49 TH SCIENTIFIC MEETING
OF THE ITALIAN
STATISTICAL SOCIETY
PALERMO 20-22 JUNE

1. Preface

This book includes the papers presented at the "49th Meeting of the Italian Statistic Society". The conference has registered 445 participants, 350 reports divided into 4 plenary sessions, 20 specialised sessions, 25 sessions solicited, 27 sessions spontaneous, 2 poster sessions. The high number of participants, the high quality of the interventions, the productive spirit of the conference, the ability to respect the time table, are the main indices of the full success of this conference. The meeting hosted also, as plenary sessions, the ISTAT annual report 2018, and a round table on statistics and job markets. Methodological plenary sessions concerned with ordinal data, the dynamics of climate change and models in biomedicine.

Moreover, two related events were held: Start-up Research (SUR) and Stats Under the Stars (SUS4). The SUS4 event attracted many sponsors of statistical, financial, editorial fields as well as numerous students, not only from Italy but also from abroad (Groningen, Tyumen, Barcelona, and Valencia): 98 students for a total of 25 teams. The SUR was a 2-day meeting where small research groups of young scholars, advised by senior researchers with a well-established experience in different areas of Statistics, was asked to develop innovative methods and models to analyse a common dataset from the Neurosciences.

2. Plenary Sessions

A new paradigm for rating data models
Un nuovo paradigma per modelli su dati di preferenza

Domenico Piccolo

Abstract Rating data arise in several disciplines and the class of Generalized Linear Models (GLM) provides a consolidated methodology for their analysis: such structures (and a plethora of variants) model the cumulative probabilities of ordinal scores as functions of subjects' covariates. A different perspective can be adopted when considering that discrete choices as ordinal assessments are the result of a complex interaction between subjective perception and external circumstances. Thus, an explicit specification of the inherent uncertainty of the data generating process is needed. This paradigm has triggered a variety of researches and applications, conveying in the unifying framework of GEneralized Mixtures with uncertainty (GEM) which encompasses also classical cumulative models. Some critical discussions conclude the paper.

Abstract *Dati di preferenza sono presenti in differenti ambiti e la classe dei modelli lineari generalizzati fornisce una metodologia consolidata per la loro analisi. Una prospettiva differente deriva dal considerare le scelte discrete che producono dati ordinali come un processo derivante da (almeno) due componenti: una percezione soggettiva (feeling) ed una ineliminabile indecisione (uncertainty). Cosí, una specificazione esplicita dell'indecisione nel processo generatore dei dati di preferenza si é resa necessaria. Tale paradigma ha generato numerose varianti e sviluppi che includono anche l'approccio piú tradizionale. Il lavoro introduce i modelli* GEM *e si conclude con alcune considerazioni critiche.*

Key words: Scientific paradigm, Rating data, Empirical evidence, Statistical models, CUB models, GEM models

1 Introduction

Statistical models are formal tools to describe, understand and predict real phenomena on the basis of some recognizable mechanism to be effectively estimated and tested on empirical data. This approach is ubiquitous in modern research and establishes the basis to advance disputable topics in any field: a model can be falsified and rejected to favour a more sustainable alternative, as it is for any progress in scientific research and human knowledge.

In this perspective, the specification step of a model derives from empirical evidence, rational deductions, analogy and similarities. Given a set of data and contextual information, statistical methods are nowadays sufficiently developed to provide suitable specifications: time series, longitudinal models, qualitative variables, count data, survival measures, continuous or discrete observations, experimental design, reliability and quality control, etc. are settings where consolidated theories and effective methods suggest consistent specifications.

These topics will be discussed in the field of ordinal data modelling, as ratings of objects or activities, opinions towards facts, expressions of preferences, agreement to sentences, judgements, evaluations of items, perceptions, subjective sensations, concerns, worry, fear, anxiety, etc. All these expressions are collected as ratings/scores by means of verbal or pseudo-verbal categories. Such data are available in different fields: Marketing researches, Socio-political surveys, Psychological enquiries, Sensory sciences and Medicine, among others. For these analyses, several approaches are available as log-linear and marginal models [48], contingency tables inference [47], and so on. In fact, the leitmotif of our discussion is that observed rating data are realizations of a (genuine) discrete or of a discretized process derived by an intrinsically continuous (latent) variable [6].

2 The classical paradigm

Emulating the approach introduced for the logistic regression, the paradigm of cumulative models considers the probability of responses less or equal to a rating r as a function of selected regressors. A convenient link is necessary to establish a one-to-one correspondence between a 0-1 measure (the probability) and a real quantity (the value of the regressors); as a consequence, probit, logit, complementary log-log links, etc. are proposed to specify the corresponding models.

The vast quantity of results derived from such procedures represents the dominant paradigm in theoretical and empirical literature about the statistical analysis of rating data. The process of data generation is introduced by invoking -for each subject- a latent variable Y_i^*, taking values along the real line and related to the values $\boldsymbol{t}_i$ of p explanatory subjects' covariates via the classical regression model: $Y_i^* = \boldsymbol{t}_i\boldsymbol{\beta} + \varepsilon_i, i = 1,2,\dots,n$. For a given m, the relationship with the discrete ordinal variable R_i, defined over the discrete support $\{1,2,\dots,m\}$, is provided by:

$$\alpha_{r-1} < Y_i^* \leq \alpha_r \qquad \Longleftrightarrow \qquad R_i = r\,, \quad r = 1,2,\dots,m\,,$$

where $-\infty = \alpha_0 < \alpha_1 < \ldots < \alpha_m = +\infty$ are the thresholds (cutpoints) of the continuous scale of the latent variables Y_i^*.

Then, if $\varepsilon_i \sim F_\varepsilon(.)$, the probability mass function of R_i, for $r = 1,2,\dots,m$, is:

$$Pr(R_i = r) = Pr(\alpha_{r-1} < Y_i^* \leq \alpha_r) = F_\varepsilon(\alpha_r - \boldsymbol{t}_i\boldsymbol{\beta}) - F_\varepsilon(\alpha_{r-1} - \boldsymbol{t}_i\boldsymbol{\beta}), \qquad (1)$$

where $Pr(R_i \leq r|\boldsymbol{\theta},\boldsymbol{t}_i) = F_\varepsilon(\alpha_r - \boldsymbol{t}_i\boldsymbol{\beta})$ for $i = 1,2,\dots,n$ and $r = 1,2,\dots,m$.

This specification requires the knowledge of $\boldsymbol{\theta} = (\boldsymbol{\alpha}', \boldsymbol{\beta}')$ parameters, that is the $(m-1)$ intercept values $\boldsymbol{\alpha} = (\alpha_1,\dots,\alpha_{m-1})'$ in addition to the explicit covariate parameters $\boldsymbol{\beta} = (\beta_1,\dots,\beta_p)'$.

When selecting logistic random variables ε_i, the probability of a single rating turns out to be:

$$Pr(R_i = r|\boldsymbol{\theta},\boldsymbol{t}_i) = \frac{1}{1+\exp(-[\alpha_r - \boldsymbol{t}_i\boldsymbol{\beta}])} - \frac{1}{1+\exp(-[\alpha_{r-1} - \boldsymbol{t}_i\boldsymbol{\beta}])}\,, \qquad (2)$$

for $i = 1,2,\dots,n$ and $r = 1,2,\dots,m$. As a consequence of proportionality properties, these models are known as *proportional odds models* (POM) [1, 66].

Cumulative models have been embedded into the GLM perspective [51] and generalized in several directions: multilevel, varying choice of thresholds, multivariate setting, *conditional logits* including both subjects' and objects' covariates [52], variable effect $\boldsymbol{t}_i\boldsymbol{\beta}_j$ as in *stereotype* models [5], or thresholds which depend on covariates as in *partial proportional odds models* [57], and models with dispersion effects as the *location-scale models* [50] or *location-shift models* [67].

Quite often, the interpretation of these models takes advantage of odds and log-odds measures which are quantities easily manageable by Medicine and Biomedical researchers; similarly, plotting devices explain the direction and the effect of significant covariates on the ordinal responses and new graphical solutions have been recently advanced [68]. In order to anchor the estimated results to easier and more interpretable indexes [2, 3] some difficulties have been emphasized.

Indeed, some drawbacks of the classical specification should be noticed:

- Data generating process refers to a latent variable whose unobservable distribution defines the discrete distribution for the observable ratings.
- It is difficult to accept that -in any circumstance- subjects perform choices by considering ratings not greater than a fixed one, whereas it is more common to consider choices as determined by the “stimulus” associated to a single category and its surrounding values. In fact, the relationship (2) is difficult to manage for deriving immediately the effect of a set of covariates on the categorical response.
- If ratings generated by several items have to be clustered, ranked or classified, unconditionally from covariates, the classical setting leads to a saturated model, which implies an arithmetic equivalence between observed and assumed distributions.

A different paradigm has been proposed for rating data [58, 28] which is substantially based on the explicit modelling of the data generating process of the ordinal observations [44].

3 A generating process for rating data

Finite mixtures have been advanced by several Authors for analysing ordinal data (see [62] for a review) and most of them are motivated for improving fitting. They assume a convex combinations of probability distributions belonging to the same class of models or discretize continuous random variables to get appropriate probability mass functions for the observed ratings: in this vein, the reference to the Beta distribution with several variants is frequent: [55, 32, 65, 31, 70], among others. A different proposal arises from stochastic binary search algorithm [8].

In this scenario, psychological rationale related to the choice of ordinal scores leads to the introduction of CUB models [58]. A mixture distribution is specified to model the *propensity* to adhere to a meditated choice (formally described by a shifted Binomial random variable) and to a totally random one (described by a discrete Uniform distribution). Original motivations for the selection of these random variables were mostly based on a simplicity criterion [28]. However, the Binomial random model may be interpreted as a counting process of a sequential selection among the m categories and accounts for the genuine feeling of the response (appendix of [43]). Then, the Uniform distribution has been introduced as the most extreme among all discrete alternatives and accounts for the inherent uncertainty of the choice [39, 34, 63]. Independently, a psychological support to a direct modelling of a discrete component in the ordinal choices has been recently proposed by Allik [4].

Then, for a known $m > 3$, given a matrix $\boldsymbol{T}$ of values for subjects' covariates, a CUB model for the i-th subject implies both stochastic and deterministic relationships defined, respectively, as:

$$\begin{cases} Pr\,(R_i = r \mid \boldsymbol{T}) = \pi_i\, b_r(\xi_i) + (1-\pi_i)\, p_r^U\,, & r = 1,2,\dots,m; \\ \pi_i = \pi_i(\boldsymbol{\beta}) = \dfrac{1}{1+e^{-\boldsymbol{z}_i\boldsymbol{\beta}}}\,; \qquad \xi_i = \xi_i(\boldsymbol{\gamma}) = \dfrac{1}{1+e^{-\boldsymbol{w}_i\boldsymbol{\gamma}}}\,; & i = 1,2,\dots,n\,. \end{cases} \tag{3}$$

We set $b_r\,(\xi_i) = \binom{m-1}{r-1}\xi_i^{m-r}\,(1-\xi_i)^{r-1}$ and $p_r^U = 1/m$, $r = 1,2,\dots,m$, for the shifted Binomial and Uniform probability mass functions introduced to model feeling and uncertainty, respectively. Here, $(\boldsymbol{z}_i', \boldsymbol{w}_i')'$ are the values of the subjects' covariates extracted from the subjects' covariates data matrix $\boldsymbol{T}$. The acronym CUB stands for *C*ombination of a (discrete) *U*niform and (shifted) *B*inomial distribution.

Given the parameterization (3), it should be noticed that:

- the set of values $\boldsymbol{z}_i$ and $\boldsymbol{w}_i$ may be coincident, overlapped or completely different;

- whereas $1-\xi_i$ characterize the Binomial distribution of the mixture and are immediately related to the strength of the feeling component (they involve the modal value of the responses), the uncertainty parameters $1-\pi_i$ are just the weights of the Uniform distribution assumed for the indecision in the responses (thus, they are not involved in the specification of p_r^U);
- although psychological arguments are sufficient for motivating uncertainty as an important component of an ordinal choice, it is possible to show that uncertainty may be also generated when genuine Binomial choices manifest small variations in the feeling parameters.
- CUB models are able to detect a possible relationship between feeling and uncertainty when a common covariate is significant for those components.

Any one-to-one mapping $\mathbb{R}^p \leftrightarrow [0,1]$ between parameters and covariates is legitimate but the logistic function is to be preferred for simplicity and robustness properties [42]. Thus, the relationships:

$$logit\,(1-\pi_i)\,=\,-\boldsymbol{z}_i\boldsymbol{\beta}\,;\quad logit\,(1-\xi_i)\,=\,-\boldsymbol{w}_i\boldsymbol{\gamma};\qquad i=1,2,\ldots,n. \tag{4}$$

immediately relates uncertainty weights and feeling measures to subjects' covariates.

Although model (3) has been introduced with covariates, one may specify a CUB distribution without such a constraint:

- if $\pi = aver(\pi_i)$ and $\xi = aver(\xi_i)$ are some averages of the individual parameters, the parameters $(\pi,\,\xi)$ can be used to compare the responses to different items;
- for a given i-th subject, the features of the implied CUB model conditional to $(\boldsymbol{z}_i,\,\boldsymbol{w}_i)$ may be investigated by letting $\pi_i = \pi$ and $\xi_i = \xi$.

In this way, a CUB probability distribution is defined as:

$$Pr\,(R=r\mid\boldsymbol{\theta}) = \pi\,b_r\,(\xi) + (1-\pi)\,p_r^U,\qquad r=1,2,\ldots,m. \tag{5}$$

where $\boldsymbol{\theta} = (\pi,\xi)' \in \Omega\,(\boldsymbol{\theta}) = \{(\pi,\xi):\ 0<\pi\leq 1, 0\leq\xi\leq 1\}$ and the parameter space $\Omega\,(\boldsymbol{\theta})$ is the (open left) unit square.

A CUB model is *identifiable* [36] for any $m>3$ whereas $m=3$ implies a saturated model. Not all the well-defined discrete distributions are *admissible* for a CUB model as, for instance, bimodal probability functions. However, if multimodality is a consequence of latent classes then a CUB model with an explanatory variable related to those classes is adequately fitted according to (3).

A qualifying feature of CUB models is their visualization: given the one-to-one correspondence between the probability mass function (5) and a single point in the parameter space $\Omega\,(\boldsymbol{\theta})$, it is immediate to compare different items in terms of feeling and uncertainty; furthermore, by including subjects' covariates as in (3), the effect of each covariate on either components is visualized and response profiles can be identified. Finally, when CUB models estimated for different clusters –specified by time, space, circumstances and/or covariates– the changes in the responses (in terms of feeling and uncertainty) are immediately shown in the same parameter space. In this respect, also more refined devices –as, for instance, Scatter Plot of Estimates (*SPE*)– have been advanced [45].

Inferential issues have been solved by asymptotically efficient maximum likelihood methods performed by EM procedures [59] which are implemented in an R package [45]. Residual analysis may be conducted [29]. Alternative inferential procedures as Bayesian approaches [25] and permutation tests [9] have been also established.

Successful applications of CUB models have been obtained in different fields and for dissimilar objectives [21, 26, 10, 15, 11, 24, 13, 17]. In addition, formal and empirical comparisons with cumulative models have been extensively discussed on both real and simulated data sets [62]. Especially, the performance of the novel class of models has been checked when heterogeneity is a heavy component: in these circumstances, the better performance of CUB model as measured by *BIC* criterion, for instance, is the consequence of parsimony. Moreover, CUB models correctly assign heterogeneity to a possible uncertainty as related to explanatory covariates, whereas in POM heterogeneity is scattered over the categories by means of estimated cutpoints.

In this class of models, feeling causes no interpretation problem since it is immediately related to the attraction towards the item (modal values of the distribution and feeling parameters are strictly related); on the contrary, some doubts concern the nature of the uncertainty component [33], especially when no subjects' covariates are introduced. Surely, the measure conveyed by $1-\pi$ includes at least three meanings:

- *subjective indecision*: the measure $1-\pi_i$ is related to the personal indecision of the i-th respondent;
- *heterogeneity*: for CUB model without covariates, $1-\pi$ summarizes heterogeneity of the responses with respect to a given item [12, 16];
- *predictability*: in case of predicting ordinal outcomes, π is a direct measure of predictability of the model with respect to two extremes: a discrete Uniform ($\pi \to 0$) and shifted Binomial ($\pi = 1$) distributions.

Indeed, the special mixture proposed for ordinal data allows for a single rating to convey information on both *feeling* and *uncertainty* parameters:

i) the observed r is directly related to ξ since the probability of high/low values of r may increase or decrease with $1-\xi$;

ii) the observed r has also a bond with π since, for each score r, it increases or decreases the relative frequencies of: $\left|Pr(R=r)-\dfrac{1}{m}\right| \propto \pi$. Then, modifying the distance from the Uniform situation, each response modifies also the information concerning the uncertainty.

4 The family of CUB models

Previous models have been generalized in several directions to adequately fit rating data and exploit parsimony in different contexts. Among the many variants, we mention the inclusion of *shelter effect* [37], also with covariates (G*e*CUB) [43], the cases when almost one dominant preference is expressed (CUSH) [16] or some proposal with varying uncertainty (as VCUB [34] and CAUB [63] for *response style effects*) and also by including random effects in the components (HCUB [38] and RCUB [64]) and connections with fuzzy analysis of questionnaires [30].

Then, CUB models have been usefully applied in presence of "don't know" answers (DK-CUB [54, 41]), for detecting latent classes (LC-CUB [35]), for managing missing values in ordered data [24], for considering a MIMIC jointly with a CUB model [19] and for implementing model-based trees [18]. Noticeable is the discussion of similarities with log-linear models [56].

Further significant issues are the multi-items treatments, when also objects' characteristics are considered [61], and some genuine and promising multivariate proposals [7, 22, 23, 20].

An important advancement considers *overdispersion* as a further component to be examined. Thus, the feeling parameter is interpreted as a random variable specified by a Beta distribution: so, a (shifted) Beta-Binomial distribution is considered for the feeling component and CUBE models are introduced [39, 60, 46]. This class is truly general since it includes several previous specifications (as IHG [27], for instance); in addition, it adds higher flexibility to CUB models with an extra parameter. Since CUB are nested into CUBE models, relative testing is immediate.

The importance to take explicitly uncertainty into account in designing statistical models for rating data has received an increasing consideration (as in CUP models: [69]); indeed, the inclusion of classical approach in the emerging paradigms is a desirable opportunity.

In fact, due to the complex functioning of decision making process, two components are definitely dominant: i) a primary attraction/repulsion towards the item which is related to the personal history of the subject and his/her beliefs with respect to the item; ii) an inherent indecision derived by the circumstances surrounding the choice. This argument is grounded on empirical evidence since any choice is a human decision, where taste, emotion, sentiment are substantial issues which manifest themselves as a random component denoted as *feeling*. Moreover, choice changes over time, with respect to the environment, the modality (verbal, visual, numerical, etc.) and the tool (face-to-face response, telephone, questionnaire, online, etc.) by which data are collected: these circumstances cause an inherent indecision denoted as *uncertainty*.

Then, each respondent provides observations which are realizations of a choice R_i generated by mixing the feeling X_i and the uncertainty V_i. Formally, let m be the number of categories and $\boldsymbol{t}_i^{(X)} \in \boldsymbol{T}$, $\boldsymbol{t}_i^{(V)} \in \boldsymbol{T}$, where $\boldsymbol{T}$ includes the values of the selected covariates to explain feeling and uncertainty, respectively.

For any well-defined discrete distributions for feeling X_i and uncertainty V_i, respectively, a *GEneralized Mixture model with uncertainty* (GEM) is defined as follows:

$$Pr\,(R_i = r \mid \boldsymbol{\theta}) = \pi_i \, Pr\left(X_i = r \mid \boldsymbol{t}_i^{(X)}, \boldsymbol{\Psi}\right) + (1-\pi_i)\, Pr\,(V_i = r)\,, \tag{6}$$

for $i = 1,\dots,n$ and $r = 1,\dots,m$. Here, $\pi_i = \pi(\boldsymbol{t}_i^{(V)}, \boldsymbol{\beta}) \in (0,\,1]$ are introduced to weight the two components and $\boldsymbol{\Psi}$ includes all the parameters necessary for a full specification of X_i. The probability distribution of the *uncertainty* component V_i is assumed known over the support $\{1,\dots,m\}$ on the basis of *a priori* assumptions.

GEM models (6) are a very flexible class of models to interpret and fit rating data since they may specify: main flavour of the responses and their uncertainty/heterogeneity, overdispersion in respondents' feeling, presence of a possible inflated category and different probability distributions for given covariates: a distribution function for a latent variable to be discretized (classical approach); a probability mass function (novel approach). Both of them may include uncertainty in their specification for better fitting and interpretation.

Thus, GEM is the new paradigm since it is an *inclusive class of models for ordinal data* which encompasses both classical and mixture models in a unique representation where distributions are not compelled to belong to the exponential family.

5 Occam's razor: believe it or not

Occam's razor refers to one of the first principle in scientific research: "*Non sunt multiplicanda entia sine necessitate*" (Entities are not to be multiplied without necessity).

Cumulative models without covariates are saturated and this circumstance causes logical problems which have not been considered too much in the literature. The point is that estimable thresholds act as frequency parameters to perfectly fit the observed distribution; the introduction of explanatory variables modifies this perfect fit by adding variability to data. The paradox is that the starting point is a deterministic model and this structure becomes a stochastic one by adding further information.

Now, let $\mathfrak{E}(\mathscr{M} \mid A)$ be the measure of the explicative power of a model $\mathscr{M}$ when the information set is A: it may be log-likelihood, pseudo-R^2, fitting measure, divergence, BIC, deviance, etc. Then, let us denote by $\mathfrak{E}(\mathscr{M} \mid A \cup B)$ the same quantity when the information set is enlarged by a not-empty set B disjoint with A. Of course, $A \subset (A \cup B)$ and $\mathfrak{E}(\mathscr{M} \mid A) < \mathfrak{E}(\mathscr{M} \mid A \cup B)$ for any informative data set B. According to Occam's razor principle, a statistician should prefer a model based on $(A \cup B)$ if and only if the enlarged information improves the explicative power of A, otherwise B is a "*multiplicanda entia sine necessitate*".

In the class $\mathscr{M}$ of cumulative models, let A be the information set consisting of observed ratings and B the set of values of explanatory variables. Then, $\mathfrak{E}(\mathscr{M} \mid A \cup B) < \mathfrak{E}(\mathscr{M} \mid A)$ since any explicative power measure will reach its maximum in case of perfect coincidence of predictions and observations. Thus, under this perspective, the application of these models might appear controversial.

These considerations favour the novel paradigm since in the parametric mixture models modelling it is possible to fit and interpret data by splitting the explicative power of the probability structure from the added contribution given by explanatory covariates. This approach starts with a stochastic model and improves its performance by adding genuine information.

6 Conclusions

The core of the paper is to underline the paradigmatic nature of the modelling approach to rating data. According to Kuhn [49], a paradigm includes "the practices that define a scientific discipline at a certain point in time". Indeed, changes in paradigms have been recently proposed in order to better comprehend the subjective mechanism of a discrete selection out of a list of ordinal categories. The crisis of the established approach is more evident for clustering of items, visualization and interpretation purposes, especially in the big data era. Simulated and real data analysis support the usefulness of the chosen mixture modelling approach as a prominent alternative, thus fostering an integrated rationale.

Although some of them are useful, "all models are substantially wrong" and this aphorism is valid also for a novel paradigm. The substantive problem is to establish the starting point for further advances in order to achieve better models which should ever be improved. As statisticians, we must be aware of the role and importance of uncertainty in human decisions and CUB models may be considered as building blocks of more complex statistical specifications; above all, they act as a benchmark for more refined analyses.

An open-minded research process implies that a new paradigm is to be contrasted by the current one, being able to pursue all previous commitments and even solve new challenges. A convincing proposal easily captures new followers; it may be applied in different circumstances and former paradigms may be more and more critically considered. Unfortunately, since models are questionable by definition and given that human mind has inertial attitude towards novelties (it is a heavy effort to assume a new paradigm in consolidated procedures), the breaking point is often deferred in time.

Probably, time is not ripe yet for a paradigm shift. Nevertheless, a comprehensive family of models with appealing interpretation and parsimony features, a number of published papers supporting the new approach in different fields, an increasing diffusion of models which include uncertainty with a prominent role, the availability of a free software which effectively performs inferential procedures and graphical analysis are convergent signals that the prospective paradigm is slowly emerging.

Statistical challenges and opportunities in modelling coupled behaviour-disease dynamics of vaccine refusal

Modellazione del rifiuto vaccinale come interazione delle dinamiche delle malattie infettive e del comportamento individuale: sfide ed opportunità per le discipline statistiche

Chris T. Bauch

Abstract Vaccine refusal has proven to be a persistent foe in efforts to protect populations from infectious diseases. One hypothesis about its origin posits a coupling between vaccinating behaviour and disease transmission: when infection prevalence is sufficiently low, individuals become complacent and vaccinating becomes less desirable, causing a decline in vaccine coverage and resurgence of the disease. This dynamic is being explored in a growing number of mathematical models. Here, I present a differential equation model of coupled behaviour-disease dynamics for vaccine-preventable paediatric infections, and I discuss previous research that has applied various statistical methodologies to parameterize and validate the model. I will show how methodologies such as model selection analysis and statistical learning, in conjunction with mechanistic modelling, can be used to test for the presence of phenomena related to coupled behaviour-disease dynamics during episodes of vaccine refusal. These phenomena include social learning and imitation, social norms, criticality, and coupling between vaccinating behaviour and disease prevalence. Some of these methodologies exploit new data sources such as online social media. I conclude that the study and modelling of vaccine refusal can greatly benefit from using mechanistic models informed by both traditional and state-of-the-art statistical methodologies.

Abstract *L'opposizione ai vaccini è un fenomeno persistente che indebolisce la capacità delle comunità di difendersi dalle malattie infettive. La spiegazione di base del rifiuto vaccinale postula l'esistenza di un'interazione tra decisione di vaccinare e trasmissione dell'infezione: quando la prevalenza di infezione è sufficientemente bassa il beneficio percepito dalla vaccinazione è a sua volta basso, il che a lungo andare causerà una discesa della copertura vaccinale, creando le premesse per una "risorgenza" della malattia. Queste dinamiche sono state analizzate in un numero crescente di studi modellistici. In questo lavoro presento un modello per in-*

fezioni pediatriche prevenibili da vaccino, come il morbillo, che accoppia le dinamiche dell'infezione con quelle delle decisioni vaccinali, e discuto le ricerche di tipo statistico che si sono occupate della parametrizzazione e validazione di queste classi di modelli. In particolare cerco di mettere in luce il ruolo delle metodologie statistiche (p.e., teoria dell'informazione, statistical learning, etc) per verificare la presenza di fenomeni di interazione tra decisioni individuali e prevalenza dell'infezione durante epoche di rifiuto dei vaccini. Lo studio di questi fenomeni, che includono l'apprendimento via imitazione, il ruolo delle norme sociali, e la presenza di vari effetti "critici", ha potuto in tempi recenti sfruttare le potenzialità dei dati forniti dai "social". Concludo discutendo l'importanza di combinare le metodologie statistiche tradizionali con le nuove tecniche della "data science" nello studio dell'opposizione ai vaccini.

Key words: behavioural epidemiology, vaccine refusal, coupled behaviour-disease systems, statistical learning, model selection

1 Vaccine-preventable infectious diseases: some background

Infectious diseases have long imposed a considerable burden on human health [36]. Improvements in nutrition, sanitation, hygiene and vaccines have considerably reduced this burden [9]. Smallpox was globally eradicated largely due to use of ring vaccination [20]. Even measles–which is highly transmissible–has been eliminated through universal vaccination programs in many countries, and the elimination of measles from the WHO Region of the Americas raises the possibility that even measles could one day be globally eradicated [16]. As our vaccine technologies and ability to administer them improve, universal vaccine access could become replaced as the primary barrier to elimination and eradication by vaccine refusal. In high- and low-income countries alike, vaccine refusal has led to resurgence of previously eliminated diseases such as measles [28], and has even delayed the eradication of polio by at least a decade [33].

Vaccines provide direct protection to vaccinated individuals by stimulating their immune response to specific antigens, but most vaccines also provide indirect protection for unvaccinated individuals by interrupting pathogen transmission [1, 31]. The transmission of infectious diseases can be mathematically modelled through compartmental models, which assume that individuals are divided into mutually exclusive compartments based on their infection status, and which tracks the transitions between these compartments through linear or nonlinear processes [1, 31]. For instance, the classic Susceptible-Infectious-Recovered (SIR) deterministic model with vaccination, births and deaths assumes that the population is divided into susceptible, infectious and recovered (immune) individuals, and is represented by:

$$\frac{dS}{dt} = \mu(1-p\varepsilon) - \beta SI - \mu S, \tag{1}$$

$$\frac{dI}{dt} = \beta SI - \gamma I - \mu I, \tag{2}$$

$$\frac{dR}{dt} = \mu p\varepsilon + \gamma I - \mu R. \tag{3}$$

where S is the proportion of the population that is susceptible, I is the proportion infectious, R is the proportion recovered, $\mu > 0$ is the mean birth/death rate, $\beta > 0$ is the mean transmission rate, $1/\gamma > 0$ is the mean duration of the infectious period, $0 \leq p \leq 1$ is the vaccine coverage, and $0 \leq \varepsilon \leq 1$ is the vaccine efficacy [31]. We assume that a proportion p of individuals are vaccinated at birth and, moreover, a proportion ε of those individuals were efficaciously immunised, entering the R compartment. The remaining proportion $1 - p\varepsilon$ enter the susceptible compartment at birth. We also assume that the birth rate equals the death rate and hence the population size is constant. Note that the R equation does not appear in the S or I equations, and since birth and death rates are equal, $R = 1 - S - I$ therefore we can characterize the system entirely in terms of S and I. This system has two equilibria:

$$E_1 = (S_1, I_1) = (1 - p\varepsilon, 0) \tag{4}$$

$$E_2 = (S_2, I_2) = \left(\frac{\gamma + \mu}{\beta}, \frac{\mu}{\gamma + \mu} \left(1 - p\varepsilon - \frac{\gamma + \mu}{\beta} \right) \right) \tag{5}$$

It is possible to show that the elimination threshold–the proportion of individuals who should be vaccinated in order to eliminate the infection–is given by

$$p_{crit} = \frac{1}{\varepsilon} \left(1 - \frac{1}{R_0} \right) \tag{6}$$

where the basic reproductive ratio $R_0 = \beta/(\gamma + \mu)$ is interpreted as the average number of secondary infections produced by a single infected individuals in an otherwise susceptible population [1]. (In the absence of vaccination, when $R_0 < 1$, the *disease-free equilibrium* E_1 is stable, but when $R_0 > 1$, the disease-free state loses stability and the system converges instead to the *endemic equilibrium* E_2.) When $p \geq p_{crit}$, the disease-free state E_1 is globally asymptotically stable, hence the infection is eliminated [31]. However, when $p < p_{crit}$, E_2 is globally asymptotically stable and the infection is endemic [31].

2 Coupled behaviour-disease systems

The SIR model, equations (1)-(3), represents a world where vaccine coverage is fixed at a specified level p. This is probably applicable where a decision-maker can assume that all eligible individuals will receive a vaccine. However, as we have noted in the first few paragraphs of this paper, vaccine refusal is an increasing problem. Therefore, we cannot always take it for granted that p will be fixed at sufficiently high to eliminate an infection from a population.

Multiple factors influence vaccine decision-making. However, several lines of evidence indicate that individuals are more likely to get vaccinated if (1) they perceive a risk of becoming infected (either due to an ongoing outbreak, possible future outbreaks, or due to a personal history of infection), (2) they perceive a risk of serious complications due to infection, and/or (3) they believe that the vaccine is safe and effective [25, 15, 13, 10, 44]. Indeed, we might have predicted the first factor from the SIR model: once $p = p_{crit}$ is obtained, the infection has been eliminated. In that case, any small real or perceived risk of suffering an adverse effect from the vaccine appears large compared to zero risk of being infected, thus the vaccine becomes undesirable and vaccine coverage can fall back below p_{crit}. Hence, we have a situation where individuals influence disease prevalence through their decision to become vaccinated, but disease prevalence in turn influences vaccine decision-making through individuals' desire to avoid becoming infected. We can therefore conceptualize this as a coupled behaviour-disease system, where disease dynamics and behavioural dynamics are combined into a single coupled system (Figure 1). An increase in vaccine coverage reduces infection prevalence (negative feedback), whereas an increase in infection prevalence boosts perception of infection risk and therefore boosts vaccine coverage (positive feedback), hence together they form a negative feedback loop leading to a stable state of endemic infection and intermediate vaccine coverage. Similar approaches to coupling human and natural systems have been taken up by ecologists and environmental scientists studying terrestrial and other ecosystems [34, 32, 2, 8, 30].

The importance of this interaction between infection and behaviour was not lost on the mathematical epidemiologists of the late twentieth century. Perhaps the earliest work to incorporate behaviour into epidemic dynamics was by Capasso and Serio, who proposed a model where the infection incidence term βSI in the SIR compartmental model is modified to take into account behavioural reactions to changing infection incidence during an outbreak [14]. Year later, the HIV/AIDS pandemic stimulated research on modelling the dynamics of core groups in infection transmission models, where recruitment into the core group depends on infection prevalence [27]. Economists and epidemiologists studied the problem from the perspective conflicts between individual interest and socially optimal approaches starting in the 1980s and 1990s as well [21, 11]. Subsequently, models of coupled

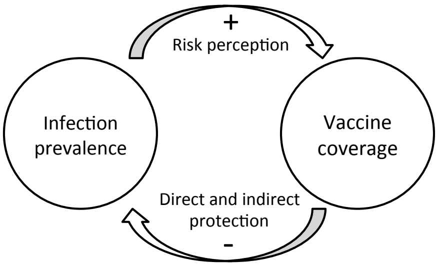

Fig. 1 Schematic diagram of a coupled behaviour-disease system. Increasing vaccine coverage reduces infection prevalence, which in turn causes a drop in vaccine coverage if the population becomes complacent due to lack of infections. The result is a negative feedback loop.

behaviour-disease interactions started becoming popular starting in the mid-2000s [7, 3, 26, 18, 19] (see Refs. [23, 6, 35, 45, 22, 46, 43] for reviews).

A game theoretical treatment of vaccine refusal provides a clear example of how adding adaptive human behaviour changes the predictions of epidemic models. For instance, following the approach of Ref. [5] for equations (1)–(3), it is possible to find the Nash equilibrium vaccine coverage p^* at which the payoff for an individual to vaccinate equals the payoff for an individual not to vaccinate. This turns out to be the vaccine coverage that should be exhibited by a population of rational, self-interested agents [5]. The expression is

$$p^* = \frac{1}{\varepsilon}\left(1 - \frac{1}{R_0(1 - r_v/r_i)}\right) \tag{7}$$

where r_v is the perceived risk of vaccine side effects and r_i is the perceived risk of infection complications. By comparing this expression to equation (6) for the elimination threshold, it is clear that $p^* < p_{crit}$ when $0 < r_v < r_i$. Due to the free-rider effect, it should therefore be impossible to eliminate an infection under a voluntary vaccination policy in a population of rational, self-interested agents [21, 5].

However, individuals are not rational self-interested agents when it pertains to vaccinating decisions [25, 15, 13, 10, 44]. For instance, peer imitation is an important feature of vaccinating behaviour that can be incorporated into epidemic models [17]. In the remainder of this paper we use a model that accounts for more realistic processes including imitation (social learning), social norms, and use of rule-of-thumb (heuristics) to determine infection risks [37]. The SIR equations are modified by replacing constant vaccine coverage p by a dynamic vaccine coverage x, where x is determined by a differential equation capturing how individuals learn vaccine opinions from others. A perfectly efficacious vaccine is assumed ($\varepsilon = 1$) which is a good approximation to the actual effectiveness for multi-course doses of most common pediatric vaccines. The model equations are:

$$\frac{dS}{dt} = \mu(1-x) - \beta SI - \mu S, \tag{8}$$

$$\frac{dI}{dt} = \beta SI - \gamma I - \mu I, \tag{9}$$

$$\frac{dR}{dt} = \mu x + \gamma I - \mu R, \tag{10}$$

$$\frac{dx}{dt} = \kappa x(1-x)\left[-\omega + I + \delta(2x-1)\right]. \tag{11}$$

In these equations, x is the proportion of the population favouring vaccination; $\omega \equiv r_v/mr_i$ controls the relative effects of the perceived risk of vaccine complications r_v, the perceived risk of infection complications r_i, and a proportionality constant m determining the perceived probability of becoming infected as a function of current infection prevalence $I(t)$ (the ‘rule of thumb’ for determining individual risk of becoming infected); δ is the strength of social norms; κ represents the social learning rate; and other parameters and variables are as in equations (1)–(3). In this model, individuals are either vaccinators or non-vaccinators and sample other individuals at a specified rate. If the other person being sampled is playing a different strategy and is receiving a higher utility, the given individual will change to that strategy with a probability proportional to the expected gain in utility (see Ref. [37] for details). When I is higher, more individuals will switch to a vaccinator strategy by imitating others. But when ω is higher due to higher perceived vaccine risk, or lower perceived risk of infection or infection complications, then more individuals will switch to a non-vaccinator strategy. The social norms term $\delta(2x-1)$ moves the population in the direction of whichever strategy is more popular, and thus captures peer pressure. We may remove the R equation since R does not appear in the other equations, hence dynamics can be described completely through (S,I,x).

The coupled behaviour-disease model, equations (8)–(11), exhibits a broad range of behaviour including 5 equilibria: a disease-free equilibrium where no one gets vaccinated, (1,0,0); a disease-free equilibrium where everyone gets vaccinated, (0,0,1); a disease-free equilibrium where part of the population are vaccinators; an endemic equilibrium where no one gets vaccinated; and an endemic equilibrium where part of the population are vaccinators. The model also exhibits stable limit cycles where x and I oscillate (Figure 2). The model is characterized in Ref. [37].

