryo aneuploidies (PGT-A) strategy?

Summary answer: This SWOT analysis highlights that preimplantation diagnosis has taken the slippery slope of implementation of a novel approach without adequate evaluation of threats and weaknesses.

What is known already: The acceptance by the clinical community of the PGT-A is still evolving. Currently, the use of PGT-A is steadily increasing due to the evaluation of all 24 chromosomes by comprehensive chromosome screening. Moreover, blastocyst biopsy seems to be less harmful than Day-3 biopsy. PGT-A is now actively marketed as increasing implantation rates, and consequently decreasing time to pregnancy, recurrent miscarriages and repeated implantation failures. However, current studies do not provide sufficiently robust evidence to consider PGT-A as a proven and beneficial treatment and whether it should be offered routinely to IVF patients is still at the hearth of the debate.

Study design, size, duration: The SWOT (strengths, weaknesses, opportunities, and threats) analysis represents a strategic planning tool of quality management usually used in business but also adaptable to every field of medicine. The SWOT analysis framework helps focus on the strengths, understands the weaknesses that can assist in managing and minimizing the threats, and allows to take the greatest possible advantage of the opportunities available.

Participants/materials, setting, methods: This study is based on material obtained by searching PUBMED between January 2012 and January 2018, using the following keywords: 'preimplantation genetic screening' or 'PGS' or 'PGT-A', alone or in combination with 'biopsy', 'clinical outcome', 'RCT', 'SET', 'obstetrical outcome', 'follow-up'. All pertinent articles were carefully assessed and their reference lists were evaluated to detect other studies that could be included in this SWOT analysis. Peer-reviewed, English-language journal articles were included.

Main results and the role of chance: STRENGTHS: There is a general agreement on ability of PGT-A to increase the implantation rate as confirmed by three randomized control trials (RCTs) in young and good prognosis populations and one RCT in advanced maternal age (AMA) patients. Moreover, a reduction of miscarriage rate was observed only in AMA population, with a consequent decrease of time to pregnancy.

WEAKNESSES: Only three RCTs, have been published with biopsy at the blastocyst stage, all of which have been criticized because of poor study design. The RCT in AMA patients was performed considering cleavage-stage biopsy. Cumulative live birth rate remains unchanged. A critical issue is the management of mosaicisms.

OPPORTUNITIES: PGT-A offers the possibility (i) to perform a single embryo transfer, decreasing multiple pregnancies, (ii) to reduce time to achieve a healthy live birth and (iii) to assist with patient counseling regarding expectations and outcomes.

THREATS: The high cost, the invasive nature, the poor standardization and the very limited data about obstetrical/perinatal outcomes and about long-term effects represent drawbacks and hazards when PGT-A is offered routinely to IVF patients.

Limitations, reasons for caution: It is necessary to consider that a SWOT analysis only covers issues that can definitely be considered a strength, a weakness, an opportunity or a threat. Moreover, it is not able to prioritize issues and to provide solutions offering alternative decisions.

Wider implications of the findings: These findings are alarming in regard to the effectiveness and accuracy of the procedure. They also highlight the importance of high quality relevant RCTs that are urgently needed.

Trial registration number: Not applicable.

P-765 Letrozole and risk of major congenital malformations: a systematic review and meta-analysis

J. Pundir[1], P. Bhide[2], L. Sabatini[1], R.S. Legro[3], L. Rombauts[4], H. Teede[5], A. Coomarasamy[6], S. Thangaratinam[7]

[1]St Bartholomew's Hospital, Centre of Reproductive Medicine, London, United Kingdom
[2]Homerton University Hospital, Fertility and Assisted Reproduction-, London, United Kingdom
[3]Penn State University College of Medicine, Obstetrics and Gynecology and Public Health Sciences, Hershey- Pennsylvania, U.S.A.
[4]Monash University, Reproductive Medicine- Monash Health, Clayton, Australia
[5]Monash University, Monash Centre for Health Research and Implementation, Clayton, Australia
[6]University of Birmingham, Tommy's National Centre for Miscarriage Research, Birmingham, United Kingdom
[7]Queen Mary University of London, Women's Health Research Unit- The Blizard Institute, London, United Kingdom

Study question: Is letrozole, used for ovulation induction (OI) or Assisted reproductive treatment (ART) associated with increased risk of major congenital malformations compared with other agents?

Summary answer: Letrozole is associated with significantly lower risk of major congenital malformations compared with clomiphene and no significant difference when compared with natural conception or gonadotrophins.

What is known already: OI agents such as clomiphene have been used in sub-fertile women with anovulatory cycles or unexplained infertility and in ART cycles. Letrozole, an aromatase inhibitor, has many advantages over clomiphene, but has not been approved for OI. It is classified as a category 'x' drug, primarily due to a conference presentation in 2005, suggesting that, it is associated with higher risk of major congenital malformations when compared with low risk naturally conceived babies, despite the fact that this paper had methodological concerns, raising questions on its validity.

Study design, size, duration: Systematic review and meta-analysis of randomised and non-randomised controlled trials that evaluated the risk of major congenital malformations in babies born with the use of Letrozole in infertile women.

Participants/materials, setting, methods: We searched MEDLINE, EMBASE, Cochrane library, Register and Meta-register for RCTs, and WHO trials' search portal without any language restrictions. Studies that evaluated infertile women undergoing fertility treatment (OI or ART cycles) and compared letrozole with natural conception or other agents and reported on risk of major congenital malformations in the newborn were included. We pooled the results using fixed effects meta-analysis and reported the findings as relative risk (RR) with 95% confidence intervals (CI).

Main results and the role of chance: We included seven studies which enrolled 2603 babies born from OI and 5 studies with 37,349 babies born from ART cycles.

Comparison with Clomiphene - Pooling the data from 8 studies which compared letrozole with clomiphene (7 studies for OI; one study for fresh ART cycle), letrozole was associated with significantly lower risk of major congenital malformations when compared with clomiphene (RR 0.62; 95% CI 0.39, 0.99; $p = 0.05$; $I^2 = 0\%$; $n = 2455$).

Comparison with Natural conception/natural cycle ART - Pooling the data from 7 studies which compared letrozole with natural conception or natural cycle ART (3 studies for natural conception; one study for fresh ART natural cycle; 3 studies for Frozen embryo transfer in natural cycle), there was no significant difference in risk of major congenital malformations between the two groups (RR 1.13; 95% CI 0.86, 1.49; $p = 0.37$; $I^2 = 0\%$; $n = 21,627$).

Comparison with gonadotrophins/HRT ART - Pooling the data from 4 studies which compared letrozole with gonadotrophins or HRT (one study for gonadotrophin OI; 3 studies for Frozen embryo transfer in HRT cycle) there was no significant risk of major congenital malformations between the two groups (RR 1.18; 95% CI 0.86, 1.61; $p = 0.31$; $I^2 = 0\%$; $n = 18168$).

Limitations, reasons for caution: Even though limited to three RCTs and nine observational cohort studies, this systematic review and meta-analysis provides safety data on large cohort of babies born following the use of letrozole for infertility treatment.

Wider implications of the findings: Letrozole appears to be safe in terms of risk of major congenital malformations in the newborn of infertile mothers undergoing fertility treatment with OI or ART. These reassuring safety data contradict undocumented concerns about the teratogenicity of letrozole and support its use as a first line OI agent.

Trial registration number: NA.

P-766 Analysing risk factors for monozygotic multiple pregnancy after single embryo transfer in the Japanese national ART registry

Y. Ikemoto[1], A. Ochiai[1], S. Yamashita[1,2], S. Ikuma[1], S. Nojiri[3,4], K. Kuroda[T,5]

[1]Juntendo University Faculty of Medicine, Obstetrics and Gynecology, Tokyo, Japan
[2]Oita University Faculty of Medicine, Obstetrics and Gynecology, Oita, Japan
[3]Juntendo University, Medical Technology Innovation Center, Tokyo, Japan
[4]Juntendo University Hospital, Clinical Research and Trial Center, Tokyo, Japan
[5]Sugiyama Clinic Shinjuku, Obstetrics and Gynecology, Tokyo, Japan

Study question: To determine the prevalence and risk factors for monozygotic multiple pregnancy (MMP) after single embryo transfer (SET).

Summary answer: The prevalence of MMP after SET was 0.68%. The risk factors for MMP after SET included frozen-thawed embryo transfer, blastocyst culture and assisted hatching (AH).

What is known already: In Japan, the prevalence of multiple pregnancy after assisted reproductive technology (ART) decreased from approximately 10% in 2007 to 3% in 2014 owing to the proposed SET recommendation by the Japan Society of Obstetrics and Gynecology (JSOG) for the reduction of multiple births in 2008. Therefore, to improve the clinical pregnancy rate in Japan, increased elective SET using blastocyst transfer, frozen-thawed embryo transfer and AH had been increased. Blastocyst culture was reported to be a risk factor for monozygotic twinning after SET. However, other risk factors for MMP after SET were poorly understood.

Study design, size, duration: A retrospective observational study was performed based on registered ART data from the JSOG between 2007 and 2014. Among 937,848 SET cycles, 274,605 pregnancies were recognised. The present study was approved by the Registration and Research Subcommittee of the JSOG and our hospital's ethics committee.

Participants/materials, setting, methods: MMP was defined as one gestational sac (GS) with two or more foetuses or two GSs with three or more foetuses. To identify possible factors affecting the prevalence of MMP, multiple logistic regression analysis was performed using singleton pregnancy after SET as control. A *P* value of <0.05 was defined as statistically significant.

Main results and the role of chance: Out of 274,605 pregnancies after fresh and frozen-thawed SET, 1,863 were MMPs (prevalence rate of 0.68%), including 1,808 monozygotic twin and 55 triplet pregnancies. Statistical analysis revealed that the prevalence of MMP after frozen-thawed SET cycles [odds ratio (OR): 1.34; 95% confidence interval (CI): 1.16–1.55], blastocyst culture (OR: 1.79; 95% CI: 1.54–2.09) or AH (OR: 1.21; 95% CI: 1.08–1.35) was higher than that of singleton pregnancy after SET. In fresh ET cycles, the prevalence

rate of MMP after one blastocyst transfer was significantly higher than that after SET cycles with cleavage embryos (OR: 2.20; 95% CI: 1.83–2.66). However, no significant difference in ovarian stimulation and fertilisation methods had been observed.

Limitations, reasons for caution: In the current Japanese ART registry system, data regarding frozen-thawed ET do not include information about ovarian stimulation and fertilisation methods. Moreover, registration for AH had only been started in 2010.

Wider implications of the findings: Strict selection of good quality embryos through blastocyst culture, as well as embryo manipulation using frozen-thawed embryo transfer and AH to improve pregnancy rates, may increase the risk of MMP. However, procedures involving an oocyte, such as intracytoplasmic sperm injection, showed no such increase in risk.

Trial registration number: not applicable.

P-767 Anti-Mullerian hormone level decrease and efficacy of ART programs in HIV-infected women

F. Selimova[1], E. Mityurina[1], S. Perminova[1], A. Abubakirov[1], N. Kozyrina[2]

[1]Research Center of Obstetrics- Gynecology and Perinatology- Ministry of Health of Russia, 1st Gynecologic Department, Moscow, Russia C.I.S.
[2]Central Research Institute of Epidemiology of Rospotrebnadzor, Specialized research labopratory for AIDS epidemiology, Moscow, Russia C.I.S.

Study question: To assess the levels of anti-Mullerian hormone (AMH) and efficacy of ART programs in HIV-infected women.

Summary answer: Decreased AMH level and low pregnancy rate were found in HIV-infected women in IVF programs that might be associated both with infection and HAART.

What is known already: The studies assessing ART efficacy in couples with HIV-infected women are sparse and controversial. Some of them have demonstrated that HIV infected patient show a decrease of ovarian reserve parameters and a low efficacy of ART programs. Other studies do not find any difference in ovarian reserve parameters, ovarian function stimulation and ovo- and embryogenesis in HIV-infected women as compared to healthy patients. Different evidence suggest that the frequency of developing pregnancy ranges from 6.7 to 24.1%, which is significantly lower as compared to non-HIV-infected women. The reason of low efficacy of IVF program in this patient group remains unclear.

Study design, size, duration: The prospective case-control study included 113 patients seeking in IVF. The main group included 49 HIV-infected patients; 64 patients with HIV-negative serology were included in a control group. In the main group, 111 IVF cycles were performed, including 62 treatment and 49 cryocycles; the corresponding number of cycles in control group was 68 and 33, respectively.

Participants/materials, setting, methods: Stimulation of superovulation was performed according to long IVF protocols and GnRH-antagonist-based protocols using recombinant FSH and hMG. While preparing the endometrium in cryocycles, natural estrogen- and micronized progesterone-contaning medications were used. The infectious status of the patients was assessed based on the data on the disease stage, viral load, CD4+ count and the duration of HAART.

Main results and the role of chance: AMH concentration was significantly lower (median, 1.86 vs 2.8 ng/mL; $p = 0.006$), while FSH levels were statistically significantly higher (7.9 IU/L vs 6.2 IU/L; $p = 0.004$) in HIV-infected women group as compared to HIV-negative patients. Analysis of stimulation cycle parameters did not show any significant differences in the initial or total gonadotropin doses or stimulation duration in both groups. However, a lower number of oocytes (8.5 ± 0.9 vs 12.5 ± 0.7; $p = 0.001$), mature oocytes (7.1 ± 0.7 vs 9.6 ± 0.5; $p = 0.002$), zygotes (5.9 ± 0.6 and 8.1 ± 0.4; $p = 0.001$), cleavage stage embryos (5.6 ± 0.6 vs 7.8 ± 0.4; $p = 0.001$) and blastocysts (2.7 ± 0.4 vs 4.5 ± 0.4; $p = 0.004$) were recovered in HIV-infected patients as compared to control group. Selective single embryo transfer was conducted on the culture days 3 or 5 in both groups. A lower frequency of clinical pregnancy was revealed in patients with HIV infection as compared to HIV-negative women, both in ART treatment cycles (12.8% vs 38.3%; $p = 0.007$) and cryocycles (20.4% vs 51.5%; $p = 0.002$).

Limitations, reasons for caution: small scale.

Wider implications of the findings: can be applied on a large number of patients.

Trial registration number: непригодный

P-768 Impact of vitrification of cleavage stage embryos versus slow-freezing method on neonatal outcome: a multicenter retrospective cohort study with propensity score analysis

F. Gu[1], P. Li[2], H. Du[3], C. Ding[1], C. Zhou[1], Y. Xu[1]

[1]The First Affiliated Hospital of Sun Yatsen university, Center for Reproductive Medicine, Guangzhou, China
[2]Jiangmen Central Hospital of Sun Yat-sen University, Department of Obstetrics and Gynecology, Jiangmen, China
[3]Third Affiliated Hospital of Guangzhou Medical University, Center for Reproductive Medicine, Guangzhou, China

Study question: Does the embryo cryopreservation method have an impact on the neonatal birthweight of newborns from thawed embryo transfer (TET) cycles?

Summary answer: Singleton birthweight did not vary significantly after a vitrified embryo transfer compared with a slow-frozen cleavage embryo transfer. Transfer of vitrified Day 3 embryos did not increase the risk of low birthweight (LBW), macrosomia or other adverse neonatal outcomes.

What is known already: Vitrification has been successfully used for embryo cryopreservation and is superior to slow-freezing technique regarding the embryo survival rate and live birth rate. However, whether the vitrification method would affect fetal growth and thus the neonatal outcome is still controversial. Most studies addressed this issue by comparing the neonatal outcome after transferring vitrified embryos with fresh embryo transfer. So far, comparative data of two cryopreservation methods with respect to the singletons' birthweight outcome is limited.

Study design, size, duration: This research was a multicenter cohort study, including three large reproductive medical centers in South China. All singleton neonates born after Day 3 frozen-thawed embryo transfer cycles from January 2012 to December 2015 were analyzed. Each patient contributed only one cycle per group.

Participants/materials, setting, methods: All singletons born alive after 28th week of gestation were analyzed. Blastocyst transfer, preimplantation genetic diagnosis and intrauterine insemination cycles were excluded. The main outcome measure is neonatal birthweight outcome including average birthweight and the risk of both macrosomia (>4000 g) and LBW (<2500 g). Propensity score matching was used to select equal-sized vitrified and slow-freezed cohorts with similar characteristics. Multivariable regression analysis was then used to explore the impact of freezing methods on neonatal outcomes by adjusting potential maternal and clinical confounders.

Main results and the role of chance: A total of 1667 cases from vitrified embryo transfer and 341 babies from slow-freezed group were included. After propensity score matching, 281 pairs of newborns were finally generated for comparison. The median gestational age was both 39 (38-40) weeks in each cohort and the birthweights were comparable (3188.7 ± 479.0 g vs. 3231.0 ± 469.6 g, $p>0.05$). There were no significant differences between the two groups on the incidence of LBW (5.3% vs. 5.7%) and macrosomia (6.0% vs. 6.0%). The incidence of other outcomes including very preterm birth (0.7% vs. 0.4%), preterm birth (6.4%vs.7.4%) and sex ratio (49.3% vs 47.2%) were all comparable between the vitrified and slow freeze groups, $p>0.05$. In multivariable regression analysis, freezing methods were not found to be associated with neonatal birthweight.The odds ratio (OR) for LBW and macrosomia in the vitrified cohort is 0.93 (95%CI 0.45-1.93) and 1.00 (95% CI 0.50-2.00) compared to the slow-freezed cohort without significant difference.

Limitations, reasons for caution: As a retrospective study, our analysis depends on previously recorded data. Moreover, researches for the long-term effects of vitrification method on the health of children are essential in the near future.

Wider implications of the findings: Vitrification/warming is not inferior to slow-freezing/thawing with regard to neonatal birthweight outcome. Based on this evidence and its superiority regarding clinical outcomes, vitrification for cryopreservation will gradually take over the use of slow-freezing in the near future.

Trial registration number: The study was funded by the National Key Research and Development Program (2016YFC100205). The authors have no conflicts of interest to declare.

P-769 Key performance indicators (KPIs) based on poor prognosis patients are more sensitive on evaluating IVF laboratory staff skills: a prospective cohort study

Y. Du, Y. Chen, Y. Zou, J. Ma, Y. Geng, Y. Zhang

Tianjin Central Hospital Of Gynecology Obsterics, Department of Reproductive Medicine, Tianjin, China

Study question: Is it better to follow the poor prognosis patients (PPP) compared with the gold standard patients (GSP) in IVF during new lab staff orientation?

Summary answer: The poor prognosis patients may be a more sensitive group to the new staff skills.

What is known already: It is clear that given that cryopreservation protocols, vitrification methods, evolved empirically and still depend heavily on operator skills, systems to monitor laboratorial performance gained much importance in Frozen–thawed embryo transfer practice. Consequently, KPIs are indicators deemed essential for evaluating before implementing a change, the laboratory's routine; establishing minimum standards for proficiency; monitoring ongoing performance within quality management. However, the largest variable in an IVF laboratory is the patient. For the purpose of measuring the outcome of the lab, this patient variable needs to be either factored into the analysis, or attempted to be minimized.

Study design, size, duration: This study is the prospective cohort study including 1048 infertile patients from June 2016 to December 2017. We performed a two-part prospectively study in IVF. Part A involved 548 infertile poor prognosis patients; Part B involved 500 infertile gold standard patients.

Participants/materials, setting, methods: Patients were categorized as PPPs and GSPs group based on age and functional ovarian reserve parameters. Embryos of both group patients were randomized at the time of cryopreservation to allocate to senior or junior embryologist group, and all embryos were frozen with vitrification. The primary outcome of this study was the implantation rate (IR) per embryo transferred after thawed. We then compared pregnancy rates and post-thaw outcome in terms of Morphological survival and fully intact.

Main results and the role of chance: Part A revealed in 548 poor prognosis patients, 987 embryos were thawed and Part B involved 912 embryos from gold standard patients were warmed in 524 cycles. The IR per embryo thawed by junior embryologists (16.6% (79/475)) was significantly lower after transfer than by senior ones (21.8% (112/512), $P = 0.045$; $\chi2 = 4.01$) in poor prognosis patients group. Similarly, embryos fully intact rate thawed by junior embryologists (79.2 %(376/475)) was significantly lower than by senior ones (84.6% (433/512); $P = 0.033$; $\chi2 = 4.523$). The survival rate was similar in both operators groups (97.3% (462/475) (96.7% (495/512); $P = 0.728$; $\chi2 = 0.121$) in poor prognosis patients group. In Part B, gold standard patients, no significant differences were found in implantation-, survival-, or fully intact rates after transfering the cleavage stage day 3 embryos frozen-thawed by two embryologists groups, respectively.

Limitations, reasons for caution: Culture media, temperature and gas levels were similar in the culturing and transfer, but cleavage stage day 3 embryos with poorer grades of morphology were not cryopreserved or transferred, limiting the ability to generalize our findings for grades of morphology not included in this study.

Wider implications of the findings: The poor prognosis patients may be a more sensitive group to potentially new product/procedure, even if preclinical research has been completed.

Trial registration number: not applicable.

P-770 The rising use of ICSI for non-male factor infertility without evidence of a clinical need or patient advantage

C. Leary, T.K. Cunningham, P. Lesny

Women and Children's Hospital, The Hull IVF Unit, Kingston-upon-Hull, United Kingdom

Study question: Is ICSI being increasingly used in Clinics across Europe for non-male factor infertility and are there any benefits to using the technique when it is not clinically indicated.

Summary answer: A 16-year review of the incidence of male factor infertility in a single clinic provides no evidence for declining semen parameters and necessity for ICSI.

What is known already: Worldwide, approximately two thirds of all ART procedures performed involved ICSI. It is widely reported that across Europe, the proportion of ICSI treatment cycles has risen in recent years, regardless of the etiology of infertility. ICSI carries a number of identified risks and the benefits for use in non-male factor infertility are limited to mitigating the risk of failed fertilisation, which occurs in less than 10% of cycles.

Study design, size, duration: To address this question, we thus conducted a retrospective review of patient notes over a 16 year period for ICSI indication, usage and outcome (fertilisation and pregnancy).

Participants/materials, setting, methods: In a single clinical IVF setting, an assessment was conducted of how many patients per annum presented with semen parameters indicative of ICSI.

Main results and the role of chance: Between 2002 and 2017 a total of 5248 patients were investigated, 2032 were diagnosed as having male factor infertility on the basis of having one or more semen parameters below the WHO semen thresholds for normozoospermia. Male factor infertility accounted for 38.7% (±4.1) patient aetiologies over the study period with no evidence of rising incidence in recent years ($r = 0.001$; $p = 0.9$). Fertilisation rates were similarly comparable as were pregnancy rates for IVF and ICSI treatments on both an annual basis and for the time-course of the study ($p>0.05$).

Limitations, reasons for caution: Although statistical power has been achieved, this is a retrospective study conducted within one clinic. Over the course of the study period, reference ranges for normal semen parameters have changed, however the stringency of the applied protocols have changed in tandem to accommodate for this.

Wider implications of the findings: The data indicate that the rising use of ICSI among ART facilities within the past decade has not been as a consequence of declining semen quality, implying the technique is used for treatment of non-male factor infertility without a clear clinical indication of its superiority over IVF.

Trial registration number: not applicable.

P-771 Induced cellular lysis and increased laser exposure during trophectoderm biopsies can generate low-level mosaic profiles: A prospective study

J.B. Whitney[1], C.M. Rios[2], R.E. Anderson[3], M.C. Schiewe[1]

[1]*Ovation Fertility, ART Lab, Newport Beach, U.S.A.*
[2]*Ovation Fertility Genetics, Lab, Las Vegas, U.S.A.*
[3]*SCCRM, ART Clinic, Newport Beach CA, U.S.A.*

Study question: Can trophectoderm biopsy technique induce mosaicism using a technician-induced, manual cell lysis research model?

Summary answer: Prospective induction of cellular damage on research aneuploid embryos revealed a positive correlation to mosaicism, suggesting that mosaicism can be a laboratory created artifact.

What is known already: NextGenertion sequencing (NGS) has enhanced the reporting of mosaicism. The importance of mosaic profiles on PGS results is not well defined, but viable pregnancies have been produced. As increased mosaicism has been associated with decreased implantation potential, it is relatively unknown how accurately mosaic profiles predict the final ploidy of the fetus. It has been proposed that mosaicism may be linked to biopsy technique, but prospective studies have not been performed. Desiring to offer a transfer for all patients and encouragement to perform mosaic embryo transfers, the

reproducibility and accuracy of mosaic reports per entire embryo is not well studied.

Study design, size, duration: Nine research consented embryos were thawed as part of a sister concordance study. Upon completion of two standard biopsy procedures for the original study, the technician attempted to perform poor biopsies with emphasis on cellular lysis and increased laser ablations. A total of 52 samples were tubed, 9-original biopsy, 26-sister concordance study, 10-poor technique, 5-remaining ICM's and 2-media blanks. All samples were blindly analyzed (NGS) by two geneticists and reported according to lab standards.

Participants/materials, setting, methods: Research consented aneuploid embryos were selected based on single/dual chromosomal aneuploidies without knowledge of original NGS profiles. Vitrified blastocysts were warmed and cultured in LifeGlobal medium under tri-gas, humidified atmospheric conditions at 37°C (≤4 hours). Each blastocyst was biopsied according to standard protocols and video recorded. Samples were blindly assessed using the MiSeq (Illumia) NGS platform. Standard lab reporting procedures were applied with a threshold of 30% gain/loss being considered euploid and 30-80% considered mosaic.

Main results and the role of chance: Evaluating full gains and losses, 49 of 50 samples (98%) achieved concordance. Of the 10 samples with technician induced lysis, 3 of 10 (30%) reported the full aneuploidy and an additional mosaic profile. The video review of biopsies showed that as cellular lysis increased so did the level of genetic noise and presence of mosaicism. Of the 2 biopsies which had >30 additional zona ablations, mosaicism was not observed but unique low-level noise was observed being strikingly different from all other samples profiles from the same embryo. Most importantly, spent media from a biopsy which had significant lysis was tubed as a "blank". The latter blank tube showed amplification portraying a chaotic profile, whereas spent biopsy from a clean biopsy (second blank control) exhibited no amplification. The concordance arm of this study, including ICM analysis, showed extreme repeatability. The efforts made to induce mosaic profiles was successful. Of the 3 samples showing mosaicism, none of the other samples from the embryo, including the ICM, showed any of the same mosaic aneuploidies.

Limitations, reasons for caution: Mosaicism, and its importance on NGS calling policies, ultimately impact patient transfer decisions. Mosaic embryos graded as aneuploid can produce healthy live births, revealing a potential technical artifact. Upmost importance should focus on proper biopsy technique if we are to better understand and reduce possible sources of mosaicism.

Wider implications of the findings: Mosaic profiles can be made from known cell lines within genetic laboratories. Yet, mosaic profiles themselves are not in question, but instead the possible loss of DNA by cellular lysis as a source of low level mosaicism. Further scrutiny on laboratory procedures is needed to properly identify true mosaic embryos.

Trial registration number: none.

P-772 Post-cervical ascites at day of oocyte pick-up (OPU) and OPU+5 days and development of ovarian hyperstimulation syndrome (OHSS)

A. Pinborg[1], A.G.A.H. Grynnerup[1], M. Toftager[1], J.W. Bogstad[1], L. Praetorius[1], A. Zedeler[1], K. Loessl[2]

[1]Copenhagen University- Hvidovre Hospital, Department of Obstetrics and Gynaecology, Hvidovre, Denmark
[2]Rigshospitalet, Fertility Clinic, Copenhagen, Denmark

Study question: Can we define a threshold of post-cervical ascites at day of OPU or OPU+5 days that predicts development of moderate to severe OHSS?

Summary answer: A 1 mm increase in post-cervical ascites at OPU and OPU+5 increases OHSS risk by 3.7% (AOR1.037 95%CI 1.013-1.062) and 4.6% (AOR1.046, 95%CI 1.31-1.61), respectively.

What is known already: OHSS is the most severe side effect of ovarian stimulation with gonadotrophins. Women with polycystic ovarian syndrome (PCOS) and a high ovarian reserve are at a higher risk of developing OHSS. During the ovarian stimulation cycle the number of follicles > 10-11 mm on the day of ovulation trigger is the best clinical predictor of OHSS. Ascites is part of the definition of OHSS, but it has never been investigated, whether a certain cut-off level of post-cervical ascites at day of OPU or OPU+5 days can predict OHSS and potentially guide when to use a freeze-all strategy.

Study design, size, duration: Secondary analyses of a multicenter RCT on 1050 patients randomized 1:1 to short GnRH-antagonist protocol or long GnRH-agonist protocol including women from 2009 to 2013 in Denmark. We used a fixed rFSH (Puregon®) dose of 150IU or 225IU according to age ≤36 years or >36 years. Inclusion criteria were 1. ART cycle, and exclusion criteria were uterine abnormality, age >40 years, testicular sperm extraction/aspiration and severe co-morbidity. Both normo- and anovulatory women were included.

Participants/materials, setting, methods: We pooled all patients from the two arms, who were examined at day of OPU (n = 990). Prediction of OHSS by the amount of post-cervical ascites in the anteroposterior plane was examined by receiver operator characteristics (ROC) analyses. Further, the ability of post-cervical ascites to predict development of OHSS at OPU and OPU+5 was explored with multivariate logistic regression analyses including the following explanatory parameters: Age, anovulatory infertility, GnRH-antagonist/agonist group and number of retrieved oocytes.

Main results and the role of chance: Of the 1008 patients reaching OPU, 990 patients had post-cervical ascites measured on the day of OPU and at OPU+5 days. A total of 199 (20%) patients developed moderate to severe OHSS, including both early and late onset. By ROC curve analysis post-cervical ascites at day of OPU and at OPU+5 days predicted OHSS with an area under the curve (AUC) of 0.599 (95% CI 0.559-0.638, p<0.01) and 0.737 (95% CI 0.699-0.774, p<0.01), respectively. The optimal cut-off value at day of OPU was 4.8 mm with a sensitivity of 41% and specificity of 79%. The optimal cut-off value at OPU+5 days was of 10.7 mm (sensitivity 81% and specificity 61%).

By logistic regression analysis a 1 mm increase in post-cervical ascites at day of OPU increased the odds of OHSS by 5.6% (OR 1.057, 95% CI 1.034-1.080). This association remained significant when adjusting for age, anovulatory infertility, GnRH-antagonist protocol and number of oocytes retrieved (adjusted OR 1.037 95% CI 1.013-1.062). At OPU+5 days, a 1 mm increase in post-cervical ascites increased the odds of OHSS by 6.3 % (OR 1.063, 95% CI 1.049-1.077) and by 4.6% in the adjusted analysis (adjusted OR 1.046, 95% CI 1.31-1.61).

Limitations, reasons for caution: We pooled the groups moderate and severe OHSS including both early and late onset OHSS. This may cause a mismatch as post-cervical ascites on day of OPU may be better to predict early than late onset OHSS.