3 Challenges and opportunities for statistics in coupled behaviour-disease modelling

3.1 Parameterization and validation

Parameterizing and validating coupled behaviour-disease models present unique challenges on account of both their larger dimensionality and their coupling. Even with rich data on the epidemiological and sociological layers of the system in separation from one another (Figure 1), one is faced with the additional challenge of obtaining data on the coupling between the two layers–an aspect often ignored in

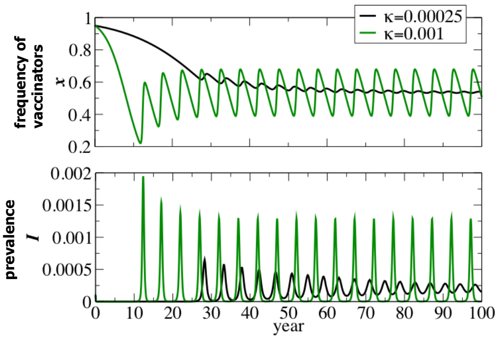

Fig. 2 Example dynamics of the coupled behaviour-disease model in equations (8)–(11). When κ is high, rapid social learning destabilizes the non-trivial equilibrium, causing infection prevalence and vaccine opinion to oscillats. Other parameters: $1/\mu = 50$ yrs., $1/\gamma = 10$ days, $\mathscr{R}_0 = 10$, $\kappa = 0.001$. Figure reproduced from Ref. [3].

traditional epidemiological and sociological studies. Accordingly, statistical inference [29], probabilistic uncertainty analysis [24], and model selection analyses such as use of information criteria [4, 37] are even more important for coupled behaviour-disease models than for sociological models or disease dynamic models in the absence of coupling. Information criteria can be particularly helpful because higher dimensionality and relative lack of data create hazards of over-fitting.

When the sample size n of a dataset is small compared to the number of parameters K being used to fit a model ($n/K < 40$), a variant of the Aikaike information criterion known as the corrected Aikaike information criterion (AICc) may be used (AICc = AIC + $2K(K+1)/(n-K-1)$) [12]. Using AICc, the baseline model in equations (8)–(11) has been compared to variant models lacking either the social learning mechanism (such that individuals switch opinions immediately as soon as the utility becomes more favourable, without learning the new opinion from peers); feedback from infection prevalence (such that infection prevalence is not a part of the utility function); or both mechanisms. The baseline model and its three variants were compared under five different forms for the possible time evolution of relative risk perception during a vaccine scare, $\omega = \omega(t)$ (see Figure 3, left-hand side). The 5 $\times$ 4 = 20 models were fitted using maximum likelihood to vaccine coverage and case notification data from the whole cell pertussis vaccine scare in the United Kingdom in the 1970s-80s (Figure 3) [4]. Comparing the AICc for these 20 models reveals interesting findings. Firstly, adding both social learning and prevalence feedback (i.e., using the baseline model) improved the AICc score and resulted in a better fit for most of the risk evolution curves (Figure 3, first column). (The comparison is worse under the bottom risk evolution curve, but this may be expected since an arbitrarily good AICc score can be obtained by adding enough degrees of freedom to the phenomenological curves that describes risk evolution.) Secondly, the variant model with infection prevalence feedback but no social learning (Figure 3, third column) exhibited highly unstable dynamics that both yields poor AICc scores and does not resemble vaccine coverage time series in any known system. This variant can be taken as a representative of *Homo economicus*–the idea that humans adopt Nash equilibria irrespective of social influences, while the baseline model including social learning could be taken as representative of *Homo socialis*–humans as social animals. Hence, this information theoretic exercise supports the notion that both infection prevalence feedback and social learning are important parts of explaining vaccine refusal in coupled behaviour-disease systems.

Model validation in coupled behavior-disease models can take the form of retrospectively testing of predictive power, for instance. For the pertussis vaccine scare, equations (8)–(11) were also fitted to the early years of the vaccine scare to see whether the model could predict the later years, and it was found that the first seven years of data provided enough information to predict the last ten years of the time series with good accuracy, despite the simplicity of the model [4]. However, the model did not show predictive power in retrospective analysis for the measles-mumps-rubella (MMR) autism vaccine scare in the UK during the 1990s-2000s. This might be due to the fact that measles dynamics were too irregular and stochastic throughout most of the MMR vaccine scare and thus a deterministic differential equation model might not be the right model to use in that situation. This is in contrast to the pertussis vaccine scare where large ‘deterministic’ outbreaks occurred.

3.2 Applications of statistical learning

The previous section described the need for data on both sociological and epidemiological subsystems. However, acquiring data for social subsystems–or sometimes even epidemiological subsystems–can be a challenge. The advent of digital data from sources like online social media has provided an alternative data source that can complement existing methods such as social surveys and case notifications [39]. Digital social data have been used not only to study online sentiment relating to vaccinating behaviour [40] but also to predict the outbreaks themselves, such as through

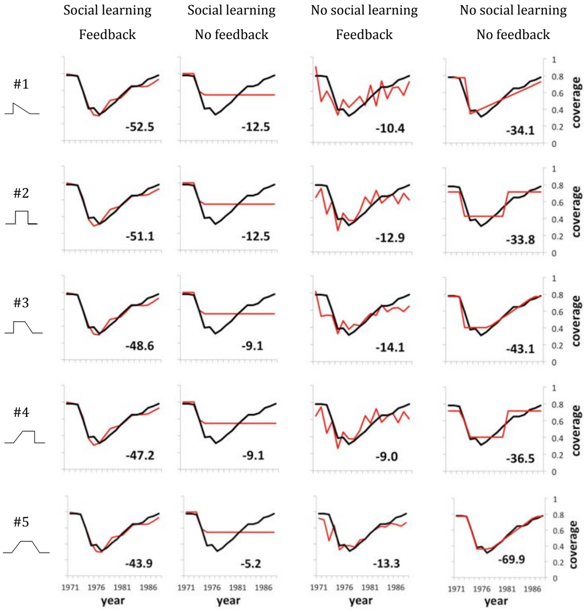

Fig. 3 Aikaike information criterion (AICc) scores and model fit of the coupled behaviour-disease model compared to variants for the UK whole pertussis vaccine scare. Pertussis vaccine coverage in the UK showed a steep decline over 5 years, from ∼80% to ∼30%, before commencing a slow return trajectory to high coverage levels (black lines). The red lines show best-fitting models for the baseline model (first column) and three variant models (second to fourth columns), for 5 risk evolution curves (rows, with form of curve shown on left). The numerical value in each subpanel is the AICc value for the fit: more negative AICc values correspond to better scores, i.e., the model exhibits a better balance of explanatory power with as few parameters as possible. Figure reproduced from Ref. [4].

symptom searches on the Internet [39]. Accordingly, it can help investigators obtain data on social dynamics, disease dynamics, and their coupled dynamics.

However, the amount of digital data is staggering compared to the size of most conventional epidemiological datasets and it cannot be manually processed. Hence, methods such as machine learning are required to analyze the data [42]. A particularly common type of machine learning is statistical learning, in which a computer is used to construct a probabilistic model of a dataset that exhibits statistical regularities. The statistical learning algorithm may use a training set in order to improve its probabilistic models. In Ref. [38], a statistical learning algorithm called a linear support vector machine (SVM) is used to study the 2014-15 California measles outbreak, in which vaccine refusal played a considerable role. The algorithm classified tweets about MMR vaccines into 'pro-vaccine', 'anti-vaccine', and 'other' categories. The number of pro-vaccine tweets were taken to correspond to x in equations (8)–(11) (see Ref. [38] for discussion of limitations of this assumption).

When the perceived vaccine risk ω increases sufficiently, equations (8)–(11) exhibit a tipping point beyond which vaccine uptake falls dramatically and the disease becomes endemic again [38]. The authors hypothesized that California was approaching this tipping point in the years before the relatively small Disneyland outbreak, and then receded from the tipping point afterward as vaccination became popular again. The approach and recession from a tipping point can be detected far in advance through changes in statistical indicators such as the lag-1 autocorrelation, coefficient of variation, and variance of a time series [41, 8]. The authors show that three empirical datasets based on SVM-classified tweets generally show expected trends, as predicted by equations (1)–(3) (Figure 4) [38].

This research suggests that vaccinating behaviour in coupled behaviour-disease systems can be classified as a critical phenomenon, and may exhibit early warning signals before widespread changes in behaviour such as the occurrence of large-scale vaccine scares. Interestingly, the coefficient of variation of the anti-vaccine time series of tweets shows a decline before the tipping point, instead of an increase as shown in all other time series tested and as might be expected from other research on tipping points in related systems [38]. The model predicts the same decline for the coefficient of variation of antivaccinators, however, illustrating the importance of using mechanistic models when interpreting statistical indicators.

4 Summary and Discussion

These examples illustrate the statistical challenges that emerge when parameterizing and validating coupled behaviour-disease models, as well as the synergies and opportunities that may arise when statistical and mechanistic approaches are used in conjunction. In the example of the model selection exercise, we saw how comparing the AICc scores of different models supported the notion that vaccinating behaviour is closer to the *Homo socialis* description than the *Homo economicus* description. In the example of using statistical learning to analyze tipping points, we saw how algorithms like linear support vector machines can be used to analyze vast amounts of online social media data to look for early warning signals of tipping points. The need for using mechanistic models to help interpret statistical patterns was shown by the decrease in coefficient of variation near a tipping point for anti-vaccinators, instead of the increase that is more commonly expected.

This research also suggests a more general approach by which mechanistic models can help us to make sense out of the bewildering complexity of social data. Dynamics generally simplify near tipping points, such that different types of complex nonlinear systems with highly divergent dynamics generally exhibit only the same restricted set of possible dynamics near a tipping point [41]. Hence, looking for evidence of tipping points in social media data is one possible way to begin moving from current predominantly descriptive statistical approaches to social media data, to statistically-informed mechanistic theories of social interactions.

These cases are only two selection-biased examples from a vast array of published work on how statistics and mathematics can be used together to study coupled behaviour-disease systems. For instance, a further opportunity not addressed here is the use of stochastic models, which maybe be particularly relevant close to the disease elimination threshold, or when rare but scary events perceived to be associated with vaccines or diseases occur. Moreover, new data sources such as online social media are already generating new statistical methodologies, and will likely continue to do so in the future. In conclusion, mechanistic approaches to coupled behaviour-disease dynamics of vaccine refusal can benefit from close attention to use of rel-

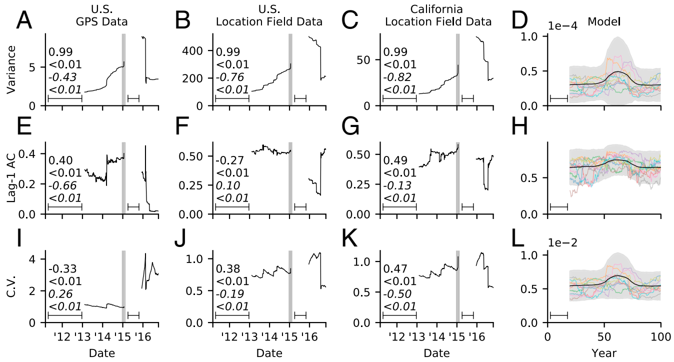

Fig. 4 Critical slowing down in pro-vaccine tweets near a tipping point, before and after Disneyland measles outbreak. (A-D) Variance, (E-H) lag-1 AC, and (I-L) coefficient of variation for (A, E, and I) US GPS-derived data, (B, F, and J) US Location Field-derived data, (C, G, and K) California Location Field-derived data data, and (D, H, and l) model predictions. The residual time series was used for variance and lag-1 AC. Kendall tau rank correlation coefficients are displayed before (regular font) and after (italic) the Disneyland peak with p values denoted by $<$. Window width used to compute rolling averages is indicated by line interval. Shaded region indicates outbreak time period. Model panels show indicators averaged across 500 stochastic model realizations (black), 2 SDs (shaded), and 10 example realizations (colored lines). Figure reproduced from Ref. [38].

evant empirical data for parameterization and validation, analyzed with both traditional and state-of-the-art statistical methods. Such empirically-driven modelling may help us tackle problems of vaccine refusal around the world, and perhaps even speed the global eradication of some vaccine-preventable infections.

Bayesian Nonparametric Learning

Bayesian nonparametric covariate driven clustering

Un modello bayesiano nonparametrico per clustering in presenza di covariate

Raffaele Argiento, Ilaria Bianchini, Alessandra Guglielmi and Ettore Lanzarone

Abstract In this paper we introduce a Bayesian model for clustering individuals with covariates. This model combines the joint distribution of data in the sample, given the parameter and covariates, with a prior for this parameter. Here, the partition of the sample subjects is the parameter, and the prior we assume encourages two subjects to co-cluster when they have similar covariates. Cluster estimates are based on the posterior distribution of the random partition, given data. As an application, we fit our model to a dataset on gap times between recurrent blood donations from AVIS (Italian Volunteer Blood-donors Association), the largest provider of blood donations in Italy.

Abstract *Introduciamo un modello per il clustering di individui in presenza di covariate. Il modello combina la distribuzione congiunta dei dati, condizionatamente al parametero e alle covariate, con una prior per il parametro stesso, secondo l'approccio bayesiano. Qui il parametro è la partizione dei soggetti nel campione. La prior che introduciamo incoraggia due soggetti a stare nello stesso gruppo se hanno covariate simili. Applicheremo il nostro modello ad un dataset che riguarda le donazioni di sangue ripetute nel tempo.*

1 Introduction

In this paper, we introduce a Bayesian model for clustering individuals with covariates. Typically, in the Bayesian framework, there are two approaches for clustering. The first one assumes data to be independently distributed according to a mixture of parametric densities (possibly depending on covariates), with k components; k may be finite, with a prior on k, or infinite ($k = +\infty$), corresponding to a Bayesian nonparametric mixture. The second approach assumes a prior directly on the partition of sample subjects into clusters. Dirichlet process mixtures (DPMs), popularized by [4], are an example of Bayesian nonparametric models, where the weights of the infinite mixture are constructed using the stick-breaking representation (see [14]). Advantages of DPMs over finite mixtures with a prior on the number of components are the existence of generic Markov chain Monte Carlo (MCMC) algorithms for posterior inference to adapt to various applications and elegant mathematical properties of the nonparametric model; see [11] for a discussion on both models. Any DPM induces a random partition of the subject labels $\{1,2,\ldots,n\}$ through the values of the parameters $(\theta_1,\ldots,\theta_n)$ identifying the mixture component the observations are sampled from; in fact, since the mixing measure is almost surely discrete, there are ties in $(\theta_1,\ldots,\theta_n)$ with positive probability. Two subjects i and l share the same cluster if and only if $\theta_i = \theta_l$. In general, this relationship holds for any Bayesian nonparametric mixture model where the mixing measure is an almost surely discrete random probability measure.

In this paper, we follow the second Bayesian approach to clustering, which is more direct, since the random parameter of the model is the subject of the inference itself, i.e. the partition of the sample subjects. To define the model, we assign the joint conditional distribution of data in the sample, given the random partition, and the prior for this parameter. Corresponding cluster estimates are summaries of the posterior distribution of the random partition, given data. In particular, our prior depends on covariates, and we encourage, a priori, two subjects to co-cluster when they have similar covariates.

Our model is a generalization of the PPMx model proposed in [12], a product partition model with covariates information, extending the product partition model by [7]. This latter assumes a prior probability mass function for the random partition $\rho_n = \{A_1,\ldots,A_{k_n}\}$ proportional to the product of functions defined over the clusters, which are called cohesion. In [12], as well as in its generalizations, the cohesion function is restricted to be the one induced by the Dirichlet process, namely $c(S_j) = \kappa(n_j - 1)!$, where κ is a positive constant and n_j is the size of cluster A_j. However, this cohesion inherits "the rich-gets-richer" property of the Dirichlet process, i.e. sampled posterior partitions consist of a small number of large clusters, where new observations are more likely to join already-large clusters with probability proportional to the cardinality of the cluster.

To overcome this limitation, we introduce a more general class of PPMx models, with cohesion induced by normalized completely random measures (NormCRMs); see [13]. We perturb the product partition expression of the prior of the random partition via a similarity function g which depends on all the covariates associated to subjects in each cluster. Such g can be any non-negative function of some similarity measure guaranteeing that the prior probability that two items belong to the same cluster increases if their similarity increases. Note that we call our model "nonparametric", even though the random partition parameter has finite dimension; however its dimension is huge and increases with sample size. We are also able to build a general MCMC sampler to perform posterior analysis that does not depend on the specific choice of similarity. We test our model on a simulated dataset, and on a dataset on gap times between recurrent blood donations from AVIS (Italian Volunteer Blood-donors Association), the largest provider of blood donations in Italy. For the latter application, the problem is to find suitable methods to cluster recurrent event data, and predict a new recurrent event, using covariates describing personal characteristics of the sample individuals. In this paper, we model the sequence of gap times between recurrent events (blood donations) since donors are expected to donate blood not before a fixed amount of time imposed by the law. According to AVIS standard practice, the gap time between donations is the quantity that can be influenced for a better planning of the overall daily blood supply.

2 Bayesian covariate driven clustering

In a regression context, let $\boldsymbol{y}_i, \boldsymbol{x}_i$, $i = 1,\dots,n$ be the vector of responses and covariates for subject i, with $dim(\boldsymbol{y}_i) = n_i$; we assume $n_i = 1$ for all i in this section for greater clarity. We denote by $\boldsymbol{y}_j^*$ (and $\boldsymbol{x}_j^*$) the set of all responses y_i (and covariate vectors $\boldsymbol{x}_i$) in cluster A_j; the notation will be used later in the paper. We start from a family of regression models $f(\cdot;\boldsymbol{x},\theta)$, $\theta \in \Theta \subset \mathbb{R}^l$, and specify a hierarchical model that encourages subjects with similar covariates to be in the same cluster, using a data dependent prior for the random partition of data. We assume that data are independent across groups, conditionally on covariates and the cluster specific parameters; these are i.i.d from a base distribution P_0. Covariates enter both in the likelihood and the prior in our model. Concretely, we assume:

$$Y_1,\dots Y_n|\mathbf{x}_1,\dots,\mathbf{x}_n,\theta_1^*,\dots,\theta_{k_n}^*,\rho_n \sim \prod_{j=1}^{k_n} f(\mathbf{y}_j^*|\mathbf{x}_j^*,\theta_j^*) \tag{1}$$

$$\theta_1^*,\dots,\theta_{k_n}^*|\rho_n \overset{\text{iid}}{\sim} P_0 \tag{2}$$

$$p(\rho_n = \{A_1,\dots,A_{k_n}\}|\mathbf{x}_1,\dots,\mathbf{x}_n) \propto \int_0^{+\infty} D(u,n) \prod_{j=1}^{k_n} c(u,n_j) g(\mathbf{x}_j^*) du \tag{3}$$

where n_j denotes the size of cluster A_j, $g(\mathbf{x}_j^*)$ is the similarity function on cluster A_j such that $g(\emptyset) = 1$, and P_0 is a diffuse probability on the parameter space. Here $D(u,n)$ and $c(u,n_j)$ are defined as:

$$D(u,n) = \frac{u^{n-1}}{\Gamma(n)} \exp\{-\kappa \int_0^{+\infty} \left(1 - \mathrm{e}^{-us}\right) \rho(s) ds\}$$

where $\rho(ds) = \dfrac{1}{\Gamma(1-\sigma)} s^{-1-\sigma} \mathrm{e}^{-s} \mathbb{1}_{(0,+\infty)}(s) ds$ and

$$c(u,n_j) = \int_0^{+\infty} \kappa s^{n_j} \mathrm{e}^{-us} \rho(s) ds = \frac{\kappa\, \Gamma(n_j-\sigma)}{\Gamma(1-\sigma)} \frac{1}{(1+u)^{n_j-\sigma}}. \tag{4}$$

The intensity $\rho(ds)$, the positive parameter κ and the probability P_0 define a specific class of normalized completely random measures, called normalized generalized gamma process (NGG). Parameter σ has a deep influence on the clustering behavior. In particular, the discount parameter σ affects the variance: the larger it is, the more disperse is the distribution on the number of clusters. This feature mitigates "the rich-gets-richer" effect, typical of the Dirichlet process, leading to more homogeneous clusters. For more details on the behavior of σ in NGG's, see for instance [3], [10] and [2].

The likelihood specification in (1) may be any model, from simple regression models to the more complex models for gap times of recurrent events as in the AVIS application. The prior (3) is a perturbation of a prior for ρ_n, called product partition model (PPM) and introduced in [7]. When $g \equiv 1$, i.e. there are no extra information from covariates, the prior mass of each cluster depends only on its size through $c(u,n_j)$; when g is a proper function, the higher is the value of $g(\mathbf{x}_j^*)$, i.e. the more similar are covariates in cluster j, the higher is the prior probability mass of that cluster. This interpretation is justified since the prior $p(\rho_n|\mathbf{x}_1,\ldots,\mathbf{x}_n)$ in (3) can be equivalently written as

$$p(\rho_n|\mathbf{x}_1,\ldots,\mathbf{x}_n,u) \propto M(u) \prod_{j=1}^{k_n} c(u,n_j) g(\mathbf{x}_j^*) \tag{5}$$

for some prior density on the auxiliary variable $u > 0$. In other words, our model is an extension on the PPMx model, namely, it is a mixture of PPMx models (5).

It is quite natural to let the similarity to be a non-increasing function of the distance among covariates in the cluster, namely

$$\mathscr{D}_{A_j} = \sum_{i \in A_j} d(\mathbf{x}_i, \mathbf{c}_{A_j}) \tag{6}$$

where $\mathbf{c}_{A_j}$ is the centroid of the set of covariates in cluster j and d is a suitable distance function that we discuss later. Moreover, we assume $g(\mathscr{D}_{A_j}) := 1$ if the size of the set A_j is 1, i.e. $|A_j| = 1$.

The choice of the similarity is crucial, since this function controls how covariates affect the clustering. For this reason, we propose a list of similarity functions that proved to work reasonably well in practice; among those, here we list:

$g_A(\mathbf{x}_j^*;\lambda) = \mathrm{e}^{-t^{\alpha}}$, for $\alpha > 0$ ($\alpha = 0.5, 1, 2$), with $t = \lambda \mathscr{D}_{A_j}$;

$g_C(\mathbf{x}_j^*;\lambda)$ equals to $\mathrm{e}^{-t\log t}$ if $t \geq \frac{1}{e}$, or to $\frac{\mathrm{e}^{1/e-1}}{t}$ if $t < \frac{1}{e}$, where $t = \lambda \mathscr{D}_{A_j}$.

Here $\lambda > 0$ is a tuning parameter. The similarity function g_A is intuitive, i.e. its behaviour for $t \to +\infty$ is exponential. As far as the expression of g_C is concerned, we have proposed the expression $\mathrm{e}^{-t\log t}$ in such a way that, for large t, we contrast the asymptotic behavior of the cohesion function (4) induced by the NGG process. In fact, our model works well if the prior is not completely driven by covariates, because otherwise we could lose all the advantages of a Bayesian model-based clustering approach (e.g., uncertainty quantification, prediction, sharing information across clusters).

When the similarity is g_A, if we choose a very small λ, we concentrate the values of $\lambda\mathscr{D}_A$ around the origin, and hence we obtain similar values for $g_A(\cdot)$: in this case, the effect of covariate information on the prior of ρ_n will be very mild, since the range of values that the similarity can assume is very limited. A similar argument is valid for large values of λ. In conclusion, we calibrate λ such that g_A is evaluated in the range, say, $(0,3)$, for this particular choice of similarity.

In the applications we consider later, covariates will always be continuous or binary; categorical or ordinal covariates are translated into dummies. Hence, if $\mathbf{x}_1$ and $\mathbf{x}_2$ are vectors of covariates, $\mathbf{x}_j = (\mathbf{x}_j^c, \mathbf{x}_j^b)$, where $\mathbf{x}_j^c$ is the sub-vector of all the continuous covariates and $\mathbf{x}_j^b$ is the sub-vector of all binary covariates, we define the function d in (6) as

$$d(\mathbf{x}_1,\mathbf{x}_2) = d^c(\mathbf{x}_1^c,\mathbf{x}_2^c) + d^b(\mathbf{x}_1^b,\mathbf{x}_2^b), \tag{7}$$

where d^c is the Malahanobis distance between vectors, i.e. the Euclidean distance between *standardized* vectors of covariates, and d^b is the Hamming distance between vectors of binary covariates. The choice of the distance in (7) is not unique, but alternatives are among the subject of current research.

The way we define g does not increase the complexity of the algorithm for posterior inference. Indeed, we are able to devise a general MCMC sampler to perform posterior analysis that does not depend on the specific choice of similarity. The full-conditionals of the Gibbs sampler are relatively easy to implement in this case, since our algorithm generalizes the augmented marginal algorithm for mixture models in [9] and [5].

3 Simulated data

We apply model (1)-(3) in the regression context. Here $f(\mathbf{y}_j^*|\mathbf{x}_j^*,\theta_j^*)$ is the Gaussian regression model. We simulated a dataset of points $(y_i, x_{i1},\ldots,x_{ip})$ for $i=1,\ldots,n$, with $n=200$ and $p=4$. The last 2 covariates are binary and were generated from the Bernoulli distribution, while the first 2 were generated from Gaussian densities. The responses y_i's were generated from a linear regression model with linear predictor $\boldsymbol{x}_i^T\boldsymbol{\beta}$, where $\boldsymbol{\beta}^0 := (\beta_0^0,\beta_1^0,\beta_2^0,\beta_3^0,\beta_4^0)$ and variance $\sigma_e^2 = 0.5$. We have generated 3 different groups by generating both covariates and responses from distributions with different parameters.

We run the Gibbs sampler algorithm to obtain 5,000 final iterations from the full posterior distribution, with initial burn-in of 2,000 and thinning of 10 iterations.

A-posteriori we classified all datapoints according to the optimal partition, under the different similarity functions; results are summarized in Table 1. By optimal partition we mean the realization, in the MCMC chain, of the random partition ρ_n which minimizes posterior expected value of the Binder's loss function with equal missclassification weights [8]. Observe that there are no missclassified data using similarity g_A, while 4% of data are missclassified using g_C, while the missclassification error increases to 16% if we do not assume covariate information ($g \equiv 1$).

Table 1 Missclassification rates for the simulated dataset

missclassif rate	g_A	g_C	$g \equiv 1$
	0%	4%	16%

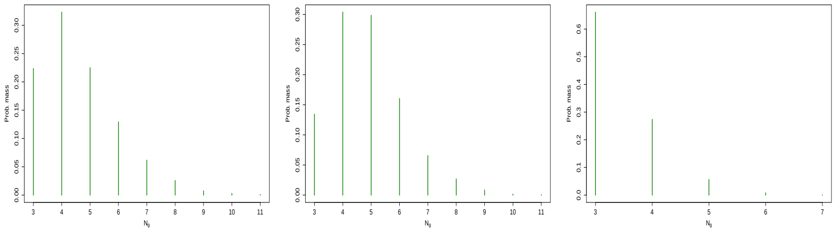

Fig. 1 Posterior distribution of K_n under g_A (left), g_C (center) and $g \equiv 1$ (right).

We computed the posterior distribution of K_n, the number of clusters, in the three cases; see Figure 1. Figure 2 displays the predictive distribution corresponding to covariates $\boldsymbol{x}_1$ of the first subject. The green vertical line corresponds to the actual observation y_1. It is clear that in the last case, i.e. when we do not include covariate information in the prior for the random partition, the predictive law is not able to distinguish to which of the three groups the subject belongs (thus, we have three peaks in the law). In cases A and C the predictive law exhibits only one main peak: the covariate information helps, in this case, in selecting the right group for the observation. This is also proved by the missclassification table above.

We underline that our prior encourages subjects with the same covariates to be in the same cluster, so that the posterior will generally allocate these subjects in the same cluster as well. On the other hand, if two subjects have very different covariates, our prior would classify them to different clusters, even if their responses are similar. However, the likelihood, i.e. the conditional distribution of data given the parameter, could correct the prior probability, if this is the case, and could allocate two subjects with different covariates to the same cluster.

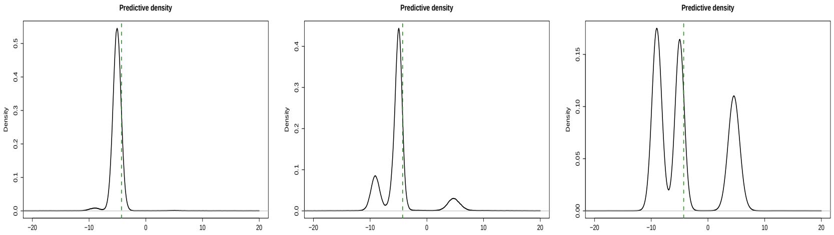

Fig. 2 Predictive distribution of Y_1 under g_A (left), g_C (center) and $g \equiv 1$ (right); vertical lines denote the true value

4 Blood donation data

Our data concern new donors of whole blood donating in a fixed time window in the main building of AVIS in Milano. Data are recurrent donation times, with extra information summarized in a set of covariates, collected by AVIS physicians. The last gap times are administratively censored for almost all the donors, except those having their last donation exactly on that date. The dataset contains 17198 donations, made by 3333 donors.

The statistical focus here is the clustering of donors according to the trajectories of gap times. Figure 3 reports the histogram of this variable (in the log-scale) for men and women. The skewness of these histograms can be explained since, according to

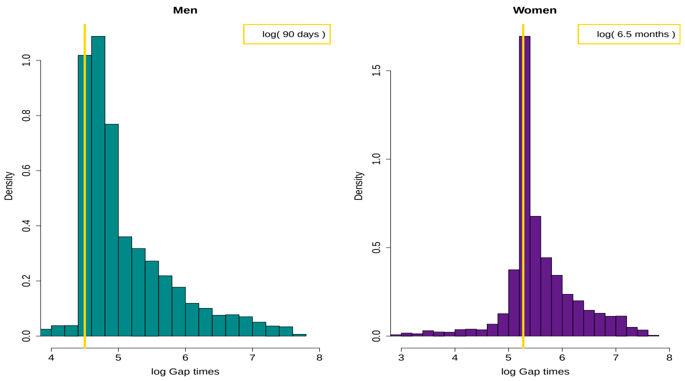

Fig. 3 Histogram of the logarithm of the observed gap-times divided according to gender, male (left) and women (right).

the Italian law, the maximum number of whole blood donations is 4 per year for men and 2 for women, with a minimum of 90 days between a donation and the next one. Note that the minimum for men is around 4.5 ($e^{4.5} \simeq 90$ days). For women, the distribution has a mode approximately in 5.3 in the log scale: this means 200 days, that corresponds to about 6 month and a half. Observe that donors may donate before the minimum imposed by law, under good donor's health conditions and the physician's consent.

We model gap times of successive donations as a regression model for recurrent gap times with two linear predictor terms, involving fixed-time and time varying covariates. The distribution of each gap time, in the log scale, is assumed to be skew-normal (see Figure 3); using parameterization in [6], we model the logarithm of the t-th gap time of donor i as Gaussian distributed. Cluster specific parameters are the intercept, the skewness parameter, and the variance of the response. We assume the prior for the random partition as in (5). Among donor's covariates, we include gender, blood type and RH factor, age, body mass index (BMI) and other information.

Preliminary analysis shows that, a posteriori, age and BMI (time-varying) have an effect on the gap time, as well as gender and RH factor. Details on the cluster estimate will be given during the talk.

A Comparative overview of some recent Bayesian nonparametric approaches for the size of a population

Una rassegna comparativa su alcuni recenti approcci nonparametrici bayesiani per la stima della numerosità di una popolazione

Luca Tardella and Danilo Alunni Fegatelli

Abstract We review some recent approaches that have been used to address the difficult problem of estimating the unknown size of a finite population. We start from illustrating what types of inferential difficulties one should expect when no parametric assumption is made on the class of distributions for the distribution of counts of the number of multiple occurrences of the same unit when the observed counts are modelled in terms of Poisson mixtures. We then consider the problem from the species sampling model perspective where each unit is represented by the distinct species and a sequence of exchangeable unit label observations are available. We discuss the implementation of the alternative approaches with real datasets and we compare their performance with simulated data.

Abstract *In questo lavoro passiamo in rassegna alcuni recenti approcci bayesiani nonparametrici per stimare la numerosità incognita di una popolazione finita. Iniziamo dall'illustrare le difficoltà inferenziali che si devono affrontare quando nessuna assunzione parametrica restringe la classe di distribuzioni che regola il tasso medio di conteggio non negativo delle occorrenze multiple delle unità distinte nel campione. Consideriamo quindi il problema dalla prospettiva dei modelli per species sampling dove le unità corrispondono alle specie distinte e si assume una successione scambiabile etichette di specie osservabili. Si effettuano analisi comparative sull'implementazione dei diversi approcci su dati reali e sulla performance con simulati*

1 Introduction

In this paper we consider the estimation of the total size of a finite population based on a single sample of individual detections. There are many instances in which such problem is of interest starting from the complete enumeration of elusive populations (Böhning and van der Heijden, 2009), software debugging to get the total number of errors (Lloyd et al., 1999) and the species richness problem in ecology (Bunge and Fitzpatrick, 1993; Chao and Bunge, 2002; Wang and Lindsay, 2005; Chao and Chiu, 2016) to measure and preserve biodiversity. We assume there are N distinct units in the population labelled as $i = 1,...,N$ which can be encountered (or detected) C_i times where each C_i is a non-negative integer. Indeed, only those units which are encountered at least once ($C_i > 0$) during the sampling stage are actually detected. Hence, if we denote with M the maximum number of multiple encounters (count) observed for a single unit, the positive frequencies of frequencies statistics $(f_1,...f_k,...,f_M)$, where f_k is the number of distinct units i which have been encountered exactly k times (i.e. for which $C_i = k$), provide a possibly incomplete enumeration $n = \sum_{k=1}^{M} f_k$ of the total population size N since $N = f_0 + n \geq n$. In fact, there are $f_0 > 0$ undetected units for which $C_i = 0$. There have been several attempts in the literature to address the problem of estimating N starting from modelling of the frequencies of frequencies distribution. In fact, this distribution is often determined by the nonparametric modelling of the individual encounter count data. One of the most flexible and general models commonly used in this setting is a mixture of Poisson distributions where the mixing distribution can be arbitrary. Indeed this setting has been dealt with both from the classical side with likelihood-based estimates Norris and Pollock (1998); Wang and Lindsay (2005) or Abundance-based Coverage Estimator (ACE), lower bounds and their variants (Chao and Lee, 1992; Mao, 2006; Mao et al., 2013) and from the Bayesian perspective Barger and Bunge (2010); Guindani et al. (2014). An alternative approach can be based on modelling the sequence of single encounters which is well known in the literature as species sampling model where it is assumed an exchangeable sequence of labels $X_1,...,X_j,...,X_s$ where a label uniquely and perfectly identifies each distinct species (to be understood as a distinct unit of the population) with $s = \sum_{k=1}^{M} k f_k$. In fact, in the species sampling terminology the word population size can be misleading since the total population size N of our original formulation corresponds to the total number of distinct species and is one of the main inferential objectives, whereas the total number of encounters of the different species corresponds to the number s of sequentially observed labels of the species sampling units. Exchangeability of labels ensures that the frequencies statistics $(f_1,...f_k,...,f_M)$ are the relevant statistics for inferring the population structure, including the probability of a new discovery and hence a possible assessment of the total number of distinct species N. Moreover, in most of the recent contribution in the Bayesian species sampling modelling (Lijoi et al., 2007; Arbel et al., 2017) the underlying population size, denoted with N in our setting, is indeed assumed to be infinite since the relative abundances of the population of species correspond to the random atoms of an almost surely discrete random probability measure belonging to the so-called Gibbs-type class. Noticeable exceptions of species sampling models assuming a finite population structure are considered in Gnedin (2010), Cerquetti (2011), Bissiri et al. (2013) and Zhou et al. (2017).

2 Alternative Bayesian Nonparametric approaches

In this section we briefly review the main features of some recent alternative approaches used to infer on the characteristics of a population which have individuals that have varying probability to be encountered in a sampling stage. More specifically we will consider the Dirichlet process mixture approach of Guindani et al. (2014) and the moment based approach in Alunni Fegatelli (2013). We also find it interesting to provide a comparative analysis with nonparametric Bayesian species sampling approach based on a two-parameter (α, β) Poisson-Dirichlet random measure as in Lijoi et al. (2007) with $0 \leq \alpha < 1$ and $\beta \geq -\alpha$. Indeed the comparability with the latter approach should take into account the structurally different underlying assumption on the population size although, in practice, the alternative approaches can be used to analyze the same real datasets. However, we will also consider a more appropriate comparison with a structurally different two-parameter (α, β) Poisson-Dirichlet random measure with $\alpha < 0$ and $\beta = -N\alpha$ for which the random measure has a finite support on N distinct units.

2.1 Dirichlet process mixture of Poisson counts

Guindani et al. (2014) propose to analyse observed positive counts of unique proteomic and genomic units with a semiparametric mixture of Poisson distributions in the presence of overdispersion and uncertainty on the true number of unique proteins or genes in a specific tissue (population). They assume the following hierarchical model: for a fixed population size N, any population unit $i = 1, ..., N$ is possibly detected according to $C_i|\lambda_i \sim Pois(\lambda_i)$, $\lambda_i|F \sim F$ and $F \sim DP(F_0, \tau)$ i.e. a Dirichlet process prior on an almost surely random discrete distribution F on the individual Poisson rate parameter λ_i. The Dirichlet process prior requires the specification of an expected distribution F_0 for λ and a positive total mass parameter τ regulating the concentration of the expected relative abundances corresponding to each unit of the population. They propose the use of a $Gamma(a, b)$ distribution for F_0. Indeed N is the main unknown parameter of interest and a prior distribution is needed. They acknowledge that the choice of the prior on N has a relevant impact and requires careful consideration. They starts arguing that in lack of genuine expert prior information a prior centered around the number of observed sequences n can provide a reasonable default choice. However, for simulation study purposes they implement their model with a uniform prior over a compact support.