Wider implications of the findings: Identification of early predictors is of importance for avoiding OHSS. Post-cervical ascites at the day of OPU and OPU+5 can predict OHSS. However, the accuracy of the test demonstrates that we cannot rely solely on the threshold of post-cervical ascites in the decision making of whether to transfer an embryo.

Trial registration number: ClinicalTrial.gov: NCT00756028

P-773 Perinatal outcome in singletons after frozen-thawed blastocyst transfer: hormone replacement treatment cycles versus natural cycles

K. Sekigawa, F. Suyama, W. Beck, Y. Mukoda, K. Sasaki, H. Okubo, M. Sato, S. Hara, S. Ikuta, R. Tokutomi, A. Jinno, S. Akimoto, H. Tajima, H. Asada, Y. Yoshimura

Shin-yurigaoka General Hospital, Obstetrics and Gynecology, Kawasaki City-Kanagawa Prefecture, Japan

Study question: Are there differences in perinatal outcomes between singletons after hormone replacement cycle frozen-thawed blastocyst transfer (HRT-BT) and natural cycle frozen-thawed blastocyst transfer (NC-BT) deliveries?

Summary answer: A tendency toward more cases of heavy for date in HRT-BT was observed, but the difference was not statistically significant.

What is known already: Several studies show that the birthweights of singletons delivered after frozen-thawed embryo transfer are significantly higher than those delivered after fresh embryo transfer. A contributing factor to the increased birthweight may be hormonal environment of the endometrium before or after embryo transfer – and not the frozen-thawed procedure itself.

There are few studies that compare the mean singleton birthweights after HRT cycles versus natural cycles.

Study design, size, duration: We performed a retrospective case study of women who underwent frozen-thawed blastocyst transfer at our hospital with singleton pregnancy and a live birth after 22 weeks of gestation between 2013 and 2016. The study included 191 singletons born after blastocyst transfer (BT): HRT-BT; n = 137 and NC-BT; n = 54.

Participants/materials, setting, methods: We compared HRT-BT deliveries with NC-BT deliveries. We measured birth defects, preterm birth (PTB), hypertensive disorder of pregnancy (HDP), placenta previa, and heavy for date (HFD). The crude and adjusted odds ratios (AOR) and 95% confidence interval (CI) were calculated using a logistic regression analysis. Adjustment was made for the maternal age at BT (categorized in 35≥, 35<) and parity.

Main results and the role of chance: HFD was observed in 30 cases (21.9%) of HRT-BT and 6 cases (11.1%) of NC-BT (AOR, 2.30; 95% CI, 0.89—5.9). HDP was observed in 8 cases (5.8%) of HRT-BT and in one case (1.9%) of NC-BT (AOR, 3.20; 95% CI, 0.39—26.6). PTB was observed in 3 cases (3.2%) of HRT-BT and 1 case (3.1%) of NC-BT. Placenta previa was observed in 3 cases (2.2%) of HRT-BT and did not occur in NC-BT. Birth defects were observed in 5 cases (3.6%) of HRT-BT and 1 case (1.8%) of NC-BT. There were 3 cases of congenital heart disease, 1 case of 7q-, and 1 case of Prader-Willi syndrome in HRT-BT. There was one case of trisomy 21 in NC-BT. PTB and placenta previa were rare in this study, thus, we could not calculate the AOR. A tendency toward more cases of HFD in HRT-BT was observed, but the difference was not statistically significant.

Limitations, reasons for caution: This is a retrospective study based on a small sample size, performed by a single medical center.

Wider implications of the findings: The primary factor of increasing cases of HFD after BT may be the hormonal environment of the endometrium before or after BT. If duplicated data are included, future studies may show that HRT cycles are significantly associated with more cases of HFD.

Trial registration number: none.

P-774 Twinning in Greece in the recent 10-year period of 2004-2013; comparison of between IVF-conceived and naturally-conceived twins

I. Dedes[1], S. Zachaki[2], M. Kalomoiraki[2], C. Giannakos[3], D. Baroutis[4], S. Gavrili[5]

[1]*General District Hospital Athens "Alexandra"- Greece, Neonatal Intensive Unit-, Athens, Greece*
[2]*NCSR "Demokritos"- Athens- Greece., Laboratory of Health Physics- Radiobiology & Cytogenetics-, Athens, Greece*
[3]*National Technical University of Athens- Athens- Greece, School of Electrical & Computer Engineering, Athens, Greece*
[4]*University of Athens- Athens- Greece, Medical School of Athens, Athens, Greece*
[5]*General District Hospital Athens "Alexandra"- Greece., Neonatal Intensive Unit, Athens, Greece*

Study question: To estimate the twinning rate in Greece during 2004-2013 and possible differences on somatometric characteristics IVF-conceived and naturally-conceived live born pairs of twins at birth.

Summary answer: The 10-year twinning frequency was 2.6%. The IVF-conceived pregnancies were 26.7% showing lower birth-weight and gestational age and higher IUGR frequency compared to the naturally-conceived.

What is known already: One of the consequences of the applied medically-assisted reproduction, mainly *in vitro* fertilization (IVF) techniques for treatment of infertility is the higher rate of multiple gestations and consequently the higher number of high-risk pregnancies. The health problems of multiple pregnancies in mothers and neonates are more pronounced than the single type, presenting higher neonatal morbidity and mortality rates. Comparison of somatometric characteristics between IVF-conceived and naturally-conceived twins at birth may contribute to the evaluation of the new medically-assisted reproductive methods to neonates' health and development.

Study design, size, duration: We studied all multiple births that took place in General District Hospital Athens "Alexandra" during a recent 10-year period, 2004-2013. The "Alexandra" Hospital is the biggest public university hospital in Greece that carries out a large number of deliveries annually. For each multiple delivery, number of neonates, mode of conception, delivery and gestational age were recorded. For all pairs of twins morbidity, mortality, gender, birth weight, and intra-uterine growth retardation (IUGR) data were recorded.

Participants/materials, setting, methods: We studied all multiple births in all deliveries that took place in "Alexandra" during a recent 10-year period (2004-2013). Gender, birth weight, gestational age, mode of conception, delivery and IUGR data were recorded. Annual incidence of twinning rate was calculated. Frequency of each characteristic was calculated to show possible differences between IVF and naturally-conceived neonates. Statistical analysis for comparing the categorical data chi-square test was used. All tests were performed with p-values set to 0.05.

Main results and the role of chance: During the study period 1,235 multiple births in all 46,747 deliveries were noted; 45 (3.6%) were triple pregnancies and 1,190 (95.4%) double. The 10-year frequency of twinning rate was 2.6%, with the highest in 2010 (3.4%) and the lower in 2007 (1.6%). The *in vitro* fertilization (IVF) pregnancies were 330/1,235 multiple pregnancies (26.7%), while the rest 905/1,235 (73.3%) represent natural conception.

The mortality rate was 82/1,235 deliveries (6.6%); 40 deliveries had one dead baby and 42 both dead babies. The conception was achieved after IVF in 18/82 (22%) and 64/82 deliveries (78%) were conceived naturally. The mortality rate was similar between IVF and natural conception.

Concerning the live-born neonates, the frequency of IVF-pregnancies was 25.6% (305/1190) and naturally-conceived was 74.4% (885/1190). Male: female ratio was 0.88 for IVF-conceived and 1.02 for naturally-conceived neonates. Mean birth weight and gestational age were lower in IVF-conceived neonates than in naturally-conceived neonates; 2096.83 *g vs* 2162.31 *g* and 34^{+1} and 34^{+5} wga, respectively.

Evaluation for intrauterine growth restriction showed similar frequency of IUGR neonates between the 2 groups; 37% (113/305) in IVF (65.1% one IUGR neonate and 34.9% both IUGR neonates) and 38.4% (340/885) in naturally-conceived neonates (67% one IUGR neonate and 33% both neonates).

Limitations, reasons for caution: Limitations of the present study include lack of data concerning the medication taken by the mother during pregnancy and other pathological conditions such as chorioamnionitis and gestational diabetes. Future studies focusing on long-term outcome of IVF-conceived and naturally-conceived neonates should enable us to draw conclusions about their course and development.

Wider implications of the findings: The present study comprises an attempt to present the twinning rate and pregnancies outcome in Greece during the 10-year period 2004-2013. Mortality rates and somatometric characteristics of the IVF-conceived and naturally-conceived neonates at birth along with long-term outcome will enable more precise description of growth and developmental outcomes among twins.

Trial registration number: Not applicable.

P-775 Oocyte donation is not an independent risk factor for adverse perinatal outcomes in IVF pregnancies: results of a 5-year cohort in a UK high-risk unit

P. Melo, P.R. Supramaniam, M. Mittal, L.N. Lim

Department of Obstetrics and Gynaecology, John Radcliffe Hospital, Oxford, United Kingdom

Study question: Does oocyte donation increase the risk of adverse perinatal outcomes such as preterm birth, low birth weight, postpartum haemorrhage, stillbirth, neonatal death and low Apgar?

Summary answer: Oocyte donation is not an independent risk factor for adverse perinatal outcomes when compared with autologous IVF.

What is known already: Female age remains by far the main predictor of success in IVF, largely due to a loss of ovarian follicle reserve and oocyte quality as women get older. Oocyte donation has thus become a viable alternative in recent decades for patients with reduced egg quality or quantity. However,

there is a paucity of data on the implications of egg donation upon obstetric and neonatal outcomes for the index pregnancy. In particular, previous analyses have failed to identify predictors of adverse perinatal events, mainly due to a lack of information on confounding variables such as maternal BMI and previous uterine surgery.

Study design, size, duration: This was a retrospective cohort study conducted at the John Radcliffe Hospital in Oxford, UK, a tertiary referral centre. Demographic data and perinatal outcomes of women with singleton pregnancies resulting in live births after autologous and donor-oocyte IVF were obtained from electronic hospital records. A total of 792 singleton pregnancies, delivering between December 2012 and January 2018, were included in the analysis: 100 (12.6%) resulted from oocyte donation and 692 (87.3%) from autologous IVF.

Participants/materials, setting, methods: Univariate analysis was initially performed to identify significant differences ($p<0.05$) between the donor-oocyte and autologous IVF groups. A multivariate binary logistic regression model with backward stepwise elimination was then created to identify potential confounders (e.g. age, smoking, BMI, ethnicity, low-dose aspirin at booking, gestation at delivery, mode of birth) and determine predictors of poor outcomes (e.g. preterm birth [≥24and<37 weeks], need for operative delivery, blood loss ≥1000 mL, birth weight<10th centile [small for gestational age, SGA]).

Main results and the role of chance: Overall there were 491/792 (62%) primigravidas. Median age and BMI were lower in the autologous IVF group (35 vs 43 years,$p<0.001$; and 23.8 vs 25.4 kg/m^2,$p = 0.015$). Those with donated oocytes were more likely to take aspirin (18% vs 6.8%,$p = 0.001$). The rates of obesity (BMI≥30,$p = 0.104$), pre-pregnancy diabetes ($p = 147$), smoking ($p = 0.75$), previous uterine surgery (e.g.myomectomy/caesarean,$p = 0.318$) and chronic hypertension ($p = 0.07$) were similar in both groups.

Median gestation at delivery was 39 weeks in both groups ($p = 0.66$). There was no difference in the rates of preterm birth (9.5%,$p = 0.71$) and SGA between groups (9.6%,$p = 0.137$). Median Apgar at 5 minutes was 10 ($p = 0.49$). There were 2/792 (0.3%) stillbirths, both occurring in the autologous IVF subgroup. There were no neonatal deaths.

Women conceiving with oocyte donation were more likely to require caesarean delivery (72.4% vs 59.6%,$p = 0.015$) and sustain significant haemorrhage (26.8% vs17.1%,$p = 0.025$). Following logistic regression analysis, independent risk factors for caesarean included previous uterine surgery (OR5.5, 95%CI 2.07-15.20), primiparity (OR2.88, 95%CI 2.02-4.11), increasing age (OR1.12, 95%CI 1.09-1.16) and higher maternal BMI (OR1.061, 95%CI 1.02-1.10). Caesarean delivery was an independent risk factor for postpartum haemorrhage ≥1000 mL (OR4.18, 95%CI 2.52-6.93). Egg donation was not independently linked to risk of caesarean (OR0.94, 95%CI 0.51-1.72) or postpartum haemorrhage ≥1000 mL (OR1.23, 95%CI 0.67-2.23).

Limitations, reasons for caution: The main limitation of this study was its retrospective design. Prospectively collected data using a larger sample would be required to corroborate our results.

Wider implications of the findings: We show that oocyte donation is safe and does not increase the incidence of adverse perinatal outcomes in IVF when adjusting for confounders. The higher risk of caesarean birth and subsequent haemorrhage likely derives from the fact that women conceiving with donated eggs are older and have a larger BMI.

Trial registration number: Not applicable.

P-776 Comparison of follicular fluid candidate proteins involved in inflammation or angiogenesis and prediction of OHSS in assisted reproductive technology (ART); A pilot study

K. Lossl[1,4], M. Toftager[1], A. Zedeler[1], J. Bogstad[1], L. Prætorius[1], M.L. Grøndahl[2,3], C. Yding Andersen[3], A. Pinborg[1]

[1]*The Fertility Clinic, Copenhagen University Hospital Hvidovre, Copenhagen, Denmark*

[2]*Laboratory of Reproductive Biology, Copenhagen University Hospital Rigshospitalet, Copenhagen, Denmark*

[3]*The Fertility Clinic, Copenhagen University Hospital Herlev, Copenhagen, Denmark*

[4]*The Fertility Clinic, Copenhagen University Hospital Rigshospitalet, Copenhagen, Denmark*

Study question: Does the pre-ovulatory follicular fluid (FF) level of selected candidate proteins differ between women with and without OHSS and guide when to use 'freeze-all' strategy?

Summary answer: The pre-ovulatory FF level of soluble urokinase plasminogen activator receptor (SuPAR), a potential new inflammatory biomarker, was significantly lower in women developing OHSS.

What is known already: In ART, number of follicles ≥10-11 mm on trigger-day correlates to OHSS-risk. However, some women with a high number of follicles do not develop OHSS. This could reflect that not only the follicular quantity but also the quality, the intra-follicular milieu, contribute to the syndrome. Proteins involved in inflammation or angiogenesis may be involved in the development of OHSS. As increasing SuPAR plasma levels are thought to reflect increased activation state of the immune system, we hypothesized that the pre-ovulatory FF SuPAR level could be a potential new inflammatory biomarker predicting OHSS. There are no previous publications on FF SuPAR levels.

Study design, size, duration: FF was collected during a RCT including 1050 women in their first ART cycle during year 2009-2013 comparing OHSS in short versus long protocol. This sub-study is a case control study including FF measurements from subjects with ≥15 oocytes retrieved who developed severe OHSS (n = 25, Cases), subjects with ≥15 oocytes who did NOT develop moderate-severe OHSS (n = 25, Control1), and subjects with 5-8 oocytes who did NOT develop moderate-severe OHSS (n = 25, Control2).

Participants/materials, setting, methods: For each Case (n = 25), one Control1 (n = 25) and one Control2 (n = 25) was selected by matching subjects by treatment protocol (short versus long), pregnancy (+/-), age, BMI, and anovulation (+/-). FF from one large pre-ovulatory follicle was collected, centrifuged and frozen until the study-related measurements of SuPAR, placental growth factor (PlGH), vascular endothelial growth factor (VEGF), and angiopoitin I and II levels by commercially available Elisa-kits, and C-reactive protein (CRP) by a high-sensitivity immunoturbidimetric assay.

Main results and the role of chance: The FF levels of SuPAR differed significantly between the three groups (P = 0.018) with mean (SD) levels of 2.3 (0.4) ng/ml, 2.6 (0.8) ng/ml and 2.8 (0.6) ng/ml in Cases, Control1's and Control2's, respectively. When Cases (OHSS, n = 25) where compared to the combined Control groups (no moderate-severe OHSS, n = 50) the mean difference between groups was -0.40 ng/ml (95% confidence interval -0.71 to -0.09) ng/ml, (P = 0.012). Receiver operating characteristic (ROC) curve analysis demonstrated that the level of SuPAR could predict severe OHSS (AUC 0.678; 95% CI 0.553-0.803) with a sensitivity of 64% and a specificity of 66%. The level of CRP, another well-known marker of inflammation, as well as the levels of selected candidate proteins involved in angiogenesis (VEGF, PlGF and angiopoitin I and II) did not differ between the three groups or between Cases and combined Controls. Patients in the three groups were matched for anovulation (+/-) with a total of 23 subjects presenting anovulation and 52 without. The follicular level of CRP was significantly higher among subjects with anovulation; median (range) 2.0 (0.2-8.5) mg/L compared to 0.85 (0.2-6.1) mg/L in regular cycling women (P = 0.34).

Limitations, reasons for caution: Although the FF SuPAR level significantly predicted severe OHSS in the present dataset, the relatively low sensitivity and specificity currently makes a clinical application unlikely. Further, as this is the first study of SuPAR levels in relation to ART, further studies are required to determine possible predictive value of SuPAR.

Wider implications of the findings: Our findings indicate that the intra-follicular activation state of the immune system at oocyte-pickup is not increased in women developing severe OHSS. Furthermore, the FF level of the selected candidate proteins involved in angiogenesis was unchanged, especially VEGF that has been claimed to play an important role in OHSS.

Trial registration number: ClinicalTrial.gov: NCT00756028 (Primary RCT)

P-777 Achieving competency in embryo transfer and monitoring ongoing performance

M. Prior[1], J. Hopkisson[2], N. Raine-Fenning[1]

[1]*University of Nottingham, Obstetrics and Gynaecology, Nottingham, United Kingdom*

[2]*Nurture Fertility, Nurture Fertility, Nottingham, United Kingdom*

Study question: To evaluate cumulative summation (CUSUM) and mean averages in assessing the learning curve and ongoing competency of reproductive medicine trainees performing embryo.

Summary answer: Learning curve cumulative summation (LC-CUSUM) can provide a useful way of charting progress, but offers false reassurance, masking the possibility the trainee requires further training.

What is known already: Critical to successful in vitro fertilisation (IVF) is the ability to transfer embryos safely and efficiently into the uterus. When learning, it is important for the trainee to achieve competency as quickly as possible. Assessing the learning curve and ongoing competency can be achieved by plotting mean averages of pregnancy outcome. However, this is limited by over sensitivity in the initial phase and poor sensitivity as the number of procedures increases. CUSUM provides an alternative statistical model to monitor performance by detecting if a process is 'out of control' following a mathematical model which can be easily interpreted graphically.

Study design, size, duration: This prospective study included five trainees learning embryo transfer at a Nurture Fertility between November 2011 and November 2016. All trainees underwent a theoretical embryo transfer training session followed by a two-month period of observation before performing embryo transfers.

Participants/materials, setting, methods: Embryo transfer was performed in theatre with the woman in dorsal lithotomy position. Embryos were transferred using a pre-loaded flexible Wallace catheter or using an elective malleable guide prior to passing the flexible catheter within the obturator. Embryos were placed 2 cm from the fundus, with trans-abdominal ultrasound guidance. A successful outcome was defined as a positive urine pregnancy test, 14 days after embryo transfer. Charts plotting the mean average and CUSUM were prepared.

Main results and the role of chance: Five hundred embryo transfers were analysed. One hundred consecutive embryo transfers and pregnancy outcome data were available for each trainee. The overall pregnancy rates for each trainee were 44%, 61%, 53%, 57% and 44% respectively. Once competency was achieved the mean pregnancy rate for all trainees was 78%.

Plots of mean averages were unhelpful in determining when a trainee was competence, showing initial wide swings before reaching steady state.

When assessing embryo transfer competency using LC-CUSUM the five trainees achieved competency at the 5th, 5th, 8th 13th and 27th procedure respectively. Each consecutive outcome was plotted on a chart using LC-CUSUM, with a downward step for a success and upward step for failure, until the competency threshold was crossed. Graphical representation was helpful to demonstrate when competency was reached.

Subsequent monitoring of embryo transfer performance was plotted on the same chart using CUSUM to monitor their performance. Four trainees maintained their success rate within acceptable limits. The CUSUM chart for one trainee alarmed at observation 17 into the monitoring period when their CUSUM score breached the threshold. This allowed additional individualised support and training to be initiated.

Limitations, reasons for caution: Results may be affected by confounders such as the quality of embryos, number transferred, culture media, embryologist, patient characteristics and so on. CUSUM also offers false reassurance, masking the possibility the trainee requires further training. Furthermore, statistics ignore vital aspects of learning such as formative feedback, self-assessment and reflection.

Wider implications of the findings: Statistical plots using mean average or CUSUM can provide useful graphical information when learning new practical procedures such as embryo transfer as part of a wider training program. Further studies should assess CUSUM for long term quality control.

Trial registration number: not applicable.

P-778 Are course of the pregnancy and perinatal outcome any different after transfer of poor quality day 5 embryos?

S. Korosec[1], I. Virant Klun[1], U. Belak[2], T. Magdalenic[2], E. Vrtacnik Bokal[1]

[1]Univerzitetni Klinicni Center Ljubljana, Department for Human Reproduction, Ljubljana, Slovenia

[2]University of Ljubljana, Medical Faculty, Ljubljana, Slovenia

Study question: Does the morphology of embryos transferred on day 5 after oocyte retrieval affect pregnancy complications, birth complications or newborn pathology rates?

Summary answer: Patients having embryos of different quality transferred on day 5 after oocyte retrieval have similar rates of pregnancy complications, birth complications and newborn pathology.

What is known already: Questioning child health remains the concern in transfer of poor morphology embryos. Up to date, no significant differences between good and poor embryo quality have been observed in newborn congenital diseases. Lower implantation and higher abortion rates are known to be directly connected to poor embryo morphology. Adverse pregnancy and birth outcome, including low gestational age, premature birth and restricted intrauterine growth, have already been connected to the poor embryo quality indirectly, through poor reproductive history of the patients.

Study design, size, duration: Retrospective cohort study included 380 patients and 451 newborns after IVF-ET procedure performed in University Medical Centre Ljubljana between January 2011 and December 2015. According to quality of embryos transferred, maternal characteristics, course of pregnancy and perinatal outcome were observed.

Participants/materials, setting, methods: Data were collected through Perinatal information system of Slovenia. Three-hundred-nine pregnancies (309 singleton and 71 twin) were divided in three groups regarding quality of transferred embryos in the IVF procedure (group A – one or two blastocysts of best quality, group B - one good and one poor quality blastocyst, group C - one or poor blastocysts or morulae). Blastocyst morphology was assessed accordning to Gardner blastocyst score (development1-6, tropfoblast A-C and embryoblast A-C).

Main results and the role of chance: There were 239 patients in group A, 77 patients group B and 64 in group C. There were no significant differences in maternal age and number of IVF procedues. Mothers in group A had significantly more oocytes retrieved. Mothers of singletons in group C had significantly higher rate of BMI belov 18,5 (16% vs 3,5% and 1,6%; $p<0,05$, Student t-test) and significantly lower BMI overall. Comparison was also significant between individual groups (A versus C, $p = 0,03$; B versus C, $p<0,005$, Pearson chi-square test). In group C there were significantly more ceasarian sections performed (40,6% vs 35.1% vs 22,1%, $p = 0.44$). Otherwise we found no other significant differences in pregnancy complications (bleeding in each trimester, preeclampsia, multiple pregnancies, placental pathology), birth complications (ceasarian section, bleeding, premature birth) or mobidity of the newborns (birth weight, gestation, small for gestation, Apgar score, congenital disease, admission to intensive care, mortality).

Limitations, reasons for caution: Beside relatively low number of patients in groups B and C, the limitation of study was the composition of group C defined by transfer of poor quality embryos. Blastocysts with poor embryoblast/trophoblast were in the same group as normal morulae, which would be better to observe separately.

Wider implications of the findings: Reassuring results showed no significant differences in pregnancy and birth pathology or neonatal morbidity regarding quality of transferred embryos. However, we found a different insight into the pathology and lifestyle of infertile women, showing that too low BMI can affect embryo quality simiraly or even more than higher BMI.

Trial registration number: Republic Medical Ethical Comeete on 14.2.2017, number 0120-47/2017-3

P-779 Perinatal outcomes in children born after IVF using a GnRh-agonist protocol versus a GnRh antagonist protocol: a Catalan cohort study based on 4562 newborns

M. Vidal Segui, M. Sastre Cuadri, M.A. Checa Vizcaino

Hospital del Mar - Parc de Salut Mar, Obstètrics and Gynecology, Barcelona, Spain

Study question: To ascertain whether perinatal outcomes are affected by the type of GnRH and/or gonadotrophins used for the controlled ovarian hyperstimulation (COH) cycle.

Summary answer: Perinatal outcomes are not affected by the protocol used for the COH neither by the type of gonadotrophins.

What is known already: One of the well established parts of assisted reproductive techniques (ART) is the utilization of gonadotrophin-releasing hormones (GnRh), antagonists or agonists, and gonadotrophins for the COH. Several studies performed to compare distinct protocols of GnRh and gonadotrophins showed no significant differences between live birth rates (effectiveness) neither among ovarian hyperstimulation syndrome rates (safety). Despite this lack of differences, what is also described during COH is a hyperestrogenic environment that could lead to biochemical alterations during implantation and placentation, which may affect obstetric and perinatal results. Our study ascertain whether perinatal outcomes are affected by drugs that generate higher estradiol levels.

Study design, size, duration: We conducted a register-based cohort study using prospective data from the Department of Health of the Regional Government of Catalonia between 2008 and 2013. A total of 4562 women were included.

Participants/materials, setting, methods: The participants were women undergoing COH using autologous eggs who had a singleton pregnancy delivered from the 24th week onward. Two different groups were made for the study: women undergoing COH using a GnRh antagonist based protocol and women undergoing COH using a a GnRh-agonist based protocol. Additionally, two subgroups were made according where recombinant or urinary gonadotrophins were used.Primary outcomes were birthweight and gestational age at delivery.

Main results and the role of chance: Women undergoing COH with a GnRh antagonist protocol and women using a GnRh-agonist protocol had comparable results regarding birthweight (BW) (3,144 ± 542.5 g and 3,161.6 ± 536.18 g, respectively; P = 1.08) and gestational age at delivery (GA) (38.7 ± 2.12 and 38.1 ± 2.08 weeks, respectively; P=.87) and these outcomes persisted after adjusting for confounding factors. Furthermore, we observed no statistically significant differences in the main perinatal outcomes analyzed in the subgroups of recombinant and urinary gonadotrophins (BW: 3,158.1 ± 539.6 g and 3,140 ± 537.1 g, respectively; P = .96 and GA: 38.8 ± 2.04 and 38.6 ± 2.24 weeks, respectively; P = 1.6).

Limitations, reasons for caution: The main limitation of the study is the retrospective design. This kind of evaluation precludes an analysis of some potentially relevant data that were missing from the registry and also results in a significant loss of cases because of missing data in the main variables.

Wider implications of the findings: Perinatal outcomes are not affected by the protocol used for COH. Hence, the choice of the GnRH analog, gonadotrophins and their combinations should be based on other clinical aspects. However, prospective studies would be required to support these findings.

Trial registration number: Not applicable.

P-780 Off-label use of androgens and letrozole in infertile women – a multinational survey in Europe and Australia

M.F. Andersen[1], P. Drakopoulos[2], P. Humaidan[3], J.L. Gomez[4], I. Bruna[5], L. Rombauts[6], S.D.S. Ribeiro[7], C. Dosouto[8], B. Coroleu[8], P.N. Barri[8], N.P. Polyzos[8]

[1]The Fertility Clinic, Skive Regional Hospital, Department of Clinical Medicine
[2]Vrije Universiteit Brussel, Department of Reproductive Medicine, Brussel, Belgium
[3]Department of Clinical Medicine- Aarhus University, The Fertility Clinic- Skive Regional Hospital, Skive, Denmark
[4]FIVMadrid, Department of Reproductive Medicine, Madrid, Spain
[5]Director Médico de HM Fertility Centers, Hospital Universitario Madrid-Montepríncipe, Madrid, Spain
[6]Monash University, Reproductive Medicine- Monash Health, Clayton Victoria, Australia
[7]Universitair Ziekenhuis Brussel, Reproductive Medicine- Genetics and Immunology, Brussel, Belgium
[8]Dexeus University Hospital, Department of Reproductive Medicine, Barcelona, Spain

Study question: Do fertility experts often recommend off-label regimens (androgens or letrozole) in reproductive medicine, and is this based on robust scientific evidence?

Summary answer: Clinicians very often recommend off label androgens and letrozole in reproductive medicine. This is not always driven by robust evidence in favor of treatment.

What is known already: Although off-label use of drugs and supplements is common in all medical domains, the magnitude of off-label regimen prescription and the rationale behind this, remains unclear in the field of reproductive medicine. Androgens and letrozole are possibly the most widely used off–label drugs among infertile women; still, available evidence regarding their safety and efficacy appear to be fairly different. Accumulating evidence support the beneficial effect of letrozole in unovulatory women undergoing ovulation induction, while evidence regarding the use of androgens for poor ovarian responders is weak and contradictory.

Study design, size, duration: This is a cross-sectional online survey conducted in 5 different countries (Denmark, Norway, Spain, Belgium and Australia), including all private and public specialists in reproductive medicine in order to evaluate fertility specialists' attitudes towards the use of off-label medication. The survey took place between October 2016 and December 2017.

Participants/materials, setting, methods: Online survey invitations were sent to all members of the Danish, the Norwegian, the Spanish, the Australian and the Belgian Fertility Society.

Main results and the role of chance: In total, 222 fertility specialists responded among 1136 who were contacted electronically (response rate 20%).

Cumulatively, 75.5% of the physicians recommended off-label use of androgens or letrozole for their patients. Overall, letrozole was used more frequently by clinicians 65% (CI 57%-72%), as compared with testosterone 49.1% (CI 38%-59%), although the difference was not statistically significant, p = 0.59 and more frequently than DHEA 29.3% (CI 16%-41%), p<0.001. Significantly more fertility specialists recommended testosterone as compared with DHEA for poor ovarian responders p<0.001.

Almost half (42.5%) of the fertility specialists who did not recommend the use of androgens reported that their decision was based on the lack of scientific evidence, whereas the 2 main reasons for not using letrozole was either because this was not part of clinicians' guidelines (24,9%) or because the drug was not officially approved for use in ART (19%).

Limitations, reasons for caution: Fertility care providers who recommend androgens or letrozole might have been more likely to respond to the survey and this could exaggerate the use of the procedure reported here.

Wider implications of the findings: A majority of clinicians are using off-label letrozole which is supported by the accumulating evidence for treatment of anovulatory patients. However it is remarkable that almost half of the clinicians continue to use androgens in poor responders, despite the lack of evidence and the caution raised in published articles.

Trial registration number: Not applicable.