2.2 Gibbs-type prior and nonparametric Bayesian species sampling

Lijoi et al. (2007) use a Bayesian nonparametric approach to evaluate the probability of discovering new species in the population conditionally on the number s of species recorded in a sample. The discovery probability represents a natural tool for a quantitative assessment of concepts such as species richness and sample coverage that is the proportion of distinct species present in the observed sample. In particular, they provide a way of estimating the proportion of yet unobserved species which is the complementary sample coverage fraction. However, we must point out from the outset that the species sampling setting and terminology should be carefully rephrased and understood within the original context described in Section 1. Indeed, in the species sampling model of Lijoi et al. (2007) an exchangeable sequence of s observable labels $X_1,...,X_j,...,X_s$ are sampled and the corresponding number n of distinct labels $X_1^*,...,X_n^*$ allows to compute the counts $C_{i,s} = \sum_{j=1}^{s} I(X_j = X_i^*)$ and those counts are sufficient statistics for inferring the sample coverage $1 - U_s = \sum_i \pi_i I(C_{i,s} = 0)$ conditionally on the observed labels. π_i's are the probability masses attached to each distinct label X_i^* which are in turn assumed to be random according to a Gibbs-type prior which selects a.s. discrete distributions with a countable support of distinct points corresponding to a countable subset of labels. In Favaro et al. (2012) and Arbel et al. (2017) an empirical Bayes approach is used to infer on the underlying parameters of the Gibbs-type prior and derive point estimate and interval estimate of the discovery probability of a new species in the Poisson-Dirichlet case. In fact, one could try to relate this discovery probability to the fraction of yet unseen species which can then be turned into an estimate of the total population size N using the relation $E[n] = N(1 - U_s)$. However, this could be rigorously justified only if the number of point masses, i.e. N is assumed to be finite almost surely which happens in the presence of Gibbs-type prior of fixed type $\alpha < 0$ according to Gnedin and Pitman (2005). However in this case one can more directly derive a fully Bayesian inference based on the conditional (on a fixed N) probability of the observed counts and the underlying mixing measure for the finite number of species N. To our knowledge such approach has not been considered in the literature. Indeed a recent attempt in the same direction has been put forward by Zhou et al. (2017) although with no emphasis on the estimation of N.

2.3 Moment-based mixtures of truncated Poisson counts

In Alunni Fegatelli (2013) and Alunni Fegatelli and Tardella (2018) a Bayesian nonparametric approach is proposed. It starts from highlighting that when a finite sample of counts are observed from a mixture of Poisson distributions with unconstrained mixing F for the Poisson rate parameter the sample basically carries information on the mixing F only for a finite number of features. More precisely, if M is the maximum number of observed counts, it depends only on the first M moments of a suitable finite measure Q representing a one-to-one reparameterization of F with the remaining moments of Q being completely unidentified by the sampling distribution (see details in Alunni Fegatelli and Tardella (2018)). In fact, the corresponding likelihood for N and the first M moments of Q, $(m_1(Q),....,m_M(Q))$ is

$$L(N,F;\mathbf{n}) = L(N,Q;\mathbf{n}) = L(N,m_1(Q),....,m_M(Q)) \propto \binom{N}{n} \prod_{k=0}^{T} \left[\frac{m_k(Q)}{k!}\right]^{n_k}$$

This yields the idea of working around a suitable moment-based approximation of the former likelihood which relies on a suitable truncation of the support of the rate parameter in a bounded interval $[0,u]$ and can then be used to derive a suitable default prior in terms of the Jeffreys rule for $(m_1,...,m_M)$ conditionally on N and u. A suitable Rissanen prior on the integer valued population size parameter N and a possible ad hoc choice of the prior on the truncation u complete the specification of the Bayesian model. Indeed it must be remarked that in Barger and Bunge (2010) alternative improper priors are derived as default priors from the reference and the Jeffreys prior approaches. The authors also provide justification for independent prior distributions for the parameter of interest N and the nuisance parameters of the stochastic abundance distribution.

3 Numerical Illustration

A simulation study was used to investigate on the frequentist performance of the three Bayesian nonparametric procedure. We considered the same 12 simulation settings proposed in Wang (2010) where the distribution of the species abundance varied from gamma, gamma mixture, lognormal and lognormal mixture, to discrete distributions, with the expected coverage of the sampled species ranging from 0.20 to 0.90. The corresponding results labelled s_1 through s_{12} are shown in Figure 1 where on the top row shows the average point estimates resulting from 100 simulated datasets for each simulation setting. In the other two rows the root mean square error and the coverage of equal tail 0.95 interval estimates are reported. Differently from the original work, where the estimates were evaluated only for $N = 1000$, we considered also a true population size of 10000. For a fairer comparison with respect to the Poisson-Dirichlet species sampling distribution we have also considered simulation settings s_{13}, s_{14} and s_{15} using a Poisson-Dirichlet structure with parameters $\alpha = -2$ and $\beta = -N\alpha$ and with observed sample coverage equal to 0.3, 0.5 and 0.8 respectively. For both values of N there wasn't a procedure resulting better than others for each simulation setting. However, overall, point and interval estimates for the moment-based method seemed to be the most stable, robust and with a smaller average (over all simulation settings) mean square error. Poor adaptivity of the Poisson-Dirichlet model might be explained by the fact that it indeed incorporates a smaller number of free parameters. We again stress on the fact that simulations were based on finite values of N. Hence, comparisons with the model proposed in Lijoi et al.

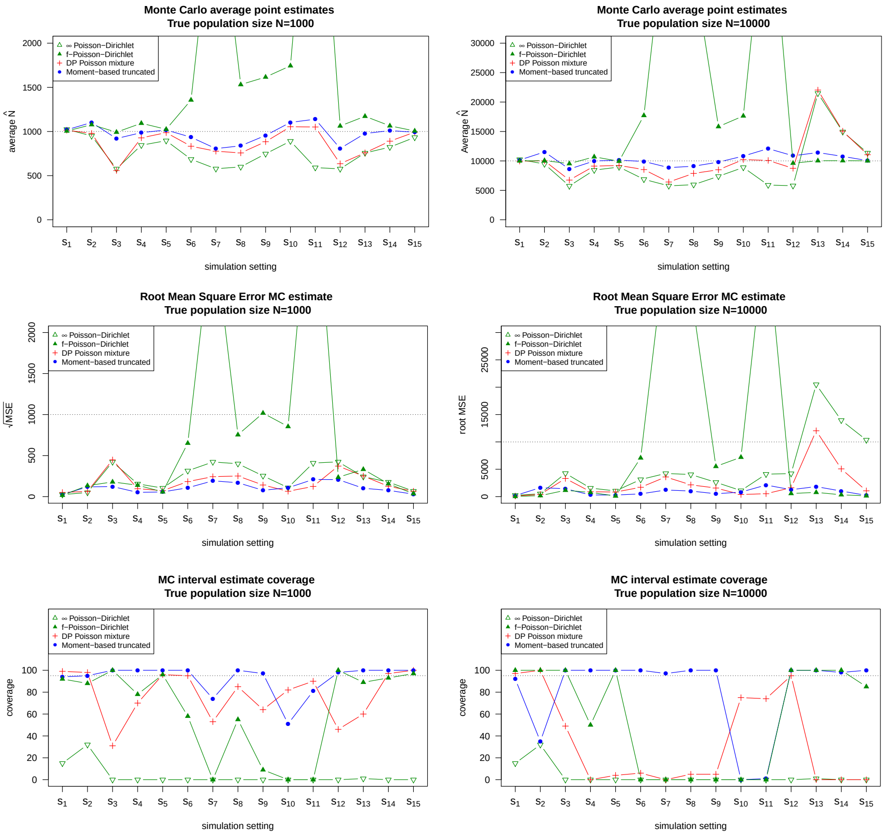

Fig. 1 Comparative performance of 4 alternative Bayesian methods

(2007) are admittedly unfair since in their approach they consider an infinite number of species. However one must also take into account that the comparison is of interest since that approach can be used in real applications where the population size cannot be indeed assumed to unbounded.

4 Concluding remarks

Particular attention to the performance of alternative methods in an inferential context where inference can be challenging and non standard asymptotics is expected. In this framework Bayesian posterior inference can be more sensitive to the prior input and this should be properly taken into account in the absence of genuine prior information. In this sense we believe that our simulation study conducted under alternative simulation settings as those proposed in the frequentist analysis of Wang (2010) could provide some practical suggestion for practitioners. Indeed we have also highlighted some possible drawbacks in using Bayesian nonparametric methods for species sampling based on Gibbs-type prior relying on the assumption of infinitely many species. A more extensive simulation study should be carried out to understand at what extent Bayesian nonparametric methods are sensible and numerically robust when the size of the underlying population grows. To our knowledge there is lack of theoretical understanding of this asymptotic behaviour even in the classical frequentist framework Wang (2010).

Logit stick-breaking priors for partially exchangeable count data

Distribuzioni a priori stick-breaking logistiche per dati di conteggio parzialmente scambiabili

Tommaso Rigon

Abstract Recently, Rigon and Durante (2018) discussed a Bayesian nonparametric dependent mixture model, which is based on a predictor-dependent stick-breaking construction. They provided theoretical support and proposed a variety of algorithms for posterior inference, including a Gibbs sampler. Their results rely on a formal representation of the stick-breaking construction, which has an appealing interpretation in terms of continuation-ratio logistic regressions. In this paper we review the contribution of Rigon and Durante (2018), and we extend their proposal to the case of partial exchangeability with count data. As an illustration of this methodology, we analyze the number of epileptic seizures of a single patient in a clinical trial.

Abstract *Recentemente, Rigon e Durante (2018) hanno discusso un modello di mistura bayesiano nonparametrico basato su una costruzione di tipo stick-breaking e dipendente da covariate. Gli autori hanno fornito sostegno teorico e hanno introdotto vari algoritmi per condurre inferenza a posteriori, incluso un campionamento di tipo Gibbs. I loro risultati si basano su una rappresentazione formale della costruzione stick-breaking, la quale ha un'interessante interpretazione in termini di regressioni logistiche sequenziali. In questo contributo, viene sintetizzata la proposta di Rigon e Durante (2018), e viene estesa la loro proposta nel caso parzialmente scambiabile con dati di conteggio. Per illustrare le loro metodologie, vengono analizzati il numero di attacchi epilettici di un singolo paziente durante un test clinico.*

Key words: Continuation-ratio logistic regression, Partial exchangeability, Poisson mixture model.

1 Introduction

Let $Y_1,\dots,Y_n \in \mathbb{N}$ be a collection of count response variables, each corresponding to a qualitative covariate $x_i \in \{1,\dots,J\}$, for $i = 1,\dots,n$. The observations $y_1,\dots,y_n$ from $Y_1,\dots,Y_n$ can be naturally divided in J distinct groups, given the covariates $x_1,\dots,x_n$. Our goal is to flexibly model the conditional distributions $\mathrm{pr}(Y = y \mid x = j) = p_j(y)$, for $j = 1,\dots,J$, under the assumption that each data point y_i is a conditionally independent draw from

$$(Y_i \mid x_i = j) \overset{\text{ind}}{\sim} p_j, \qquad i = 1,\dots,n, \tag{1}$$

where p_j denotes the probability mass function of the random variable $(Y_i \mid x_i = j)$. Within the Bayesian framework, assumption (1) is known as *partial exchangeability*, and model elicitation is completed by specifying a prior law Q_J for the vector of probability distributions: $(p_1,\dots,p_J) \sim Q_J$. Broadly speaking, the partial exchangeability assumption reflects an idea of homogeneity within the J subsets of observations but not across them. The prior measure Q_J governs dependence between groups, allowing borrowing of information across them. Maximal dependence, i.e. *exchangeability*, is attained if Q_J is such that $p_1 = \cdots = p_J$ almost surely, reflecting the prior belief that observations belong to the same latent population. Conversely, the case of full heterogeneity arises if each random probability distribution p_j is independent on $p_{j'}$ for any $j \neq j'$, implying that the distinct J groups share no information.

A common and flexible formulation for Q_J is given by mixture models of the form $p_j(y) = \int_\Theta K(y;\theta)\mathrm{d}P_j(\theta)$, where $K(y;\theta)$ denotes a known kernel function and $P_j(\theta)$ a random discrete mixing measure which is allowed to change across groups. In this paper we consider the class of predictor–dependent infinite mixture of Poisson distributions

$$p_j(y) = \int_\Theta \mathrm{Pois}(y;\theta)\mathrm{d}P_j(\theta) = \sum_{h=1}^{+\infty} \pi_{hj}\mathrm{Pois}(y;\theta_h), \qquad j = 1,\dots,J, \tag{2}$$

where $\pi_{hj} = \nu_{hj}\prod_{l=1}^{h-1}(1-\nu_{lj})$ are group–dependent mixing probabilities having a stick-breaking representation [11], and $\mathrm{Pois}(y;\theta)$ denotes the probability mass function of a Poisson with mean θ. Additionally, we assume that the atoms θ_h in (2) are independent and identically distributed (iid) draws from a diffuse baseline measure P_0, that is, $\theta_h \sim P_0$ independently for $h = 1,\dots,+\infty$ and independently on the weights π_{hj}. As for the stick-breaking weights ν_{hj}, we let

$$\mathrm{logit}(\nu_{hj}) = \alpha_{hj}, \qquad \text{with} \quad \alpha_h = (\alpha_{h1},\dots,\alpha_{hJ})^\intercal \overset{\text{iid}}{\sim} \mathrm{N}_J(\mu_\alpha,\Sigma_\alpha), \tag{3}$$

independently for every $h = 1,\dots,+\infty$. Specification of equations (2)-(3) can be regarded as a particular instance of the more general logit stick-breaking process (LSBP) of [8, 9], in which the covariate space is finite dimensional and with a Poisson kernel. As such, it inherits all the theoretical and computational properties of LSBP processes, some of which are reviewed in this manuscript.

Let us first consider an equivalent formulation of the logit stick-breaking Poisson mixture model of equations (2)-(3). Leveraging standard hierarchical representations of mixture models, the independent samples $y_1,\dots,y_n$ can be obtained equivalently from the random variable

$$\begin{aligned}(Y_i \mid G_i = h) &\sim \text{Pois}(\theta_h),\\ \text{pr}(G_i = h \mid x_i = j) = \pi_{hj} &= \nu_{hj}\prod_{l=1}^{h-1}(1-\nu_{lj}),\end{aligned} \tag{4}$$

for every unit $i = 1,\dots,n$, where $G_i \in \{1,2,\dots,+\infty\}$ is a categorical random variable denoting the mixture component associated to the i-th unit. Each indicator G_i has probability mass function $p(G_i \mid x_i = j)$ which can be written, after some algebraic manipulation, as

$$p(G_i \mid x_i = j) = \prod_{h=1}^{+\infty} \pi_{hj}^{\mathbb{1}(G_i=h)} = \prod_{h=1}^{+\infty} \nu_{hj}^{\mathbb{1}(G_i=h)}(1-\nu_{hj})^{\mathbb{1}(G_i>h)}, \tag{5}$$

for any $j = 1,\dots,J$. Equation (5) suggests an appealing interpretation of the stick-breaking weights ν_{hj} as the allocation probabilities to component h, conditionally on the event of surviving to the previous $1,\dots,h-1$ components, precisely

$$\nu_{hj} = \text{pr}(G_i = h \mid G_i > h-1, x_i = j), \tag{6}$$

for each $h = 1,\dots,+\infty$ and $j = 1,\dots,J$. This result, together with the prior formulation of equation (3), allows to interpret the stick-breaking construction (4) in terms of continuation–ratio logistic regressions [12]. This connection with the literature on sequential inference for categorical data is common to all the stick-breaking priors [e.g. 1, 8–10] and provides substantial benefits. Indeed, this characterization implies a simple sequential generative process for each membership indicator G_i and facilitates the implementation of a Gibbs sampler for posterior inference.

We briefly recall here the generative mechanism underlying equations (4), as described in [9], for the j-th group of observations. In the first step of the sequential process, each unit of the j-th group is either assigned to the first component $G_i = 1$ with probability ν_{1j} or to one of the subsequents with probability $1-\nu_{1j}$. If $G_i = 1$ the process stops, otherwise we draw another binary indicator, with probability ν_{2j}, to decide whether $G_i = 2$ or $G_i > 2$. The following steps proceed in a similar manner. Thus, we can reformulate each $\mathbb{1}(G_i = h) = \zeta_{ih}$, that is, the assignment indicator of each unit to the h-th component, in terms of binary sequential choices

$$\zeta_{ih} = z_{ih}\prod_{l=1}^{h-1}(1-z_{il}), \quad (z_{ih} \mid x_i = j) \sim \text{Bern}(\nu_{hj}), \tag{7}$$

for each $h = 1,\dots,+\infty$ and $j = 1,\dots,J$, where z_{ih} is a Bernoulli random variable representing the h-th sequential decision.

2 Theoretical properties

Let $(P_1,\dots,P_J)$ denote the vector of dependent random probability measures on $\mathbb{R}^+$ induced by the LSBP in equation (2). Thus, each random probability measure P_j can be represented as

$$P_j(\cdot) = \sum_{h=1}^{+\infty} \pi_{hj}\delta_{\theta_h}(\cdot), \qquad j = 1,\dots,J. \tag{8}$$

The stick-breaking representation of the π_{hj} implies that the random weights π_{hj} sum to 1 almost surely. Although this result is straightforward to derive, it should not taken for granted because of the analogy with [11], which leverages on peculiar characteristics of the Dirichlet process. This property is formalized in Proposition 1.

Proposition 1 (Rigon and Durante (2018)). *Let $(P_1,\dots,P_J)$ be a vector of random probability measures defined as in* (8) *and with stick-breaking weights defined as in* (3). *Then, $\sum_{h=1}^{+\infty}\pi_{hj} = 1$ almost surely for any $j = 1,\dots,J$.*

Proposition 2 provides some insights about the first two moments of the random vector $(P_1,\dots,P_J)$.

Proposition 2 (Rigon and Durante (2018)). *Let $(P_1,\dots,P_J)$ be a vector of random probability measures defined as in* (8)*, with stick-breaking weights defined as in* (3)*. Then, for any measurable set B, and for any $j = 1,\dots,J$ and $j' = 1\dots,J$, it holds*

$$\begin{aligned} \mathrm{E}\{P_j(B)\} &= P_0(B), \\ \mathrm{cov}\{P_j(B),P_{j'}(B)\} &= P_0(B)(1-P_0(B))\frac{\mathrm{E}(\nu_{1j}\nu_{1j'})}{\mathrm{E}(\nu_{1j})+\mathrm{E}(\nu_{1j'})-\mathrm{E}(\nu_{1j}\nu_{1j'})}. \end{aligned}$$

The expectation of $P_j(\cdot)$ coincides with the base measure $P_0(\cdot)$, which can be therefore interpreted as the prior guess for the mixing measure for any $j = 1,\dots,J$. Also, the variance of the random probability $P_j(B)$ can be recovered from the above covariance by letting $j = j'$. Unfortunately, the expectations in Proposition 2 are not available in closed form, although they can be easily computed numerically.

As noted by [9], the prior covariance between pairs of random probabilities is governed by the hyperparameters in specification (3) and it is always positive. From a modeling standpoint, this suggests that full heterogeneity among groups—using the terminology of Section 1—can be approximated for some suitable choice of the hyperparameters but it cannot be attained completely. A similar reasoning holds also for maximal dependence among groups which, again, arises only as a limiting case.

3 Posterior inference via Gibbs sampling

In this section we adapt the Gibbs sampler of [9] to the proposed infinite mixture model of Poisson distributions. Our approach exploits representation (4) and the continuation–ratio characterization of the logit stick-breaking prior. By conditioning on the latent indicators $G_1,\dots,G_n$, the model reduces to a set of standard conjugate updates—one for each mixture component—as long as the prior distribution of the atoms is

$$\theta_h \sim \mathrm{Gamma}(a_\theta, b_\theta), \qquad h = 1,\dots,+\infty.$$

Moreover, exploiting the sequential representation, posterior inference for the stick-breaking parameters α_h in (3) proceeds as in a Bayesian logistic regression in which the latent binary indicators z_{ih} in (7) play the role of the response variables, precisely

$$(z_{ih} \mid x_i) \sim \mathrm{Bern}\left(\{1+\exp(-\psi(x_i)^\intercal \alpha_h)\}^{-1}\right), \tag{9}$$

for each $i = 1,\dots,n$ and $h = 1,\dots,+\infty$, where $\psi(x_i) = \{\mathbb{1}(x_i = 1),\dots,\mathbb{1}(x_i = J)\}^\intercal$, and with $\mathbb{1}(\cdot)$ denoting the indicator function. To perform conjugate inference also for α_h, we adapt a recent Pólya-Gamma data augmentation scheme for logistic regression [7] to our statistical model, which relies on the following integral identity

$$\frac{e^{z_{ih}\psi(x_i)^\intercal\alpha_h}}{1+e^{\psi(x_i)^\intercal\alpha_h}} = \frac{1}{2}\int_{\mathbb{R}^+} f(\omega_{ih})\exp\left\{(z_{ih}-0.5)\psi(x_i)^\intercal\alpha_h - \omega_{ih}(\psi(x_i)^\intercal\alpha_h)^2/2\right\}\mathrm{d}\omega_{ih},$$

for each $i = 1,\dots,n$ and $h = 1,\dots,+\infty$, where $f(\omega_{ih})$ denotes the density function of a Pólya-gamma random variable $\textsc{pg}(1,0)$. Thus, the updating of α_h for any $h = 1,\dots,+\infty$ can be easily accomplished noticing that—given the Pólya-gamma random variables ω_{ih}—the contributions to the log-likelihood are quadratic in α_h and hence conjugate under the Gaussian priors (3). Moreover, the conditional density

$$f(\omega_{ih} \mid \alpha_h) = \frac{\exp[-0.5\{\psi(x_i)^\intercal\alpha_h\}^2\omega_{ih}]f(\omega_{ih})}{[\cosh\{0.5\psi(x_i)^\intercal\alpha_h\}]^{-1}},$$

defined for every $i = 1,\dots,n$ and $h = 1,\dots,+\infty$, is still a Pólya-Gamma random variable—and therefore conjugate—with updated parameters $f(\omega_{ih} \mid \alpha_h) \sim \textsc{pg}(1,\psi(x_i)^\intercal\alpha_h)$. This scheme allows posterior inference under a classical Bayesian linear regression.

Before providing a detailed derivation of the Gibbs sampler, we first describe a truncated version of the vector of random probability measure $(P_1,\dots,P_J)$, which can be regarded as an approximation of the infinite process. In line with [8–10], we develop a Gibbs sampler based on this finite representation, which has key computational benefits. We induce the truncation by letting $\nu_{Hj} = 1$ for some integer $H > 1$ and any $j = 1,\dots,J$, which guarantees that $\sum_{h=1}^{H}\pi_{hj} = 1$ almost surely. According to Theorem 1 in [9], the discrepancy between the two processes is exponentially decreasing in H, and therefore the number of components has not to be very large in practice to accurately approximate the infinite representation. Refer to [9] for a

Algorithm 1: Steps of the Gibbs sampler

```
begin
    [1] Assign each unit $i = 1, \dots, n$ to a mixture component $h = 1, \dots, H$;
    for $i$ from 1 to $n$ do
        Sample $G_i \in (1, \dots, H)$ from the categorical variable with probabilities
            $$\text{pr}(G_i = h \mid -) = \frac{\pi_{hx_i} \text{Pois}(y_i; \theta_h)}{\sum_{q=1}^{H} \pi_{qx_i} \text{Pois}(y_i; \theta_q)},$$
        for every $h = 1, \dots, H$.
    [2] Update the parameters $\alpha_h$, $h = 1, \dots, H-1$;
    for $h$ from 1 to $H-1$ do
        for every $i$ such that $G_i > h-1$ do
            Sample the Pólya-Gamma data $\omega_{ih}$ from $(\omega_{ih} \mid -) \sim \text{PG}(1, \psi(x_i)^\intercal \alpha_h)$.
        Given the Pólya-Gamma data, update $\alpha_h$ from the full conditional
            $$(\alpha_h \mid -) \sim \text{N}_J(\mu_{\alpha_h}, \Sigma_{\alpha_h}),$$
        having $\mu_{\alpha_h} = \Sigma_{\alpha_h}\{\Psi_h^\intercal \kappa_h + \Sigma_\alpha^{-1}\mu_\alpha\}$, $\Sigma_{\alpha_h} = \{\Psi_h^\intercal \Omega_h \Psi_h + \Sigma_\alpha^{-1}\}^{-1}$,
        $\Omega_h = \text{diag}(\omega_{i1}, \dots, \omega_{i\bar{n}_h})$ and $\kappa_h = (z_{i1} - 0.5, \dots, z_{i\bar{n}_h} - 0.5)^\intercal$, with $z_{ih} = 1$ if
        $G_i = h$ and $z_{ih} = 0$ if $G_i > h$.
    [3] Update the kernel parameters $\theta_h$, $h = 1, \dots, H$, in (2), leveraging standard results;
    for $h$ from 1 to $H$ do
        Sample the parameters $\theta_h$ from the full conditional
            $$(\theta_h \mid -) \sim \text{Gamma}\left(a_\theta + \sum_{i:G_i=h} y_i,\ b_\theta + \sum_{i=1}^{n} \mathbb{1}(G_i = h)\right).$$
```

more formal treatment. As a historical remark, the idea of truncating discrete nonparametric priors was firstly given by [6] and later developed by [3]. Theorem 1 in [9] is somehow the analogue of these results, for a class of models beyond exchangeability.

Let Ψ_h denote the $\bar{n}_h \times J$ predictor matrix in (9) having row entries $\psi(x_i)^\intercal$, for only those statistical units i such that and $G_i > h - 1$. The Gibbs sampler for the truncated representation of model (2) alternates between the full conjugate updating steps in Algorithm 1.

4 Illustration

As an illustration of the proposed methodology, we apply the LSBP Poisson mixture model to the `seizure` dataset, which was already analyzed in [13] and is available in the `flexmix` R package [2]. Data are extracted from a clinical trial conducted at the British Columbia's Children's Hospital, aiming to assess the effect of intravenous gamma globulin in reducing the daily frequency of epileptic seizures. Our dataset consists of daily myoclonic seizure counts (`seizures`) for a single subject, comprising a series of $n = 140$ days. After 27 days of baseline observation (`Treatment: No`), the subject received monthly infusions of intravenous gamma globulin (`Treatment: Yes`). The relative frequency of counts are shown in the upper plots of Figure 1, where the two groups—days with treatment and days without treatment—are compared.

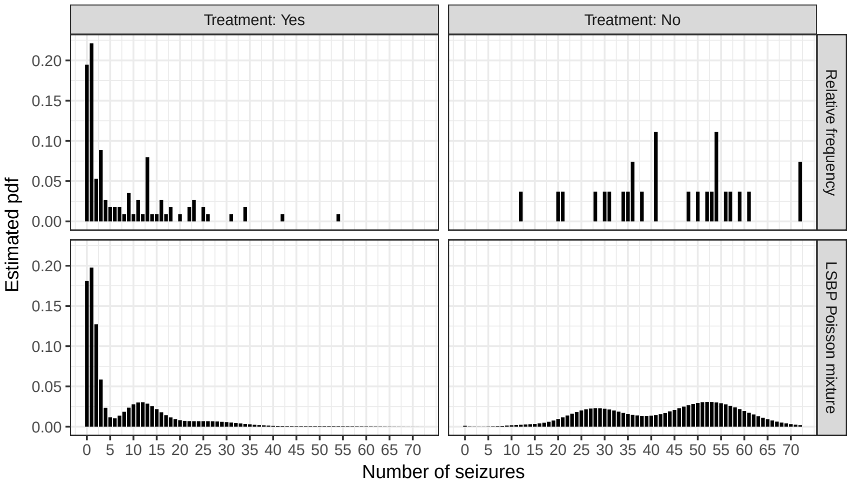

Fig. 1 Upper plots: for the two groups of observations (`Treatment: Yes` and `Treatment: No`), the relative frequencies of the daily number of myoclonic seizure counts are reported. Lower plots: for both groups of observations the (MCMC) posterior expectation of the probability mass function arising from the LSBP model is reported.

As evidenced by the raw frequencies displayed in Figure 1—which seem to present a multimodal structure—and consistent with the discussion in [13], a simple parametric formulation might be overly restrictive for the data at our disposal, thus motivating flexible representations. Additionally, regardless the effectiveness of the treatment, some form of dependence structure among observations from the two groups is expected, since they all refer to the same subject.

Consistent with these considerations, we model the `seizures` counts using the flexible mixture of Poissons described in Section 1. The number of groups is $J = 2$. As prior hyperparameters for the stick-breaking weights in (3), we set $\mu_\alpha = (0,0)$ and $\Sigma_\alpha = \mathrm{diag}(1000,1000)$, expressing the prior belief of a moderate amount of dependence among groups. As for the kernels parameters, we set $a_\theta = b_\theta = 0.05$, inducing a prior centered on 1 with a relatively large variance. Finally, we truncated the infinite mixture model choosing a conservative upper bound $H = 20$ for the number of mixture components. Although other hyperparameters settings are certainly possible, this would require a careful sensitivity analysis, which is beyond the scope of this paper. The Gibbs sampler in Section 3 was run for 50000 iterations, discarding the first 5000 draws as a burn-in period. The traceplots showed a satisfactory mixing and no evidence against convergence.

In the lower plots of Figure 1 we report the MCMC approximation of the posterior expectation for the probability mass function under the proposed LSBP Poisson mixture model, for the two groups. From this simple posterior check, it is apparent that our model is able to capture the main tendencies of the data. In particular, the proposed mixture model effectively resembles the multimodal behavior of the data.

A paired comparison model for the analysis of on-field variables in football matches

Gunther Schauberger and Andreas Groll

Abstract We use on-field variables from football matches in the German Bundesliga and connect them to the sportive success or failure of the single teams in a paired comparison model where each match in a Bundesliga season is treated as a paired comparison between the two competing teams. We propose an extended paired comparison model that extends the classical Bradley-Terry model to ordinal response variables and includes different types of covariates. We apply penalized likelihood estimation and use specific L_1 penalty terms for fusion and selection in order to reduce the complexity of the model and to find clusters of teams with equal covariate effects. The proposed model is a very general one and can easily be applied to other sports data or to data from different research fields. We apply the model to data from the latest season of the German Bundesliga.

Key words: Bundesliga, Paired Comparison, BTLLasso, Penalization

1 Introduction

In modern football, various variables as, for example, the distance a team runs or its percentage of ball possession, are collected throughout a match. However, there is a lack of methods to make use of these on-field variables simultaneously and to connect them with the final result of the match. We propose to treat each football match as a paired comparison between the two competing teams and to analyse the results of football data by an extended paired comparison model.

Gunther Schauberger
Chair of Epidemiology, Technical University Munich, e-mail: gunther.schauberger@tum.de,

Andreas Groll
Faculty of Statistics, Technische Universität Dortmund e-mail: groll@statistik.tu-dortmund.de

Paired comparisons occur if two objects out of a set of objects are compared with respect to an underlying latent trait. In the case of football matches in national leagues all teams from the respective league are considered to be these objects. Football matches can be treated as paired comparisons between two teams where the playing abilities of the teams represent the underlying latent traits that are compared.

Our main goal is to set up a paired comparison model that is able to incorporate so-called on-field variables as covariates. In general, if covariates are to be considered in paired comparison, one has to distinguish between subjects and objects of the paired comparisons. A covariate can either vary across the subjects or the objects of a paired comparison, or, as in our case, both over subjects and objects. In football matches, the teams are the objects while a single match can be considered to be the subject that conducts the comparison between the two objects/teams. If one considers a variable like the percentage of ball possession a team has in a specific match, this variable varies both from team to team and from match to match. Therefore, in our application subject-object-specific covariates are considered. After all, the proposed model could in principle consider all three types of variables simultaneously.

The Bradley-Terry model (Bradley and Terry, 1952) is the standard model for paired comparison data. Assuming a set of objects $\{a_1,\dots,a_m\}$, in its most simple form the Bradley-Terry model is given by

$$P(a_r \succ a_s) = P(Y_{(r,s)} = 1) = \frac{\exp(\gamma_r - \gamma_s)}{1+\exp(\gamma_r - \gamma_s)}. \qquad (1)$$

One models the probability that a certain object a_r dominates or is preferred over another object a_s, $a_r \succ a_s$. The random variable $Y_{(r,s)}$ is defined to be $Y_{(r,s)} = 1$ if a_r dominates a_s and $Y_{(r,s)} = 0$ otherwise. The parameters γ_r represent the attractiveness or strength of the respective objects. In football matches, the random variable $Y_{(r,s)}$ which represents the paired comparison between a_r and a_s needs to have at least $K = 3$ possible categories instead of two because in football one needs to account for the possibility of draws. However, if one distinguishes, for example, clear wins and losses from wins and losses with only one goal difference one could also use $K = 5$ categories. In general, for the case of ordered responses $Y_{(r,s)} \in \{1,\dots,K\}$ the model is extended accordingly to

$$P(Y_{(r,s)} \le k) = \frac{\exp(\theta_k + \gamma_r - \gamma_s)}{1+\exp(\theta_k + \gamma_r - \gamma_s)}, \quad k = 1,\dots,K, \qquad (2)$$

which essentially corresponds to the generalization from a binary logistic regression model to a cumulative logistic regression model. In our application, the strength parameters γ_r represent the playing abilities of the teams.

In general, for the ordinal paired comparison model (2) it is assumed that the response categories have a symmetric interpretation so that $P(Y_{(r,s)} = k) = P(Y_{(s,r)} = K-k+1)$ holds. Therefore, the threshold parameters should be restricted by $\theta_k = -\theta_{K-k}$ and, if K is even, $\theta_{K/2} = 0$ to guarantee for symmetric probabilities. The threshold for the last category is fixed to $\theta_K = \infty$ so that $P(Y_{(r,s)} \le K) = 1$ will hold.

The probability for a single response category can be derived from the difference between two adjacent categories, $P(Y_{(r,s)} = k) = P(Y_{(r,s)} \leq k) - P(Y_{(r,s)} \leq k-1)$. To guarantee for non-negative probabilities of the single response categories one restricts $\theta_1 \leq \theta_2 \leq \ldots \leq \theta_K$.

When football matches are considered as paired comparisons one has to consider that so-called order effects are possible. To some extent, order effects contradict the assumption of symmetric response categories which was described above. When order effects are present, the order of the two objects (i.e. which object is the first-named object and which is the second-named object) is not random and possibly has an influence on the outcome. In football (especially in national leagues) this is obviously the case as the first-named object is the home team and, hence, usually has a home advantage over the (second-named) away team. To include such an order effect in model (2) we extend the model to

$$P(Y_{(r,s)} \leq k) = \frac{\exp(\delta + \theta_k + \gamma_r - \gamma_s)}{1 + \exp(\delta + \theta_k + \gamma_r - \gamma_s)}, \quad k = 1, \ldots, 5, \tag{3}$$

where δ represents an order effect. In football matches, this parameter represents the home effect (or home advantage if positive). It is possible to assume a global home effect δ which is equal for all teams or team-specific home effects δ_r.

2 Bundesliga Data

The main goal of this work is to analyze if (and which) on-field variables that are collected throughout a match are associated to the final result of football matches. In total, our data set contains all the following variables separately for each team and each match:

Distance	Total amount of km run
BallPossession	Percentage of ball possession
TacklingRate	Rate of tacklings won
ShotsonGoal	Total number of shots on goal
Passes	Total number of passes
CompletionRate	Percentage of passes reaching teammates
FoulsSuffered	Number of fouls suffered
Offside	Number of offsides (in attack)

The data were collected from the website of the German football magazin kicker (http://www.kicker.de/). Exemplarily, Table 1 shows the collected data for the opening match of the season 2016/17 between Bayern München and Hamburger SV.

Bayern München		Hamburger SV
Goals	5 : 0	Goals
Shots on goal	23 : 5	Shots on goal
Distance	108.54 : 111.28	Distance
Completion rate	90 : 64	Completion rate
Ball possession	77 : 23	Ball possession
Tackling rate	52 : 48	Tackling rate
Fouls	10 : 12	Fouls
Offside	3 : 0	Offside

Table 1 Illustrating table for original data situation showing data for the opening match in season 2016/17 between Bayern München and Hamburger SV. Source: http://www.kicker.de/

3 A Paired Comparison Model for Football Matches Including On-field Variables

When using a paired comparison model for football matches the standard Bradley-Terry model needs to be extended in several ways. In model (3) we already extended the Bradley-Terry model to handle both an ordinal response (in particular draws) and home effects. Now the model is further extended to incorporate on-field variables, which in the context of paired comparisons are considered as subject-object-specific variables. We propose to use the general model for ordinal response data $Y_{i(r,s)} \in \{1,\dots,K\}$ denoted by

$$\begin{aligned} P(Y_{i(r,s)} \leq k) &= \frac{\exp(\delta_r + \theta_k + \gamma_{ir} - \gamma_{is})}{1 + \exp(\delta_r + \theta_k + \gamma_{ir} - \gamma_{is})} \\ &= \frac{\exp(\delta_r + \theta_k + \beta_{r0} - \beta_{s0} + z_{ir}^T\alpha_r - z_{is}^T\alpha_s)}{1 + \exp(\delta_r + \theta_k + \beta_{r0} - \beta_{s0} + z_{ir}^T\alpha_r - z_{is}^T\alpha_s)} \,. \end{aligned} \tag{4}$$

The model allows for the inclusion of so-called subject-object-specific covariates z_{ir}. It belongs to the general model family proposed by Schauberger and Tutz (2017a) for the inclusion of different types of covariates in paired comparison models. Within this framework, Tutz and Schauberger (2015) present a model including object-specific covariates z_r and Schauberger and Tutz (2017b) present a model including subject-specific covariates z_i. In Schauberger et al. (2017), the presented model is applied to data from the Bundesliga season 2015/16.

The response $Y_{i(r,s)}$ encodes an ordered response with K categories (including a category for draws) for a match between team a_r and team a_s on matchday i where a_r plays at its home ground. The linear predictor of the model contains the following terms:

δ_r team-specific home effects of team a_r

θ_k category-specific threshold parameters
β_{r0} team-specific intercepts
z_{ir} p-dimensional covariate vector that varies over teams and matches
α_r p-dimensional parameter vector that varies over teams.

Instead of fixed abilities γ_r, the teams have abilities $\gamma_{ir} = \beta_{r0} + z_{ir}^T \alpha_r$ which differ for each matchday depending on the covariates of team a_r on matchday i. In its general form, the model has a lot of parameters that need to be estimated. It could, for example, be simplified if both the home effect and the covariate effects were included with global instead of team-specific parameters. For this purpose, we use penalty terms to decide whether the home effect or single covariate effects should be considered with team-specific or global parameters. In particular, the absolute values of all pairwise differences between the team-specific home advantages are penalized using the L_1 penalty term

$$P(\delta_1, \ldots, \delta_m) = \sum_{r<s} |\delta_r - \delta_s| \,. \tag{5}$$

The penalty term enforces the clustering of teams with equal home effects as it is able to set differences between parameters to exactly zero. Therefore, the penalty could for example produce three clusters of teams where each of the clusters has a different home effect. As an extreme case, the penalty leads to one global home effect if all differences are set zero.

Also the team-specific covariate effects are penalized. The respective penalty term penalizes the absolute values of all pairwise differences of the covariate parameters and of the parameters themselves, i.e.

$$J(\alpha_1, \ldots, \alpha_m) = \sum_{j=1}^{p} \sum_{r<s} |\alpha_{rj} - \alpha_{sj}| + \sum_{j=1}^{p} \sum_{r=1}^{m} |\alpha_{rj}| \,. \tag{6}$$

The penalty enforces clustering of teams with respect to certain on-field variables, possibly leading to global effects instead of team-specific effects. Moreover, due to the penalization of the absolute values, covariates can be eliminated completely from the model. For comparability of the penalties and the resulting effects, all covariates have to be transformed to a joint scale.

Finally, both penalty terms are combined and the respective penalized likelihood

$$l_p(\cdot) = l(\cdot) - \lambda \left(P(\delta_1, \ldots, \delta_m) + J(\alpha_1, \ldots, \alpha_m) \right)$$

is maximized, $l(\cdot)$ denoting the (unpenalized) likelihood. The tuning parameter λ is chosen by 10-fold cross-validation with respect to the so-called ranked probability score (RPS) proposed by Gneiting and Raftery (2007). The RPS for ordinal response $y \in \{1, \ldots, K\}$ can be denoted by

$$RPS(y, \hat{\pi}(k)) = \sum_{k=1}^{K} (\hat{\pi}(k) - \mathbb{1}(y \leq k))^2,$$

where $\pi(k)$ represents the cumulative probability $\pi(k) = P(y \leq k)$. In contrast to other possible error measures (e.g. the deviance or the Brier score), it takes the ordinal structure of the response into account.

4 Application to Bundesliga Season 2016/17

We now apply the model to data from the Bundesliga season 2016/17. The data contain each of the 306 macthes of this season on the 34 matchdays. For easier interpretation of the intercepts, the covariates were centered (per team around the team-specific means). Centering of covariates only changes the paths (and interpretation) of the team-specific intercepts. Now, the intercepts represent the ability of a team when every covariate is set to the team-specific mean. Beside that, the paths and the interpretation of the covariate effects are not affected by the centering of the covariates. They represent the effect of a covariate on the ability of a team when the respective covariate deviates from the team-specific mean.

Figure 1 illustrates the parameters' paths for the proposed model, separately for each covariate along the tuning parameter λ. The dashed vertical line indicates the model that was selected by 10-fold cross-validation. In contrast to the home effects and all covariate effects, the team-specific intercepts are not penalized and, consequently, do not show any particular clusters of teams. Bayern München clearly dominated the league in this season which is also represented by a very high team-specific intercept.

The paths of the home and the covariate effects clearly illustrate the clustering effect of the penalty terms. It can be seen that the home effect seems to be equal for all teams. The home effect is positive and, therefore, represents an actual home advantage for all teams as it was expected. The greatest effect of all covariates can be seen for *Distance*. It has a strong positive effect for all teams. The teams gain better results in matches where they had a good running performance. Interestingly, the covariate *BallPossession* has negative effects for all teams. Here, only Darmstadt 98 is separate from the other teams with an even more negative effect while all other teams form a big cluster for this variable. None of the variables is eliminated completely from the model, each variable has effects for at least two of the teams. *TacklingRate* and *ShotsonGoal* have (small) positive effects for all teams. Figure 2 shows the RPS of the cross-validation along the tuning parameter λ.

5 Concluding remarks

This work deals with data from the German Bundesliga from the season 2016/17 and considers several on-field variables in a paired comparison model. We propose a model that is able to make use of the big amount of data that is collected in modern football and to simultaneously connect the corresponding variables to the outcome

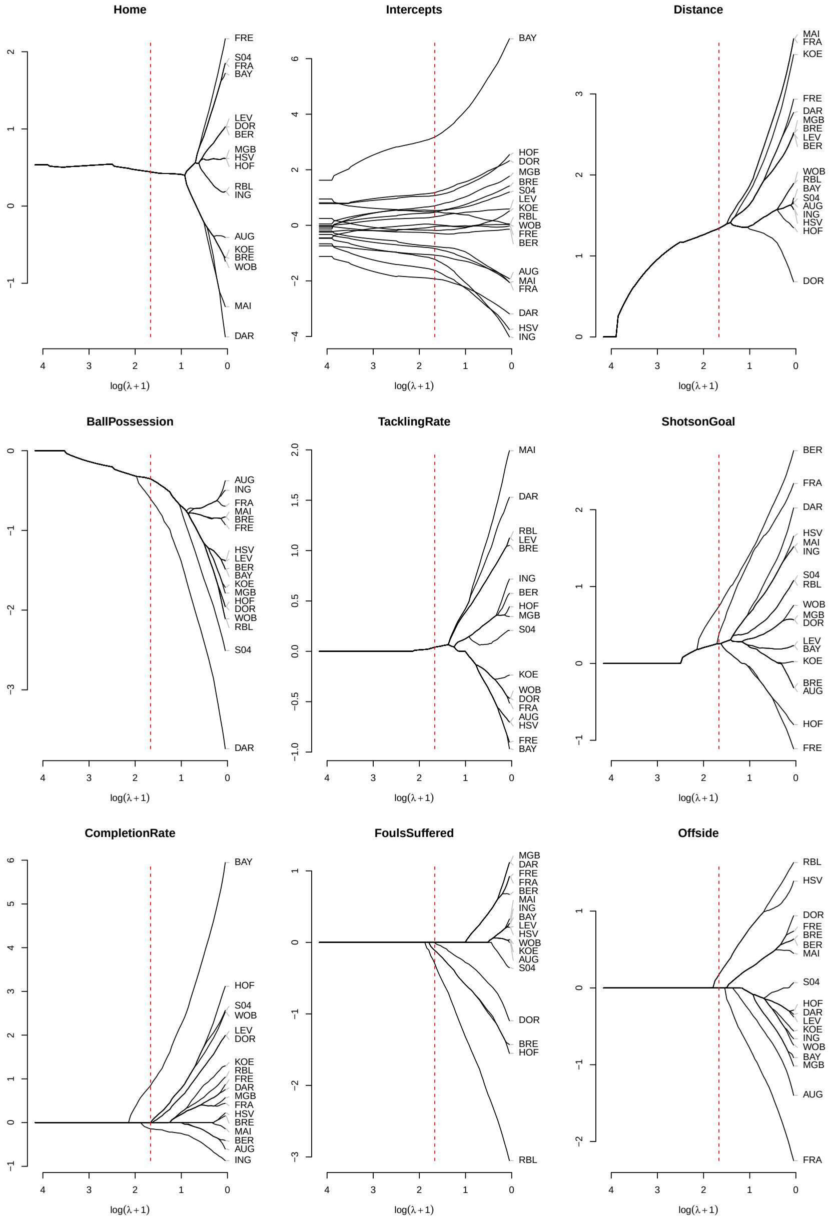

Fig. 1 Parameter paths, separately for home effect, intercepts and all (centered) covariates. Dashed vertical line represents the optimal model according to 10-fold cross-validation.

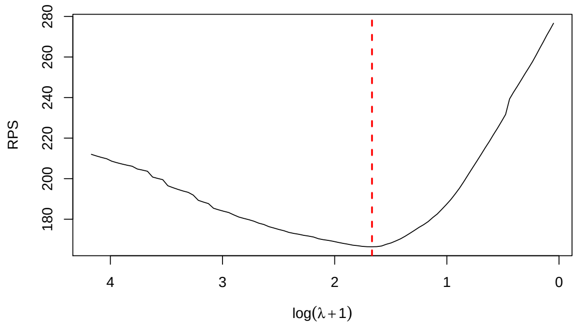

Fig. 2 Ranked probability score (RPS) for cross-validation along tuning parameter λ for model (4). Dashed vertical line represents optimal model according to 10-fold cross-validation.

of the matches. Complex modeling approaches are rather scarce in this area. The model incorporates football matches into the framework of paired comparisons and uses the general model proposed by Schauberger and Tutz (2017a) for the incorporation of different types of variables into paired comparison models.

In contrast to standard paired comparison models, the model offers a much more flexible and less restricted approach. Each team is assigned with individual strengths per matchday, depending on the on-field covariates of the team. This extension of the simple Bradley-Terry model allows for a much better discrimination between the different match outcomes and, therefore, for a better predictive performance.

Are the shots predictive for the football results?

I tiri sono predittivi per modellare il numero di reti nel calcio?

Leonardo Egidi, Francesco Pauli, Nicola Torelli

Abstract In modelling football outcomes, scores' data are regularly used for the estimation of the attack and the defence strength of each team. However, these teams' abilities are quite complex and are correlated with many quantities inherent to the game. Additional available information, relevant for their estimation, are shots, both made and conceded. For such a reason, we propose a hierarchical model that incorporates this information in three stages for each game and each team: number of scores, number of shots on target and number of total shots. We fit the model on English Premier League data and obtained predictions for future matches.

Abstract *Nel modellare i risultati calcistici, i dati sui goal sono solitamente utilizzati per stimare le abilità di attacco e difesa di ogni squadra. Tuttavia, queste abilità hanno una natura complessa e sono correlate con molte quantità inerenti al gioco. Un'ulteriore informazione disponibile, rilevante per stimare questi parametri, è data dai tiri, sia quelli realizzati che quelli concessi. A tale scopo proponiamo un modello gerarchico che incorpora questa informazione in tre stadi per ogni partita e ogni squadra: numero di goal, numero di tiri nello specchio e numero di tiri totali. Abbiamo applicato il modello sui dati della Premier League inglese e ottenuto previsioni per partite future.*

Key words: modelling football outcomes, hierarchical model, shot, prediction

1 Introduction

Modelling the outcome of a football match is the subject of much debate, and various models based on different assumptions have been proposed. The basic assump-

Leonardo Egidi, Francesco Pauli, Nicola Torelli
Dipartimento di Scienze Economiche, Aziendali, Matematiche e Statistiche, 'Bruno de Finetti', Università degli Studi di Trieste, Via Tigor 22, 34124 Trieste, Italy, e-mail: legidi@units.it, francesco.pauli@deams.units.it, nicola.torelli@deams.units.it

tion is that the number of goals scored by the two teams follow two Poisson distributions (Maher, 1982; Baio and Blangiardo, 2010)—possibly with rates parameters accounting for different sources of information, such as bookmakers odds (Egidi et al., 2018)—but many researchers investigated the correlation between them by proposing a more complicated bivariate Poisson distribution (Karlis and Ntzoufras, 2003).

Another typical assumption is the inclusion in the models of some teams' effects to describe the attack and the defence strengths of the competing teams. For this aim, the advent of some dynamic structures (Owen, 2011; Koopman and Lit, 2015) allowed these parameters to vary over the time, in order to specify an intuitive temporal evolution of these teams' skills along the match days and the seasons. The historical match results, possibly along with a set of further covariates, are usually the only data used for the estimation of these abilities. However, the scoring and the defence abilities are strongly correlated with the shots and the shots conceded respectively. For such a reason, including this information into a model designed for predicting the scores could provide relevant benefits both in terms of the realistic description of the game and the prediction of future matches outcomes. As an example of the relevance of the shots on target and the total shots on the statistical prediction of match results for the Italian football league Serie A, see Carpita et al. (2015).

In this paper, we propose a Bayesian hierarchical model consisting of a data-hierarchy in three stages for each game and each team, where the nested quantities are: number of scores, number of shots on target and number of total shots. The number of scores and the number of shots on target follow two binomial distributions respectively, with probability and population treated as further parameters. Intuitively, the total shots also consist of all those attempts—e.g., long distance shots, last minute shots—which may represent a noisy proxy for the attack skills, and for such a reason they represent the last level of the assumed hierarchy.

As far as we know from reviewing the current literature, this proposal represents a novelty also in terms of parameters' interpretation: binomial probabilities associated to the first two levels reflect the conversion rate of the shots on target in goals and the precision rate of all the shot attempts, respectively. In Sect. 2 we introduce the entire model, and we focus on the Gaussian process for the attack and the defence abilities. Moreover, we assess the binomial assumption for the scores through a Pearson's chi-squared test. We present the application on the English Premier League in Sect. 3, along with parameters' estimates and predictions for the test set season. Sect. 4 concludes.

2 A joint model for the shots and the scores

Here, $\boldsymbol{y}_m = (y_{m1}, y_{m2})$ denotes the vector of observed scores, where y_{m1} and y_{m2} are the number of goals scored by the home team and by the away team in the m-th match of the dataset, respectively. Let $\boldsymbol{s}_m = (s_{m1}, s_{m2})$ denote the shots on the target and $\boldsymbol{w}_m = (w_{m1}, w_{m2})$ the total number of shots, respectively. For each m, the data information is represented by the joint vector $(\boldsymbol{y}, \boldsymbol{s}, \boldsymbol{w})$. The total number of teams considered across the seasons is $T = 34$. In what follows, the nested indexes $h(m), a(m) = 1, \dots, T$ and $\tau(m)$ identify the home team, the away team and the season τ associated with the m-th game, respectively. The three-stages hierarchical model for the scores and the shots is then specified as follows:

$$\begin{aligned} y_{m1} &\sim \mathsf{Binomial}(s_{m1}, p_{h(m),\tau(m)}) \\ y_{m2} &\sim \mathsf{Binomial}(s_{m2}, q_{a(m),\tau(m)}) \\ s_{m1} &\sim \mathsf{Binomial}(w_{m1}, u_{h(m)}) \\ s_{m2} &\sim \mathsf{Binomial}(w_{m2}, v_{a(m)}) \\ w_{mj}|\theta_{mj} &\sim \mathsf{NegBinomial}(\theta_{mj}, \phi), \;\; j = 1,2. \end{aligned} \tag{1}$$

The *conversion probabilities* p and q are modelled with two inverse logit, depending on the attack and the defence strengths of the competing teams:

$$\begin{aligned} p_{h(m),\tau(m)} &= \text{logit}^{-1}(\mu + att_{h(m),\tau(m)} + def_{a(m),\tau(m)}) \\ p_{a(m),\tau(m)} &= \text{logit}^{-1}(att_{a(m),\tau(m)} + def_{h(m),\tau(m)}). \end{aligned} \tag{2}$$

The attack and defence parameters are assumed to follow two Gaussian processes:

$$\begin{aligned} att_{,\tau} &\sim \mathsf{GP}(\mu_{att}(\tau), k(\tau)), \\ def_{,\tau} &\sim \mathsf{GP}(\mu_{def}(\tau), k(\tau)), \end{aligned} \tag{3}$$

with mean functions $\mu_{att}(\tau) = att_{\cdot,\tau-1}$, $\mu_{def}(\tau) = def_{\cdot,\tau-1}$, and covariance function with generic element $k(\tau)_{i,j} = \exp\{-(\tau_i - \tau_j)^2\} + 0.1$. As outlined in the literature, a 'zero-sum' identifiability constraint within each season is required: for T teams we assume: $\sum_{t=1}^{T} att_{t,\tau} = 0$, $\sum_{t=1}^{T} def_{t,\tau} = 0, \tau = 1, \dots \mathscr{T}$.

The *shots' precision probabilities* u and v and the *shooting rates* θ_{m1}, θ_{m2} are given a Beta distribution with hyperparameters δ, ε and a Gamma distribution with hyperparameters α, β, respectively:

$$u_{h(m)} \sim \mathsf{Beta}(\delta_{h(m)}, \varepsilon_{h(m)}), \; v_{a(m)} \sim \mathsf{Beta}(\delta_{a(m)}, \varepsilon_{a(m)}) \tag{4}$$

$$\theta_{m1} \sim \mathsf{Gamma}(\alpha_{h(m)}, \beta_{h(m)}), \; \theta_{m2} \sim \mathsf{Gamma}(\alpha_{a(m)}, \beta_{a(m)}). \tag{5}$$

The model is completed by the specification of weakly informative priors for the home effect parameter μ, the overdispersion parameter ϕ, and the hyperparameters $\alpha, \beta, \delta, \varepsilon$.

It is of interest to assess the legitimacy of the binomial distribution for the model above. For this purpose, we consider the empirical distribution of the scores conditioned on a given number of shots on target, $y_{\cdot j}|s_{\cdot j} = z$, $z \in \mathbb{N}$, and we check whether this sample may be thought as drawn from a Binomial(n, p), with n and p fixed. For each z, we performed some Pearson χ^2-tests comparing the empirical distribution of the scores conditioned on the z-th shot on target and the hypothesized binomial distribution, with n and p estimated from the data. For both the home and the away scores, for each z the Pearson χ^2 test suggests to not reject the null hypothesis of binomial distribution (all the p-values are always greater than the threshold $\alpha = 0.05$).

3 Application: Premier League from 2007/2008 to 2016/2017

We collected the historical data arising from 10 seasons of the English Premier League (EPL), from 2007/2008 to 2016/2017. The data structure of the model is presented in Table 1 with respect to the first match day in EPL 2007/2008. The goal is fitting the model and deriving the parameters' estimates. Secondly, we make predictions for a set of future matches. Model coding has been written using Stan (Carpenter et al., 2017), precisely the Rstan interface. We strictly followed the software guidelines for monitoring the chains' convergence and speeding up the computational times. The chosen number of Hamiltonian Markov Chain iterations is 2000, with a burnin period of 500.

Table 1 Data structure for the first match day, EPL, 2007/2008 season. Each column reports: match, season, home team, away team, home goals, away goals, home shots, away shots , home shots on target, away shots on target.

Match	Season	$h[m]$	$a[m]$	y_{m1}	y_{m2}	w_{m1}	w_{m2}	s_{m1}	s_{m2}
1	07/08	Aston Villa	Liverpool	1	2	10	17	6	7
2	07/08	Bolton	Newcastle	1	3	13	7	9	5
3	07/08	Derby	Portsmouth	2	2	12	12	5	6
4	07/08	Everton	Wigan	2	1	12	14	8	4
5	07/08	Middlesbrough	Blackburn	1	2	10	4	6	4
6	07/08	Sunderland	Tottenham	1	0	9	6	4	3
7	07/08	West Ham	Man City	0	2	9	14	2	5
8	07/08	Arsenal	Fulham	2	1	19	12	13	9
9	07/08	Chelsea	Birmingham	3	2	19	6	11	4
10	07/08	Man United	Reading	0	0	22	3	9	2

3.1 Parameters' estimates

As usual in Bayesian inference, posterior means ± posterior standard deviations or posterior quantiles are the summaries for describing and visualizing the posterior distribution of the parameters.

The attack and defence abilities are directly connected with the scoring probabilities in (2), and modelled as Gaussian processes in (3) in terms of seasonal evolution. Fig. 1 displays the 50% posterior intervals for the attack (solid red line) and the defence (solid black line) in formula (3) across the seasons. Higher values for the attack are associated with a greater propensity to convert the shots on target in goals; conversely, lower values for the defence correspond to a better ability to not concede goals. These plots may explain something unexpected even for football experts and help in revealing new instances behind events thought as completely unpredictable. For instance, Leicester won the Premier League 2015/2016 with associated initial odds such as 1:5000, and no one, at the beginning of the season, could have predicted that performance. However, there is a surprising trend that emerges clearly: starting from 2007/2008 season, Leicester dramatically improved the propensity to convert the shots in goal and, at the same time, reinforced its defence. The values registered for the attack and the defence are among the highest and the lowest in the EPL respectively. Maybe, the victory of Leicester, despite highly surprising, was less unpredictable than what the experts had thought.

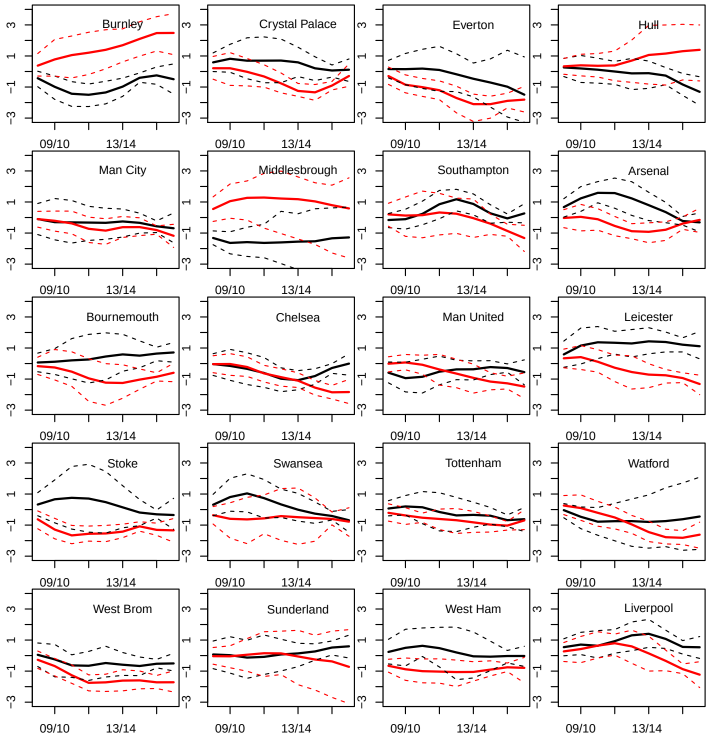

Fig. 1 Posterior estimates for the attack (solid black lines) and defence (solid red lines) across the nine seasons considered, from 2008/2009 to 2016/2017, for the twenty teams belonging to the EPL in the 2016/2017 season.

The power of model (1) is to represent a sort of scores' genesis, able to approximately reproduce the features of the real game. The scores represent the final level, depending on the population of the shots on target, which in turn depends on the population of the total shots. The posterior means ± standard error for the average conversion probabilities p, q and the home precision probabilities u are displayed in Fig. 2 (left panel). For the majority of the teams, the precision probabilities (black bars) are higher than the conversion probabilities (red and blue bars), and this is intuitive in terms of football features: usually, the ratio between the shots on target and the total shots tends to be higher than the ratio between the goals and the shots on target. However, Middlesbrough, one of the three relegated teams at the end of the 2016/2017 season, is associated with the highest precision probability—half of its shots are on the target—but with the lowest conversion—only about one attempt over ten in the targets corresponds to a score. Conversely, the precision probabilities for Leicester almost overlap the conversion probabilities. For what concerns the total shots, Fig. 2 (right panel) displays the average shots rates, where Chelsea, Manchester City, Tottenham and Liverpool register the highest values. For each team, the trend is to kick more when playing at home.

Although a broad analysis of these statistics should benefit from other comparisons and covariates, we imagine these kinds of plots and summaries could be beneficial for football managers or tactic experts, at least in a naive perspective summarized by the quote 'kick less, kick better'.

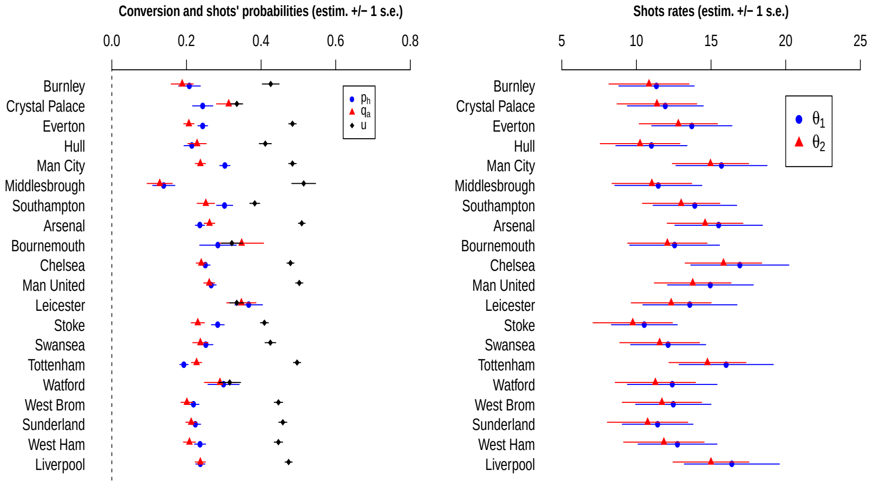

Fig. 2 Average of the posterior estimates for the conversion probabilities p_h and q_a and for the home precision probabilities u (left panel); average of the posterior estimates for the shots rates $\theta_{\cdot 1}, \theta_{\cdot 2}$ (right panel) for the twenty teams belonging to the EPL 2016/2017.

3.2 Prediction and posterior probabilities

Making predictions for future games and seasons is of great appeal for sport statisticians. We used historical data arising from the past seasons for making predictions about the tenth season, the EPL 2016/2017. As usual in a Bayesian framework, the prediction for a new dataset may be performed directly via the posterior predictive distribution for our unknown set of observable values. Fig. 3 displays the posterior 50% credible bars (grey ribbons) for the predicted achieved points for each team for the season 2016/2017, together with the observed final ranks. At a first glance, the model correctly detects Chelsea as EPL champion at the end of the 2016/2017 season, and Middlesbrough and Hull City relegated in Championship. Manchester City, Tottehnham and Arsenal appear to be definitely underestimated, whereas Manchester United and Leicester are quite overestimated. Globally, the predictions reflect the observed pattern.

Table 2 reports the model posterior probabilities being the first, the second and the third relegated team; as may be noticed, Sunderland was pretty unlikely to be relegated in Championship. Conversely, Burnley had an high probability to be relegated, but it performed better than the predictions.

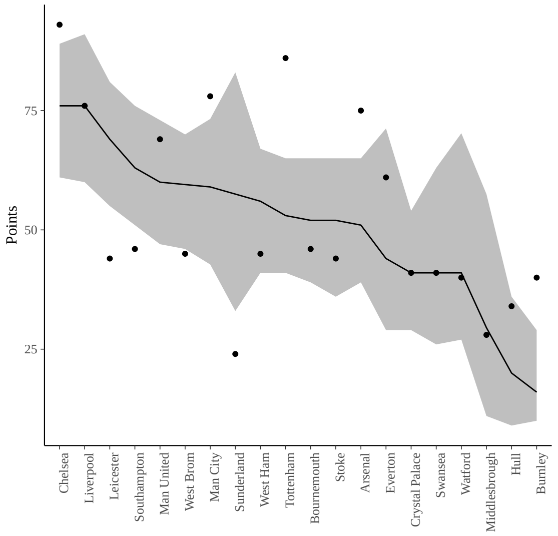

Fig. 3 Posterior 50% credible bars (grey ribbons) for the achieved final points of English Premier League 2016/2017. Black dots are the observed points. Black lines are the posterior medians.

Table 2 Estimated posterior probabilities for each team being the first, the second, and the third relegated team in the Premier League, 2016/2017, together with the observed rank and the number of points achieved (relegated predicted teams by the model are emphasized).

Team	P(1st rel)	P(2nd rel)	P(3d rel)	Actual rank	Points
Burnley	0.096	0.161	0.245	16	40
Hull	0.103	0.198	0.254	18	34
Middlesbrough	0.063	0.117	0.226	19	28
Sunderland	0.055	0.045	0.027	20	24

4 Discussion

We have proposed a Bayesian hierarchical model consisting of a three-stage hierarchy for the scores, the shots on target and the number of total shots. The main novelty is the inclusion of an important latent football feature represented by the kicking ability of each team, modelled both in terms of intensity and precision. Preliminary results on future matches seem to be promising in terms of predictive accuracy. Model comparisons and goodness of fit tools are issues of future interest.

Zero-inflated ordinal data models with application to sport (*in*)activity

Modelli per dati ordinali zero-inflazionati con applicazione all'(in)attività sportiva

Maria Iannario and Rosaria Simone

Abstract Traditional models for ordinal data (as CUB models or cumulative models with logit/probit link, among others) present limits in explaining the surplus of zero observations, especially when the zeros may relate to two distinct situations of non-participation/inactivity and infrequent participation, for instance. We consider an extension of standard models: zero-inflated CUB models and zero inflated ordered cumulative (ZIOC) probit/logit models handling the GECUB models and using a double-hurdle combination of a split (logit/probit) model and an ordered probit/logit model, respectively. Both extensions, potentially, relate to different sets of covariates. Finally, models are applied to Sport surveys. Specifically the paper investigates the determinants of sport (*in*)activity: the frequency and the probability of sports participation. It distinguishes between genuine "non-participants" and the ones who do not participate at a time but might do under different circumstances.

Abstract *I modelli tradizionali per i dati ordinali (come modelli* CUB *o cumulativi con link logit/probit, tra gli altri) presentano limiti nello spiegare il surplus di osservazioni nella categoria zero, specialmente quando gli zeri possono riguardare due distinte situazioni di non partecipazione/non attività e/o partecipazione non frequente. Il lavoro propone un'estensione di modelli standard: i modelli* CUB zero inflated *e i modelli ordinal probit/logit con inflazione di zeri (*ZIOC*). I primi costituiscono una revisione dei modelli* GECUB *(modelli* CUB *con effetto shelter), i secondi costituiscono una mistura di modelli (probit/logit) dicotomici e modelli probit/logit ordinali. Entrambe le estensioni possono riferirsi a diversi gruppi di covariate. Infine, i modelli sono applicati a dati rilevati da indagini sullo sport. In particolare, lo studio esplora le determinanti dell'(in)attività sportiva: la frequenza e la probabilità di partecipazione ad attività sportive. Distingue tra veri "non partecipanti"*

e coloro che non partecipano al momento dell'indagine, ma potrebbero se in circostanze diverse.

Key words: CUB models, Ordinal logit/probit models, Ordered outcomes, discrete data, sport inactivity, zero-inflated responses

1 Introduction

Excess of zeros is a commonly encountered phenomenon that limits the use of traditional regression models for analysing ordinal data in contexts where respondents express a graduated perception on a specific item or experiments identify levels of increasing assessments.

The situation occurs with ordinal scales in which there is an anchor that represents the absence of the symptom or activity, such as none, never or normal. This level usually tagged *zero* may be scored by respondents certainly not at risk (without symptom or who do not practice any activity/exercise) and respondents with a non-zero probability of risk.

Survey data concerning epidemiological studies or choices, particularly those that refer to an explicit time dimension, may include genuine non-participants whatever the circumstances are, as well as individuals who would decide to participate if the circumstances were different. It is, therefore, likely that these two types of zeros are driven by different behaviour. One example is a study by Harris and Zhao (2007) on the consumer choice problem of tobacco consumption or the analysis of Downward et al. (2011) on sports participation, among others.

Aim of the paper is introducing methodologies that allow users of ordinal scale data to more accurately model the distribution of ordinal outcomes in which some subjects are susceptible to exhibit the response and some are not (i.e. the dependent variable exhibits zero inflation). The study explores the determinants of sport (*in*)activity: the frequency and the probability of sports participation. It distinguishes between genuine "non-participants" and the ones who do not participate at a time but might do under different circumstances. Thus, it includes whether or not to participate in sport and, subsequently, what intensity of participation is undertaken. It is able to distinguish between structured and sampling zeros implementing some results obtained for count data in the ordinal data context.

With respect to the standard models for ordinal data the new methodologies exceed some gaps related to the model of zeros by taking into account the potentially two-fold decision made with respect to participation. Here we propose extensions of standard models: zero-inflated CUB (ZICUB) models and zero inflated ordered cumulative (ZIOC) probit/logit models handling the GECUB models and using a double-hurdle combination of a split (logit/probit) model and an ordered probit/logit models, respectively. Both extensions, potentially, relate to different sets of covariates. The modelling assumption is that different decisions govern the choice to participate and the frequency of participation in sport. The remainder of the paper is as follows.

Section 2 reviews the methods used for the analysis. Section 3 describes the data set and main estimation results with a summary of the main findings and opportunities for further research.

2 Methods

Let Y be a discrete random variable that assumes the ordered values of $0,1,...,J$. Standard ordinal cumulative (Agresti, 2010) or CUB models (Piccolo, 2003) map a single latent variable Y^* to the observable Y, with Y^* related to a set of covariates or consider the response as a weighted mixture of respondents' propensity to adhere to a meditated choice (formally described by a shifted Binomial random variable) and a totally uninformative choice (described by a discrete Uniform distribution) with a possible *shelter* effect (Iannario, 2012; Iannario and Piccolo, 2016), respectively. Here we propose a zero inflated cumulative (ZIOC) model that involves two latent equations with uncorrelated error terms: a logit/probit equation and an ordered logit/probit equation by introducing ZIOL/ZIOP models (subsection 2.1). Or in order to further disentangle the *inflated effect* concentrated at category *zero* we may introduce a variant of GECUB models (subsection 2.2).

2.1 Zero Inflated Cumulative Models

Let r denote a binary variable indicating the split between Regime 0 ($r=0$, for "non participants") and Regime 1 ($r=1$ for "participants"), which is related to the latent variable $r^*=\boldsymbol{x}'\boldsymbol{\beta}+\varepsilon$ where $\boldsymbol{x}$ is a vector of p individual characteristics (covariates) that determine the choice of regimes, $\boldsymbol{\beta}$ is a p-vector of unknown regression parameters, and ε is a random variable with cumulative distribution function $G_\varepsilon(.)$. Accordingly, the probability of an individual being in Regime 1 is given by

$$Pr(r=1|\boldsymbol{x})=Pr(r^*>0|\boldsymbol{x})=G_\varepsilon(\boldsymbol{x}'\boldsymbol{\beta}),$$

where we assume $G_\varepsilon(.)$ strictly increasing and symmetric around zero. Standard choices for the distribution function are the logit link function, $G(t)=1/(1+e^{-t})$, corresponding to the logistic distribution, or the probit link function, $G(t)=\Phi(t)$, with Φ the cdf of the standard normal distribution.

Conditional on $r=1$, respondents levels under Regime 1 are represented by $\tilde{Y}(\tilde{Y}=0,1,\dots,J)$, which is generated by a cumulative link model based upon a second underlying latent variable $\tilde{Y}^*$, where

$$\tilde{Y}^*=\boldsymbol{z}'\boldsymbol{\gamma}+u,$$

with $\boldsymbol{z}$ being a vector of covariates with unknown parameters $\boldsymbol{\gamma}$ and $u\sim G_\varepsilon(.)$. The observed ordinal variable $\tilde{Y}$ takes as values the labels 0 if $\tilde{Y}^*\leq 0$, J if $\tilde{Y}^*\geq\alpha_{J-1}$

otherwise,

$$\tilde{Y} = j \qquad \iff \qquad \alpha_{j-1} < \tilde{Y}^* \le \alpha_j \qquad j = 1,2,\dots,J-1\,, \qquad j > 2\,,$$

where $\alpha_j\,(j = 1,\dots,J-1)$ are the intercept values to be estimated in addition to the covariate coefficients $\boldsymbol{\gamma}$. Notice that Regime 1 also allows for zero scores. That is, to observe $Y = 0$ we require either that $r = 0$ (the individual is a non participant) or jointly that $r = 1$ and $\tilde{Y} = 0$ (the individual is a zero consumption participant). To observe a positive score, instead, we require jointly that the individual is a participant $(r = 1)$ and $\tilde{Y}^* > 0$. If we assume that the error terms from the first stage equation and the second stage cumulative outcome equation, that is e and u, are not correlated the probability mass function of the ZIOC model is

$$Pr\,(Y) = \begin{cases} Pr\,(Y = 0 \mid z,\boldsymbol{x}) = Pr\,(r = 0 \mid \boldsymbol{x}) + Pr\,(r = 1 \mid \boldsymbol{x})\,Pr\,\big(\tilde{Y} = 0 \mid \boldsymbol{z}, r = 1\big) \\ Pr\,(Y = j \mid z,\boldsymbol{x}) = Pr\,(r = 1 \mid \boldsymbol{x})\;Pr\,\big(\tilde{Y} = j \mid z, r = 1\big)\;\;(j = 1,\dots,J) \end{cases}$$

$$= \begin{cases} Pr\,(Y = 0 \mid z,\boldsymbol{x}) = [1 - G_\varepsilon(\boldsymbol{x}'\boldsymbol{\beta})] + G_\varepsilon(\boldsymbol{x}'\boldsymbol{\beta})G_\varepsilon(-\boldsymbol{z}'\boldsymbol{\gamma}) \\ Pr\,(Y = j \mid z,\boldsymbol{x}) = G_\varepsilon(\boldsymbol{x}'\boldsymbol{\beta})[G_\varepsilon(\alpha_j - \boldsymbol{z}'\boldsymbol{\gamma}) - G_\varepsilon(\alpha_{j-1} - \boldsymbol{z}'\boldsymbol{\gamma})]\,(j = 1,\dots,J-1) \\ Pr\,(Y = J \mid z,\boldsymbol{x}) = G_\varepsilon(\boldsymbol{x}'\boldsymbol{\beta})[1 - G_\varepsilon(\alpha_{J-1} - \boldsymbol{z}'\boldsymbol{\gamma}). \end{cases}$$

In this way, the probability of a zero score has been inflated as it is a combination of the probability of zero consumption from the cumulative model framework and the probability of non-participation from the split logit/probit model. Notice that the choice of distribution function G_ε allows to consider the Zero Inflated Ordinal Probit (ZIOP) as in Harris and Zao (2007) or Zero Inflated Ordinal Logit (ZIOL) models. Once the full set of probabilities has been specified, and given an *iid* sample $(i = 1,\dots,n)$ from the population on $(Y_i, \boldsymbol{x}_i, z_i)$, the parameters of the full model $\boldsymbol{\theta} = (\boldsymbol{\beta}', \boldsymbol{\gamma}', \boldsymbol{\alpha}')'$ may be estimated using the maximum likelihood (ML) methods. The log-likelihood function is $\ell(\boldsymbol{\theta}) = \sum_{i=1}^{n} \sum_{j=0}^{J} I[Y_i = j] \log Pr\,(Y_i = j|\boldsymbol{x}_i, z_i, \boldsymbol{\theta})$, where $I[Y_i = j]$ is the indicator function of $(Y_i = j)$.