P-781 Impact of pluripotency state and Activin A supplementation on derivation of primordial germ cell-like cells from human embryonic stem cells

S. Mishra[1], M. Van der Jeught[1], J. Taelman[1], M. Popovic[1], K.J. Szymańska[2], D. Deforce[3], P. De Sutter[1], S.M. Chuva de Sousa Lopes[4], B. Heindryckx[1]

[1]Universitair Ziekenhuis Gent, Ghent-Fertility and Stem cell Team G-FaST-Reproductive Medicine, Gent, Belgium
[2]Ghent University, Physiology Group- Department of Basic Medical Sciences, Ghent, Belgium
[3]Ghent University, Laboratory of Pharmaceutical Biotechnology- Faculty of Pharmaceutical Sciences, Ghent, Belgium
[4]Leiden University Medical Centre-, Department of Anatomy and Embryology, Leiden, The Netherlands

Study question: Is there an effect of the pluripotency state and Activin A supplementation on differentiation of human embryonic stem cells towards the germline?

Summary answer: Germline precursors were formed in all conditions, apart from the naïve RSET condition. Activin A supplementation appeared to boost this expression.

What is known already: Gametogenesis from human embryonic stem cells (hESC) in vitro may provide new long-term perspectives for genetic parenthood for patients currently facing sterility. Recent studies have shown that human primordial germ cell-like cells (hPGCLCs) with SOX17/OCT4 expression can be obtained from hESC grown in a '4i' state, by culturing them as embryoid bodies (EBs) with BMP4, EGF, SCF, hLIF and ROCKi. Moreover, our group previously showed that primed hESC cultured as EBs in presence of BMP4 and Activin A showed increased propensity to express genes for post-migratory germ cells compared to EBs exposed to BMP4 alone.

Study design, size, duration: The germline competence of different states of pluripotency such as naive hESC and other states inhibiting one or more signalling pathways are yet to be studied in parallel and warrants further investigation.

To study this we used: two in-house derived female hESC lines were cultured in primed, primed-Wnt-inhibitor(Wnt-i), 4i (naive) and RSET (naive) conditions.

Participants/materials, setting, methods: The cells were tested for pluripotency markers using immunostaining and cultured as EBs in two groups; germ cell differentiation medium with Activin A(20ug/ml) and other without Activin A. Day 4 EBs were fixed and stained for germ cell and pluripotency markers, visualised as z-stacks on a Leica SP8 Confocal Microscope, and analysed using IMAGEJ/FIJI.

Main results and the role of chance: We found that the specific pluripotency state affects the germline induction potential of hESC. In both cell lines, EBs from primed, Wnt-i and '4i' cells expressed SOX17 and OCT4 double positive cells at varying levels after 4 days. In contrast, EBs from the naïve RSET condition did not show these markers. Positive cells also expressed Podoplanin (PDPN) on their surface, a PGC marker in embryos of cynomogolous monkeys. Therefore, the obtained hPGCLCs were positive for SOX17/OCT4 and SOX17/PDPN. EBs from Wnt-i hESCs had a similar germline competence as primed hESCs. EB's from '4i' had the highest germline competence in the standard differentiation medium. Addition of Activin A to the differentiation medium resulted in markedly increased proportion of hPGCLCs in EB's all the three conditions except RSET.

Limitations, reasons for caution: In order to present scientifically robust data, the current study, which is based on confocal imaging only should be further supported by transcriptome data of the obtained hPGCLCs, which should be compared to the profiles of in vivo harvested early human PGCs.

Wider implications of the findings: The current study aims to identify embryonic germ cell markers on hPGCLCs and to standardise the process of deriving gametes from pluripotent stem cells. Adaptation of culture conditions based on this knowledge may ultimately advance efforts to derive germ cells in vitro for patients currently facing sterility.

Trial registration number: Not Applicable.

P-782 Induction of spermatogenesis under 3-Dimentional tissue culture conditions by in vitro transplantation of human spermatogonial stem cells isolated from frozen-thawed testis tissue

M. Mohaqiq[1], M. Movahedin[2°], Z. Mazaheri[3], N. Amir Janati[4]

[3]*Anatomical Sciences Department, Faculty of Medical sciences, Tarbiat Modares University*
[4]*Andrologia and Embryology Department, Avicenna Research Institute, Tehran*
[°]*Corresponding Address: P.O.Code: 14115-331, Department of Anatomical Sciences, Faculty of Medical Sciences*

Study question: Can testis organ culture support progression of spermatogenesis after in vitro transplantation of spermatogonial stem cells under conditions of testicular tissue culture?

Summary answer: Conditions of the 3-Dimentional testicular tissue culture after spermatogonial stem cell transplantation can support the progress of spermatogenesis to produce haploid cells.

What is known already: Inducing spermatogenesis by long term preserved germ cells to produce mature and functional sperm is one of the main goals of reproductive medicine. Germ cell transplantation is one of the ways reaching to this goal. In vivo transplantation has been done successfully and frequently. But in the in vitro transplantation and organ culture method Sato et al in 2013 are first one that published protocol. They reported sperm producing from in vitro transplantation of mouse spermatogonial stem cells and organ culture.

Study design, size, duration: This study is based on 5 biopsy samples taken from different azoospermic patients with 20 to 45 years old. For each experimental group, 3 to 5 NMRI mouse were used at the age of 4 weeks.

Participants/materials, setting, methods: SSCs were obtained from patient's TESE (Testicular Sperm Extraction). To confirm identification of SSCs, PLZF protein was detected. Labeled cells by DiI were transplanted to adult mouse testis which treated by 40 mg/kg busulfan. Host testes set in organ culture condition. Another testis without transplantation set in organ culture condition as control group. Cultured testes were assessed by histomorphometric studies, tracing of DiI, immunohistochemistry and molecular (Real Time PCR) studies after 8 weeks.

Main results and the role of chance: The results of histomorphometric studies showed that the mean number of spermatogonial cells, spermatocytes and spermatids in the transplantation group was significantly more than the control group ($P<0.05$) and most of the cells responded positively to the detection of DiI. Immunohistochemical studies in host testes fragments in the experimental group express the *PLZF*, *SCP3* and *ACRBP* proteins in spermatogonial cells, spermatocyte and spermatozoa, respectively, which confirmed the human nature of these cells. Also, in molecular studies of *PLZF*, *Tekt1* and *TP1*, the results indicated that the genes were positive in the test group, while not in the control group.

Limitations, reasons for caution: Obtaining human samples were very difficult. There were few patients who gave satisfaction for researches.

Wider implications of the findings: The results of this study indicate that the in vitro transplantation system and testicular tissue culture have the ability to support the progression of spermatogenesis to obtaining haploid cells.

Trial registration number: our trial was non-clinical.

P-783 Transplantation of human menstrual blood-derived stromal cells promotes recovery of cyclophosphamide-induced premature ovarian insufficiency

F. Penghui, T. Jichun

China Medical University, Department of Obstetrics and Gynecology- Reproductive Medical Center- Shengjing Hospital, Shenyang, China

Study question: How can menstrual blood-derived stromal cells (MenSCs) take reparative effects on premature ovarian insufficiency?

Summary answer: Menstrual blood-derived stromal cells can effectively inhibit apoptosis of granulosa cells and therefore renovate ovarian function damaged by Cyclophosphamide.

What is known already: Premature ovarian insufficiency (POI) is characterized by abnormal menstruation with hormonal disorders in female aged before 40, and 1%~3% female are suffering from it whereas certain etiologies and pathophysiological mechanisms are not clearly defined. Recently, different sources of mesenchymal stem cells have been found to be therapeutic in premature ovarian insufficiency such as umbilical cord, skin, amniotic fluid, endometrial mesenchymal stem cells, etc. In these studies, paracrine fashions of mesenchymal stem cells play the principal role in the restoration of ovarian function.

Study design, size, duration: Experiments were divided into three groups (blank group without treatment, control group with cyclophosphamide injected abdominally and treatment group with MenSCs and cyclophosphamide preconditioned). In vivo, female mice were injected with cyclophosphamide in advance; and one week later, those in experiment goups were treated with MenSCs and the rest with PBS until 10 days. In vitro, KGN cells were cultured with medium or cyclophosphamide or cocultured with MenSCs for 24 hours.

Participants/materials, setting, methods: Stromal cells were isolated from menstrual blood, infected with green fluorescence protein. KGN cells line

were cultured for experiments in vitro. Female mice were divided into three groups (blank group without treatment, control group with cyclophosphamide injected abdominally and treatment group with MenSCs through tail veins with cyclophosphamide preconditioned). Then, identificating and proving the reparative effects by CCK-8 assay, FACS, in-vitro differention, H&E staining, Western, RT-PCR, immunofluorescence, TUNEL-apoptosis assay, RNA Sequencing, etc.

Main results and the role of chance: In our present study, we demonstrated that MenSCs showed properties of mesenchymal stem cells with surface markers $CD90^+$, $CD73^+$, $CD105^+$, $CD44^+$, $CD38^-$, $CD45^-$ and $CD34^-$. Osteogenic, chondrogenic and adipogenic defferentiation indicated the multipotency of MenSCs. In vivo, apoptotic cells in ovarian tissues especial granulosa cells decreased compared with control group according to TNUEL and Hoechst assays. Body weight of mice, ovarian and uterine weight and number of live births were significantly different among blank and experiment groups compared with control group. In addition, MenSCs were able to up-regulate the expression of MIS, VASA, Ki67, VEGF and LHR of ovarian tissues, modulating blood hormones with IFN-γand FSH down-regulated and E_2 and AMH up-regulated. In vitro, MenSCs reduced apoptosis of KGN cells in accordance with the downward trend of caspase molecules. RNA sequencing demonstrated that MenSCs restore ovarian function through regulating biological metabolism, angiogenesis, muticellular organismal process, cell differentiation, apoptotic process and so on with 82 related genes up-regulated and 261 relative genes down-regulated.

Limitations, reasons for caution: Our study revealed the reparative effects on POI induced by chemotherapeutic agent via inhibiting apoptosis of granulosa cells. However, the etiologies of this syndrome is not only for this reason. Thus, we need further investigation to explore the effect of MenSCs in different models such as immunogeneous POI.

Wider implications of the findings: MenSCs are capable of promoting recovery of POI by inhibiting the activation of caspase signaling in granulosa cells. It is noteworthy that related trials of MenSCs in POI treatment were mainly conducted confined to rodent animals; therefore it is necessary for us to take further investigation in mammals.

Trial registration number: not applicable.

P-784 Transcriptomic features of KRT7 positive cells derived from BMP4-treated human induced pluripotent stem cells (hiPSCs)

N. Tsuchida[1], H. Akutsu[2], J. Kojima[1], H. Ito[1], N. Kuji[1], H. Nishi[1]

[1]Tokyo Medical University Hospital, Obstetrics and gynecology, Tokyo, Japan
[2]National Center for Child Health and Development, Center for regenerative medicine, Tokyo, Japan

Study question: Do KRT7 positive cells derived from BMP4-treated hiPSCs have trophoblast-specific features?

Summary answer: The KRT7 positive differentiated cells exhibit trophoblast features.

What is known already: Early development of human placenta remains poorly understood due to lack of proper model systems. Previous reports demonstrated that human Embryonic Stem Cells (hESCs) and hiPSCs treated with bone morphogenetic protein4 (BMP4) could differentiate into extra-embryonic tissue and they could be a useful model of the early trophoblast differentiation. However, the differentiated cells are heterogeneous, which include both trophoblast (TB) and mesoderm lineage cells.

Study design, size, duration: In order to identify the characteristics of the trophoblast lineage cells from BMP4-treated hiPSCs, cells were collected using a pan-trophoblast marker, KRT7, with flow cytometry and performed comprehensive gene expression analysis.

Participants/materials, setting, methods: Four types of hiPSCs were treated with 50 ng/ml of BMP4 in a Xeno-free medium for 10 days. After the expression of KRT7 was confirmed by immunofluorescence analysis, KRT7-positive cells were collected using flow cytometry and analyzed by DNA microarray (Agilent SurePrint G3 Human Gene Expression v3 8×60 K Microarray). The difference of the gene expression profiles between KRT7-positive cells and hiPSCs were compared, and the expressions of some genes were validated by quantitative RT-PCR.

Main results and the role of chance: All the BMP4-treated cells were stained by immunocytochemistry for KRT7. Microarray analysis demonstrated that 833 genes were commonly expressed in all the four hiPSC groups, including POU5F1, SOX2, and NANOG. 259 upregulated genes were commonly expressed in all the four BMP4 treated cell groups, including some trophectoderm-specific genes (GATA3 and GCM1) and TB-specific genes (CGA, CGB, and syncytin2). Cluster analysis and Principal Component Analysis revealed that most gene clusters were divided into two groups: hiPSCs and KRT7-positive cells. Comparing our microarray data to the large-scale analysis of human transcriptome, the features of KRT7-positive BMP-4 treated cells were most similar to placenta.

Limitations, reasons for caution: Although the KRT7 positive BMP4-treated hiPSCs are similar to the early stage of placenta in terms of the transcriptomic character, it is difficult to reproduce early placentation because there is no in vivo model to compare with this model.

Wider implications of the findings: The results suggest that some of the genes upregulated in all the BMP4-treated groups might play an important role in early placental development. Further studies are needed to confirm their functions.

Trial registration number: None.

P-785 Topical administration of human umbilical cord-derived mesenchymal stem cells on scaffolds accelerates endometrial regeneration in a rat model of Asherman's syndrome by paracrine effect

L. Xin[1], Z. Songying[2], M. Lie[3]

[1]Zhejiang University, School of Medicine, Hangzhou, China
[2]Sir Run Run Shaw Hospital, Assisted Reproduction Unit- Department of Obstetrics and Gynecology, Hangzhou, China
[3]Zhejiang University, Department of polymer science and engineering, Hangzhou, China

Study question: Can collagen/hu-mscs scaffolds provide a new treatment for Asherman's syndrome?

Summary answer: Transplantation of collagen/hu-mscs scaffolds was established to be effective in promoting endometrial regeneration in a rat model of Asherman's syndrome.

What is known already: In women of reproductive age, severe injuries of endometrium are often accompanied by endometrial scar formation, and a lack of endometrial functional layer leads to infertility or miscarriage. Human umbilical cord-derived mesenchymal stem cells have been confirmed to promote tissue recovery in many organs. Collagen scaffolds have been widely applicated in regenerative medicine because of their abundant source, low immuogenicity, wonderful biocompatibility and degradability.

Study design, size, duration: Collagen/hu-mscs scaffolds were constructed. A total of 154 SD rats were involved and received different treatments. Uteri were examined at 15, 30 and 60 days after surgery. The function of regenerated endometrium was assessed at 60 days afer surgery. A non-contact co-culture system was made to explore the mechanism of hu-mscs on endometrial regeneration in vitro.

Participants/materials, setting, methods: Hu-mscs were purchased from Boyalife Group°Collagen scaffolds were obtained using dry-heat crosslinking method. Hu-mscs were seeded onto degradable collagen scaffolds. The cell-seeded scaffold was transplanted onto the inner uterine surface of a rat intrauterine adhesion model. At 15,30 and 60 days after surgery, uteri were examined by histological analysis. Fertility test was made 60 days afer surgery. The paracrine effect of hu-mscs on endometrial regeneration was established by a non-contact co-culture system in vitro.

Main results and the role of chance: Hu-mscs were mainly located to the functional layer of regenerated endometrium. At 15,30 days after collagen/hu-mscs scaffolds transplantation, the regenerated endometrium expressed higher level of VEGFa, TGF-β, PDGFbb and MMP-2 than the endometrium in collagen group or spontaneous repair group. The collagen/hu-mscs scaffold promoted endometrial regeneration and collagen degradation, induced local endometrial cells proliferation, facilitated microvasculature regeneration, and restored the endometrium's ability to receive embryos. Furthermore, we demonstrated that

hu-mscs promoted human endometrial stromal cells proliferation and inhibited apoptosis through paracrine effect in vitro.

Limitations, reasons for caution: The results of this research are inadequate to apply directly in human because human uterine and rat uterus differ in structure and function. Further large animal experiments, such as monkeys, are needed.