2.2 Zero Inflated CUB Models

Let $\check{Y} \sim CUB_{she=1}(\check{\pi}, \xi, \delta; J+1)$ be a CUB distributed random variable over $J+1$ categories and *shelter* at $c = 1$:

$$Pr\,\big(\check{Y} = j \mid \check{\pi}, \xi, \delta\big) = \delta\,D_j^{(c)} + (1-\delta)\,\big[\check{\pi}\,b_j(\xi) + (1-\check{\pi})\,h_j\big],\;\; j = 1,2,\dots,J+1,$$

where $h_j = \dfrac{1}{J+1}$ is the discrete Uniform distribution over the given support and $b_j(\xi)$ denotes the shifted Binomial distribution with parameter $1-\xi$.

Then, a ZICUB model for the response variable $Y \in \{0,\dots,J\}$ is specified by setting $Y = \check{Y} - 1$. In this way

$$P_r(Y) = \begin{cases} Pr(Y=0|\boldsymbol{\theta}) = \delta + (1-\delta)\left[\pi b_1(\xi_i) + (1-\pi)\dfrac{1}{J+1}\right] \\ Pr(Y=j|\boldsymbol{\theta}) = (1-\delta)\left[\pi b_{j+1}(\xi) + (1-\pi)\dfrac{1}{J+1}\right], \quad j=1,\dots,J. \end{cases}$$

In addition to examine the effects of risk factors on the response variable it may be proposed the inclusion of covariates on the parameters through canonical logit link:

$$logit(\delta_i) = \boldsymbol{\omega}'\boldsymbol{x}_i;\;\; logit(\pi_i) = \boldsymbol{\eta}'\boldsymbol{z}_i;\;\; logit(\xi_i) = \boldsymbol{\zeta}'\boldsymbol{w}_i\,.$$

Here, $\boldsymbol{\theta} = (\boldsymbol{\omega}', \boldsymbol{\eta}', \boldsymbol{\zeta}')'$ is the parameter vector characterizing the distribution of $(Y_1, Y_2, \dots, Y_n)$ with $\boldsymbol{\omega}', \boldsymbol{\eta}', \boldsymbol{\zeta}'$ denoting the parameter vector for the *shelter*, uncertainty and feeling components, respectively, and $\boldsymbol{x}_i \in \boldsymbol{X}, \boldsymbol{z}_i \in \boldsymbol{Z}$ and $\boldsymbol{w}_i \in \boldsymbol{W}$ being the selected covariates for the i-th subject of the three components. The zero-inflated variant of GECUB models also assumes that some zeros are observed due to a specific structure in the data.

Here, given an observed random sample $(Y_i, \boldsymbol{x}_i, \boldsymbol{z}_i, \boldsymbol{w}_i)$, for $i = 1, 2, \dots, n$, the log-likelihood function is $\ell(\boldsymbol{\theta}) = \sum_{i=1}^{n} \sum_{j=0}^{J} I[y_i = j] \log P_r(Y_i = j|\boldsymbol{x}_i, \boldsymbol{z}_i, \boldsymbol{w}_i, \boldsymbol{\theta})$, where $I[Y_i = j]$ is the indicator function of $(Y_i = j)$.

3 Data and application

The determinant of sport (*in*)activity will be discussed on the basis of two case studies involving data collected in 2016 and 2017, respectively, through a web link related to the BDsports project (http://bodai.unibs.it/bdsports/). The case studies have been selected to highlight pitfalls and advantages of the two main proposals and to allow the distinction between genuine inactive respondents and the ones who do not play sport at a time of surveys.

In the last decade the modelling of sports participation decision has increased in complexity. The sports participation variable is measured in different ways; relatively few studies consider the time spent on sports participation or the frequency of such participation as we done in this paper. The dependent variable under investigation for 2016 is a rating on a 7 point scale whereas for 2017 is a rating on 11 categories (see Figure 1), asking each respondent the time dedicated to sport practice on weekly basis: from ‘0 = Rarely practiced any sport/not practiced any sport at all’, ‘1 = Less than one hour’ up to ‘6 = More than 7 hours’ (up to ‘10’ for 2017). Notice that the two surveys are about two different main topics (sport preferences and habits for the first survey, on the exercise addiction for the second ones); however both of them present a rating question on sport activity. Because the dependent variable is ordered rather than continuous and because, as noted in the Introduction, ‘zero’ participation could measure never participated (genuine inactive) or not recently/rarely participated a Zero-inflated ordered (ZIOP) estimator and ZICUB models are employed for 2016 whereas a ZIOL and ZICUB models for 2017. The modelling assumption is that different decisions govern the choice to participate and the frequency of participation in sport. Hurdle models are not considered by following what it is in Downward et al. (2011).

Evidence in the literature reveals that the probability of sports activity decreases with *age* (Barber and Havitz, 2001; Downward and Rasciute, 2010; among others) with less difference in gender among the older adults (Bauman et al. 2009). *Gender*, in fact, is the other covariate that has a highly important influence on sports activity. There is evidence about the fact that men, in general, not only participate in sport more than women (Downward and Rasciute, 2010; Eberth and Smith, 2010; Hovemann and Wicker, 2009; Lera-López and Rapún-Gárate, 2007) but they also show a higher frequency of participation (Barber and Havitz, 2001; Eberth and Smith, 2010). These differences may be attributed to biological factors, and cultural and social influences (Humphreys and Ruseski, 2010). Another determinant of sport (*in*)activity is the smoking habit; it has (with alcohol consumption) negative effects on sport practice especially in relation to age (Perretti et al. 2002).

Thus, in our analysis the selected covariates for 2016 are *gender, age* and the *smoking* habit. Results concerning a sample of $n = 647$ respondents are in Table 1 with the thresholds (cutpoints) on the underlying scale for ZIOP model $\hat{\alpha}_1 = -4.683$, $\hat{\alpha}_2 = -0.918$, $\hat{\alpha}_3 = -0.751$, $\hat{\alpha}_4 = -0.188$, $\hat{\alpha}_5 = -0.026$, $\hat{\alpha}_6 = 1.382$.

As revealed by estimation results of ZIOP model (Table 1) and mentioned in the literature sport activity reduces with older age; furthermore, smokers are generally inactive as well as women. Both estimated models confirm the effect of *age* for the inflation in the zero category that in ZICUB models is explicitly due to *smoking* habits. The best performance in terms of BIC index is for ZICUB model (bold in Table).

Similar results have been obtained for the analysis of the second survey (2017) where *gender, age* and the dichotomous response to the question “do you practice any sport or physical activity?” are considered ($n = 554$). Results are in Table 2 with the thresholds (cutpoints) on the underlying scale for ZIOL model $\hat{\alpha}_1 = -6.975$,

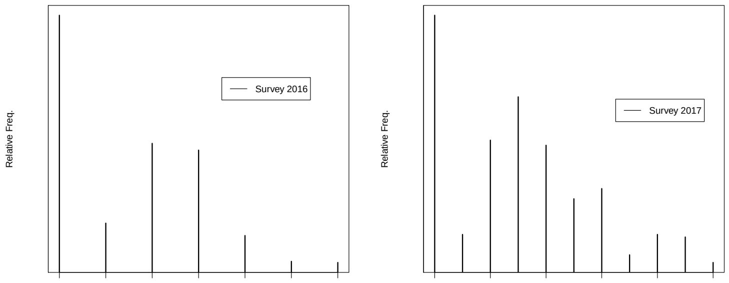

Fig. 1 Frequency distribution of the time spent on sports participation ($J = 0, 1, \dots, 6$; Survey 2016 left side) ($j = 0, 1, \dots, 10$; Survey 2017 right side)

Table 1 Regression results for ZICUB and ZIOP models

Models	Covariates	Parameters	Estimates	StdErr
ZICUB	*Constant*	$\hat{\omega}_0$	−0.871	0.115
	Smoke	$\hat{\omega}_1$	0.556	0.201
	Constant	$\hat{\eta}_0$	2.773	0.715
	Age	$\hat{\eta}_1$	−0.057	0.022
	Constant	$\hat{\zeta}_0$	0.283	0.063
	Woman	$\hat{\zeta}_1$	0.163	0.085
	$\ell(\boldsymbol{\theta})$	−1056.233	*BIC*	**2172.876**
ZIOP	Age	$\hat{\beta}_1$	0.611	0.087
	Constant	$\hat{\gamma}_0$	−0.309	0.112
	Woman	$\hat{\gamma}_1$	−0.345	0.104
	Smoke	$\hat{\gamma}_2$	0.014	0.005
	$\ell(\boldsymbol{\theta})$	−1067.021	*BIC*	2177.189

$\hat{\alpha}_2 = -1.128$, $\hat{\alpha}_3 = -0.825$, $\hat{\alpha}_4 = -0.571$, $\hat{\alpha}_5 = -0.543$, $\hat{\alpha}_6 = -0.074$, $\hat{\alpha}_7 = 0.011$, $\hat{\alpha}_8 = 0.300$, $\hat{\alpha}_9 = 1.034$.

Here it possible to notice the different impact of *age* on the uncertainty component for ZICUB model; for ZIOL model, instead, it has been confirmed the increasing inactivity for older respondents. Furthermore, to be woman and the answer to no sport/physical activity practiced represent requisites which express sport inactivity. In ZICUB model the effect of *gender* influences the feeling component by explaining woman inactivity, especially for "no practice at all" respondents. Generally this last model presents a better performance (BIC index in bold); here the inflation in zero consistently increases with the response "no practice". Data and the *R* code for the implementation of the methods are available upon request from Authors.

Finally, by testing different covariates and models to explain sport (*in*)activity it turns out that *age, gender, smoking* habit and *no sport/physical activity* exercised affect the occurrence of sedentary behaviour: given all these drivers it is possible to analyse the effect of age for zero inflation in ZIOC models, and smoking habits and no sport/physical activity practised for ZICUB models. Both implemented methods confirm the main results of the literature. Although the choice between the two zero-inflated approaches is generally based on the aim of the study, the evaluation in terms of fitting results and the interpretation of covariates may address the selection. Moreover, it is important to highlight some computational drawbacks related to the performance of ZIOC models.

Generally assessing the nature of the zero scores is becoming a more and more relevant issue demanding for the use of both the proposals. They can be used to estimate the proportion of zeros coming from each regime, and to evaluate how the split changes with observed characteristics.

Simulation studies will be planned to further validate and compare the efficacy of the proposals.

Table 2 Regression results for ZICUB and ZIOL models

Models	Covariates	Parameters	Estimates	Std Err
ZICUB	*Constant*	$\hat{\omega}_0$	−5.281	2.357
	No practice at all	$\hat{\omega}_1$	7.202	2.382
	Constant	$\hat{\eta}_0$	−2.895	0.860
	Age	$\hat{\eta}_1$	0.112	0.035
	Constant	$\hat{\zeta}_0$	0.347	0.130
	Woman	$\hat{\zeta}_1$	1.175	0.282
	No practice at all	$\hat{\zeta}_2$	0.212	0.084
	$\ell(\boldsymbol{\theta})$	−1085.695	*BIC*	**2215.61**
ZIOL	Age	$\hat{\beta}_1$	3.595	0.764
	Constant	$\hat{\gamma}_0$	−0.429	0.398
	Woman	$\hat{\gamma}_1$	−5.177	0.529
	No practice at all	$\hat{\gamma}_2$	−0.060	0.012
	$\ell(\boldsymbol{\theta})$	−1078.085	*BIC*	2244.611

Being young and becoming adult in the Third Millennium: definition issues and processes analysis

Do Social Media Data predict changes in young adults' employment status? Evidence from Italy

I Social Media data possono predire variazioni dello stato occupazione giovanile? Un caso studio in Italia

Andrea Bonanomi and Emiliano Sironi

Abstract This study addresses the conditions in which young Italian people find themselves during the active job search via Social Media Data. Focusing especially on NEETs, the aims of the study are: 1) to predict the changes in employment status from traditional information by using the longitudinal representative survey Rapporto Giovani; 2) to identify the target population inferring from their online digital traces; 3) to predict changes in employment status from social media data. We tried to predict the employment status transitions based on the digital behaviour using a new Facebook application, *LikeYouth*, that gathers information regarding Facebook profile and Likes on Facebook Pages of each user.

Abstract *Questo lavoro affronta le condizioni dei giovani italiani durante ricerca attiva di lavoro, mediante l'utilizzo di social media data. Concentrandoci in particolare sui NEET, gli obiettivi dello studio sono: 1) prevedere i cambiamenti nello stato occupazionale dalle informazioni tradizionali tratte dall'indagine longitudinale rappresentativa "Rapporto Giovani"; 2) identificare la popolazione target inferendola dalle tracce digitali online; 3) prevedere i cambiamenti nello stato occupazionale dai social media data. Abbiamo cercato di prevedere i cambiamenti nello stato di occupazione in base al comportamento digitale mediante l'uso di una nuova applicazione Facebook, LikeYouth, che raccoglie informazioni sul profilo di Facebook e i "like" alle pagine di Facebook di ciascun utente.*

Key words: Social Media Data, Employment Status, Rapporto Giovani, LikeYouth.

1 Introduction

Transition to adulthood evolved over the past decades. While in archaic societies most transitions took place by discrete “leaps” and were signed by “rites of passage”, modern societies present a different approach: transitions are represented increasingly as being individual. Since nowadays the transition to adulthood has become longer, the family of origin has assumed more value and power in influencing young people. Italians leave home on average at a later age with respect to young people in other European countries. The peculiarities of the Italian situation can be explained from both cultural and structural standpoints. On one hand, the presence of strong inter-generational ties is coherent with longer stays in the family of origin. On the other hand, the unfavourable labour market and the welfare system that is not generous to young generations tend to discourage individual autonomy and an active job search (Alfieri et *al*, 2015). According to the Organisation for Economic Co-operation and Development, on April 2016, the rate of youth unemployment in Italy was equal to 37.7%. This study aims at improving the current understanding of the conditions in which young Italians find themselves in during the acquisition of autonomy and in the active job search via tradition survey and tradition type of analysis, and via Social Media Data and Digital Behaviours. We place the focal point on the *Not in Employment, Education, or Training* population, hereafter NEET and on the grade of Autonomy that Young Italians have (i.e. in the decision of leaving home). NEETs are at risk for social marginalization. The failure to tap into the economic aspirations limits not only their income and skill development, but also their likelihood of later employability, autonomy, and life planning. In light of this picture, addressing the transition from and to the NEET condition in Italy is becoming an emerging issue in order to reduce the risks of social exclusion and of entering poverty for a large part of Italian young adults. The aim of the paper is to focus on the dynamic to enter or exit the NEET condition through the study of its determinants. To integrate demographic data from social surveys, with social media information, the specific aims of the study are threefold:

1) to predict the changes in employment status from information obtained by the longitudinal representative survey Youth Report (Rapporto Giovani, Istituto Toniolo, 2016).

2) to identify the target population inferring from their online digital traces and to uncover digital behaviours of the community of interest easily accessible from online social platforms, which can then be used as indicators of the most privileged communication channels for unemployment or educational advertising campaigns;

3) to predict changes in employment status from social media data. For this last aim, we tried to predict the changes in employment status in NEET population based on the digital behaviour (especially on Facebook's *likes*) using a new Facebook application, *LikeYouth*. Having obtained the participants' informed consent, the application gathers information regarding their public Facebook profile and their *likes* on Facebook Pages.

2 Employment status change: an explicative model. Data and Methods

To address the determinants of the changes in the employment status of Italian Young Adults, we use data from the database of the "Rapporto Giovani" survey renewed in 2015 by the Toniolo Institute for Advanced Studies with the involvement of the CARIPLO Foundation and IPSOS LTD as executive partners. The initial sample consists of 9,358 individuals aged between 18 and 29 years. The individuals were chosen with a stratified sampling technique and they are representative of young adults residing in Italy (for gender, age, geographical origin, education, marital status, etc.). For describing the evolution from and to the NEET status the survey has been repeated interviewing the same subjects in 2016 (on 6,172 cases) and in 2015 (on 3,034 cases). We implemented two binary logistic regression models to investigate respectively the determinants of 1) the transition from the condition of NEET to the condition of Not NEET between 2015 and 2017 and of 2) the transition from the condition of Not NEET to the condition of NEET in the same time window. In the first model, the dependent variable is a categorical indicator taking value 1 if the respondent, who was not engaged either in education or in training at the time of the first interview (2015), left the NEET condition over the following 24 months. Conversely, the second model focuses on the sub sample of individuals that were in a Not NEET condition at the time of the first interview: the dependent variable is a categorical indicator taking value 1 if the respondent entered the NEET condition over the following 24 months. The variables, measured at the time of the first interview, used in the empirical analysis to predict the condition of NEET are listed as follows: *Gender, Age, Geographical Area Respondent's education, Parents' education, Quality of relationship with parents, Support, Autonomy.* This group of variables has been included in the model in line with previous studies (Alfieri et al., 2015) devoted to investigating the long run predictors for the NEET condition. In addition, we add a *Life Satisfaction,* derived from Diener et al. (1985). Empirical results displayed in Table 1 show interesting and informative results with respect to process of transition who leads individuals in or out of the condition of NEET. Estimates not necessarily show opposite patterns, underlining different drivers for the two transitional processes examined. The first model focuses on the transition from a condition of NEET to the condition of Not NEET, displaying the significance of age groups and of the gender. In more detail, younger individuals are more likely to leave the NEET condition, being constant the other variables, and to enter in labor market or in the education system. Females seem to be more penalized in leaving the condition of NEET instead.

With respect to the effect of geographical heterogeneity, as expected, it looks clear that individuals belonging to the northern regions have greater opportunity to leaving the condition of NEET, due to better conditions in labor market and to an improved macroeconomic context. If the geographical context is fully explanatory in predicting the permanence or less in the NEET condition, a key determinant seems to be the education level of the respondents: more educated individuals are more likely to exit from the NEET conditions. These results fully support the importance of education in promoting the social mobility, also in the Italian context.

With respect to the second model, the main results show that individuals that live in the south of Italy experience a higher risk of becoming NEET. These results show a profile that is complementary to what we observed in the first model. Once again, the respondents' education plays a decisive role in reducing the risk of becoming NEET: lower educated individuals seem to be more exposed to a change in their employment status. Finally, we observe a relevant result concerning the role of the life satisfaction index, only in predicting the entrance to the NEET condition. Individuals that are less satisfied with their life, even if employed or students at the time of the first interview are more likely to fall in the NEET condition in the following 24 months. Surprisingly, the education level of the parents does not have a significant impact in modifying the respondents' employment status, such as the quality of the relationship with the parents, the autonomy and the support indices.

3 *LikeYouth* Project: data collection and method

The information gathered for this project originates from two different sources; from the representative survey of the "Rapporto Giovani" and from the *LikeYouth* application. The sample consists of 9,358 individuals aged between 18 and 32 years (M = 25.7, SD = 4.7). Every subject, at the end of the survey, was invited to access to *LikeYouth*. The population gathering from *LikeYouth* consists of 1,858 individuals. The comparison between subjects accessing *LikeYouth* and subjects not accessing *LikeYouth* does not show significant differences respect to the most important demographic variables (i.e: Total Sample: mean age 25±4.7, 50.8% male, 42.0% resident in the North of Italy, 18.0% with a high education level, 80.8% single, 19.9% NEET; Participants of *LikeYouth*: mean age 25.8± 4.4, 48.9% male, 39.7% resident in the North of Italy, 18.7% with an high education level, 80.4\% single, 21.9% NEET). No statistical concordance index shows a significant difference also for psychometric indicators. Participants of *LikeYouth* may, therefore, be considered a representative sample of the Italian youth population.

To this extend we designed a generic experimentation schema, aiming to assess and compare the predictive power of the digital behaviors. We postulated the study as a supervised classification process, automatically identifying the employment status and the potentiality that a specific person belongs to a category or not (i.e. NEET or NOT NEET), inferring only from their digital data. Additionally, we trained a predictive model for each of some demographic attributes. We employed a widely used ensemble learning method for classification was employed, namely a Random Forest (RF) classifier (Breiman, 2001). We evaluate our performance with the weighted area under of the receiver-operating characteristic (AUROC). The weighted AUROC statistic (Li and Fine, 2010) was preferred over the commonly used *accuracy* metric, since the former takes into account the effect of unbalanced labels, which holds true for most of our attributes. All the prediction scores reported through this paper are in terms of the weighted AUROC.

The entire feature space, **X**, is randomly shuffled and split in two mutually exclusive sets, the training set *Tr*, (80% of **X**) and the testing set *Ts* (20% of **X**). Furthermore, for each target variable we estimated the relative rank (i.e. depth) of each feature, as emerged from the "Gini" impurity function, assessing in this way the relative importance of a specific feature to the predictability of the target variable. We use as predictors the Facebook Pages the users visited and the respective Categories, as defined by the Facebook metadata. This information is represented as a sparse user-page and user-category matrix, the entries of which were set equal to the raw counts of visits and 0 otherwise.

3.1 Results of Prediction of NEET Status via Social Media Data

1,858 young people from the "Rapporto Giovani" visited, during their "history" on Facebook, more than 330,000 different Facebook pages, grouped (from Facebook information) in 155 categories. The assignment of the category is determined, at the time of the making the page, by the administrator of the page itself. It is not, therefore, an objective assignment, but a subjective decision of the developer of the page. Thus, a new taxonomic categorization of the initial categories was made, creating 12 macro categories for a quantitative analysis of the results, and about thirty categories for a more qualitative interpretation of the same. On average, every subject has liked almost 400 Facebook pages, belonging to about 50 different categories. For the first area and community of interest, the NEETs, we are able to predict whether an unknown person is potential NEET or not with accuracy 63%. The model is trained on the population originating from the "Rapporto Giovani" survey for which there has been a manual labelling of the NEET status characterisation by a field expert. For a more qualitative and interpretative analysis of data, we chose to consider only a subset of the Facebook pages, that is those pages that have been visited by at least 20 young people in our sample and that had at least 100,000 *likes*, that is, they were very popular and well-known pages in Facebook. 2,422 pages satisfied the two conditions. They were the predictors of the models in the second part of the analysis. Different data analysis techniques have been tested: Cohen's *K*, Phi Correlation Coefficient for dichotomous variables, Random Forest with Breiman's algorithm, CART Decision Tree. For each Facebook page, each technique produced a score of "importance". With a meta-analysis approach, the scores were weighted and normalized. At the end of this procedure, for each Facebook page, a normalized index was created in the closed subset [–1; +1]. Scores close to –1 are predictors of the condition of Not NEET, scores close to +1 are predictors of the NEET condition. Top indicators of NEET status are Facebook pages or categories related to consumer goods, in particular food, beverage, beauty and health (in particular baby and kids goods), TV Channel, Retail and Consumer Merchandise. The use of Facebook appears as a leisure tool and not much as utility or service. Top indicators of Not-NEET status are Facebook pages/categories related to travel, culture, humour and satire, performance art, news media and politics. Further models are being developed for particular cohorts of the population of interest (male/female, under/over 24 years). Table 2 shows some particularly predictive pages of the two-different status.

Table 2: Most predictive Facebook pages of NEET or Not-NEET Status

Cohorts	***NEET***	***Not-NEET***
Males	Worky.biz	Expo2015
	Verissimo	Repubblica.it
Females	Prenatal	MatteoRenziCheFacose
	Lidl Italia	Grey's Anatomy
Under 24 years	Just Cavalli	Dr. House
	Girella	Barack Obama
Over 24 years	Humana Italia	Il Milanese Imbruttito
	ScontieBuoniAcquisto.it	Report

In general, NEETs visit discount pages, promotions, prize competitions, offers, which can be explained for various reasons. Certainly, NEETs have more free time than workers and students, so they can spend their time searching this kind of pages on Facebook. Moreover, they are pushed by their weaker economic situation, to ensure themselves an acceptable quality of life. Not NEETs have a more active and conscious digital behaviour, and typically they like pages of culture, information, satire, so not closely linked to advertising and media exposure, while NEETs visit more pages linked to the Consumer Merchandise world, and therefore linked to massive advertising campaigns on Facebook.

3.2 Results of Prediction of the Change of Employment Status via Social Media Data

Since we were interested in the change of employment status in three years (from 2015 to 2017), we considered two types of changes: from the NEET Status to the Not-NEET Status and vice versa, from Not-NEET to NEET. We considered only subjects who, in Rapporto Giovani Survey, have responded at least to two surveys, so to have a longitudinal view, and we divided the population of *LikeYouth* in two subgroups, the NEET and the Not-NEET. In the first groups (N=300), we considered the subjects who have changed the employment status, from the NEET condition to the Not-NEET one. In the second groups (N=1,171) we considered the subjects who have changed the employment status, from the Not-NEET condition to the NEET one. Table 3 shows some particularly predictive pages of the two different changes of status and the AUROC statistics. In the first subgroups, the percentage of the subjects have changed their status is equal to 36.3%, in the second one only 7.2% of the subjects have changed their status. The AUROC statistics are equal, respectively, to 0.57 and 0.55. The information of the most predictive pages of change of status can be particularly useful in order to target campaigns directly within these pages, so to reach the target set with high probability of success. The low values of AUROC statistics are due, probably, by the reduced sample size of these two models, which require significantly larger sample sizes, but they can justify further studies and investment in this project.

Table 3: Most predictive Facebook pages of Change of Status

4 Conclusions

The study of the employment status change was conducted by two different approaches. In the traditional one, by using two Logistic Regression Models to determine the antecedents of the changes in the employment status (from NEET to Not-NEET and vice versa) with the database of the "Rapporto Giovani", it emerges that a key determinant seems to be the education level of the respondents: more educated individuals are more likely to exit from the NEET conditions. These results support the importance of education in promoting the social mobility. Moreover, we observe a relevant inverse result concerning the role of the life satisfaction index, only in predicting the entrance to the NEET condition. The second approach is an innovative one, by using social media data as predictors of the changes, with the *LikeYouth* database, a new Facebook App. Since taking advantage of the Facebook platform popularity, it can reach out to the population in need with relatively limited economic and temporal requirements. The challenges emerging from this approach are related to the engagement strategies. The analysis conducted by LikeYouth on 1,858 young people of the "Rapporto Giovani" panel gave comforting results, both on the sample's representativeness and on the predictive and classifying performance of modelling used on Social Media Data. This analysis also showed the passivity of the young NEETs, which, compared to other peers, appear to be more passive, less entrepreneurial and less oriented to cultural, educational and information interests. However, especially in the males' cohort, a part of young people visits pages related to labour market and job search portals. Therefore, they begin to implement possible strategies to get out of their status of inactivity. It is important overturning the vision that society and politics often have on the digital social networking tool. They could use as a sort of social activator. The extreme flexibility of social networks has to be exploited in its full potential.

Parenthood: an advanced step in the transition to adulthood

Diventare genitori: una fase avanzata della transizione allo stato adulto

Cinzia Castagnaro, Antonella Guarneri and Eleonora Meli

Abstract Parenthood constitutes a crucial stage and one of the most challenging phases of the life cycle. Timing of the transition to adulthood has changed across cohorts according to two different patterns, housing independence and family formation. Postponement of childbearing appears a rational choice for women to assure higher educational level and labour market participation, but it refers also to a value and sociocultural change.

A remarkable postponement is taking place in Italy: TFR rapidly lowers as can be seen by fertility trends in cohort analysis. By cohorts, the average number of children per woman in Italy decreases: 2.5 in the early 1920s (mean age at childbearing 28.6 years), 2 of the post-war generations (mean age 27.0) and the estimate of 1.44 of the 1976s (mean age about 31). At the same time, the proportion of women without children doubled from 1950 (11.1%) to 1976 (21.8%, estimate). Women without children between 18 and 49 years are about 5.5 million, almost half of the women of this age group.

The aim of this paper is to explore the transition to adulthood, analysing reproductive behaviours. The approach adopted is by cohort parity. A special focus is devoted to characterize childless people.

Abstract *La genitorialità costituisce una tappa cruciale e una delle fasi più determinanti del ciclo di vita. Il momento in cui si realizza la transizione allo stato adulto ha subito forti variazioni attraverso le generazioni considerando distintamente due differenti aspetti, l'indipendenza abitativa e la formazione della famiglia. La posticipazione della maternità appare come una scelta razionale per le*

donne per poter raggiungere un alto livello d'istruzione e una maggiore partecipazione nel mercato del lavoro, ma si può inserire anche in un più ampio cambiamento socioculturale e del sistema dei valori.

Contestualmente alla posticipazione della maternità, in Italia il tasso di fecondità totale sta rapidamente diminuendo, così come visibile dall'analisi per coorte. Il numero medio di figli per donna è passato dai 2,5 delle donne nate nei primi anni Venti (con un'età media al parto pari a 28,6) ai 2 delle generazioni successive alla seconda guerra mondiale (età media al parto di 27 anni) per arrivare a 1,44 figli per la generazione del 1976 (età media di 31 anni). Allo stesso tempo la proporzione di donne senza figli è raddoppiata dalla generazione del 1950 (11,1%) a quella del 1976 (stimata pari a 21,8%). Le donne senza figli tra 18 e 49 anni sono circa 5,5 milioni, quasi la metà delle donne di questa fascia di età.

L'obiettivo del lavoro è esplorare la transizione allo stato adulto, analizzando i comportamenti riproduttivi. L'approccio adottato è prevalentemente quello per coorte e un'attenzione particolare sarà dedicata alla caratterizzazione dei childless.

Key words: parenthood, cohort, postponement, childless

1 Introduction

Parenthood constitutes a crucial stage and one of the most challenging phases of the life cycle.

Timing of the transition to adulthood has changed across cohorts according to two different patterns, housing independence and family formation. The most recent cohorts are characterized by increasing school leaving age and delayed entry into the labour market and these delays show a strong effect in the postponement of the steps towards family formation. Postponement of childbearing appears as a rational choice to assure higher educational level (van de Kaa, 1987), labour market participation, but it refers also to a change of values, as an issue linked to gender equity, housing conditions and economic uncertainty.

Referring to childbearing, when a pronounced postponement is taking place, as it is now happening in Italy, the average number of children per woman is rapidly lowered. Because of the impact of changing in the timing of births, a clearer picture of fertility emerges when analysing the cohort trends.

During the latest fifty years women enter in motherhood at increasingly later ages. The delay in childbearing (Kohler, Billari, Ortega, 2002, Sobotka 2004) has an effect for many women to remain childless, delay childbearing at ages when women's fecundity is already in decline (te Velde, Pearson, 2002, te Velde *et al.*, 2012).

2 Aims, data and methods

The aim of this paper is to explore the transition to adulthood, analysing reproductive behaviours. The approach adopted is by cohort parity. A special focus is devoted to characterize childless people.

To describe the general Italian context about fertility most recent data on births are considered. These individual data refer to all births enrolled in the Italian resident population register; trough this register it’s possible to obtain information on births according to a set of demographic variables about the newborn and their parents. Moreover, to adopt a time series perspective it is worthwhile to analyse data contained in the Italian Fertility Database (IFD), a database built and maintained by the Italian Institute of Statistics (Istat). The IFD contains data on births of the resident population since 1952 and it is updated each year with data drawn from other Istat sources. Data are available at NUTS-2 level and by cohort of mothers (the first complete cohort is referred to 1933). These data underwent several rounds of adjustments, specific for different periods, which allowed reconstructing data by birth order.

The cohort approach seems to be particularly suitable to describe differential characteristics of women. The idea is to put in comparison some specific birth cohorts to single out the different attitudes and the main effects of the timing-quantum interaction.

Using data of the last Italian Multipurpose Household Survey “Families, social subjects and life course” (FSS), carried out by Istat in 2016, it is possible to shed light on reproductive behaviours and choices, considering the main individual socio-demographic characteristics of people and the crucial steps of their life cycle.

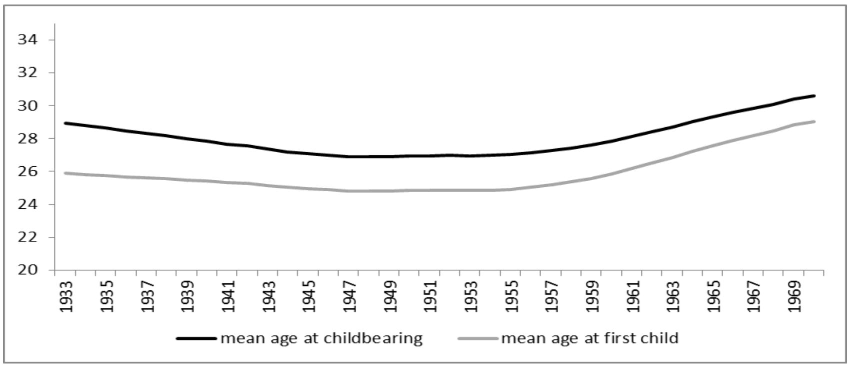
In order to study the factors influencing these different paths and family behaviours, the analysis draws differential profiles of childless and childfree people.

3 The cohort approach: *timing* and *quantum*

The decision of fulfilling the reproductive process is very important in the life history of a parent, as it indicates a long-term project that involves not only the parents but also their descendants. This decision arrives later and later in Italy passing from one cohort to another. This postponement is clearly visible observing the increase in mean age at first child and consequently at childbearing (Figure 1).

The general idea is to verify if the postponement lead to a recovery due to the most recent cohorts compared to the older ones, as observed in some other countries (e.g. Norway, Sweden or Western Europe countries). Theoretically the late-starters in most recent cohorts could achieve slightly more children than the late starters in the earlier cohorts (Berrington, Stone and Beaujouan, 2015). However this recovery does not counterbalance, in the Italian case, the collapse in fertility affecting younger ages in most recent cohorts. Across generations to show a deep change it is not only the timing but also the quantum.

Figure 1: Mean age at first child and mean age at childbearing by mothers' cohort



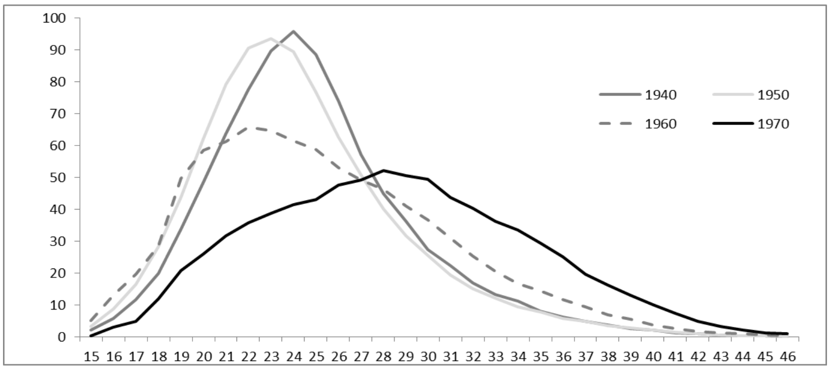
Source: Istat

The average number of children per woman in Italy decreases and the mean age at childbearing shows a U-shaped pattern: from 2.5 in the early 1920s cohort (mean age at childbearing 28.6 years), to 2 of the post-war generations (mean age 27), to the estimate of 1.44 of the 1976 cohort (mean age about 31).

A noticeable decrease in fertility necessarily entails profound modifications in terms of composition of the offspring by birth order. The fertility rates referring to the births of the first order have undergone a relatively limited variation, at least up to the generations of women in the mid-1960s: from 0.89 first children for 1950 women to 0.87 for 1965 cohort. For younger cohorts, more evident changes are observed. As a matter of fact, the proportion of women without children doubled from 1950 (11.1%) to 1976 (21.8%, estimates).

The age profiles display a clear postponement attitude observing 1960 cohort and particularly 1970 cohort (Figure 2).

Figure 2: Fertility rates at first child by mothers' age and cohort



Source: Istat

The contribution of different cohorts led to only 464 thousand births estimated in 2017, over 22,000 less than 2015 and over 100,000 less than 2008 (commonly considered as the first year of the economic crisis). Economic crisis reflected significantly on family's formation. A new phase of decrease in the birth rate that started after 2008 shows a strong contraction of the first children, from 283.922 in 2008 to 227.412 in 2016.

The decline in births is partly due to the so-called "structural" effects induced by significant changes in the female population in the fertile age, conventionally set between 15 and 49 years. The effect of the age structure is responsible for almost three quarters of the difference in births observed between 2008 and 2016. The remaining share depends instead on the decrease in the propensity to have children (from 1.45 children per woman at 1.34).

Women have accentuated the postponement of reproductive experience towards advanced ages; compared to 1995, the year of minimum fertility (1.19 children on average per woman), the mean age at childbearing increases by almost two years, reaching 31.8 years; even the mean age at first child grows to 31 years in 2016 (almost three years more than in 1995).

The delay in childbearing is likely to be the cause for many women to remain childless; as a matter of fact, the postponement at later ages may become a renunciation in having children. As above mentioned, a part of childless women chose childlessness, so it has to be considered on one hand as a personal preference, and on the other hand motherhood postponement as a choice for career possibility or other life goals (Blossfeld, Hiunink, 1991, Andersson 2000, Kneale, Joshi 2008). In order to consider the personal choice in not having children, childlessness has to be studied as childfree condition (Houseknecht, 1979).

4 To be childless or childfree: similarities and peculiarities

The consistent increase in the number of women without children for the younger generations raises many questions about its interpretation and its impact on the future evolution of fertility. Is this an increase due to difficulties in carrying out family projects or adopting a different life model that does not envisage becoming a parent? Using data from the Italian survey "Families, social subjects and life course" it is possible to analyse childless women characteristics (Istat, 2017). Considering women aged between 18 and 49, the childless women are about 5 and a half million in 2016, 45.1% of the women of this age group. Considering men, almost 57.4% of them are childless in the same age group (around 7 million) (Istat, 2017). The younger they are the higher the proportion of people without children: over 55% of people younger than 35 have no children, this proportion decreases first for women (less than one to three is childless over 35 years old, while for men the same proportion is reached over 45 years old).

Among childless people, about 534 thousand declared that having children does not fit into their life project (equal to 2.2% of people 18-49 years old); for men the rate is higher than for women (2.5% vs 1.8%), especially in the 35-44 age group (3.5% among men between 35 and 39 years and 2.9% of 40-44 year-olds). For women the most high is between 40-44 year-olds (2.8% say they do not have and do not want children) (Table 1).

These results show that the phenomenon of women (and couples) without children by choice is very limited in our country and that, conversely, the increase in the share of women without children are mostly due to obstacles to the implementation of family projects; the effect of the postponement that can be transformed into renunciation should not be overlooked with the approach of the most advanced ages of women's reproductive life.