Wider implications of the findings: Transplantation of collagen/hu-mscs scaffold offers a reliable method in the treatment of women with Asherman's syndrome and promote fertility recovery.

Trial registration number: not applicable.

P-786 Germ-like cells generation from human menstrual blood-derived stem cells on a 3-D composite nanofibrous scaffold

S. Ghorbani[1], H. Eyni[1], M. Pourdonya[2], Z. Kazemi[2], S. Sarkhanloo[2], M. Soleimani[3]

[1]Tarbiat Modares University, Anatomical Sciences, Tehran, Iran
[2]Ardabil University of Medical Science, Medical, Ardabil, Iran
[3]Tarbiat Modares University, Hematology, Tehran, Iran

Study question: Can the fabricated 3-D nanofibrous composite scaffolds with retinoic acid trigger human menstrual blood-derived stem cells (MenSCs) to differentiate towards germ-like cells?

Summary answer: The stem cell and germ cell-specific genes expression on transcriptional in differentiated-MenSCs proofed 3-D composite scaffold-seeded MenSCs could enhance germ-like generation.

What is known already: Several factors contributing to infertility can involve men, women or both partners, and in some cases no cause can be identified. Providing a platform to generate functional germ cells in laboratories could have modified the current view on assisted reproduction technologies.

It has been proved that cells often exhibit unnatural characteristics when cultured on a two dimensional (2D) surface as a monolayer in comparison with native three-dimensional (3D) tissues. Therefore, in this study, usefulness of PLA/MWCNTs scaffolds in germ line cell culture by taking advantage of the affinity exhibited by CNTs for MenSCs differentiation to germ-like cells has been examined.

Study design, size, duration: The 3-D wet-electrospun composite scaffolds were designed to compare infiltration, proliferation, and differentiation potential of menstrual blood-derived stem cells toward germ cell lineage with 2D culture. Therefore, isolated MenSCs at a density of $1.5 10^4$ cells/cm^2 in inducing media containing DMEM/F12 supplemented with 10% FBS and 10^{-7}M retinoic acid (RA) on 2D (without scaffolds) and 3D (with fabricated PLA and PLA/MWCNTs scaffolds) culture vessels for 7 and 14 days were differentiated towards germ cells.

Participants/materials, setting, methods: After MenSCs isolation and scaffold fabrication, such assays as SEM, FTIR, Contact angel, Live/dead and MTT was used to evaluate the biocompatibility and properties of the matrix as well as morphology of differentiated-MenSCs. Reverse-transcription PCR (Oct4, C-kit, VASA, DAZL, SYCP3 and STRA8) was used to assess the germ cell development in 3-D engineered bio-scaffolds.

Main results and the role of chance: The results, showed that the porous structure of PLA and PLA/MWCNTs scaffolds provide sufficient dimensions for cell ingrowths. This was evidenced in the SEM of differentiated MenSCs showing excellent attachment, penetration, and aggregation of these cells on the scaffolds where these parameters in the PLA/MWCNTs were better than PLA. These results clearly demonstrated that scaffolds that were used not only provided a suitable support for cell homing but also enhanced proliferation of MenSCs.

The results of stem cell and germ-like cell genes expression showed that MenSCs expressed stem cell and germ-like cell genes in 3D group (PLA, PLA/MWCNTs) as well as 2D group. In this research, merging RA with carbon nanotubes in the PLA/MWCNTs group showed more effect on germ-like cells generation from MenSCs. The results from gene expression and differentiated cells morphology in all groups demonstrate that the CNTs can enhance MenSCs differentiation toward germ-like cells.

Limitations, reasons for caution: Germ-like cells produced by MenSCs in vitro on such favorable 3-D porous microenvironments could provide a continuous supply for gamete generation, but naturally, the clinical application of MenSCs-derived germ cells in humans would require great caution.

Wider implications of the findings: The previous studies showed that generation of mature germ cells in vitro may require complex niches. Due to the appropriate 3-D structure of the new fabricated scaffold, it seems be a powerful microenvironment to support the germ cells generation from MenSCs and may pave way for infertility treatment.

Trial registration number: Not applicable.

P-787 Different dynamic distribution of H3K27ac and H3K4me3 epigenetic active marks at imprinted genes during in vitro primordial germ cells differentiation

I. Muñoa-Hoyos, I. Urizar-Arenaza, M. Gianzo, N. Subiran

University of the Basque Country, Physiology in the Faculty of Medicine and Dentistry, Leioa, Spain

Study question: To elucidate the chromatin dynamics of histone modifications at imprinted genes during primordial germ cell (PGCs) differentiation in mouse.

Summary answer: Imprinted genes present differences in the dynamic distribution of H3K27ac and H3K4me3 histone modification marks compared to whole genome distribution pattern during PGC differentiation.

What is known already: Epigenetic reprogramming plays an important role in germ cell differentiation to guarantee the normal development of epigenetic information transmitted across generations. In fact, it has been pointed out the importance of a global genome demethylation and an optimal chromatin configuration for an efficient reprogramming, among other epigenetic mechanisms. However, some genes, such as imprinted genes, can escape the reprogramming process and still be partially methylated at the end of reprogramming, suggesting the presence of a potential mechanisms important for transgenerational epigenetic inheritance. In spite of that, the chromatin distribution of imprinted genes during PGC differentiation is completely unknown.

Study design, size, duration: Chip-Sequencing analysis of histone active marks (H3K27ac and H3K4me3) and histone repressive mark (H3K27me3) during *in vitro* PGC differentiation. Induction of *in vitro* PGC was carried out form mouse embryonic stem cells (ESCs), to epiblast-like cells (EpiLCs) and finally into primordial germ cell-like cells (PGCLCs) at day 2 and 6 (d2PGCLCs and d6PGCLCs respectively).

Participants/materials, setting, methods: Bioinformatic approaches from Next-Generation Sequencing (NGS). NCBI database (GEO accession number: GSE60204).

Main results and the role of chance: First, we have evaluated the normal pattern of chromatin state dynamics in both active marks and the repressive mark. H3K27ac and H3K4me3 levels showed a reduction from ESCs to EpiLCs and d2PGCLCs, followed by a recovery in d6PGCLCs. In return, the transitions of H3K27me3 during in vitro PGC specification exhibited a small drop from ESCs to EpiLCs, and reached the highest level in d2PGCLCs, to finally recover the low level in d6PGCLCs.

Next, we have analyzed the transitions of these three epigenetic marks more deeply focusing on imprinted genes. As a result, we have found out that, maternally and paternally imprinted genes have different distribution in both active marks, H3K27ac and H3K4me3, but not in the repressive mark, H3K27me3 that seems to maintain the same pattern as the general.

Finally, we have studied the chromatin dynamics of the repetitive elements during PGC differentiation, as these elements also have been described to escape from the demethylation process. Unlike the previous case, we have observed that there is no change in the distribution of these three histone marks in repetitive elements, compared to the general pattern.

Limitations, reasons for caution: To perform the in vitro analysis.

Wider implications of the findings: Maternally and paternally imprinted genes seem to have a different chromatine remodeling pattern in H3K27ac and H3K4me3 active marks, during PGC differentiation. This fact reaffirms imprinted genes as potential candidates to escape the reprogramming process and sheds light on the complex mechanism of epigenetic inheritance.

Trial registration number: Not applicable' for non-clinical trials.

P-788 The synergetic effects of multiwall carbon nanotubes/poly lactic acid 3-D composite nanofibrous scaffold containing naringenin on spermatogenesis

H. Eyni Seen[1], S. Ghorbani[1], M. Pourdonya[2], Z. Kazemi[2], S. Sarkhanloo[2], R. Shabani[3], M. Mehdizadeh[3], F. Amjadi[3]

[1]*Tarbiat Modares University, Anatomical Science, tehran, Iran*
[2]*Ardabil University of Medical Sciences, Medical, Ardabil, Iran*
[3]*Iran University of Medical Sciences, Anatomical Sciences, Tehran, Iran*

Study question: Can the fabricated 3-D nanofibrous composite scaffolds with naringenin induct spermatogenesis in the spermatogonial stem cells (SSCs)?

Summary answer: The stem cell and germ cell-specific markers expression on transcriptional and protein in the SSCs proofed successful spermatogenesis induction 3-D composite scaffold-seeded SSCs.

What is known already: The efficiency of spermatogenesis concerns the presence of the Sertoli cell–SSCs niche. This connection between proliferating SSCs and surrounding testicular environment enables them to receive a variety of signals and factors necessary for SSC self-renewal and differentiation. Fortunately, new developments in engineered three-dimensional cultures have helped mimic the structure as well as function of the natural extra cellular matrix to improve cellular behavior of SSCs in vitro. Therefore, in this study, we have incorporated MWCNTs into PLA, with hypothesis that this carbon-based scaffold combined with an antioxidant, naringening, may have enhanced proliferation and differentiation of SSCs compared to 2D-medium.

Study design, size, duration: The 3-D wet-electrospun composite scaffolds were designed to compare proliferation, and differentiation SSCs with 2D culture. Therefore, isolated SSCs at a density of 10^4 cells/cm^2 in inducing media containing DMEM/F12 supplemented with 10% FBS, 50 ng/ml BMP4 and 20 ng/ml GDNF on 2D (without scaffolds and 10 μM naringenin) and 3D (with fabricated PLA/ MWCNTs scaffolds and 10 μM naringenin) culture vessels for 7 and 14 days were differentiated towards germ cells.

Participants/materials, setting, methods: After SSCs isolation and scaffold fabrication, such assays as SEM, FTIR and MTT was used to evaluate the biocompatibility and properties of the matrix as well as morphology of differentiated-SSCs. Reverse-transcription PCR (PLZF, C-kit, ID4 and SYCP3) and immunocytochemistry (PLZF, C-kit and ID4) were used to assess the germ cell development in 3-D engineered bio-scaffolds. Also, reactive oxygen species (ROS) was used to asses ROS amount in 2D and 3D groups.

Main results and the role of chance: The results showed that the porous structure PLA/MWCNTs scaffolds provide sufficient dimensions for cell ingrowths. This was evidenced in the SEM of differentiated SSCs showing excellent attachment, penetration, and aggregation of these cells on the scaffolds. These results clearly demonstrated that scaffolds that were used not only provided a suitable support for cell homing but also enhanced proliferation and differentiation of SSCs.

The results of stem cell and germ cell markers expression showed that SSCs expressed stem cell and germ cell genes in 3D group (PLA/MWCNTs) as well as 2D group. In this research, merging naringenin with carbon nanotubes in the PLA/MWCNTs group showed more effect on germ cells generation from SSCs. The results from gene and protein expression and differentiated cells morphology in all groups demonstrate that the CNTs can enhance SSCs differentiation toward germ cells. Also, ROS level was less in 3D group in comparison with 2D group.

Limitations, reasons for caution: Germ cells produced by SSCs in vitro on such favorable 3-D porous microenvironments could provide a continuous supply for gamete generation but the functionality of germ cells needs to be investigated by other methods such ART.

Wider implications of the findings: The previous studies showed that generation of mature germ cells in vitro may require complex niches. Due to the appropriate 3-D structure of the new fabricated scaffold, it seems be a powerful microenvironment to support the germ cells generation from SSCs and may pave way for infertility treatment.

Trial registration number: Not applicable.

P-789 Imprinting status of human parthenogenetic embryonic stem cells: analysis of 63 imprinted genes expression levels in two undifferentiated and early differentiated stages

Q. Mai[1], X. Mai[2], K. Huang[3], C. Zhou[3]

[1]*The First Affiliated Hospital of Sum Yat-sen University-, Reproductive Medical Center, Guangzhou, China*
[2]*Guangzhou women and children's medical center, Reproductive Medical Center, Guangzhou, China*
[3]*The First Affiliated Hospital of Sum Yat-sen University, Reproductive Medical Center, Guangzhou, China*

Study question: What is imprinted genes expressive status of human pathenogenetic embryonic stem cells (hPESCs)?

Summary answer: Human parthenogentic embryonic stem cells show a substantial degree of epigenetic stability with respect to imprinted genes.

What is known already: Human parthenogenetic embryonic stem cells represent a source of histocompatible tissues for transplantation and thus their use avoids immune rejection and ethical obstacles. Human parthenogenetic embryonic stem cells carry two copies of the maternal genome and lack a paternal genome. Given that the disruption of imprinting is associated with human diseases, there are main concerns about imprinted genes expressive status of human parthenogenetic stem cells and the influence of aberrant imprinted genes on stem cell derivative.

Study design, size, duration: The expression levels of imprinted genes were compared between human parthenogentic embryonic stem cells and human biparental embryonic stem cells. Two undifferentiated human parthenogentic embryonic stem cell lines were cultured in vitro and digested for passaging every 5 days. For early differentiation and collection of embryonic body, human parthenogetic embryonic stem cells and human biparental embryonic stem cells were cultured in the medium with RA for two weeks.

Participants/materials, setting, methods: We investigated the expression profile of all 63 genes that are known to be human imprinted (27 maternally and 36 paternally expressed) in two undifferentiated human parthenogentic embryonic stem cell lines by quantitative real Time reverse transcription-PCR and the change of imprinted genes' expression were compared with the result of two human embryonic stem cell lines (hESCs). Four DMRs of different expressive imprinted genes were detected in undifferentiated hPESCs and hESCs by bisulfite sequencing.

Main results and the role of chance: All the maternally expressed genes were expressed at similar levels in both human parthenogentic embryonic stem cell lines and in human embryonic stem cell line except ZNF264 and ATP10A. 21 detected paternally expressed genes were expressed at the same levels in two human parthenogentic embryonic stem cell lines as in the human embryonic stem cell line, whereas 15 paternally expressed genes were significantly downregulated or inactivated. During prolonged passage, the expression levels of the majority of imprinted genes remained stable in two human parthenogentic embryonic stem cell lines. PEG3/ZIM2 DMRs, SNURF/SNRPN DMRs and KVDMR1 DMRs are highly methylated in two early passages (p27) undifferentiated human parthenogentic embryonic stem cells and its embryonic bodies, whereas DMRs in early passages (p27) undifferentiated human embryonic stem cells and its EBs are half methylated, and clones are almost completely methylated or demethylated. Comparing with human embryonic stem cells, two human parthenogentic embryonic stem cell lines showed the same imprinted genes expressive trending in early differentiation stage. The expression levels of H19, IGF2, SLC22A2, SLC22A3/SLC22A18 and CPA4 were both significantly up-regulated in early differentiation process of human parthenogentic embryonic stem cells and human embryonic stem cells.

Limitations, reasons for caution: The limitation of this study is imprinted gene expression levels were only detected in undifferentiated and early differentiated hPESCs. The aberrant imprinted gene status was not detected in the

derivative of hPESCs and their influence on hPESCs differentiation and derivate cells function were still unknown.

Wider implications of the findings: This study quantitatively analyzed the expression patterns of imprinted genes of undifferentiated and early differentiated stage hESCs from parthenogenetic embryos. To our knowledge, this is by far the most wide-range study on survey imprinting profile of hPESCs and evaluating epigenetic status of hPESCs from the aspect of imprinting genes expression.

Trial registration number: not applicable.

P-790 human embryonic stem cells carrying an unbalanced translocation demonstrate impaired differentiation capacity

Y. Sun, P. Xie, Q. Ouyang

School of Basic Medical Science- Central South University-, Institute of Reproductive and Stem Cell Engineering-, Changsha-, China

Study question: whether human embryonic stem cells carrying unbalanced translocation can be used as a model to analyze the development potential of unbalanced translocation embryos?

Summary answer: HESC lines carrying unbalanced translocation after preimplantation genetic diagnosis (PGD) are excellent in vitro model of partial monosomy and/or trisomy for early embryonic development.