Table 1: Childless and childfree people by gender and age (per 100 people with the same characteristics) - Year 2016

Gender	Age groups	Childless	Childfree
Male	18-24	98.4	2.7
	25-29	88.9	1.5
	30-34	64.6	1.9
	35-39	46.4	3.5
	40-44	32.3	2.9
	45-49	28.1	2.3
	18-49	57.4	2.5
Female	18-24	93.3	1.9
	25-29	73.9	1.6
	30-34	46.8	1.3
	35-39	27.6	1.4
	40-44	24.2	2.8
	45-49	19.8	1.6
	18-49	45.1	1.8

	25-29	81.7	1.6
	30-34	55.5	1.6
	35-39	37.1	2.4
	40-44	28.2	2.8
	45-49	24.0	2.0
	18-49	51.3	2.2

Source: Istat

Analysing the individual characteristics, as well known people with higher educational qualifications are less likely to have children (61.3% for males and 55.5% for females) compared to the lower educational level (49.4% for males and 34.0% for females). The highest quota of people that do not have parenthood in their life project is among men and women with university qualifications.

Among unemployed people there is the highest share of childless (64.5%) and childfree (3.2%). Reproductive projects of unemployed people change according to gender showing opposite patterns: the highest quota of childfree is for men (5.0%) whereas the lowest is for women (0.8%); in addition employed women register the highest proportion of childfree (2.5%).

The presence or absence of a partner has a significant impact on reproductive choices. Being single makes more likely to be childless or childfree (respectively 86.7% and 3.8%) as well as having a partner with whom one is not cohabiting (84.8% and 3.0%); these are all elements that characterize people who do not have children and do not intend to have children, because they do not fit into their life projects, to a greater extent if they are men.

Besides the sentimental situation, the role that these people play in their family provides information on the relapse that the phase of the life cycle has on parental planning. People living alone are less likely to be a parent or plan parenthood (respectively 80.0% and 4.9%).

In a gender perspective, 77.9% of single men have no children and 5.5% do not plan fatherhood, because the idea does not fit with their life's plans. On the other hand among women there are higher shares of childless for singles (83.5%) and childfree when they do not have core relationship within a family (9.1% and 4.3% of women in a couple without children).

5 Conclusion and future developments

The childless population shows a high degree of heterogeneity (Tocchioni, 2017). Only a part plans never to have children (Tanturri and Mencarini 2008), and not all of them do not change idea across time (Moore, 2017).

To draw the profiles of different categories of people without children a logistic model will be applied to estimate the probability to be childfree vs childless (not childfree). The analysis will focus on women and men who are at least 35 years old at the time of the interview, considering only people who had already 'crossed' their most fecund period.

Main covariates to be included in the model are: socio-demographic characteristics, type of couple, support networks, economic and health conditions. An important covariate is the education level; as a matter of fact, education plays an important role in the reproductive behaviour.

The phenomenon of postponement of childbirth is even more evident for mother with a high educational level, thus causing an overlap or, sometimes, an inversion of family making steps. These different paths to parenthood could be the focus of further analyses exploiting FSS data 2016 edition.

Economic Statistics and Big Data

Improvements in Italian CPI/HICP deriving from the use of scanner data

Alessandro Brunetti, Stefania Fatello, Federico Polidoro, Antonella Simone[1]

Abstract Scanner data are a crucial innovative "big data" source to estimate inflation, providing several advantages that derive from the detailed information available about sales and quantities at weekly frequency, GTIN by GTIN, outlet by outlet throughout the entire national territory. In paragraph 1 the paper makes the point about the state of play of the use of scanner data (introduced for grocery products in Italian CPI/HICP in 2018) and evaluates the benefits in terms of accuracy of inflation estimation coming from the improvement of the territorial coverage. The data of a sample of more than 1,700 hyper and supermarkets, for years 2017 and 2018, have been processed in order to calculate price indices differentiated according to outlet location (inside and outside municipal borders of the provincial chief towns) and price indices for the 80 provincial chief towns previously involved, to be compared with the indices calculated for the entire Italian territory (paragraph 2). The results in terms of improved accuracy are analyzed at national and geographical area level (paragraph 3). Perspectives of Italian scanner data project (brought forward by ISTAT) are finally sketched in paragraph 4.

Key words: Scanner data, inflation, accuracy, territorial coverage

1. The use of scanner data to estimate inflation in Italy: the state of play

Starting from January 2018 ISTAT introduced scanner data of grocery products (thus excluding fresh food) in the production process of estimation of inflation. This

[1] Alessandro Brunetti, ISTAT, albrunet@istat.it
Stefania Fatello, ISTAT, fatello@istat.it
Federico Polidoro, ISTAT, polidoro@istat.it
Antonella Simone, ISTAT, ansimone@istat.it

innovation concerns 79 aggregates of product belonging to 5 ECOICOP Divisions (01, 02, 05, 09, 12).

Since the end of 2013 a stable cooperation was established among ISTAT, Association of modern distribution, retail trade chains (RTCs) and Nielsen. Scanner data of grocery products have been collected by ISTAT through Nielsen for years 2014, 2015 and 2016 for about 1400 outlets of the main six RTCs for 37 provinces.

Afterwards, in view of the inclusion of scanner data into price indices calculations, a probabilistic design has been implemented for the selection of the sample of outlets, for which Nielsen provided ISTAT from December 2016. Scanner data for 1.781 outlets (510 hypermarkets and 1.271 supermarkets) of the main 16 RTCs covering the entire national territory are monthly collected by ISTAT on a weekly basis at item code level. Outlets have been stratified according to provinces (107), chains (16) and outlet-types (hypermarket, supermarket) for a total of 867 strata, taking into account only the strata with at least one outlet. Probabilities of selection were assigned to each outlet based on the corresponding turnover value. Table 1 shows the number of the strata, the number of the outlets and the coverage in terms of turnover, at regional and national levels for years 2018. The coverage for the year 2017 is slightly lower because a small RTC has been excluded from the analysis.

Concerning the selection of the sample of items, a static approach that mimics traditional price collection method has been adopted[1]. Specifically, a cut off sample of barcodes (GTINs) has been selected within each outlet/aggregate of products (covering 40% of turnover but selecting no more than the first 30 GTINs in terms of turnover). The products selected in December are kept fixed during the following year. A “thank” of potentially replacing outlets (258) and GTINs (until a coverage of 60% of turnover within each outlet/aggregate) has been detected in order to better manage the possible replacements during 2018.

About 1.370.000 price quotes are collected each week to estimate inflation. For each GTIN, prices are calculated taking into account turnover and quantities (weekly price=weekly turnover/weekly quantities). Monthly prices are calculated with arithmetic mean of weekly prices weighted with quantities.

Scanner data indices of aggregate of products are calculated at outlet level as unweighted Jevons index (geometric mean) of GTINs elementary indices. Provincial scanner data indices of aggregate of products are calculated with weighted arithmetic mean of outlet indices using sampling weights. Finally, for each aggregate of products, scanner data indices and indices referred to other channels of retail trade distribution are aggregated with weighted arithmetic mean using expenditure weights.

To calculate weights for the integration of regional indices of modern and traditional distribution at regional level, data are broken down using regional estimates from National Account (at ECOICOP sub-class level), regional

[1] The static approach to sampling is discussed in EUROSTAT [2017].

expenditure by type of distribution from Ministry of Economic Development and qualitative information on the shopping habits of consumers coming from HBS.

2. The improvements of the territorial coverage of indices and its effect on the accuracy of inflation estimates

Scanner data allow calculating the indexes for the entire national territory using data from outlets of all Italian provinces and located both in the municipal area and outside. With the aim of evaluating the benefits in terms of accuracy of inflation estimation coming from the improvement of the coverage in territorial terms, price indices are calculated by taking into account the outlet location (i.e. inside municipal area of the provincial chief towns: HICP SD MA) and by distinguishing the 80 provincial chief towns previously involved in the consumer price survey from the rest of the provinces whose data now are made available by scanner data (HICP SD 80P).

Table 2 shows the number of outlets used for the calculation of the different indices at national and macro-regional level for years 2018.

Table 2: Number of outlets at national and macro-regional level – Year 2018

Macroregion	**All outlets**		**Outlets in 80 provinces**		**Outlets in municipal area**	
	N° outlets	***% outlets***	***N° outlets***	***% outlets***	***N° outlets***	***% outlets***
North	942	52,9	857	58,8	304	50,6
Centre	363	20,4	286	19,6	133	22,1
South	476	26,7	315	21,6	164	27,3
Italy	**1781**	**100,0**	**1458**	**100,0**	**601**	**100,0**

In order to point out the methodology used for this analysis, it is necessary to start with a short description of the procedure for the aggregation of indices[1].

[1] For a detailed description of the procedures adopted by Istat for the calculation of the consumer price indices, see ISTAT [2012].

Let us introduce the following symbols[1]:

- *n* denotes the *n*-th product aggregate[2] (*n*=1,…,*N*);
- *g* denotes the g-th region (g=1,…,G=20);
- j denotes the j-th province (j=1,…,J(r));
- h denotes the *h*-th outlet (*h*=1,…,*H*(*j*)).

Let:

$$P_{ng,j} = \sum_{h \in j} w_{ngj,h} \cdot P_{ngj,h}$$ be the provincial index of the product aggregate *n*;

$$P_{n,g} = \sum_{j \in g} w_{ng,j} \cdot P_{ng,j}$$ be the regional index of the product aggregate *n*;

$$P_n = \sum_{g} w_{n,g} \cdot P_{n,g}$$ be the national index of the product aggregate *n*;

$$P = \sum_{n} w_n \cdot P_n$$ be the general index at the national level.

where:

$$w_{ngj,h} = \frac{e_{ngj,h}}{\sum_{h \in j} e_{ngj,h}} \;;\; w_{ng,j} = \frac{e_{ng,j}}{\sum_{j \in g} e_{ng,j}} \;;\; w_{n,g} = \frac{e_{n,g}}{\sum_{r} e_{n,g}} \;;\; w_n = \frac{e_n}{\sum_n e_n}$$

and $e_{ngj,h}$ is the expenditure estimate for product aggregate *n* in the outlet *h* of province *j* in region *g*[3].

For the scope of the present analysis, the general index *P* is to be compared with the index $\hat{P}$ which is calculated using:

- Transaction prices of the outlets (*h*') situated inside municipal borders of the provincial chief towns (HICP SD MA);
- Transaction prices of the outlets of the 80 provincial chief towns previously involved in the consumer price survey (HICP SD 80P).

Concerning the first case, the general index *P* can be usefully expressed as the weighted arithmetic mean of provincial product aggregate indices:

$$P = \sum_{nj} \frac{e_{nj}}{\sum_n e_n} \cdot P_{nj} = \sum_{nj} \pi_{nj} \cdot P_{nj}$$

[1] The notation used is adapted from that one suggested in Biggeri L., Giommi A. [1987].

[2] Product aggregates indices are indices calculated at the lower level of aggregation of product-offers.

[3] $e_{ngj,h}$ incorporates the sampling coefficient attached to the outlet *h*.

Accordingly, the impact of the improvement of territorial coverage is calculated as follows:

$$P - \hat{P} = \sum_{nj} \pi_{nj} \cdot \left(P_{nj} - \hat{P}_{nj}\right)$$

where:

$$\hat{P}_{n,j} = \sum_{h' \in j} \frac{e_{nj,h'}}{\sum_{h' \in j} e_{nj,h'}} \cdot P_{nj,h'}$$

The impact can also be decomposed as suggested in Biggeri L., Brunetti A. e Laureti T. [2008]. By indicating with k the product $N \cdot J$, with δ_{nj} the difference between sub-indices $\left(P_{nj} - \hat{P}_{nj}\right)$, with $s_{\pi_{nj}}$ and $s_{\delta_{nj}}$ the standard deviations of π_{nj} and δ_{nj}, with $R_{\pi_{nj},\delta_{nj}}$ the linear correlation coefficient between π_{nj} and δ_{nj}, with $\bar{\delta}_{nj}$ the arithmetic mean of δ_{nj}, we have:

$$P - \hat{P} = k \cdot s_{\pi_{nj}} \cdot s_{\delta_{nj}} \cdot R_{\pi_{nj},\delta_{nj}} + \bar{\delta}_{nj}$$

As for the second case, it is convenient to express the general index P as the weighted arithmetic mean of regional product aggregate indices:

$$P = \sum_{ng} \frac{e_{ng}}{\sum_{n} e_{n}} \cdot P_{ng} = \sum_{ng} \pi_{ng} \cdot P_{ng}$$

Consequently, it is possible to write:

$$P - \hat{P} = \sum_{ng} \pi_{ng} \cdot (P_{ng} - \hat{P}_{ng})$$

where:

$$\hat{P}_{n,g} = \sum_{j' \in g} \frac{e_{ng,j'}}{\sum_{j' \in g} e_{ng,j'}} \cdot P_{ng,j'}$$

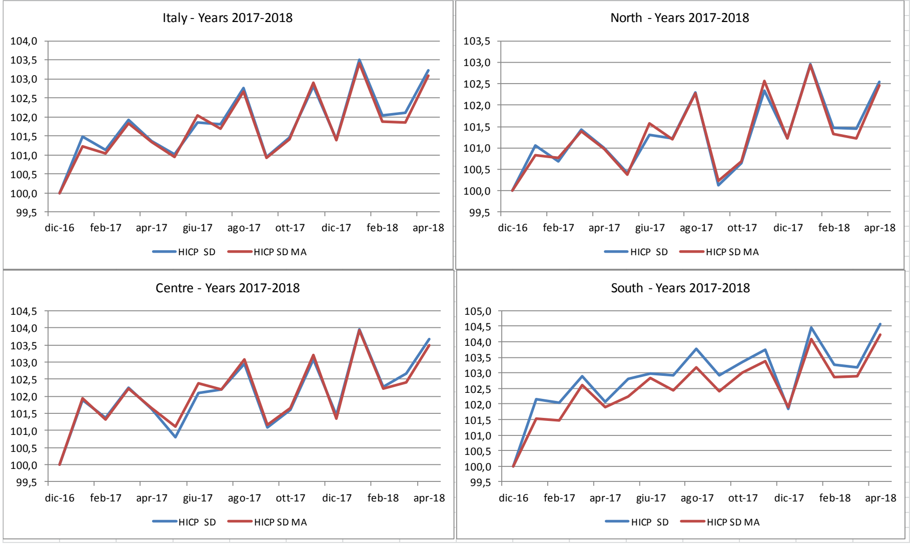
and, with similar notation:

$$P - \hat{P} = k \cdot s_{\pi_{ng}} \cdot s_{\delta_{ng}} \cdot R_{\pi_{ng},\delta_{ng}} + \bar{\delta}_{ng}$$

3. Results

By comparing indices calculated on the whole national territory and the corresponding indicators compiled taking into account only the outlets in the municipal area of the provinces (figure 1) moderate differences emerge in the first months of 2017 and 2018 and in the middle of the first year. However, when the geographical breakdown is considered, the divergences tend to be relatively larger and persistent, especially in the South of Italy (islands included) (table 3). For example, the difference of the indices, calculated on March 2018, shows that the HICP SD MA index of the South is about 0.3 percentage points below the corresponding HICP SD index, while it is 0.24 in the North and 0.15 in the Centre). The main factors explaining this divergence seem to be the relatively higher value of the standard deviation of the differences of sub-indices and the relatively high value of the linear correlation coefficient $R_{\pi_{nj},\delta_{nj}}$ (higher differences in the level of sub-indices tend to have higher weights).

Figure 1: Comparison between HICP SD and HICP SD MA - Years 2017-2018



Italy - Years 2017-2018

North - Years 2017-2018

Centre - Years 2017-2018

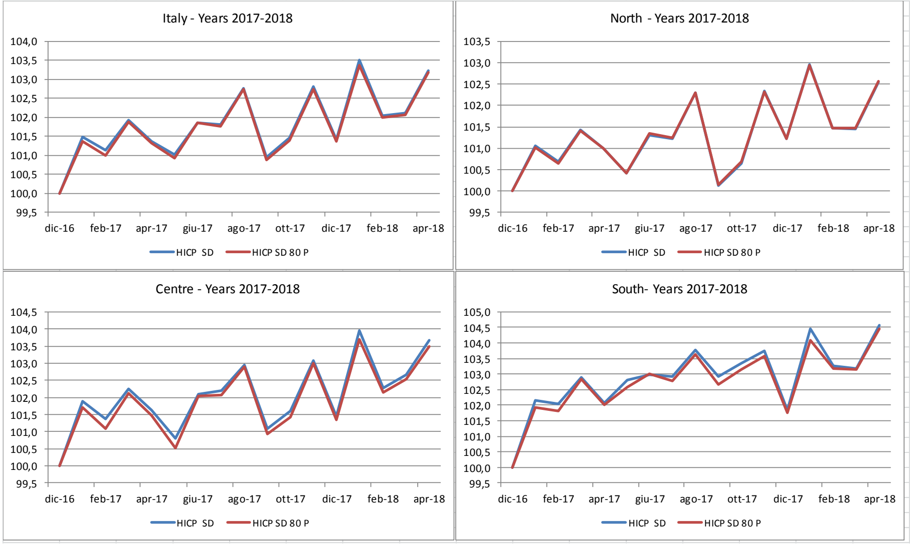
South - Years 2017-2018

Table 3: Decomposition of the difference between HICP SD and HICP SD MA. March 2018.

	Italy	**North**	**Centre**	**South**
K	8.368	3.713	1.738	2.917
$s_{\pi_{nj}}$	0,0002	0,0004	0,0012	0,0005
$s_{\delta_{nj}}$	3,3349	2,9171	2,8525	4,0235
$R_{\pi_{nj},\delta_{nj}}$	0,0139	-0,0088	0,0082	0,0460
$\bar{\delta}_{nj}$	0,1522	0,2732	0,1046	0,0267
HICP SD	100,6830	100,2363	101,2078	101,2760
HICP SD MA	100,4517	100,0011	101,0555	100,9741
HICP SD - HICP SD MA	0,2314	0,2352	0,1523	0,3019

Regarding the comparison between HICP SD and HICP SD 80P, major divergences tend to be concentrated in the South of Italy (figure 2) as well. This result reflects the fact that the share of provinces participating to the survey before the introduction of scanner data, in this part of the country, was relatively low as compare to the North and the Centre.

Figure 2: Comparison between HICP SD and HICP SD 80P - Years 2017-2018



Generally speaking, for what concerns modern retail trade distribution and comparing indices compiled from scanner data source in a time span of 16 months, the improvement in terms of accuracy coming from the coverage of the entire provincial territories are limited to three months at national level with a maximum of three decimal points of differences between grocery index calculated inside the municipal borders and that one compiled with the outlets of the entire municipal areas. For the South the differences between the two indices are more frequent and wider along the time span considered. In all the cases, the level of the indices referred to the entire provincial areas are slightly higher than those ones compiled just within the municipal borders.

If we consider the grocery index compiled taking into consideration the outlets of the 80 provinces that were involved in 2017 in the territorial data collection, the comparison with the grocery index calculated from the data of all the 107 Italian provinces, shows just some local differences (in the South and in the Centre of Italy) but without important consequences in the estimation of the grocery index at national level.

4. Next steps in the development of the ISTAT project on scanner data

Scanner data project (brought forward by ISTAT) is still on the way and it is possible to sketch some further steps.

The first one is the adoption of the so called dynamic approach (abandoning the static one) to the selection of the elementary items (GTINs) to be considered for the compilation of indices. It should be implemented starting from January 2019 and it means the use of all the elementary price quotes of all the GTINs sold monthly in the sample of outlets selected. Next months of 2018 will be dedicated to solve the main crucial issues in sight of this next step, starting from that regarding relaunches and IT environment and procedures. Dynamic approach is the choice towards other National Statistical issues at European level are converging and could represent a further improvement in the accuracy of Italian CPI/HICP.

The following steps concern the extension of the use of scanner data to other retail trade channels (discount, outlets with surface between 100 and 400 square meters) and other goods such as fresh products with variable weight and no grocery products.

Toward these aims the role of the collaboration with the modern distribution and the representative association (Association of Modern Distribution, ADM) keeps its crucial importance.

Big data and spatial price comparisons of consumer prices

Big data e confronti spaziali dei prezzi al consumo

Tiziana Laureti and Federico Polidoro

Abstract An accurate measurement of price level differences across regions within a country is essential for assessing inequality in the distribution of real incomes and consumption expenditures. However, systematic attempts to compile sub-national Purchasing Power Parities (PPPs) on a regular basis have been hampered by the labour-intensive analyses required in processing traditional price data. The increasing availability of big data may change the current approach for estimating sub-national PPPs, although only for household consumption expenditures. This paper estimates spatial price indexes using a scanner dataset set up for experimental CPI computations in 2017 and includes information on prices, quantities and quality characteristics of products at barcode level. Our dataset refers to grocery products sold in a random sample of approximately 1,800 outlets across Italy belonging to the most important retail chains (95% of modern retail trade distribution), covering 55.4% of total retail trade distribution for this product category. We use various weighted index formulas for calculating consumption sub-national PPPs at detailed territorial level and at the lowest aggregate level at which no quantity or expenditure weights are usually available. Finally we report preliminary estimates of between-regional spatial price indexes for specific product groups and for Food and Non-Food consumption aggregates.

Riassunto*: Misurare i differenziali di prezzo tra le regioni di un Paese è fondamentale per analizzare la disuguaglianza nella distribuzione dei redditi e dei consumi. Tuttavia, la produzione regolare di Parità del Potere di Acquisto (PPA) a livello sub-nazionale è stata ostacolata dalle difficoltà di utilizzare dati da fonti tradizionali. La crescente disponibilità di big data potrebbe cambiare l'attuale approccio per la stima delle PPA infra-nazionali sebbene solo in riferimento ai*

Federico Polidoro, Living conditions and Consumer prices Unit, Istat; email: polidoro@istat.it

consumi delle famiglie. Il lavoro presenta stime preliminari di indici spaziali regionali utilizzando un dataset di dati scanner costruito per la stima sperimentale degli IPC e include informazioni su prezzi, quantità e caratteristiche dei prodotti a livello di codice a barre per il 2017. Il dataset si riferisce ai prodotti grocery venduti in un campione di circa 1,800 negozi in Italia rappresentativo delle più importanti catene di vendita (95% del fatturato totale della distribuzione moderna e 55,4% del commercio al dettaglio totale di questi prodotti). Si utilizzano diversi metodi con strutture di ponderazione per il calcolo delle PPA infra-nazionali al livello più disaggregato, dove solitamente non sono disponibili informazioni su quantità e spese. Si riportano stime preliminari degli indici spaziali regionali per specifici gruppi di prodotti e per gli aggregati di consumo alimentari e non alimentari.

Key words: regional price levels, spatial price indexes, sub-national PPPs

1 Introduction

An accurate measurement of price level differences across regions within a country is essential in order to better assess regional disparities, thus enabling policy makers to adequately identify and address areas of intervention. Regional values of economic indicators such as Gross Domestic Product (GDP), income and poverty levels, should be adjusted for regional price differences, following the same logic according to which the economic well-being of different countries is compared by taking into account *international purchasing power parities* (PPPs).

At international level, PPPs for countries are compiled by the International Comparison Program (ICP), administered by the World Bank with the collaboration of the OECD, EUROSTAT and other organizations (World Bank, 2013).

Though not as widespread as international comparisons of prices through ICP, there have been research projects and studies on the compilation of spatial price indexes, also referred to as *sub-national purchasing power parities*, carried out by NSOs and individual researchers in various countries including USA, Brazil, India, Indonesia, China, Italy, Australia, New Zealand and the United Kingdom (Biggeri et al, 2017; Laureti and Rao, 2018).

The Italian National Institute of Statistics (Istat) is one of the few National Statistical Offices (NSOs) that carried out official experimental sub-national PPPs computations by using price data from Consumer Price Indexes (CPIs) and ad-hoc surveys and focusing on comparing consumer prices across the 20 Italian regions. Significant price differences emerged in 2010 and in 2008, which encouraged Istat to confirm the project for producing sub-national PPPs on a regular basis (Biggeri et al., 2017). However, systematic attempts to compile sub-national PPPs on a regular basis have been hampered by the labour-intensive analyses required for processing traditional price data, i.e. data used for CPIs, and by the cost involved for carrying out ad-hoc surveys for collecting price data. In this context, the use of big data is both a challenge and a possible solution to more than one difficulty NSOs face when constructing spatial price comparisons worldwide. A range of alternative sources, including scanner data, information obtained from administrative sources or by adopting web-scraping techniques must be investigated for making both temporal and spatial price comparisons. Since the primary use of scanner data is not to measure temporal and spatial price differences, methodological and empirical issues regarding scanner data quality, such as under-coverage for missing outlet types (i.e. hard discount) and products (i.e. perishables and seasonal products) and over-coverage (i.e. business expenditure) should be solved by price statisticians. It is worth noting that, in order to produce sub-national PPPs for the entire household consumption expenditure, other sources should be considered in addition to scanner data.

By focusing on grocery products (for which retail scanner data are currently available), it may be fruitful to use the itemized information contained in scanner data (turnover and quantities for each well-specified item code) in order to compile weighted spatial price indexes at detailed territorial level. When reviewing international practices, it is important to note that even if a fifth of EU countries have been using scanner data for compiling CPIs using different methods, as yet few studies have explored the use of new data sources for compiling spatial indexes (Laureti and Polidoro, 2017). Within the European Multipurpose Price Statistics project, Istat has recently introduced scanner data in the official CPI computation and has been exploring the possibility of using them for compiling sub-national PPPs.

The aim of this paper is to estimate household consumption sub-national PPPs for Italy in 2017 by using a scanner dataset constructed for experimental CPI computation after having carried out data cleaning and trimming outliers processes. This data set refers to a random sample of approximately 1,800 hypermarkets (more than 500) and supermarkets (almost 1,300), concerning the grocery products sold in the most important retail chains (95% of modern retail chain distribution that covers 55.4% of total retail trade distribution for this category of products). Since data are available for the 107 Italian provinces we estimate within-regional and between-regional spatial price indexes for the food and non-food consumption aggregates included in the scanner dataset.

2 Scanner data and spatial price comparisons in Italy

The first and a fairly critical step when compiling household consumption sub-national PPPs is to prepare a long list of goods and services that will be priced in the regions involved in spatial price comparisons. The list used in price comparisons needs to meet and balance the requirements of comparability and representativity. Comparability means that identical products of the same or similar quality should be priced across all the regions so that the PPPs based on these data solely reflect price level differences. Representativity is a concept associated with the relative “importance” of individual products within a group of similar products (called Basic

Heading, BH[1]): ideally, a product’s importance should be determined using information on expenditure.

In this paper we refer to a list of products derived from the dataset described above, that specifically covers 54 grocery product aggregates, belonging to five divisions of the ECOICOP (01, 02, 05, 09, 12). Annual provincial average prices for each item were used which were obtained by aggregating the weekly prices of each GTIN code sold in the supermarkets and hypermarkets of 16 modern distribution chains located in the 107 Italian provinces using turnover weights, thus obtaining a total of 487,094 different products (GTINs).

The identification of the items is based on barcodes (GTINs), which univocally classify the products across the entire national territory. In each outlet (approximately 1,800), items were selected in order to cover up to 60% of the total turnover of the product aggregate. It is worth noting that perishables and seasonal products such as vegetables, fruit and meat were excluded from the scanner data because these products are sold at price per quantity and are not pre-packaged with GTIN codes.

Although this dataset was constructed for CPI compilation, it can also be used for making spatial price comparison among Italian regions bearing in mind that only the best selling products, which are typically consumed in each Italian province and region, may have be included according to the CPI selection procedure. Therefore these products may not be strictly comparable across different provinces and regions. It is useful to note that not all of the listed products must be priced in all of the regions. However, reliable regional price comparisons can be made as long as there is reasonable overlap in the items priced in different regions. We checked this requirement by verifying if product overlaps exhibit a chain structure.

3 Methods

In order to estimate regional spatial indices for products sold in modern distribution chains by using data for the 107 Italian provinces, a two-step procedure similar to the one used in the ICP was adopted whereby provinces are grouped into regions (World Bank, 2013). In the first step, within-regional PPPs are computed by comparing price and quantity data referring to products sold in the various provinces within each region while in the second step, between-regional PPPs are obtained for each region by using deflated price data for each province.

Moreover, as in international practice, sub-national PPP compilation is undertaken at two levels, viz., at BH level and at a more aggregated level (Food and Non-Food products). The methods selected for making multilateral comparisons is based on several axiomatic properties, including two basic properties: transitivity and base region invariance. Transitivity simply means that the PPP between any two regions should be the same whether it is computed directly or indirectly through a

[1] The smallest level of aggregation at which expenditure data are available are known in ICP parlance as basic headings. Although scanner data include expenditure data at item level, we still use the term “basic heading” to indicate a group of similar products which corresponds to a sub-class in the COICOP.

third region. The second requirement is that the PPPs be base region–invariant, which means that the PPPs between any two regions should be the same regardless of the choice of base region.

Aggregation methods at BH level

First step: within-regional PPPs

Let us assume that we are attempting to make a spatial comparison of prices between *R* regions, *r=1,…,R,* with *Mr* provinces in each region *r*. In the first stage of aggregation of price data at item level, which leads to price comparisons at BH level, p_{ijr} and q_{ijr} represent price and quantity of *i-th* item in *j-th* province and in *r-th* region $(i=1,2,...,N;\ j=1,2,...,M_r; r=1,\dots,R)$.

In order to compute within-regional PPPs, we explored using different methods[1], however, due to lack of space, we only illustrate the *Region-product-dummy (RPD) method* which was also used to compute between-regional PPPs. All methods are implemented using R. If product overlaps exhibit a chain structure thus the RPD method exhibits some aspects of spatial chaining.

The RPD is the regional version of the country-product-dummy (CPD) method used in international comparisons. This method suggests that price levels are estimated by regressing logarithms of prices on provinces for each *province* and product dummy variables; the model is given for each BH by:

$$\begin{aligned}\ln p_{ijr} &= \ln PPP_j + \ln P_i + \ln u_{ijr}\\ &= \pi_j + \eta_i + v_{ijr}\\ &= \sum_{j=1}^{M_r} \pi_j D^j + \sum_{i=1}^{N} \eta_i D^i + v_{ijr}\end{aligned} \qquad (1)$$

where D^j is a provincial-dummy variable that takes value equal to 1 if the price observation is from *j-th* province in the *r-th* region; and D^i is a i-dummy variable that takes value equal to 1 if the price observation is for *i-th* commodity. The random disturbance is assumed to satisfy the standard assumptions of a multiple regression model. In order to estimate parameters of this model we impose normalization $\sum_{j=1}^{M_r} \pi_j = 0$ thus treating all regions in a symmetric manner. If $\hat{\pi}_j\ (j=1,2,...,M_r)$ are estimated parameters, the within-regional PPP for the province *j* in region *r* is given by $WR\_PPP_j = e^{\hat{\pi}_j}$. The RPD method based price comparisons are transitive and base-invariant. With the aim of taking into account the economic importance (representativity) of each product expressed by expenditure weights w_{ijr} based on turnover we used a weighted RPD model:

$$\sqrt{w_{ijr}} \ln p_{ijr} = \sum_{j=1}^{M_r} \pi_j \sqrt{w_{ijr}} D^j + \sum_{i=1}^{N} \eta_i \sqrt{w_{ijr}} D^i + \sqrt{w_{ijr}} v_{ijr} \qquad (2)$$

Second step: between-regional PPPs

[1] We used various spatial index formulae, including Fisher based GEKS, Geary-Khamis and CPD (World Bank, 2013; Laureti and Rao, 2018). We found interesting results which suggest a high variability of prices within various regions. However, they cannot be reported here due to lack of space.

In order to use provincial prices adjusted for differences among provinces within the *r-th* region item prices in all the provinces of region *r* are converted by using:

$$\hat{p}_{ijr} = \frac{p_{ijr}}{WR\_PPP_{jr}} \qquad (3)$$

The deflated prices (in log form) were used for estimating a weighted RPD model with regional dummies and weights defined by deflated expenditure for each item in the *r-th* region.

$$\sqrt{w_{ijr}}\ln p_{ijr} = \sum_{k=1}^{R}\pi_k\sqrt{w_{ijr}}D^k + \sum_{i=1}^{N}\eta_i\sqrt{w_{ijr}}D^i + \sqrt{w_{ijr}}v_{ijr} \qquad (4)$$

The between-regional PPP for the region *r* is given by $R\_PPP_r = e^{\hat{\pi}_r}$ and transitive price comparisons based on RPD method are given by:

$$P_{rk}^{RPD} = \frac{\exp(\hat{\pi}_k)}{\exp(\hat{\pi}_r)} \quad for\,all\;\; r,k = 1,2,...,R \qquad (5)$$

Aggregation method for aggregation above basic heading level

The next and final step for compiling regional price comparisons is to aggregate the results from BH level comparisons to higher level aggregates. Let us assume that there are *L* basic headings (*l=1,...,L*) and e_i^r expenditure for *i-th* BH in region *r.* We decided to use the Fisher price index since it has a range of axiomatic and economic theoretic properties. The Fisher index is given by:

$$P_{rk}^{Fisher} = \sqrt{P_{rk}^{Laspeyres}\cdot P_{rk}^{Paasche}} \qquad (6)$$

where

$$P_{rk}^{Laspeyres} = \frac{\sum_{l=1}^{L} p_l^k q_l^r}{\sum_{l=1}^{L} p_l^r q_l^r} = \sum s_i^r\left(\frac{p_l^k}{p_l^r}\right), \qquad P_{rk}^{Paasche} = \frac{\sum_{i=1}^{N} p_l^k q_l^k}{\sum_{i=1}^{N} p_l^r q_l^k} = \left[\sum_l s_l^k\left(\frac{p_l^k}{p_l^r}\right)^{-1}\right]^{-1}$$

with $s_i^r = \frac{e_i^r}{\sum_{l=1}^{L} e_l^r} = \frac{p_l^r\cdot q_l^r}{\sum_{l=1}^{L} p_l^r\cdot q_l^r}$.

As the Fisher binary index in (6) is not transitive, it is possible to use the procedure suggested by Gini (1931), Elteto and Koves (1964) and Szulc (1964) referred to as the GEKS index to generate transitive multilateral price comparisons across different regions. The resulting index is given by:

$$P_{rk}^{GEKS-Fisher} = \prod_{r=1}^{R}\left[P_{rs}^{Fisher}\cdot P_{sk}^{Fisher}\right]^{1/R} \qquad (7)$$

The GEKS-Fisher based formula is used in cross-country comparisons made within the ICP at the World Bank (2015) and the OECD-Eurostat comparisons. In order to obtain a set of R_PPPs that refer to the group of regions (Italy) we standardized the GEKS-Fisher based PPPs (S-GEKS).

4 Results

In order to compute within and between regional spatial price indexes, we ran weighted RPD for all available BHs in scanner data (L=54) using expenditure weights defined by turnover. We then aggregated the results from BH level comparisons to higher level aggregates, i.e. food and non-food products both for within and between-regional PPPs. All results obtained cannot be reported, therefore Table1 illustrates RPPP for 2 BHs while Figure 1 shows aggregated RPPPs.

Regional spatial price indexes for two specific groups of products, that is "Pasta products" (BH1), which belongs to the aggregate Food products, and "Non-electrical appliances" (BH2, e.g. razors, scissors, hairbrushes, toothbrushes, etc.) included in the Non-Food aggregate, confirm large differences in price levels among Italian regions even if BH2 shows a higher territorial heterogeneity than BH1 (range is equal to 19.03 and 13.23 respectively). In the case of BH1, 5 regions located in the South and Islands (out of 8) and 2 Northern- Central regions (out of 11) show lower prices than Lazio while for BH2 higher price indexes are observed in 3 Southern regions and 8 regions in Northern and Central Italy. This different territorial pattern of consumption spatial price indexes is not confirmed when aggregated regional PPPs are computed for Food and Non-food products (Italy=100).

As shown in Figure 1, Southern regions appear to have price levels that are below the national average both for Food and Non-Food products, with the exception of Abruzzo (101.90 and 101.33, respectively), Molise (102.90 and 101.24) and Sardegna (101.93 and 101.57). However, it is worth noting that some

Northern regions also show lower price levels than the national average, such as Emilia-Romagna (98.31 and 98.40), Veneto (99.09 and 98.48) and Piemonte for Food products (99.80). On average, Toscana proved to be the less expensive region for both product aggregates (96.24 and 95.17). These results seem to suggest that when considering the retail modern distribution, the expected relationship in terms of price levels between the North and South of Italy partially changes (for "Pasta products" locally made goods could play a key role for maintaining the traditional price differences) and propose an interesting line for future research on the influence of the various distribution channels when defining sub-national PPPs. Caution is required when interpreting these results since: a) they may be influenced by the characteristics of the modern retail trade which is not uniformly distributed across Italian territory in terms of types of retail chains and market share; b) we excluded two groups of products "Whole Milk" and "Low-Fat Milk" since there were no reliable overlaps among regions enablig spatial price comparisons; c) these results are based on data selected for CPI compilation and hard discounts are excluded.

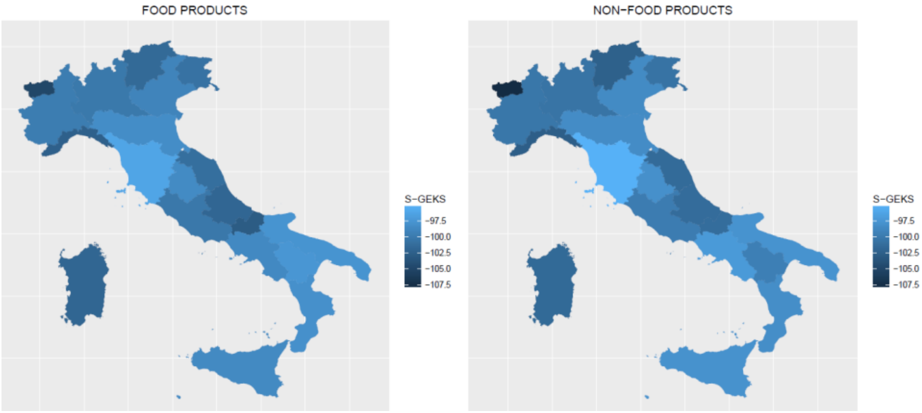

Figure 1: Between-regional PPPs for Food and Non Food products (Italy=100)

Dynamic component models for forecasting trading volumes

Modelli dinamici a componenti per la previsione dei volumi

Antonio Naimoli and Giuseppe Storti

Abstract We propose a new class of models for high-frequency trading volumes. Namely we consider a component model where the long-run dynamics are based on a Heterogeneous MIDAS polynomial structure based on an additive cascade of MIDAS filters moving at different frequencies. The merits of the proposed approach are illustrated by means of an application to three stocks traded on the XETRA market characterised by different degrees of liquidity.