What is known already: Human embryonic stem cells (hESCs) have the ability of self-renewal and multiple differentiation potential. Unbalanced translocation was known as one of the common structural chromosomal defects involved in abnormal embryogenesis. Differentiated translocated hESCs were reported that impaired expression of the trophoblastic genes may be associated with implantation failure.

Therefore, Unbalanced hESCs can serve as a tool for studying chromosome partial segments abnormalities linked to early stages of embryonic development.

Study design, size, duration: Six HESC lines were established from PGD embryos carrying unbalanced translocation. Subsequently, we aimed to indentify the biological characteristics and genetic stability of such embryonic stem cells. We further analyzed the consequences of copy number variation involved in embryonic developmental potential.

Participants/materials, setting, methods: A total of nine hESC lines were used, including three controls. HESC lines exhibit hallmarks of pluripotency, pluripotency-associated gene expression was evaluated by RT-PCR and pluripotency markers were assessed by immunocytochemistry. The differentiation capability was demonstrated by teratoma formation in vivo and embryoid body (EB) formation in vitro. Genetic stability of hESC lines was evaluated using karyotype analysis, fluorescence in situ hybridization(FISH) and Next Generation Sequencing(NGS). RNA-seq was used to compare differentially expressed gene profiles.

Main results and the role of chance: Six abnormal hESC lines were established from eleven blastocysts carried an unbalanced chromosomal defect. All hESC lines expressed the pluripotency-related genes such as POU5F1, SOX2, NANOG, KLF4, TERF1 and THY1 and stained positive for pluripotency markers POU5F1, NANOG, TRA-1-60 and TRA-1-81. Next Generation Sequencing confirmed that genome exactly matched between embryo and hESCs. Moreover, these cell lines maintained a stable karyotype of the donors during long-term culture. RNA-seq results identified that the expression level of gene was significant changes in chromosome imbalances hESC lines compared to normal hESCs. The genes expression level of partial chromosome trisomy or monosomy was upregulated or downregulated. Only three of hESC lines could differentiate into all three germ lineages. For teratoma formation and analysis, normal hESCs generated teratomas in a shorter time than unbalanced hESCs. During homogenous embryoid body differentiation, the efficiency of unbalanced hESCs aggregate formation was lower compared to normal hESCs. In conclusion, affected differentiation capacities and cell apoptosis in differentiating embryoid bodies may be caused by gene expression dosage imbalance.

Limitations, reasons for caution: Although we revealed that the embryonic development potential was impaired by CNV, the dosage imbalances of chromosomes and reduce of key gene expression may lead to lethality at early stages of human embryonic development. The underlying mechanism for early embryonic arrest or miscarriages has not been fully investigated.

Wider implications of the findings: Current research models for determining the cause of implantation failure are still very limited. These cell lines will help us to explore developmental several aspects of translocated embryos. Moreover, the effects of partial monosomy or trisomy on human development and birth need to further search.

Trial registration number: No application.

P-791 Homing of mouse spermatogonial stem cells on acellular testis following in vitro transplantation

N. Majidi Gharenaz, M. Movahedin

Department of Anatomical Sciences- Faculty of Medical Sciences- Tarbiat Modares University- Tehran- Iran, Department of Anatomical Sciences, Tehran, Iran

Study question: Could acellular testis support homing of mouse spermatogonial stem cells after in vitro transplantation?Could acellular testis support homing of mouse spermatogonial stem cells after in vitro transplantation?

Summary answer: In vitro transplantation of mouse spermatogonial stem cells in to acellular testis and two week organ culture could initiate in vitro spermatogenesis.

What is known already: Vermeulen et al reported culturing of Sertoli cells with testicular scaffold could increase the proliferation rate of the cells.

Baert et al reported that primary adult and prepubertal human testicular cells can assemble to testicular organoid with and without support of natural testicular scaffold.

Study design, size, duration: In this study we had two groups. Control group: without transplantation of Spermatogonial stem cells. Experimental group: with transplantation of Spermatogonial stem cells. For each group, 5 NMRI male mice were used at the age of 8 weeks for decellularization. Spermatogonial stem cells isolated from 6 NMRI neonate male mice, then injected to acellular testis and cultured for 2 weeks.

Participants/materials, setting, methods: Testes decellularized by 0.05% SDS for 24 h+0.05% Triton X-100 for 24 h, then were washed with 1× PBS for 24 h, and disinfected using 0.1% peracetic acid in 4% ethanol for 2 h, rinsed three times with sterile 1× PBS for 4 hours each. Spermatogonial stem cells isolated from neonate testis with twice enzymatic treatment, injectod to acellular testes and cultured on agarose gel for two weeks. Finally, immunohistochemistry and molecular studies were done.

Main results and the role of chance: Immunohistochemically studies in the control and experimental group express *PLZF* proteins in spermatogonial cells. Also, in molecular studies of *PLZF*, the results indicated that this genes was positive in the experimental group, while not in the control group.

Limitations, reasons for caution: If we want to use the result of this research in clinic, we need to be able to decellularize human whole testis for injection of spermatogonial stem cells. Decellularization human whole testis is difficult and need set up new protocol.

Wider implications of the findings: Our result showed that natural testicular scaffold could support of spermatogonial stem cells during 2 week culturing. These results in agreement with literature that reported testicular scaffold could increase proliferation of Sertoli cells and support of auto assembly testicular organoid.

Trial registration number: 0

P-792 Are we losing valuable reserves by discarding post-TESE (testicular sperm extraction) material? Analysis of the quantity and distribution of spermatogonial stem cells (SSCs) after TESE

M. Afshani[1], İ. Kaplanoğlu[2], A. Öcal[3], Ö. Çınar[4]

[1]*Eastern Mediterranean University Dr. Fazıl Küçük Faculty of Medicine, Histology and Embryology, Famagusta, Turkey*
[2]*Etlik Zübeyde Hanım Gynecology Education and Research Hospital, Assisted Reproductive Techniques and IVF Unit, Ankara, Turkey*
[3]*Etlik Zübeyde Hanım Gynecology Education and Research Hospital, Assisted Reproductive Techniques and ART Unit, Ankara, Turkey*
[4]*Ankara University School of Medicine, Histology and Embryology, Ankara, Turkey*

Study question: Assuming the relationship between IVF success and the quantity of SSCs in discarded-TESE material, should we consider post-TESE tubules as future sources of SSCs?

Summary answer: SSCs are found in post-TESE tubules which is routinely discarded. There is a statistically significant relationship between SSEA4 positivity and pregnancy rate.

What is known already: SSCs differentiate to mature spermatozoa by a process called spermatogenesis, during which stage-specific proteins play roles and can be used to evaluate the differentiation mechanisms. Spermatozoa from azoospermia patients can be obtained via surgical methods like TESE. Following TESE, not only operated region of testis heals with fibrosis causing a loss in sperm production but also remaining parts of the isolated seminiferous tubules, which may harbor SSCs, are discarded after collection of spermatozoa. The questions that what we lose after TESE in terms of SSCs and if there is a correlation between amount of SSCs and IVF success still stand.

Study design, size, duration: After ethical board approval, materials were obtained from 45 non-obstructive azoospermia patients who applied for a governmental IVF-center between 2015 and 2017. After TESE operation and the collection of spermatozoa for IVF treatment, remaining seminiferous tubules to be discarded were collected for this study. Outcomes of IVF including, fertilization, embryo development and pregnancy rates were obtained from the IVF center to evaluate the relationship between IVF success and analyzed parameters.

Participants/materials, setting, methods: Obtained tissue materials were stained with antibodies that were produced against DDX4, MAGEA4, SSEA4 and Oct4 proteins which are used to determine various differentiation steps of spermatogenesis and considered as SSCs markers. The distribution and intensity of those markers were evaluated by routinely used histological scoring techinquetechnique (H-SCORE). The correlation between IVF outcomes and H-SCORE analysis were evaluated by appropriate statistical tests. Values were presented as mean±S.D.

Main results and the role of chance: Cytoplasmic MAGEA4 and SSEA4 expressions at the basal compartments of seminiferous tubules indicated the presence of spermatogonia, while the strong juxta-luminal and mid-basal expression of DDX4 demonstrated the presence of spermatocytes and spermatids. Cytoplasmic expression of Oct4 was also detected in spermatogonia and spermatocytes but no evidence of expected nuclear expression was encountered. Since the IVF center indicated that spermatozoa were found from 27 of total 45 patients for ICSI, hereupon these groups were considered as Sp(+) and others Sp(-). First, H-SCORE outcomes of Sp(+) patients (n = 27) were compared with Sp(-) (n = 18) ones, and found that albeit outcomes of DDX4 staining in Sp(+) parameter reach to significant levels. Considering the pregnancy rates, 9 of the Sp(+) patients resulted with pregnancy, Pr(+) and only SSEA4 outcomes reach to statistically significant levels (121 ± 51) compared to Pr(-) (n = 16) ones (74 ± 49), p = 0.048. The expression pattern of germ cell markers suggested the possible chance of spermatogenesis failure at different stages of spermatogenesis within the seminiferous tubules of Sp(-) samples, whereas the H-Score values showed no significant difference of germ cell presence among the groups.

Limitations, reasons for caution: A comparison between obstructive and non-obstructive cases would be informative to understand the SSCs reserve in spermatogenesis and possible relationship with IVF success. Since seminiferous tubules show high variations in terms of positivity of SSCs markers, similar studies with higher case numbers will decrease the role of chance factor.

Wider implications of the findings: This study highlights the requirement of future studies aiming the isolation, freezing and also in-vitro maturation of SSCs particularly in oligo/astheno/azoo-spermia patients who may lose their SSCs reserve by a surgical application, TESE, and also concludes that testicular reserve needs more attention for IVF treatments like ovarian reserve.

Trial registration number: N/A.

P-793 Characterization of human granulosa progenitor cells as a potential source for the treatment of chemotherapy-induced ovarian damage

B. Cai, L. Baomin, X. Yanwen, Z. Canquan

First Affiliated Hospital of SunYat-sen University, reproductive medicine center, Guangzhou-Guangdong, China

Study question: Can human granulosa progenitor cells which derived from human mural granulosa iPSCs (GiPSCs) restore chemotherapy-induced ovarian damage and what's the underlying molecular mechanism?

Summary answer: Human granulosa progenitor cells which derived from human mural granulosa iPSCs, may restore damaged ovarian function through the Paracrine pathway.

What is known already: Young female patients who received chemotherapy frequently face premature ovarian failure (POF), for which there were currently no ideal treatments or medications. Furthermore, apoptosis of ovarian granulosa cells were an important mechanism underlying the decline in ovarian reserve and function which can be effectively alleviated through some kinds of stem cell transplantion.

Study design, size, duration: Mice ovaries were injured with cyclophosphamide to create a damaged ovary mice model. Transplanted GiPS-derived granulosa progenitor cells were injected into the tail vein of sterilized mice (n = 20), or cell culture medium was injected into the sterilized mice via the tail vein as cell-media group (n = 20). Nonsterilized mice were untreated controls (n = 20). After 1 month,ovarian tissue weight,plasma E2 level,and the number of follicles was compared in all groups.

Participants/materials, setting, methods: Human mural granulosa iPSCs were reprogrammed from mural granulosa cells collected from egg follicles retrieved from women undergoing infertility treatment using Sendai viral vectors.Then we used two step approaches comprising in vitro treatments with cocktails of growth factors (Wnt 3a,ActivinA,BMP4,ect) for 12days.After passaged 3 times,we obtained the granulosa progenitor cells(GPCs). Expression of granulosa cell, ES markers and metabolic culture medium were analyzed.These cells and media were injected into the tail vein of sterilized mice.

Main results and the role of chance: GiPS-derived granulosa progenitor cells expressed OCT4, but not GC lineage markers. Also are capable of clonogenic self-renewal and extensive proliferation *in vitro* and could differentiate into neural or mesenchymal cell lineages, as well as GCs, with the ability to produce E2 from testosterone, under defned conditions. After transplanted into the POF models 1 month,the Ovarian tissue weight,plasma E2 level,and the number of follicles were all significantly higher in cell treated group compared with chemoablated group,but approached the same effect between cell and cell media group. After using human cytokines array to analyze the cell media,revealed that many key cytokines were in high level, participating in a variety of biological processes including apoptosis, angiogenesis, cell cycle and immune response. These results suggested that GiPS-derived granulosa progenitor cells may not only effectively enhance granulosa cells growth and repair damaged ovarian tissue, but regulating the ovarian tissue niche through the Paracrine pathway.

Limitations, reasons for caution: Although GiPSCs-derived granulosa progenitor cells did not induce teratoma formation in vivo in the POF mice,the undifferentiated iPSCs are still potential risk in clinical trial in future.

Wider implications of the findings: Our research results showed that GiPSCs-derived granulosa progenitor cells can repair ovarian injury, stimulate regeneration, and improve ovarian function. GiPSCs-derived granulosa progenitor cells transplantation may provide an effective and novel method for treating POF.

Trial registration number: not applicable.

P-794 Feasibility of CRISPR-Cas9 on the human sperm cell

D. Choi, B. Chin, C. O'Neill, S. Cheung, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: What are the optimal transfection parameters to ensure viability of spermatozoa in a CRISPR-Cas9 protocol?

Summary answer: Among all different parameters tested, 1100 V, 20 ms, 1 was the optimal set to successfully transfect CRISPR-Cas9 plasmid in human spermatozoa retaining their motility.

What is known already: The CRISPR-Cas9 system recently made headway in reproductive medicine by a group of researchers that used viable human embryos to correct a mutation that causes hypertrophic cardiomyopathy, a severe heart condition in humans. Through intracytoplasmic sperm injection (ICSI), the researchers injected CRISPR-Cas9 solution and spermatozoa

simultaneously into an egg. However, there is currently no research done on using the CRISPR-Cas9 tool directly on human sperm. Importantly, to date, no known transfection parameter optimal for human sperm cells has been described, especially when compared to various known transfection parameters utilized for somatic cells.

Study design, size, duration: Our aim is to find the optimal transfection parameters for human spermatozoa that can ensure the highest viability and motility of cells after exposing them to high voltage pulses. To meet this goal, we designed a unique 24-well optimization protocol, in which 24 different sets of transfection parameters were tested. We plan to use CRISPR-Cas9 on sperm cells to knockout LAMA1, a gene that is found to be upregulated in male infertility patients.

Participants/materials, setting, methods: As a preliminary experiment, we transfected (Neon Transfection System, Invitrogen) embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) grown in vitro with Oct3/4 CRISPR-Cas9 knockout plasmid utilizing a GFP reporter gene. Successful transfection was the absence of GFP expression. We then began our first attempt using human sperm cells and evaluated different sets of parameters ranging from 800 V, 27 ms, 5 to 1700 V, 20 ms, 1.

Main results and the role of chance: The results of our preliminary experiment using ESCs and iPSCs were highly successful as they matched the threshold of 79% transfection efficiency found in prior research with DNA transfection of stem cells. Oct3/4 expression was remarkably decreased by 81 ± 2% after transfection when compared to the initial expression.

As for our experiment with human spermatozoa, we used a donor sperm sample with initial concentration of 70 ± 6×10^6/ml and a motility of 40.3 ± 4%. Following density gradient, concentration became 22 ± 11×10^6/ml and motility 86.2 ± 3%, respectively. The highest motility after transfection was only 5.9 ± 3%. Moreover, because spermatozoa were further diluted after transfection, the concentration decreased to 0.03 ± 7×10^6/ml.