Abstract *Viene proposta una nuova classe di modelli per volumi azionari ad alta frequenza. In particolare viene proposto un modello a componenti dove le dinamiche di lungo periodo sono basate su una struttura polinomiale di tipo MIDAS costituita da una cascata additiva di filtri MIDAS che si muovono a diverse frequenze. I vantaggi dell'approccio proposto vengono illustrati attraverso una applicazione a tre azioni contrattate sul mercato XETRA e caratterizzate da diversi livelli di liquidità.*

Key words: Intra-daily volume, component models, forecasting.

1 Introduction

Aim of this paper is to propose a novel dynamic component model for high-frequency trading volumes and assess its effectiveness for trading by means of an out-of-sample forecasting exercise. Volumes are indeed a crucial ingredient for the implementation of volume-weighted average price (VWAP) trading strategies.

Giuseppe Storti
Università di Salerno, Dipartimento di Scienze Economiche e Statistiche (DISES), Via Giovannni Paolo II, 132, 84084 Fisciano (SA), Italy. e-mail: `storti@unisa.it`

VWAP is one of the most common benchmarks used by institutional investors for judging the execution quality of individual stocks. The VWAP of a stock over a particular time horizon (usually one day) is simply given by the total traded value divided by the total traded volume during that period, i.e. the price of each transaction is weighted by the corresponding traded volume. The aim of using a VWAP trading target is to minimize the price impact of a given order by slicing it into smaller transaction sizes, reducing, in this way, the difference between expected price of a trade and its actual traded price. Investors, spreading the timing of transactions throughout the day, seek to achieve an average execution price as close as possible to the VWAP in order to lower market impact costs. Therefore, in this context, the key for a good strategy relies on accurate predictions of intra-daily volumes, since prices are substantially unpredictable.

The proposed specification, called the Heterogeneous MIDAS Component Multiplicative Error Model (H-MIDAS-CMEM), falls within the class of component MEM models as discussed in Brownlees et al. (2011). The most notable differences with respect to the latter are in the specification of the long-run component that is now modelled as an additive cascade of MIDAS filters moving at different frequencies from which the *heterogeneous* quality of the model comes. This specification is motivated by the empirical regularities arising from the analysis of high-frequency time series of trading volumes. After accounting for intra-day seasonality, treated employing a Fourier Flexible Form, these are typically characterised by two prominent and related features: a slowly moving long-run level and a highly persistent autocorrelation structure. In our model, these features are accounted by the heterogeneous MIDAS specification of the long-run component. Residual short term autocorrelation is then explained by an intra-daily non-periodic component that follows a unit mean reverting GARCH-type process. In addition, from an economic point of view, the cascade structure of the long-run component reproduces the natural heterogeneity of financial markets characterised by different categories of agents operating in the market at different frequencies. This results in a variety of sources separately affecting the variation of the average volume at different speeds. On a statistical ground, the cascade structure has the advantage of increasing model's flexibility since it allows to separately parametrize the dynamic contribution of each of these sources.

The estimation of model parameters is performed by the method of maximum likelihood under the assumption that the innovations are distributed according to the Zero-Augmented Generalized F (ZAF) distribution by Hautsch et al. (2014). The reason for this choice is twofold. First, it delivers a flexible probabilistic model for the conditional distribution of volumes. Second, it allows to control for the relevant proportion of zeros present in our data. In order to assess the relative merits of the proposed approach we have performed a forecasting exercise considering high-frequency trading volume for three stocks traded on the Xetra Market in the German Stock Exchange. The stocks have been selected to reflect different liquidity conditions as measured in terms of the number of non trading intra-daily intervals.

Our results show that the H-MIDAS-CMEM model is able to explain the the salient empirical features of the dynamics of high-frequency volumes. Also, we find that the H-MIDAS-CMEM is able to outperform its main competitors in terms of the usual Mean Squared Error and of the Slicing loss function proposed by Brownlees et al. (2011). Assessing the significance of differences in the predictive performance of models by the Model Confidence Set (MCS) of Hansen et al. (2011), it turns out that the H-MIDAS-CMEM is the only model always included in the set of superior models at different confidence levels.

In the reminder of the paper section 2 describes the proposed H-MIDAS-CMEM model defining its components as intra-daily periodic (subsection 2.1), intra-daily dynamic non-periodic (subsection 2.2) and long-run (subsection 2.3), respectively, while section 3 is dedicated to the out-of-sample forecasting exercise.

2 Model formulation

Let $\{x_{t,i}\}$ be a time series of intra-daily trading volumes. We denote days by $t \in \{1,\dots,T\}$, where each day is divided into I equally spaced intervals indexed by $i \in \{1,\dots,I\}$, then the total number of observations is given by $N = T \times I$.

The empirical regularities of high persistence and clustering of trading activity characterising intra-daily volumes lead us to build a Multiplicative Error Model consisting of multiple components that move at different frequencies. Extending the logic of the Component Multiplicative Error Model (CMEM) by Brownlees et al. (2011) and MIDAS regression models, we propose the H-MIDAS-CMEM which is formulated as

$$x_{t,i} = \tau_t \, g_{t,i} \, \phi_i \, \varepsilon_{t,i}. \tag{1}$$

The multiplicative innovation term $\varepsilon_{t,i}$ is assumed to be conditionally i.i.d., non-negative and to have unit mean and constant variance σ^2, i.e. $\varepsilon_{t,i}|\mathscr{F}_{t,i-1} \sim \mathscr{D}^+(1,\sigma^2)$, where $\mathscr{F}_{t,i-1}$ is the sigma-field generated by the available information until interval $i-1$ of day t. Then, the expectation of $x_{t,i}$, given the information set $\mathscr{F}_{t,i-1}$, is the product of three components characterised by a different dynamic structure. In particular, ϕ_i is an intra-daily periodic component parametrized by a Fourier Flexible Form, which reproduces the approximately U-shaped intra-daily seasonal pattern typically characterising trading activity. The $g_{t,i}$ component represents an intra-daily dynamic non-periodic component, based on a unit mean reverting GARCH-type process, that reproduces autocorrelated and persistent movements around the current long-run level. Finally, τ_t is a lower frequency component given by the sum of MIDAS filters moving at different frequencies. This component is designed to track the dynamics of the long-run level of trading volumes. Furthermore, the use of a time-varying intercept allows to reproduce sudden switches from very low to high trading intensity periods that typically occur in time series of high-frequency trading volumes. The structure of these components is described in more detail in the remainder of this section.

2.1 Intra-daily periodic component

Intra-daily volumes usually exhibit a U-shaped daily seasonal pattern, i.e. the trading activity is higher at the beginning and at the end of the day than around lunch time. To account for the periodic intraday factor we divide volumes $x_{t,i}$ by a seasonal component ϕ_i that is specified via a Fourier Flexible Form as proposed by Gallant (1981)

$$\phi_i = \sum_{q=0}^{Q} a_{0,q}\, \iota^q + \sum_{p=1}^{P} [a_{c,p}\, cos(2\pi p\, \iota) + a_{s,p}\, sin(2\pi p\, \iota)] \tag{2}$$

where $\iota = i/I \in (0,1]$ is a normalized intraday time trend.

Andersen et al. (2000) suggest that the Fourier terms in (2) do not add any significant information for $Q > 2$ and $P > 6$, so the model precision by using $Q = 2$ and $P = 6$ is enough to capture the behaviour of the intra-day periodicities.[1] Thus, assuming a multiplicative impact of intra-day periodicity effects, diurnally adjusted trading volumes are computed as

$$y_{t,i} = x_{t,i}/\phi_i. \tag{3}$$

2.2 Intra-daily dynamic non-periodic component

The intra-daily non-periodic component, unlike the seasonal component, takes distinctive and non-regular dynamics. In order to make the model identifiable, as in Engle et al. (2013), the intra-daily dynamic component follows a unit mean reverting GARCH-type process, namely $g_{t,i}$ has unconditional expectation equal to 1.

Then, the short-run component, in its simplest form, is formulated as

$$g_{t,i} = \omega^* + \alpha_1 \frac{y_{t,i-1}}{\tau_t} + \alpha_0 I(y_{t,i-1} = 0) + \beta_1 g_{t,i-1}, \tag{4}$$

where $\omega^* = (1 - \alpha_1 - (1-\pi)\alpha_0 - \beta_1)$, π is the probability that $y_{t,i} > 0$ and $I(y_{t,i-1} = 0)$ denotes an indicator function which is equal to 1 if the argument is true and to 0 otherwise.

2.3 The low frequency component

The low frequency component is modelled as a linear combination of MIDAS filters of past volumes aggregated at different frequencies. In this framework, a relevant issue is related to the identification of the frequency of the information to be used

[1] This result is confirmed by computing the Bayesian Information Criterion (BIC) for the estimation of P and Q lags.

by the filters, that notoriously acts a smoothing parameter. Therefore, using trading volumes moving at daily and hourly frequencies, the trend component τ_t is defined as

$$\begin{aligned} log\,\tau_t &= m + \theta_d \sum_{k=1}^{K_d} \varphi_k(\omega_{1,d}, \omega_{2,d}) YD_{t-k} \\ &\quad + \theta_h \sum_{k=1}^{K_d} \sum_{j=1}^{H} \varphi_{[j+(k-1)H]}(\omega_{1,h}, \omega_{2,h}) YH_{t-k}^{(H-j+1)}, \end{aligned} \tag{5}$$

where $YD_t = \sum_{i=1}^{I} y_{t,i}$, denotes the daily cumulative volume, with the subscript d referring to the daily frequency parameters. The subscript h is related to the parameters corresponding to the *hourly* frequency. If we let $t/H \in \{1,\ldots,H\times T\}$ denote the hourly frequency, with H being the number of intervals in which the day is divided, the variable $YH_t^{(j)}$ corresponds to the (j)-th hourly cumulative volume of the day t, that is $YH_t^{(j)} = \sum_{i=I\frac{(j-1)}{H}+1}^{I\frac{j}{H}} y_{t,i}$, for $j = 1,\ldots,H$. This multiple frequency specification is compatible with the heterogeneous market assumption of Müller et al. (1993), enforcing the idea that market agents can be divided in different groups characterised by different interests and strategies. Also, as pointed out in Corsi (2009), an additive cascade of linear filters moving at different frequencies allows to reproduce very persistent dynamics such as those typically observed for high-frequency trading volumes.

A common choice for determining $\varphi_k(\omega)$ is the Beta weighting scheme

$$\varphi_k(\omega) = \frac{(k/K)^{\omega_1-1}(1-k/K)^{\omega_2-1}}{\sum_{j=1}^{K}(j/K)^{\omega_1-1}(1-j/K)^{\omega_2-1}}. \tag{6}$$

As discussed in Ghysels et al. (2007), this Beta-specification is very flexible, being able to accommodate increasing, decreasing or hump-shaped weighting schemes. The Beta lag structure in (6) includes two parameters, but in our empirical applications ω_1 is always set equal to 1 such that the weights are monotonically decreasing over the lags. Furthermore, the number of lags K is properly chosen by information criteria to avoid overfitting problems.

The clustering of the trading activity involves a continuous variation of the average volume level and thus the dynamics of trading volumes are typically characterised by sudden transitions from states of very low trading activity to states of intense trading. In order to account for this switching-state behaviour we further extend the proposed modelling approach introducing a time-varying intercept in the formulation of the long-run component. This is specified as a convex combination of two different unknown parameters m_1 and m_2, that is $m_t = \lambda_t m_1 + (1-\lambda_t)m_2$. The combination weights are time-varying, since they change as a function of observable state-variables. The weight function λ_t follows a logistic specification of the type

$$\lambda_t = \frac{1}{1+exp(\gamma(\delta - s_{t-1}))}, \qquad (\gamma,\delta) > 0 \tag{7}$$

where γ and δ are unknown coefficients and s_{t-1} is an appropriately chosen state-variable.[2]

3 Out-of-sample forecasting comparison

High-frequency trading volume data used in our analysis refer to the stocks Deutsche Telekom (DTE), GEA Group (G1A) and Salzgitter (SZG) traded on the Xetra Market in the German Stock Exchange. An important feature of the data is the different number of zeros induced by non-trading intervals, since for DTE proportion of zero observations is 0.03%, for G1A 7.046% and for SZG 15.78%.

The raw tick-by-tick data have been filtered employing the procedure proposed by Brownlees and Gallo (2006), only considering regular trading hours from 9:00 am to 5:30 pm. Tick-by-tick data are aggregated computing intra-daily volumes over 10-minutes intervals, which means 51 observations per day. The data have been seasonally adjusted using the Fourier Flexible Form described in equation (2).

To evaluate the predictive ability of the H-MIDAS-CMEM models and their relative merits with respect to competitors, we perform an out-of-sample forecasting comparison over the period January-December 2007, which includes 251 days. In order to capture the salient features of the data and to safeguard against the presence of structural breaks, the model parameters are recursively estimated every day starting from January 2006 with a 1-year rolling window. Therefore at each step we predict 51 intra-daily volumes before re-estimating the models, for a total of 251 days and 12801 intra-daily observations. The out-of-sample performance of the examined models is evaluated by computing some widely used forecasting loss functions. The significance of differences in forecasting performance is assessed by the Model Confidence Set (MCS) approach (Hansen et al., 2011) which relies on a sequence of statistic tests to construct a set of superior models, in terms of predictive ability, at certain confidence level $(1-\alpha)$.

To compare the out-of-sample predictive performances we use the following loss functions

$$L^{MSE} = \sum_{t=1}^{T} \sum_{i=1}^{I} (x_{t,i} - \hat{x}_{t,i})^2$$

$$L^{Slicing} = -\sum_{t=1}^{T} \sum_{i=1}^{I} (w_{t,i} \, log \, \hat{w}_{t,i})$$

where L^{MSE} is the Mean Squared Error (MSE) of the volumes, while $L^{Slicing}$ is the Slicing loss function developed by Brownlees et al. (2011) to evaluate VWAP trading strategies. The slicing weights $\hat{w}_{t,i}$ are computed under both the static and dynamic VWAP replication strategies. The loss functions for single model shown in the top panel of Table 1 point out that the H-MIDAS-CMEM with fixed and, mainly,

[2] A suitable choice for the state-variable is the daily average of intra-daily volumes $\bar{y}_t$.

with time-varying intercept returns the lowest values for both the Mean Squared Error (L^{MSE}) and the Slicing loss using weights computed under the static (L^{SL}_{stc}) and dynamic (L^{SL}_{dyn}) VWAP replication strategy. A lower value of L^{MSE} provides evidence of a greater ability to capture the continuous variation from calms to storms periods, since intra-daily volume series are highly volatile, whereas minimizing the Slicing loss function increases the chances to achieve the VWAP target for a given trading strategy. In order to evaluate if the differences in terms of the considered loss functions are statistically significant, the MCS approach has been used. The MCS results confirm the strength of the H-MIDAS-CMEM, since the model with time-varying intercept is always included into the 75% MCS referring to the set of loss functions employed to measure the predictive ability of the models. For what concerns the H-MIDAS-CMEM with fixed intercept, it falls in the set of the superior models at the 0.75 confidence level for SZG according to the considered loss functions. This also applies to G1A, with the exception of the static Slicing loss entering at the 0.95 level. Finally, for DTE the H-MIDAS-CMEM is out of the MCS for the L^{MSE}, while falling into the 95% MCS for both the Slicing. Furthermore, the benchmark models never fall into the MCS according to the loss functions and the confidence levels considered.

Conditional Quantile-Located VaR

Valore a rischio condizionato ai quantili

Giovanni Bonaccolto, Massimiliano Caporin and Sandra Paterlini

Abstract The Conditional Value-at-Risk (CoVaR) has been proposed by [1] to measure the impact of a company in distress on the Value-at-Risk (VaR) of the financial system. We propose here an extension of the CoVaR, that is, the Conditional Quantile-Located VaR (QL-CoVaR), that better deals with tail events, when spillover effects impact the stability of the entire system. In fact, the QL-CoVaR is estimated by assuming that the financial system and the individual companies simultaneously lie in the left tails of their distributions.

Abstract *Il valore a rischio condizionato (CoVaR) é stato introdotto da [1] per quantificare l'impatto di una societá in fase di stress sul valore a rischio (VaR) del sistema finanziario. Nel presente lavoro proponiamo un'estensione del VaR (QL-CoVaR), che meglio si adatta agli eventi estremi, quando il rischio di contagio impatta sulla stabilitá dell'intera economia. Infatti, il QL-CoVaR é stimato assumendo che il sistema finanziario e le singole societá sono simultaneamente poste sulle code sinistre delle loro distribuzioni.*

1 Methods

We first introduce the Conditional Value-at-Risk (CoVaR) proposed by [1]. Then, we provide the details about the Conditional Quantile-Located Value-at-Risk (QL-CoVaR). Let y_t and $x_{i,t}$ be the returns of the financial system and of the i-th financial company at time t, respectively, for $i = 1,...,N$ and $t = 1,...,T$. Let $Q_\tau(x_{i,t}|\mathbf{I}_{t-1})$ denotes the τ-th quantile of $x_{i,t}$, for $\tau \in (0,1)$, conditional to the information set $\mathbf{I}_{t-1}$, where $\mathbf{I}_{t-1} = (y_{t-1}, x_{i,t-1}, m_{t-1})$ with m_{t-1} being a control variable at time $t-1$. Similarly, $Q_\theta(y_t|\mathbf{I}_{t-1}, x_{i,t})$ is the θ-th quantile of y_t conditional to the information set available at $t-1$ as well as to the return of the i-th company observed at time t, for $\theta \in (0,1)$. For simplicity, we set $Q_\tau(x_{i,t}|\mathbf{I}_{t-1}) \equiv Q_\tau(x_{i,t})$ and $Q_\theta(y_t|\mathbf{I}_{t-1}, x_{i,t}) \equiv Q_\theta^{(i)}(y_t)$; θ and τ take low values, typically in the interval $(0, 0.05)$. The CoVaR introduced by [1] is then estimated from the quantile regression models (see [4]):

$$Q_\tau(x_{i,t}) = \alpha_\tau^{(i)} + \beta_\tau^{(i)} m_{t-1}, \tag{1}$$

$$Q_\theta^{(i)}(y_t) = \delta_\theta^{(i)} + \lambda_\theta^{(i)} x_{i,t} + \gamma_\theta^{(i)} m_{t-1}. \tag{2}$$

Let $\widehat{Q}_\tau(x_{i,\tau}) = \widehat{\alpha}_\tau^{(i)} + \widehat{\beta}_\tau^{(i)} m_{t-1}$ be the estimated τ-th quantile of $x_{i,t}$, it is possible to compute the CoVaR at the distress and at the median state of the conditioning company, respectively, as follows:

$$CoVaR_{t,\theta,\tau}^{(i)} = \widehat{\delta}_\theta^{(i)} + \widehat{\lambda}_\theta^{(i)} \widehat{Q}_\tau(x_{i,t}) + \widehat{\gamma}_\theta^{(i)} m_{t-1}, \tag{3}$$

$$CoVaR_{t,\theta,1/2}^{(i)} = \widehat{\delta}_\theta^{(i)} + \widehat{\lambda}_\theta^{(i)} \widehat{Q}_{1/2}(x_{i,t}) + \widehat{\gamma}_\theta^{(i)} m_{t-1}, \tag{4}$$

and compute the ΔCoVaR to quantify the marginal contribution of the i-th company to the systemic risk (see [1]). Note that $CoVaR_{t,\theta,1/2}^{(i)}$ is always parameterized to the median state of the i-th conditioning company. Hence, we can omit the level 1/2 as subscript of the ΔCoVaR measure as follows:

$$\Delta CoVaR_{t,\theta,\tau}^{(i)} = CoVaR_{t,\theta,\tau}^{(i)} - CoVaR_{t,\theta,1/2}^{(i)} = \widehat{\lambda}_\theta^{(i)} \left[\widehat{Q}_\tau(x_{i,t}) - \widehat{Q}_{1/2}(x_{i,t})\right]. \tag{5}$$

For simplicity, we set $\theta = \tau$ and, then, $\Delta CoVaR_{t,\theta,\tau}^{(i)} \equiv \Delta CoVaR_{t,\tau}^{(i)}$. It is important to highlight that the parameters in (2) and the coefficients in (3) are functions of θ only, neglecting the role of τ. Therefore, the estimation process behind (3) depends on $x_{i,t}$ and not on $Q_\tau(x_{i,t})$. In contrast, we estimate the parameters in (2) assuming that the financial system and the i-th company simultaneously lie in the left tails of their distributions. We then take into account the impact exerted by $x_{i,t}$—in the neighbourhood of its τ-th quantile—on $\widehat{Q}_\theta^{(i)}(y_t)$. This allows us to increase the distress degree in the connections between the individual companies and the system to make our risk measure more sensitive to extreme events. The model we propose is defined as follows:

$$Q^{(i)}_{\theta,\tau}(y_t) = \delta^{(i)}_{\theta,\tau} + \lambda^{(i)}_{\theta,\tau} x_{i,t} + \gamma^{(i)}_{\theta,\tau} m_{t-1}, \tag{6}$$

where the parameters have both θ and τ as subscripts, as they depend on the quantiles levels of both y_t and $x_{i,t}$.

In fact, the unknown parameters in (6) are estimated from the following minimization problem:

$$\underset{\delta^{(i)}_{\theta,\tau},\lambda^{(i)}_{\theta,\tau},\gamma^{(i)}_{\theta,\tau}}{\arg\min} \sum_{t=1}^{T} \rho_\theta \left[y_t - \delta^{(i)}_{\theta,\tau} - \lambda^{(i)}_{\theta,\tau} x_{i,t} - \gamma^{(i)}_{\theta,\tau} m_{t-1} \right] K\left(\frac{\widehat{F}_{t|t-1}(x_{i,t}) - \tau}{h} \right), \tag{7}$$

where $\rho_\theta(e) = e(\theta - \mathbf{1}_{\{e<0\}})$ is the asymmetric loss function used in the quantile regression method by [4]; $\mathbf{1}_{\{\cdot\}}$ is an indicator function, taking the value of 1 if the condition in $\{\cdot\}$ is satisfied, the value of 0 otherwise; $K(\cdot)$ is the kernel function, with bandwidth h, whereas $\widehat{F}_{t|t-1}(x_{i,t})$ is the empirical conditional quantile of $x_{i,t}$. [5] used a similar approach to estimate the relations in quantiles between oil prices and stock returns.

In contrast to [5], we estimate $\widehat{F}_{t|t-1}(x_{i,t})$ dynamically using a rolling window procedure. For each window, we estimate a large set of $x_{i,t}$ quantiles in the support $\tau \in (0,1)$ from the quantile regression model (1), using the method proposed by [2] to ensure the monotonicity of the multiple quantiles for $\tau \in (0,1)$. Then, we linearly interpolate the set of quantiles to obtain the conditional distribution of $x_{i,t}$ at time t, denoted as $\widehat{F}(x_{i,t}|m_{t-1})$. Finally, we recover $\widehat{F}_{t|t-1}(x_{i,t})$, as the probability level, extrapolated from $\widehat{F}(x_{i,t}|m_{t-1})$, corresponding to the realization $x_{i,t}$.

From the method described above, we then compute the QL-CoVaR at the τ-th level as follows:

$$\mathit{QL\text{-}CoVaR}^{(i)}_{t,\theta,\tau} = \widehat{\delta}^{(i)}_{\theta,\tau} + \widehat{\lambda}^{(i)}_{\theta,\tau} \widehat{Q}_\tau(x_{i,t}) + \widehat{\gamma}^{(i)}_{\theta,\tau} m_{t-1}, \tag{8}$$

where $\widehat{Q}_\tau(x_{i,t}) = \widehat{\alpha}^{(i)}_\tau + \widehat{\beta}^{(i)}_\tau m_{t-1}$.

Then, given $\theta = \tau$, and evaluating the model also for $\tau = 1/2$, we define the ΔQL-CoVaR as:

$$\begin{aligned} \Delta\mathit{QL\text{-}CoVaR}^{(i)}_{t,\tau} &= \mathit{QL\text{-}CoVaR}^{(i)}_{t,\theta,\tau} - \mathit{QL\text{-}CoVaR}^{(i)}_{t,\theta,1/2} = \widehat{\delta}^{(i)}_{\theta,\tau} - \widehat{\delta}^{(i)}_{\theta,1/2} \\ &+ \widehat{\lambda}^{(i)}_{\theta,\tau} \left[\widehat{Q}_\tau(x_{i,t}) - \widehat{Q}_{1/2}(x_{i,t}) \right] + (\widehat{\lambda}^{(i)}_{\theta,\tau} - \widehat{\lambda}^{(i)}_{\theta,1/2}) \widehat{Q}_{1/2}(x_{i,t}) \\ &+ (\widehat{\gamma}^{(i)}_{\theta,\tau} - \widehat{\gamma}^{(i)}_{\theta,1/2}) m_{t-1}. \end{aligned} \tag{9}$$

It is important to highlight that $\Delta\mathit{QL\text{-}CoVaR}^{(i)}_{t,\tau}$ includes more components than $\Delta\mathit{CoVaR}^{(i)}_{t,\tau}$ in (5), as the coefficients in (9) also depend on the state of the i-th company. We then have further information about the relationships between the financial system and the individual companies when we focus on the left tails of their distributions. We compute the standard errors of the ΔCoVaR and the ΔQL-CoVaR coefficients using the bootstrap approach (see, e.g., [3]).

2 Empirical results

We implement the methods discussed in Section 1 on the daily returns of 1,155 U.S. financial institutions (952 banks and 203 insurance companies) in the period between October 10, 2000 and July 31, 2015, for a total of 3,864 days.[1] We note that some of the companies enter the dataset after October 10, 2000, whereas others exit before July 31, 2015. We estimate the models described in Section 1 for each of the financial companies for which we have at least 200 observations, resulting in 1,030 companies. We also build an index providing the return of the financial system (y_t) from the returns of the 1,155 financial institutions included in our dataset, weighted by their market values. As for m_t, we use the first principal component of variables that are related to bond, equity and real estate markets: i) the CBOE Volatility Index (VIX); ii) the liquidity spread (LS), computed as the difference between the three-month collateral repo rate and the three-month bill rate; iii) the change in the three-month Treasury bill rate (TB); iv) the change in the slope of the yield curve (YC), computed as the spread between the ten-year Treasury rate and the three-month bill rate; v) the change in the credit spread between BAA-rated bonds and the Treasury rate (CS), both with the ten years maturity; vi) the daily equity market return (EM); vii) the excess return of the real estate sector over the market return (RE).[2] In particular, we checked that the first principal component (m_t) of the variables listed above explains 96.50% of the variability in the data.

Table 1 Estimation of $Q_\theta^{(i)}(y_t) = \delta_\theta^{(i)} + \lambda_\theta^{(i)} x_{i,t} + \gamma_\theta^{(i)} m_{t-1}$

The table reports the summary statistics of the CoVaR's parameters estimated for the N financial companies included in our dataset. The estimates are obtained using two quantile levels—θ. In each panel, from left to right, we report the following descriptive statistics of the coefficients: the 5-th percentile (5P), the median (MED), the 95-th percentile (3Q), the interquartile range (IQR) and the percentage of times, out of N, in which they are statistically significant at the 5% confidence level (PS).

We estimate the CoVaR and the QL-CoVaR using two quantile levels—$\theta = \tau = 0.01$ and $\theta = \tau = 0.05$. As for the estimation of the QL-CoVaR parameters, we use the Gaussian kernel as $F(\cdot)$, with $h = 0.15$.[3] On the basis of the empirical set-up

[1] The data are recovered from Thomson Reuters Datastream.

[2] The control variables listed in i)—v) are taken from Thomson Reuters Datastream, whereas EM and RE are recovered from the industry portfolios built by Kenneth R. French, available at *http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html.*

[3] We used other values of h for a robustness check, that is, $h = \{0.10, 0.20\}$. We checked that the results obtained with different h values are qualitative similar and are available upon request.

The table reports the summary statistics of the QL-CoVaR parameters estimated for the N financial companies included in our dataset. We estimated the conditional quantiles for two quantile levels of θ and $h = 0.15$. From left to right, we report the following descriptive statistics of the coefficients: the 5-th percentile (5P), the median (MED), the 95-th percentile (95P), the interquartile range (IQR) and the percentage of times, out of N, in which they are statistically significant at the 5% confidence level (PS).

described above, we estimate the QL-CoVaR parameters. The results are reported in Table 2.

As expected, we can see from Table 1 that positive returns of the individual companies have a positive impact on the VaR of the financial system, as $\lambda^{(i)}_{\theta}$ takes, on average, positive values. In contrast, Table 2 reports the statistics of the QL-CoVaR coefficients, where we condition the estimates to the distress and to the median state of a single financial company. As before, the average impact exerted by the companies to both *QL-CoVaR*$^{(i)}_{\tau}$ and *QL-CoVaR*$^{(i)}_{1/2}$ is positive, but greater with respect to the standard CoVaR (the medians of both $\widehat{\lambda}^{(i)}_{\theta,\tau}$ and $\widehat{\lambda}^{(i)}_{\theta,0.5}$ are greater than the median of $\widehat{\lambda}^{(i)}_{\theta}$). Therefore, the relationships between the system and the companies become stronger by focusing on particular regions of the $x_{i,t}$ support, i.e. when $x_{i,t}$ is in a neighbourhood of a distress state.

On average, we observe larger values for $\widehat{\lambda}^{(i)}_{\theta,\tau}$ at $\theta = 0.01$ than at $\theta = 0.05$, whereas the opposite holds for $\widehat{\lambda}^{(i)}_{\theta,0.5}$. $\widehat{\lambda}^{(i)}_{\theta,\tau}$ measures the relation between $x_{i,t}$ and y_t, when the companies and the system simultaneously lie in the left tail of their distributions. The fact that $\widehat{\lambda}^{(i)}_{\theta,\tau}$ increases as θ and τ simultaneously decrease means that the co-movements between the financial system and the companies become stronger when moving leftwards along the left tails of their distributions. Consequently, the risk of contagion increases by accentuating the distress degree in the connections between the financial system and the companies. For both CoVaR and QL-CoVaR, the percentage of times in which the coefficient measuring the impact of the individual companies (λ) is statistically significant at the 5% level is greater at $\theta = \tau = 0.05$ than at $\theta = \tau = 0.01$.

Forensic Statistics

Cause of effects: an important evaluation in Forensic Science

Cause degli Effetti: una rilevante valutazione nelle Scienze Forensi

Fabio Corradi and Monica Musio

Sommario *Causes of Effects* (COE) queries concern the assessment of causal relationship in individual cases by evaluating the *probability of causation.* However is not always clear how and whether, to usefully employ scientific data for this pourpose. Given even a randomized sample we can typically only provide bounds for the *probability of causation* if some fundamental conditions, namely exogeneity, comparability and sufficiency [4] , are satisfied. In this work we make the fundamental conditions operative by means of a Bayesian model selection procedure.
Sommario *Le problematiche di Cause di Effetti (COE) riguardano la valutazione di relazioni causali individuali attraverso il calcolo della probabilità di causazione. In questo contesto non è sempre chiaro come utilizzare dati provienti da studi scientifici. Infatti anche in presenza di esperimenti randomizzati si possono solo calcolare degli intervalli per la probabilità di causazione, qualora siano soddisfatte le così dette condizioni fondamentali di esogeneità, comparabilità e sufficienza [4]. L'obiettivo di questo lavoro è di rendere operative queste condizioni tramite una procedura di selezione di modelli in ambito Bayesiano.*

Key words: Causes of Effects, Fundamental conditions, Bayesian Model Selection

1 Introduction

In causal inference it is important to distinguish two types of causal query which, although not entirely unconnected, are nevertheless very different, both in form and in the type of answer they require. The following example traces back to Holland,

Fabio Corradi
Dipartimento di Statistica, Informatica e Applicazioni, Università di Firenze, e-mail: corradi@disia.unifi.it

Monica Musio
Dipartimento di Matematica ed Informatica, Università di Cagliari e-mail: mmusio@unica.it

1986 [6] and is archetypical in causal literature.
Effects of Causes (EoC): " Ann has a headache. She is wondering whether to take aspirin. Will that cause her headache to disappear?"
Causes of Effects (CoE): "Ann had a headache and took aspirin. Her headache went away. Was that caused by the aspirin?"
EoC type questions have the form "Will A cause B ?" CoE questions have the form "Did A cause B ?", and are also known as problems of individual causation.

How to use scientific data on individual cases is a problem that is central to the courts of justice and, in forensic literature, is referred as the G2i ("Group-to-individual") problem Dawid *et al.*, (2014) [3]).
In the CoE case, Ann actually chose to take the aspirin ($E = 1$) and assumed the drug ($T = 1$), this produces her headache to disappear ($R = 1$).

In this work we concentrate on the general CoE setting and more explicitly on how to support the conditions required to evaluate the probability of causation.

2 Basic of COE

Let's consider again the CoE example about the aspirin: Ann had a headache and decided ($E = 1$) to took aspirin ($T = 1$). Her headache went away ($R = 1$). Was that caused by the aspirin? One possible answer, "Probability of Causation", PC, relies on potential responses (R_0, R_1) (where R_x denotes the value R takes when $T = x$, *i.e.* T is set to x). We know that, for Ann, $T = 1$ so that $R_1 = 1$: she took the aspirin and her headache disappeared. Now if in "counterfact" $R_0 = 1$, then Ann's headache would have disappeared even if she had not taken the aspirin, so we must conclude that it was not the aspirin that cured her. Conversely, if $R_0 = 0$ then we can indeed attribute her cure to having taken the aspirin. Everything must be also evaluated considering her choice to take the drug, $E = 1$, which could be informative of her health status or, in general, on her preference to assume the treatment. In this way our CoE causal question is formulated in terms of the contrast between the factual outcome R_1 and the counterfactual outcome R_0. Formally we can define the PC as the *conditional probability* (see, *e.g.*, Dawid *et al.*, (2016) [4])

$$\mathrm{PC}_A = \Pr(R_0 = 0 \mid H^A, E = 1, R_1 = 1) = \frac{\Pr(R_0 = 0, R_1 = 1 \mid H^A, E = 1)}{\Pr(R_1 = 1 \mid H^A, E = 1)}, \qquad (1)$$

where PC_A denotes the judge's probability distribution over attributes of Ann and H^A the background information, some relevant known information about Ann. We denote by H a set of variables $H = \{H_1, \ldots, H_K\}$ and with $H^A = \{H_1^A, \ldots, H_K^A\}$ their corresponding values for Ann. This formal approach does however leave open the questions of how to evaluate PC and what evidence can be used. The numerator of (1) is not estimable, since we can never observe both R_0 and R_1 for the same individual, hence we can never assess this dependence without making any further assumptions. CoE questions may simply not have well-determined answers, but we can sometimes set bounds so long as some *fundamental conditions* are satisfied (Dawid *et al.*, (2016) [4]). In such case it is possible to show that

$$\Pr(R_0 = 0 \mid H^A, E = 1, R_1 = 1) \geq \max\{0, 1 - \frac{1}{RR_A}\} \tag{2}$$

with

$$RR_A := \frac{\Pr(R_1 = 1 \mid H^A, E = 1)}{\Pr(R_0 = 1 \mid H^A, E = 1)}.$$

Whenever $RR_A > 2$ the Probability of Causation PC_A will exceed 50%. In a civil court this is often taken as the criterion to assign legal responsibility ”on the balance of probabilities”. How much information H^A to take into account is still an unsolved problem. The aim of this work is to evaluate how different specifications of H support the fundamental conditions. We pose the issue as a model selection problem within the class of models induced by the fundamental conditions, where each model specifies a particular choice for H. Models will be evaluated by considering their marginal likelihood and a prior on the model space.

3 Fundamental conditions

3.1 Exogeneity

The potential outcomes (R_0, R_1) have the same joint distribution among both treated and untreated study subjects having the same background information H^A as Ann.
This condition essentially assumes no confounding $(R_0, R_1) \perp\!\!\!\perp T \mid H^A$ for every specification of H. This assumption cannot be tested empirically since in the treated patients we only observe R_1 and in the untreated patients we only observe R_0. So any argument we make for exogeneity has to be justified because of the randomization and ignorance of the influence of the H characteristics on the response.

3.2 Comparability

Conditional on knowledge of the pre-treatment characteristics of Ann and the trial subjects we can regard Ann's potential responses as comparable with those of the treated subjects having characteristics H^A.
Comparability essentially says that we are not able to distinguish between Ann and the group of treated individuals as it concerns the uncertainty of their response to the treatment. This is nothing but exchangeability, a basic form of dependence introduced by de Finetti. If exchangeability holds, the joint distribution of the random variables considered for a problem are invariant to permutation, i.e. there is no way

to make a distinction among them. According to what characteristics are included in H, different individuals in the randomized sample will be compared with Ann. Then using the representation theorem we can evaluate the probability to observe Ann and the group of responses if exchangeability holds among them.

3.3 Sufficiency

Conditional on H^A, Ann's intention to take (or not) the treatment does not affect the distribution of her potential responses.

This condition requires that, given Ann's own background information H^A, her potential outcomes are not further influenced by her (known) desire to take the aspirin. We need first too address the condition required to evaluate the denominator of RR_A: *Conditional on knowledge of the pre-treatment characteristics of Ann and the trial subjects, we can regard Ann's potential responses as comparable with those of the* untreated *subjects having characteristics H^A.* This potential probability clearly concerns a counterfactual event, since Ann decided and actually took the aspirin; obviously we don't know the response if she had not taken the aspirin but we know her will to assume the drug. We assume that E is observed in the sample: for example, a patient entered into a randomized trial is conscious that he may not receive the treatment but only a placebo and nevertheless agrees to express the wish to take aspirin or not. The ambition is to evaluate $\Pr(R_0 = 1 \mid H^A, E = 1)$ using traditional experimental data for $T = 0$, without ignoring the decision of Ann to take the drug, which is *observational* in nature. $E = 1$ describes the Ann's desire to take the aspirin, information not included in H^A but possibly relevant to determine the probability of the response. If we can obtain reasonable support to the condition

$$R_0 \perp\!\!\!\perp E \mid H^A \qquad \text{i.e. if} \tag{3}$$

$$\Pr(R_0 = 1 \mid H^A, E = 1) = \Pr(R_0 = 1 \mid H^A, E = 0) \tag{4}$$

it would be possible to estimate $\Pr(R_0 = 1 \mid H^A, E = 1)$ by $\Pr(R = 1 \mid H^A, T = 0)$.