Going forward, we plan to use semen samples with higher concentration and motility to obtain a higher motile fraction after density gradient. After transfection, we intend to isolate the motile portion from the immotile by microfluidics to avoid the decaying cells' affect on viability of the motile sibling spermatozoa due to leakage of acrosomal enzyme and production of reactive oxygen species (ROS). In this way, we can allow more time for plasmids to execute the double-stranded break and for the DNA to repair itself while retaining cell viability.

Limitations, reasons for caution: The execution of transfection experiments on spermatozoa dealt with the structural peculiarity and the innate kinetic characteristics of this cell, which may have affected the accuracy and reproducibility of our analysis. However, utilization of CRISPR-Cas9 on human spermatozoa may ease qualms related to the direct genetic manipulation of embryos.

Wider implications of the findings: Our results of finding motile spermatozoa after exposing them to high voltage pulses through electroporation gives hope that correcting mutations in human sperm cells is possible. Genetic manipulation on the male gamete may prove more reliable in granting the desired effect on the resulting conceptus.

P-796 Intrauterine infusion of autologous peripheral blood mononuclear cells in frozen blastocyst transfer improves clinical outcome and metabolomic profile in repeated implantation failure- A pilot study

B. Chakravarty[1], S. Wasim[1], S. Chakrabarti[1], P. Banerjee[1], K. Chaudhury[2], P. Chakraborty[3]

[1]*Institute of Reproductive Medicine, Assisted Reproductive Technology, Kolkata, India*
[2]*Indian Institute Of Technology, smst, Kharagpur, India*
[3]*Institute of Reproductive Medicine, Infertility, Kolkata, India*

Study question: Do autologous peripheral blood mononuclear cells (PBMC) improve endometrial receptivity and clinical pregnancy in frozen embryo transfer (FET) in women with repeated implantation failure (RIF)?

Summary answer: Infusion of PBMC improves clinical pregnancy and live birth rate in RIF, which could be associated with down-regulation of metabolites like tryptophan, valine and lysine.

What is known already: Despite advancement of IVF protocols and assessment of embryo morphokinetics, methodologies continue to strive to optimize IVF success in management of RIF. Autologous PBMC is a convenient source of adult stem cell; usage being to increase implantation potential of embryos and increase in endometrial receptivity. Recent studies document metabolic profiling as a promising platform for assessment of endometrial receptivity. Furthermore, infusion of stem cells into spiral arterioles of patients with refractory Asherman's syndrome has shown improvement in implantation rate. In view of these facts, use of PBMC in the management of RIF holds a promising tool for the future.

Study design, size, duration: Prospective study from January 2016 to January 2017; 160 patients with ≥ 3embryo transfer (ET) failure (fresh and frozen) undergoing day5 FET were divided into Group A (n = 73; intrauterine infusion of PBMC) and B (n = 87; without PBMC infusion). Mononuclear cells were used as a source of stem cell, isolated from patient's peripheral blood by density gradient centrifugation using commercially available lymphoprep. Main outcome measures were: implantation rate, clinical pregnancy rate and live birth rate.

Participants/materials, setting, methods: All patients received estradiol valerate 2 mg thrice daily from d2 onwards. Intra-uterine infusion of PBMC was done on D5 of cycle in Group A. Once endometrial thickness reached ≥7 mm, progesterone was administered for five days. Blood samples were collected on day of embryo transfer. Samples were analyzed using 700-MHz NMR spectrometer and acquired spectra were subjected to chemometric and statistical analysis. $p< 0.05$ was considered to be significant as evaluated by chi-square and t-test.

Main results and the role of chance: Baseline clinical parameters and number of embryos transferred were found to be comparable in both groups. A significant increase ($p< 0.01$) in implantation rate was observed in group A (23.97%) as compared to group B (9.2%). Clinical pregnancy rate was found to be significantly higher ($p <0.05$) in group A (38.36%) versus group B (17.24%). Simultaneously, live birth rate in group A (24.66%) was significantly higher than Group B (11.49%). Miscarriage rate was higher in group A, difference being non significant. Valine, tryptophan, and l-lysine, were found to be significantly down-regulated ($p< 0.03$, $p<0.01$; $p<0.02$) with fold change values of 0.81, 0.76, 0.74 respectively in women with RIF after PBMC infusion when compared with those without administration of PBMC. However, when metabolomic markers were evaluated between pregnant and non-pregnant subjects in either group the difference was not statistically significant. Since the interplay between these molecules in RIF is complex, study holds merit for further exploration.

Limitations, reasons for caution: Owing to application of PBMC in FET cycle, we cannot evaluate the potential receptivity markers in endometrium to ascertain the immunomodulatory role of PBMC for successful blastocyst implantation. In-depth studies of the arginine metabolic pathway in endometrial tissues seem necessary to validate our findings.

Wider implications of the findings: Intra-uterine PBMC infusion can be relatively inexpensive and minimally invasive treatment for patients with RIF; simultaneously it may be beneficial in recurrent pregnancy loss aiming to improve endometrial receptivity. We speculate that serum metabolomics can provide an improved understanding of increased clinical pregnancy after PBMC infusion in women with RIF.

Trial registration number: Not applicable.

P-797 Proteomic profiling of the exosomes released by endometrial mesenchymal stem cells: possible relations with embryo development and implantation

F. Marinaro[1], V. Alvarez[1], R. Blázquez[1,2], E. López Nieto[1], B. Macías-García[3], M. Gómez Serrano[4], I. Jorge Cerrudo[2,4], J. Vázquez[2,4], F.M. Sánchez-Margallo[2,5], J. García Casado[1,2]

[4]Centro Nacional Investigaciones Cardiovasculares CNIC, Cardiovascular Proteomics Lab, Madrid, Spain
[5]Jesús Usón Minimally Invasive Surgery Centre, Jesús Usón Minimally Invasive Surgery Centre, Cáceres, Spain

Study question: Is the proteomic profile of exosomes derived from human endometrial mesenchymal stem cells (exo-endMSCs) associated with embryo development and implantation?

Summary answer: The bioinformatics analyses of exo-endMSCs have identified exosomal proteins that are involved in the maternal-embryo cross-talk influencing the embryo's developmental competence and subsequent implantation.

What is known already: Implantation failure is the most common cause of recurrent pregnancy loss in humans who resort to assisted reproduction technologies (ARTs). Among others, hormonal or metabolic disorders, advanced age, immunological factors, infections or uterine abnormalities can affect endometrial receptivity. In addition, diminished embryo developmental competence due to any of these conditions increases the likelihood of implantation failure. The cross-talk between the endometrium and the embryo is mediated by paracrine factors delivered by the exo-endMSCs, but a complete description of the proteomic profile of these microvesicles has not been reported yet.

Study design, size, duration: Endometrial Mesenchymal Stem Cells (endMSCs) were isolated from menstrual blood of healthy women (n = 2). Supernatants from these cells were collected every 72 hours. The collected supernatants were enriched and purified to isolate the released exosomes.

Participants/materials, setting, methods: The endMSCs were *in vitro* expanded and characterized by flow cytometry. The exo-endMSCs were isolated and characterized by nanoparticle tracking analysis and flow cytometry. Then, protein extracts from exo-endMSCs were processed by high-resolution liquid chromatography coupled to mass spectrometry-based proteomic analyses (HPLC-MS). Finally, the functional enrichment analysis was performed by using the DAVID functional annotation database (https://david.ncifcrf.gov/).

Main results and the role of chance: EndMSCs analysis did not demonstrate positive staining for CD34, CD45 or HLA-DR while they expressed the CD29, CD56, CD44, CD73, CD90, CD105 stemness markers. The mean size of the isolated exo-endMSCs was 153.5 ± 63.05 nm (mean ± SD) and showed a positive expression of the exosome-related proteins CD9 and CD63. A total of 714 proteins (with more than two peptides per protein at 1% FDR) were identified in the exo-endMSCs of both cell lines.

Among the 714 selected proteins, 517 of them were associated to the Gene Ontology term *extracellular exosome* (GO:0070062, $p < 0.01$, 5% FDR) and 60 of them were present in the 100 top identified proteins in ExoCarta database.

Moreover, exo-endMSCs proteins were connected to several biological processes and molecular functions related to embryo developmental competence and implantation, such as *cell-cell adhesion* (n = 55 in GO:0098609), *extracellular matrix organization* (n = 57 in GO:0030198), *cadherin binding involved in cell-cell adhesion* (n = 65 in GO:0098641), and also to the Reactome pathway *ECM proteoglycans* (n = 35 in R-HSA-3000178).

Finally, it is worth mentioning that 11 exosomal proteins have been previously identified in endometrial cells extracts from women during the peri-implantation phase.

Limitations, reasons for caution: The microvesicles used were obtained from 2 donors showing differing protein profiles. Increasing the number of endMSC lines will help to fully identify the proteome of exo-endMSCs. Further studies involving *in vitro* implantation assays and embryo transfers coupled to exo-endMSCs are required to clarify their importance as ARTs coadjutants.

Wider implications of the findings: This study demonstrated that exo-endMSCs may be involved in the embryo-maternal cross-talk. Several proteins from exo-endMSCs are also released by endometrial cells and involved in embryo implantation and development. These proteins could be considered predictive biomarkers for implantation and exo-endMSCS could be used as coadjutants during *in vitro* embryo culture.

Trial registration number: Not applicable.

P-798 Differentiating mouse induced pluripotent stem cells into male germ cells through embryoid bodies

V. Lu, A. Parrella, S. Chow, B. Chin, D. Choi, M. Irani, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: We assess the effectiveness of the hanging drop method with specific growth factors to differentiate induced pluripotent stem cells into male germ cells.

Summary answer: Embryoid bodies (EB) supplemented and maintained in hanging droplets (HD) containing specific differentiating factors generated a high proportion of mitotic germ cells.

What is known already: Many methods have been proposed to coax stem cells into male germ cells. One simple method to induce germ cell differentiation utilizes the formation of EBs, three-dimensional structures that create microtissues which simulate *in vivo* conditions. While EBs can spontaneously differentiate into various cell types without external influence, specific growth factors can be added in order to reproduce *in vivo* cell-signaling processes and ensure differentiation of a higher proportion of stem cells into germ cells.

Study design, size, duration: Over a four-month period, 100 EBs were formed from mouse induced pluripotent stem cells (*mi*PSC) using the hanging drop method. EBs were maintained in HDs after formation and differentiated in a 2-step culture system, each with a specific medium composition. Expression of PGC markers was assessed by immunofluorescence staining.

Participants/materials, setting, methods: Prior to differentiation, *mi*PSCs were maintained on mouse embryonic fibroblast (MEF) cells. Once confluent, colonies were trypsinized. HDs were formed from 25uL droplets containing *mi*PSCs at a concentration of 1×10^5 cells/ml. Step one medium contained Activin A, bFGF, and KSR. After 3 days, EBs were transferred to HDs containing step two medium composed of LIF, BMP4, BMP8b, SCF, and EGF. On day 8, EBs were treated with collagenase and stained for OCT4, VASA, and DAZL.

Main results and the role of chance: After the development of 100 EBs in their respective HDs, EBs were re-plated on day 3 to corresponding HDs containing step two medium. EBs were disaggregated through the usage of collagenase IV in order to isolate cells for immunofluorescence staining. In order to identify the stage of *in vitro* spermatogenesis achieved, OCT4, VASA, and DAZL expression was compared between EBs cultured in the 2-stage growth factor-conditioned medium system and control EBs maintained in standard culture medium. Of the isolated cells, 86% were strongly positive for OCT4 compared to 54% of cells isolated from control EBs cultured without differentiating factors. Additionally, EBs cultured with differentiating factors yielded 31% VASA-positive cells, whereas control EBs only yielded 1% VASA-positive cells. Furthermore, EBs cultured with differentiating factors yielded 4% DAZL-positive cells, whereas control EBs only yielded 1% DAZL-positive cells. The retained expression of OCT4, along with the presence of VASA-positive and DAZL-positive cells, strongly indicate that the cells reached the spermatogonia/spermatocyte cell stage. Cells that were positive for VASA and DAZL without OCT4 expression also suggest that a fraction of cells were able to progress to the advanced meiotic stages of *in vitro* spermatogenesis.

Limitations, reasons for caution: This preliminary study only attempts to achieve early stages of differentiation in *mi*PSC. One possible direction can be to use retinoic acid as a third-step culture medium to coax PGCs into meiosis. Furthermore, for this to be applicable for clinical use, trials need to be confirmed in human iPSC.

Wider implications of the findings: Artificial gametogenesis is a developing technology that will ultimately allow azoospermic men to develop spermatozoa from their stem cells. Mouse iPSC provide a step towards raising genotyped cells suitable for clinical treatment for patients with spermatogenic arrest or even germ cell aplasia.

Trial registration number: N/A.

P-799 In vitro generation of germ cells from human induced pluripotent stem cells

M. Irani, S. Chow, V. Lu, D. Choi, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can we differentiate human induced pluripotent stem cells (hiPSC) into male germ cells using the hanging drop (HD) culture system?

Summary answer: The culture of hiPSC within HDs containing several growth factors generated male germ cells of different stages of development.

What is known already: Several monolayer culture systems have been suggested for differentiating stem cells into male germ cells. However, the natural three-dimensional (3D) condition for the cells within a tissue allows them to establish important connections among each other. The culture of stem cells within embryoid bodies (EBs) in HDs has been proposed as a simple method to simulate the in vivo 3D environment. In fact, we have previously described the use of EBs within HDs containing specific factors to successfully differentiate mouse embryonic stem cells and mouse iPSC into male germ cells.

Study design, size, duration: Over a three-month period, 50 EBs were formed from hiPSC using the hanging drop method. EBs were maintained in HDs after formation and differentiated in a 2-step culture system, each with a specific medium composition. Expression of germ cell markers was assessed by immunofluorescence staining.

Participants/materials, setting, methods: HiPSCs were originally maintained undifferentiated on fibronectin in the presence of growth factors and ROCK inhibitor. Colonies were trypsinized and HDs were formed from 25uL droplets containing hiPSCs (1×10^5 cells/ml). In the first three days, the medium was composed of Activin A, bFGF, and KSR. Then, the medium of HDs was modified to contain LIF, BMP4, BMP8b, SCF, and EGF. On day 12, cells were stained for OCT4, VASA, DAZL, and BOULE.

Main results and the role of chance: On day 12, and after culturing 50 EBs for 3 days in step-1 medium followed by 9 days in step-2 medium, collagenase IV was used to disaggregate EBs. Cells were isolated and stained for OCT4, VASA, DAZL, and BOULE to determine the stage of in vitro spermatogenesis. The staining of EBs was compared to those of undifferentiated hiPSC, which were 84% positive for OCT-4 but negative for VASA, DAZL, and BOULE. EBs cultured with differentiating factors yielded 75% OCT-4-positive cells, 60% VASA-positive cells, 40% DAZL-positive cells, and 5% BOULE-positive cells. The detection of VASA–positive and DAZL–positive cells that preserved the expression of OCT-4 is a strong evidence of the differentiation of hiPSC to spermatogonia/spermatocyste cell stage. In addition, the presence of cells expressing VASA, DAZL, and/or BOULE while they were negative for OCT-4 suggests an advanced differentiation of hiPSC reaching meiotic stages.

Limitations, reasons for caution: Despite the encouraging preliminary data, this study did not confirm the completion of in vitro spermatogenesis and attainment of post-meiotic stages. A potential strategy to overcome this limitation would be the addition of retinoic acid as a third-step culture medium to coax primordial germ cells into meiosis.

Wider implications of the findings: In vitro gametogenesis is an important technology that provides an option for azoospermic men to develop spermatozoa from either their stem cells or skin fibroblasts. HiPSCs could potentially help azoospermic men who fail testicular sperm extraction due to spermatogenic arrest or germ cell aplasia to have biological children.