4 Model selection

We pose the problem of finding the group most fitting the fundamental conditions as one of model selection solved, as usual, by computing the marginal likelihood, based on the data, for each possible specifications of H. We have 2^K possible different choices for the characteristics that can be selected from H. Let J be one of these choices, that can be identified as a subset of $\{1, \ldots, K\}$. We introduce an equivalence relation $\sim$ on the set of treated individuals that agree to receive the treatment ($T = 1, E = 1$). Namely if I_1 and I_2 are two such individuals then

$$I_1 \sim I_2 \iff H_j^{I_1} = H_j^{I_2}, \quad \forall j \in J.$$

A similar definition can be given for the other subgroups ($T = 1, E = 0$), ($T = 0, E = 1$) and ($T = 0, E = 0$). Thus each equivalence relation determines a partition of one of the above four groups. These four partitions identify a *model* M_J. We denote each element of one quotient set by $X^s_{t,e}$, where $t \in \{0,1\}$, $e \in \{0,1\}$ and $s \in \{0,1,2\ldots,N\}$, $N-1$ being the number of elements of each partition. We reserve the notation $X^0_{t,e}$ to the sets of individuals who share all the characteristics with Ann. Using the same notation as before, we indicate by $\mathbf{r}_{t,e}$ the vector of responses in the main 4 groups, by $\mathbf{r}_{\{\setminus X\}}$ the vector of responses in the complementary of the set X, by $\mathbf{r}^s_{t,e}$ the vector of responses referred to a specific group of individuals and by r_A the Ann's response. The responses of the treated and untreated individuals are not considered exchangeable each other and are modeled separately using the conditional representation indexed by their own θs, which are a priori assumed independent. So the marginal likelihood we want to evaluate factorizes and we evaluate each contribution separately.

$$\begin{aligned}
&\Pr(r_A, \mathbf{r}_{1,1}, \mathbf{r}_{1,0}\mathbf{r}_{0,1}, \mathbf{r}_{0,0}|M_J) = \qquad (5)\\
&= \int_{\Theta_{T=1}} \int_{\Theta_{T=0}} \Pr(r_A, \mathbf{r}_{1,1}, \mathbf{r}_{1,0}\mathbf{r}_{0,1}, \mathbf{r}_{0,0}, \theta_{T=1}, \theta_{T=0}|M_J) d\theta_{T=1} d\theta_{T=0}\\
&= \int_{\Theta_{T=1}} \Pr(r_A, \mathbf{r}_{1,1}, \mathbf{r}_{1,0}, \theta_{T=1}|M_J) d\theta_{T=1} \int_{\Theta_{T=0}} \Pr(\mathbf{r}_{0,1}, \mathbf{r}_{0,0}, \theta_{T=0}|M_J) d\theta_{T=0}.
\end{aligned}$$

4.1 Marginal likelihood for comparability

Because of the sufficiency condition, we assume the same mixing parameter $\theta^s_{T=1}$ in the sets $X^s_{1,1}$ and $X^s_{1,0}$, whose prior is assumed a non-informative $Be(1,1)$, while for the comparability condition Ann is suppose to be exchengeable with the treated individuals sharing with Ann the same characteristics. The marginal likelihood is

$$\begin{aligned}
&\Pr(r_A, \mathbf{r}_{1,1}, \mathbf{r}_{1,0}|M_J) = \Pr\left(r_A, \mathbf{r}^0_{1,1}, \mathbf{r}^0_{1,0}, \mathbf{r}_{\setminus\{X^0_{1,1}, X^0_{1,0}\}}\right) \qquad (6)\\
&= \int_{\Theta^0_{T=1}} \Pr(r_A, \mathbf{r}^0_{1,1}, \mathbf{r}^0_{1,0}, \theta^0_{T=1}) d\theta^0_{T=1} \cdot \prod_{s \neq 0} \int_{\Theta^s_{T=1}} \Pr(\mathbf{r}^s_{1,e}, \theta^s_{T=1}) d\theta^s_{T=1} =\\
&= \frac{x^0_{1,e} + 1}{n^0_{1,e} + 2} \prod_{s \neq 0} \frac{1}{n^s_{1,e} + 1}
\end{aligned}$$

where $x^0_{1,e}$ is the number of success in the group $X^0_{1,1} \cup X^0_{1,0}$, $n^0_{1,e} = |X^0_{1,1}| + |X^0_{1,0}|$ and $n^s_{1,e} = |X^s_{1,1}| + |X^s_{1,0}|$.

4.2 Marginal likelihood for sufficiency

The sufficiency assumption requires E to have not influence on the response for the untreated with the Ann's characteristics. So, if $R_0 \perp\!\!\!\perp E|H^A$ holds, then the two groups of r.v., $\mathbf{r}^0_{0,1}, \mathbf{r}^0_{0,0}$, share a common mixing distribution parameter $\theta^0_{T=0}$, whose prior is assumed a non-informative $Be(1,1)$. We denote by $\theta^s_{T=0,E=e}$ the mixing parameter in the quotient set $X^s_{0,e}$. The marginal likelihood is:

$$\Pr(\mathbf{r}_{0,1},\mathbf{r}_{0,0}|M_J) = \Pr(\mathbf{r}^0_{0,1},\mathbf{r}^0_{0,0},\mathbf{r}_{\setminus\{X^0_{0,1},X^0_{0,0}\}}) = \int_{\Theta^0_{T=0}} \Pr(\mathbf{r}^0_{0,1},\mathbf{r}^0_{0,0},\theta^0_{T=0}) d\theta^0_{T=0} \cdot$$

$$\prod_{s\neq 0}\prod_{e\in\{0,1\}} \int_{\Theta^s_{T=0,E=e}} \Pr(\mathbf{r}^s_{0,e},\theta^s_{T=0,E=e}) d\theta^s_{T=0,E=e}$$

$$= \binom{n^0_{0,0}}{x^0_{0,0}}\binom{n^0_{0,1}}{x^0_{0,1}}\binom{n^0_{0,0}+n^0_{0,1}}{x^0_{0,0}+x^0_{0,1}}^{-1} \cdot \frac{1}{n^0_{0,0}+n^0_{0,1}+1}\prod_{s\neq 0}\prod_{e\in\{0,1\}} \frac{1}{n^s_{0,e}+1} \qquad (7)$$

where we have used a similar notation as before.

Remark 1 (Marginal likelihood and the Irving-Fisher exact test). The marginal likelihood evaluated for a subset of H formally shares the hypergeometric part with the conditional Irving-Fisher exact test statistic used to evaluate differences among the rate of success of an event in two populations. The result is not surprising since we are looking for the set of H making E irrelevant, so supporting the so called H_0 hypothesis of no-difference between the success ratio in the two groups.

4.3 Prior and posterior in the model space

By (5), the required marginal likelihood is the product of (6) and (7). The goal is to evaluate the posterior of M_J given the responses observed on Ann and on the sample. To this end we introduce a prior over the space of models. The simpler choice is to consider an uniform distribution on this space. Another choice is this one proposed by Chen and Chen, (2008) [1]. They give the same prior probability (equal to $\frac{1}{k+1}$) to all models sharing the same number of characteristics k. In this way for the generic model M_J we have:

$$\Pr(M_J) = \frac{1}{k+1}\binom{k}{|M_J|}^{-1} \cdot I(|M_J| \leq k/2) \qquad (8)$$

where the search spans all models including at most $k/2$ characteristics. This choice favours model selection according to the Occam razor principle: the fewer characteristics employed, the more probable is the model. This rationale is reasonably objective. Combining (6) and (7) and (8), we get the required posterior.

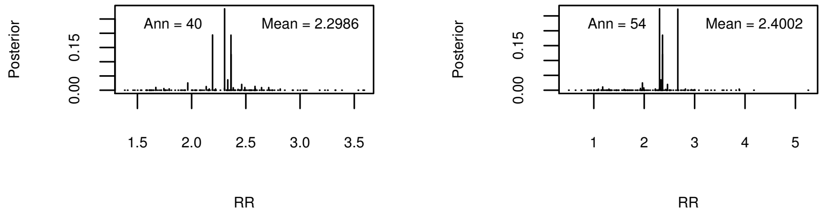

Figura 1 Risk ratios for two individuals who succeded and required the hint

5 An experiment

We carried on an experiment at the University of Florence, School of Engineering, Fall 2017. We asked to 160 students to solve a simple probabilistic question and we provided randomly an hint (the treatment T). Before the test we asked to the students if they wish to be helped or not ($E = 0$ and $E = 1$).
We are interested to investigate if there is a causal relationship between the hint and the ability to solve the question, for the students who wished to take the hint. We had 8 of these cases and for all of them we found a $RR > 2$ (obtained by averaging the results of different models according to their posterior probability, see figure (1)). This implies a lower bound for the probability of causation greater than 0.5 which suffices to indicate a causal relation between the hint and the positive result obtained by the 8 students.

As a result of our experiment we have also that, among the students who asked and had the hint, 24 did not succeed. We can image that one of them claimed that it was the hint which caused the failure. If we look now to the corresponding RR for such students, obtained as before by model averaging, we note that all of them have a values smaller then 1 (see figure 2). This is not conclusive that there is a causal relation between the hint and the failure.

In a civil trial this would not suggest to a judge to provide a compensation.

6 Conclusions

We introduced a typical Cause of Effect problem by means of an archetyppical example considering Ann and the effect of an aspirin on her headache. We have proposed a possible solution to make operational the choice of variables to include, so as to validate the fundamental assumptions underlying the assessment of Ann's probability of causation. We assume to have the possibility to perform a randomi-

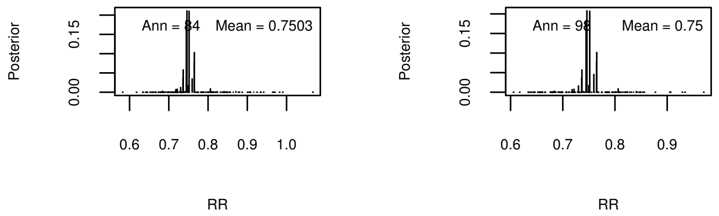

Figura 2 Risk ratios for two individuals who didn't succed and required the hint

zed sample from the Ann's population where, as usual, T is assigned following a randomized protocol and E, this is a novelty, is a question asking to the members of the sample about their preference to be treated or not.

Next step will be to extend the methodology to observational studies, to make possible in a wider range of cases the evaluation of the PC_A for Causes of Effects problems.

Evaluation and reporting of scientific evidence: the impact of partial probability assignments

La valutazione dell'evidenza scientifica: assegnazioni di probabilità parziali

Silvia Bozza, Alex Biedermann, Franco Taroni

Abstract The assessment of the value of scientific evidence can be performed by the derivation of a likelihood ratio, a rigorous concept that provides a measure of the change produced by an item of information in the odds in favor of a proposition as opposed to another. This represents a demanding task with several sources of uncertainty, due for example to elicitation of probabilities or to computational impasses. While use of such a metric is well established and supported by operational standards, opinions about what should be an appropriate way to deal with such sources of uncertainty while presenting expressions of evidential value at trial differ. Some quarters promote positions according to which practitioners should state a range of values for the probabilities of the evidence given competing propositions, and report a range of values for the likelihood ratio. However, such partial probability assignments may not make good use of available information.

Abstract *La valutazione del valore delle prove scientifiche può essere eseguita attraverso il rapporto di verosimiglianza, un concetto rigoroso che fornisce una misura del cambiamento prodotto da un elemento di prova nelle probabilità a favore di una proposizione rispetto ad un'altra. Questo rappresenta un compito impegnativo con diverse fonti di incertezza, dovute ad esempio alla necessità di assegnare valori di probabilità o a difficoltà computazionali. Mentre l'uso di tale metrica è ben consolidato e supportato da standard operativi, vi sono opinioni discordanti su quale dovrebbe essere il modo più appropriato per affrontare tali fonti di incertezza*

mentre si presentano le espressioni del valore probatorio al processo. Seguendo il dibattito in corso, gli esperti forensi sarebbero invitati ad indicare, per ragioni di trasparenza, un intervallo di valori per le probabilità dell'evidenza date le ipotesi di interesse e riportare un intervallo di valori per il rapporto di verosimiglianza. Tuttavia, tali assegnazioni di probabilità parziali potrebbero non fare un buon uso delle informazioni disponibili.

Key words: Likelihood ratio, partial probability assignments, uncertainty.

1 The likelihood ratio framework

Forensic scientists are typically faced to the evaluation of measurements on characteristics of trace evidence. The use of the likelihood ratio as a metric to assess the probative value of forensic traces is largely supported by operational standards and recommendations in forensic disciplines [3]. However, the progress towards more widespread consensus about foundational principles is still fragile and there are different views on how the strength of evidence conclusions should be reported to the court. The assessment of a likelihood ratio may turn out to be a task subjected to various sources of uncertainty, ranging from the problem of eliciting probabilities, to statistical issues related to the model choice, to sensitivity issues related to the choice of a prior distribution, or to even computational impasses that emerge when the marginal likelihoods are not available in closed form and numerical procedures need to be implemented. There is actually an open debate on the topic of whether the precision of forensic likelihood ratios should be measured and how should be reported to the court. A special edition edited by Geoff Morrison has recently been published in *Science & Justice* ([5] and subsequent papers). From one side, there is a school of thought according to which a forensic expert should report a single value for a likelihood ratio (e.g. [8], [6]). The likelihood ratio being expressed as a ratio of conditional probabilities (or marginal likelihoods whenever the evidence is expressed in terms of continuous measurements) is itself a measure of uncertainty. It represents the best assignment a forensic scientist can provide given data, model and background information. From the other side, it is questioned whether scientists should report interval quantifications as a surrogate for the value of the evidence (e.g. [7]) to acknowledge for uncertainty in likelihood ratio assessment. It is argued that reporting a single value would deprive the legal justice system of essential information needed to assess the reliability of the evidence. This discussion has echoed also in statistical literature, see for example [1].

It must be acknowledged that the discussion took different directions, leading in some cases arguments against the subjectivist interpretation of probabilities or against the Bayesian reasoning scheme, in others starting from different points of view with different interpretations of the same concept of likelihood ratio. It should be emphasized that in reality the fundamental point of this whole discussion is not the defense or not of a subjectivist approach. Nothing prevents, for example, to incorporate ‘reassuring’ relative frequencies to inform subjective probabilites ([9]). What really matters is finding the thread of the whole discussion, understanding whether to bring uncertainty about the expressions of uncertainty can actually lead to a good use of information taking into account that the ultimate goal must be to help justice.

2 On partial probability assignments

The discussion and related disagreements originate (also) from the fact that presenting a numerical value for probabilities or marginal likelihoods in the numerator and in the denominator of the likelihood ratio may give a false impression of exactitude, as such a precision may be in fact rarely realistic.

Consider the case where the evidence, E_1, is expressed in terms of a correspondence of genetic profiles between a person of interest and a recovered stain on a crime scene. What is the probability of observing corresponding evidential findings? Should the expert report his uncertainty, or not reporting it could it be misleading to the court? For this reason a forensic scientist may feel the necessity to present a range of values to minimize their personal involvement in the case. Let us therefore admit a partial probability assignment for both the numerator and the denominator of the likelihood ratio, say $\Pr(E_1 \mid H_p) = (l_p, u_p)$, for some $l_p < u_p$, and $\Pr(E_1 \mid H_d) = (l_d, u_d)$, for some $l_d < u_d$, where H_p and H_d designate propositions put forward by the prosecution and the defence, respectively.

On the other hand, a trier of fact could also be vague about their beliefs as to prior odds on the propositions that the person of interest is the source of the crime stain or another unrelated person is the source of that stain. What is the probability associated to the defendant’s liability? For this reason, let us admit a partial probability assignment for the prior probability of proposition H_p too, say $\Pr(H_p) = (l_h, u_h)$, for some $l_h < u_h$. Suppose now laboratory results are available so that the posterior probabilities of the competing propositions can be computed. For this purpose, it is useful to refer to the example originally sketched out by Frosini in 1989 ([2]) because it is well suited to the forensic issues under discussion. Consider the following partial probability assignments for the probabilites of interest:

$$\Pr(H_p) = (0.1, 0.2) \quad ; \quad \Pr(E_1 \mid H_p) = (0.6, 0.8) \quad ; \quad \Pr(E_1 \mid H_d) = (0.3, 0.5).$$

Assuming that values for the prior probabilities and for the likelihoods of the evidence under the competing propositions are uniformly spread over the assigned intervals, several values are randomly generated from each interval and for each realized triplet the posterior probability of the proposition supported by the prosecution is computed. The posterior probability, expressed by means of intervals, is $\Pr(H_p \mid E_1) = (0.12, 0.3)$. The impact of the evidence is to increase vagueness in the probability assignment for the propositions of interest changing the range of the probabilities from $(0.1, 0.2)$ to $(0.12, 0.3)$.

Suppose now that new findings are available, giving rise to new evidence (e.g. in terms of a correspondence between the recovered and control material from a suspect) denoted by E_2. Following the same line of reasoning, and considering for sake of simplicity the same partial probability assignments for the numerator and the denominator of the likelihood ratio that were assigned to evidence E_1, a new posterior partial probability assignment is obtained for the prosecution proposition, $\Pr(H_p \mid E_1, E_2) = (0.14, 0.45)$. This process can be reiterated many times. One may easily observe that the range of vagueness, at least initially, increases, though this may be felt counterintuitive as the effect of the evidence should be of reducing the initial size of the range of probabilities on the propositions of judicial interest. Posterior probabilities of the prosecution proposition H_p expressed in terms of partial probability assignments are depicted in Figure 2. Note that the range of probabilities assigned for new available findings E_i is kept fixed, $\Pr(E_i \mid H_p) = (0.6, 0.8)$ and $\Pr(E_i \mid H_d) = (0.3, 0.5)$ for $i = 1, 2, \ldots, n$. Though the observation of a correspondence between evidential findings will clearly shift the posterior odds versus the prosecution statement, one may observe that the effect of the evidence is to increase prior vagueness, at least until a large amount of findings is available.

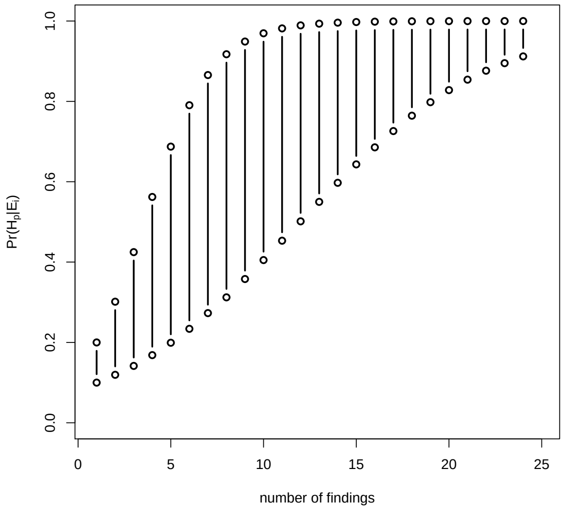

Fig. 1 Posterior probabilities proposition H_p expressed in terms of partial probability assignments: $\Pr(H_p) = (0.1, 0.2)$. Likelihoods are also expressed in terms of partial probability assignments, $\Pr(E_i \mid H_p) = (0.6, 0.8)$ and $\Pr(E_i \mid H_d) = (0.3, 0.5)$, $i = 1, \ldots, 24$.

This is clearly a simulated example. In a real case, the assumption of constant partial probability assignments for the likelihoods in the numerator and denominator in correspondence of new available evidence may be felt too restrictive and difficult to defend. Each assignment will reflect the uncertainty of the expert (or experts, whenever there are different laboratories in charge of the analyses of different recovered stains or marks) about a case-specific result. However, it serves the purpose to show in a simple way that the produced effect of such partial probability assignments is counterintuitive and it does not represent the answer the legal system would expect.

3 Conclusions

There may be different levels of resolution for the value of the likelihood ratio. This prompts scientists to elaborate ways to construct intervals or distributions over probabilities and likelihood ratios. It is argued that by reporting a single value, a forensic scientist deprives the legal justice system of essential information needed to assess the reliability of the evidence and this would amount to be highly misleading. However, nothing will be gained if a particular expression for uncertainty is itself obscured by an additional level of uncertainty ([4]). Not only such intervals provide no guidance to recipient of expert information as to how such pairs of values ought to be used, but also but also ranges of posterior probability may be larger than ranges of the corresponding prior probability. The conclusion of the discussion is that, in a given case at hand, forensic scientists ought to offer to a court of justice a given single value for the likelihood ratio. It is obviously desirable that reported likelihood ratios be accompanied with information to help fact-finders understand how and on what bases forensic scientists have reached their conclusions. Reporting a single value does not prevent a scientist, whenever asked, to respond about the strength of their beliefs.

Missing Data Handling in Complex Models

Dependence and sensitivity in regression models for longitudinal responses subject to dropout

Dipendenza e sensibilità nei modelli ad effetti casuali per dati longitudinali in presenza di dropout

Marco Alfò and Maria Francesca Marino

Abstract In longitudinal studies, subjects may be lost to follow-up and present incomplete response sequences. When the mechanism that leads to exit the study is non ignorable, a possible route is to define a model that accounts for potential dependence between the longitudinal and the dropout process. This model should have, at least, two major features: (*i*) it should (simply) reduce to an ignorable missing data model, when some conditions are met; (*ii*) the nested structure should give the way to measure sensitivity of parameter estimates to assumptions on non ignorability. In this work, we discuss random coefficient based dropout models and review measures of local sensitivity.

Abstract Negli studi longitudinali, alcuni soggetti abbandonano lo studio prima del suo completamento, presentando sequenze incomplete. Quando il meccanismo di generazione del dato mancante è non ignorabile, si può considerare un modello che descriva la dipendenza tra processo longitudinale e generazione del dato mancante stesso. Tale modello dovrebbe includere, come caso particolare, il modello per dati mancanti di tipo ignorabile, e permettere un'analisi di sensibilità delle stime rispetto alle ipotesi fatte circa il meccanismo di generazione dei dati mancanti stessi. In questo lavoro, si discutono i modelli a coefficienti casuali per l'analisi di studi longitudinali con dati mancanti non ignorabili e si confrontano misure di sensibilità locale.

1 Introduction

Longitudinal studies entail repeated measurements from the same units over time. Often, units leave the study before the planned end, leading to *dropout* (also referred to as *attrition*) According to Rubin's taxonomy [19], if the probability of a missing response, conditional on observed data, does not depend on the responses that should have been observed, the data are said to be missing completely at random (MCAR), or missing at random (MAR). When, even after conditioning on observed data, the mechanism still depends on the unobserved responses, data are referred to as missing not at random (MNAR). In the context of likelihood inference, when either the parameters in the measurement and the missingness process are not distinct or the missing data process is MNAR, missing data are non ignorable (NI). In this case, some form of joint modeling of the longitudinal response and the missing data process is required [12].

Random Coefficient Based Dropout Models (RCBDMs, [11]) may be used as a quite general approach in this context. Here, two separate (conditional) models are built for the longitudinal response and the missingness indicator. Dependence arises due to models sharing common/dependent unit- and (possibly) outcome-specific random parameters. The model specification is completed by adopting an appropriate distribution for these random parameters, which can be either fully parametric [23, 8], or semi-parametric [2, 3]. This latter approaches have been introduced in the literature to avoid the impact that parametric assumptions may have on inference [20], especially in the case of short longitudinal sequences. More elaborated approaches are also available in the literature [5, 6, 4]. Besides the advantages of the semi-parametric approach, it presents the substantial drawback that dependence *within* outcomes can not be separated by dependence *between* outcomes. Starting from this drawback, we define a bi-dimensional finite mixture model for longitudinal data subject to dropout [21]. When the missing data mechanism is ignorable, such MNAR model directly reduces to its MAR counterpart. See also [14] for a dynamic extension of the model. Sensitivity of parameter estimates to assumptions on non ignorability of the dropout process can be explored by adopting either a global or a local perspective. Within the latter, we discuss the so-called *index of sensitivity to non ignorability* (ISNI) proposed by [22] and [13]. We show that, if the proposed model specification is employed, this approach to sensitivity analysis can be seen as a particular version of local influence diagnostics [10, 17, 18]. Obviously, a *global* influence approach could be adopted as well, for example by looking at the *mean score* approach by [25].

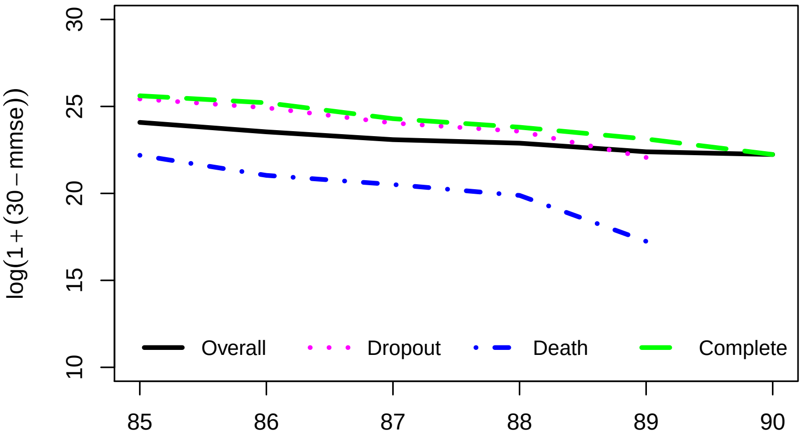
The structure of the paper follows. In section 2 we introduce the motivating application, the Leiden 85+ study, entailing the dynamics of cognitive functioning in the elderly. Section 3 discusses general random coefficient based dropout models, while sensitivity analysis is described in section 4.

2 Motivating example: Leiden 85+ data

To discuss our proposal, we consider data from the Leiden 85+ study, a retrospective study on 705 Leiden (Netherlands) inhabitants, who reached the age of 85 years between September 1997 and September 1999. The study aim was at identifying demographic and genetic determinants of cognitive functioning dynamics in the elderly. The following covariates were collected at the beginning of the study: gender, educational status (primary/higher education), plasma Apolipoprotein E (APOE) genotype (22-23, 24, 33, 34-44). Only 541 subjects present complete covariate information and will be considered in the following. Study participants were visited at their place of residence once a year until the age of 90; orientation, attention, language skills and ability to perform simple actions were assessed through a 30-items questionnaire. The Mini Mental State Examination index (MMSE, [7]), is obtained by summing the binary scores on such 30 items.

We report in Figure 1 the evolution of the mean response over time, stratified by participation.

Fig. 1: Mean *MMSE* value over time stratified by subjects' participation to the study.



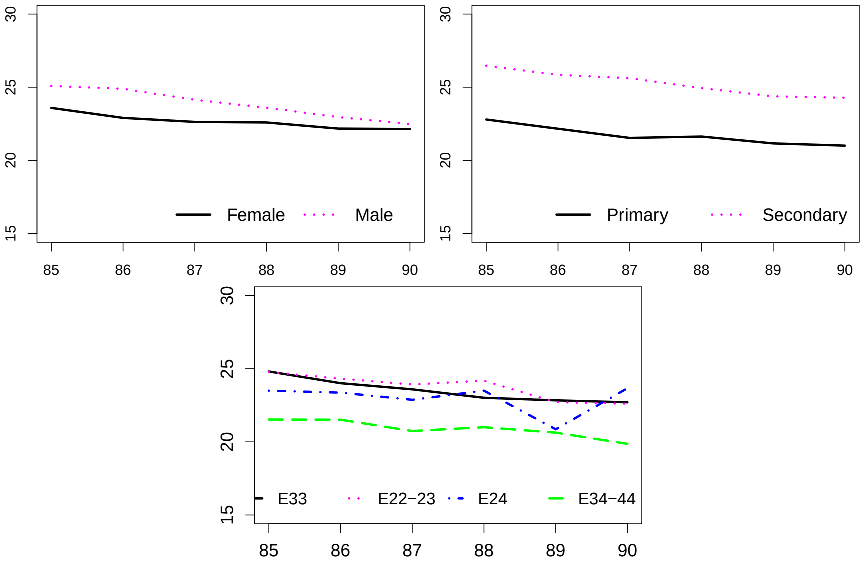
By looking at this figure, we may observe that, while the decline over time in the MMSE mean is (at least approximately) constant across the groups defined by patterns of dropouts, the differential participation in the study leads to a different slope for the overall mean score. Such a finding highlights a potential dependence between the evolution of the response over time and the dropout process, which may bias parameter estimates and corresponding inference. We report in Table 1 the distribution of the observed covariates by pattern of participation. This suggests a differential participation in the study by gender and educational level, while differences can be observed only for $APOE_{34-44}$ group.

Table 1: Leiden 85+ Study: demographic and genetic characteristics of participants

Variable	Total	Completed (%)	Did not complete (%)	(Row) Total
Gender				
Male	180 (33.27)	74 (41.11)	106 (58.89)	100
Female	361 (66.73)	192 (53.19)	169 (46.81)	100
Education				
Primary	351 (64.88)	166 (47.29)	185 (52.71)	100
Secondary	190 (35.12)	100 (52.63)	90 (47.37)	100
APO-E				
22-23	96 (17.74)	54 (56.25)	42 (43.75)	100
24	12 (2.22)	6 (50.00)	6 (50.00)	100
33	319 (58.96)	162 (50.78)	157 (49.22)	100
34-44	114 (21.08)	44 (38.60)	70 (61.40)	100
Total	541 (100)	266 (49.17)	275 (50.83)	100

Figure 2 depicts the dynamics of mean MMSE score over time by available covariates. From this figure, it is evident that cognitive impairment is lower for males than females, even if the difference seems to decrease with age, maybe due to a differential dropout by gender. No further interaction with age can be evinced, as the dynamics seem to be consistent for both levels of education, and for all the 4 levels of APOE genotype, but for the one with a very reduced sample size ($APOE_{24}$).

Fig. 2: Leiden 85+ Study: mean of MMSE score stratified by age and gender, educational level, APOE



3 Random coefficient-based dropout models

Let Y_{it} represent a response recorded on $i = 1,\dots,n$, subjects at time occasions $t = 1,\dots,T$, and let $\mathbf{x}_{it} = (x_{it1},\dots,x_{itp})'$ be a vector of observed covariates. We assume that, conditional on a q-dimensional set of individual-specific random coefficients $\mathbf{b}_i$, the observed responses are independent draws from a distribution in the Exponential Family with canonical parameter defined by

$$\theta_{it} = \eta_{it}^{Y} = \mathbf{x}_{it}'\beta + \mathbf{z}_{it}'\mathbf{b}_i.$$

The terms $\mathbf{b}_i$, $i = 1,\dots,n$, describe unobserved, individual-specific, heterogeneity (which may also be time-varying), while β is a vector of fixed parameters. Usually, $\mathbf{z}_{it} = (z_{it1},\dots,z_{itq})'$ represents a subset of $\mathbf{x}_{it}$. For identifiability purposes, standard assumptions on the random coefficient vector are introduced: $\mathrm{E}(\mathbf{b}_i) = \mathbf{0}$ and $\mathrm{Cov}(\mathbf{b}_i) = \mathbf{D}$ for $i = 1\dots,n$.

Let $\mathbf{R}_i$ denote the vector of missing data indicators, with generic element $R_{it} = 1$ if the i-th unit drops-out at any point in the window $(t-1,t)$, $R_{it} = 0$ else. As we focus on dropouts, we have $R_{it'} = 1, \forall t' > t$, so that $T_i \le T$ measures are available for each study participant. We consider studies in discrete time; however, most of the following arguments may apply, with a limited number of changes, to (continuous time) survival process as well. To describe potential dependence between the longitudinal and the dropout process, we introduce an explicit model for the latter, conditional on a set of covariates, say $\mathbf{w}_i$, and a subset of the random coefficients in the longitudinal model. That is, we assume that, conditional on $\mathbf{b}_i^* = \mathbf{C}\mathbf{b}_i$, $i = 1,\dots,n$, $\mathbf{C} \in \mathscr{M}_{\mathbf{q},\mathbf{q_R}}$, dropout indicators are independent and follow a Bernoulli distribution with probability ϕ_{it} defined by:

$$\mathrm{logit}(\phi_{it}) = \eta_{it}^{R} = \mathbf{w}_{it}'\gamma + \mathbf{v}_{it}'\mathbf{b}_i^*. \tag{1}$$

Previous equations define a so-called shared (random) coefficient model [27, 26]. The assumption is that the longitudinal response and the dropout indicator are independent conditional on the individual-specific random coefficients:

$$f_{Y,R}(\mathbf{y}_i,\mathbf{r}_i \mid \mathbf{X}_i,\mathbf{W}_i) = \int \left[\prod_{t=1}^{T_i} f_Y(y_{it} \mid \mathbf{x}_{it},\mathbf{b}_i) \prod_{t=1}^{\min(T,T_i+1)} f_R(r_{it} \mid \mathbf{w}_{it},\mathbf{b}_i)\right] dG(\mathbf{b}_i), \tag{2}$$

Dependence between the measurement and the missingness, if any, is completely accounted for by the latent effects which are also used to describe unobserved, individual-specific, heterogeneity in each of the two (univariate) profiles. This class of models has been further extended by [28] to *joint* models where a continuous time setting and a survival data model are considered:

$$h_i(t) = h_0(t)\exp(\mathbf{w}_{it}'\gamma + \alpha\eta_{it}^Y). \tag{3}$$

As an alternative, we may consider equation-specific random coefficients [1]. In this respect, let $\mathbf{b}_i = (\mathbf{b}_{i1}, \mathbf{b}_{i2})$ denote an individual- and outcome-specific random coefficient. Introducing a local independence assumption, the joint density for the couple $(\mathbf{Y}_i, \mathbf{R}_i)$ can be written as follows:

$$f_{Y,R}(\mathbf{y}_i, \mathbf{r}_i \mid \mathbf{X}_i, \mathbf{W}_i) = \int \left[\prod_{t=1}^{T_i} f_Y(y_{it}|\mathbf{x}_{it}, \mathbf{b}_{i1}) \prod_{t=1}^{\min(T,T_i+1)} f_R(r_{it}|\mathbf{w}_{it}, \mathbf{b}_{i2})\right] dG(\mathbf{b}_{i1}, \mathbf{b}_{i2}). \tag{4}$$

A further approach is that proposed by [6], where common, partially shared and independent (outcome-specific) random coefficients are considered in the measurement and the dropout process. For example, in the current context, we may write

$$\mathbf{b}_{i1} = \mathbf{b}_i + \varepsilon_{i1}\mathbf{b}_{i2} = \mathbf{b}_i + \varepsilon_{i2}, \qquad \varepsilon_{i1} \perp \varepsilon_{i2}.$$

This can be further extended to consider partially shared effects.

4 Sensitivity analysis: definition of the index

As highlighted by [15], for every MNAR model we may define a MAR counterpart that produces exactly the same fit to the observed data. Two issues are worth to be noticed. First, the MNAR model is fitted to the observed data only, assuming that the distribution of the missing responses is identical to that of the observed ones. Second, the structure describing dependence between the longitudinal responses (observed and missing) and the dropout indicators is just one out of several possible choices. Therefore, we may be interested in evaluating how much maximum likelihood estimates are influenced by hypotheses on the dropout mechanism.

Looking at *local* sensitivity, [22] defined the index of local sensitivity to non ignorability (ISNI) using a first-order Taylor expansion of the log-likelihood function. The aim was at describing the behaviour of parameter estimates in a neighbourhood of the MAR solution. The index was further extended by [9] by considering a second-order Taylor expansion; more general settings and different metrics were also considered [13, 31, 29, 30, 24].

To specify the index of local sensitivity, let $\lambda = (\lambda_{11}, \ldots, \lambda_{K_1K_2})$ denote the vector of non ignorability parameters, with $\lambda = \mathbf{0}$ corresponding to the MAR model. Furthermore, let $\hat{\Phi}(\lambda)$ denote the ML estimates obtained conditional on a given value of λ. The ISNI may be written as

$$ISNI_{\Phi} = \left.\frac{\partial\hat{\Phi}(\lambda)}{\partial\lambda}\right|_{\Phi(0)} \simeq -\left(\left.\frac{\partial^2\ell(\Phi,\Psi,\pi)}{\partial\Phi\Phi'}\right|_{\Phi(0)}\right)^{-1} \left.\frac{\partial^2\ell(\Phi,\Psi,\pi)}{\partial\Phi\lambda}\right|_{\Phi(0)} \tag{5}$$

It measures the displacement of model parameter estimates from their MAR counterpart, in the direction of λ. Following [29], the following equation holds:

$$\hat{\Phi}(\lambda) = \hat{\Phi}(\mathbf{0}) + ISNI_{\Phi}\lambda;$$

The ISNI may be also interpreted as the linear impact that λ has on $\hat{\Phi}$. By using the proposed bi-dimensional model specification, we may show that the sensitivity analysis based on $ISNI_{\Phi}$ can be linked to local influence diagnostics developed for regression models to check for influential observations by perturbing individual-specific weights [10, 17, 18]. Here, we perturb weights associated to groups of subjects, rather than individual observations, See e.g. [16] for a comparison between multiple imputation and perturbation schemes in the more general setting of masking individual microdata.

Multilevel analysis of student ratings with missing level-two covariates: a comparison of imputation techniques

Analisi multilivello dell'opinione degli studenti universitari in presenza di valori mancanti delle variabili di secondo livello: un confronto tra metodi di imputazione

Maria Francesca Marino e Carla Rampichini

Abstract We analyse the relationship between student ratings of university courses and several characteristics of the student, the course and the teacher. In particular, we exploit data from a survey collecting information about teacher beliefs and practices at the University of Padua in a.y. 2012/13. Student ratings are nested into classes, calling for multilevel modelling. However, due to survey non-response, the information about beliefs and practices is missing for about half of the teachers, posing a serious issue of missing data at level 2. To avoid listwise deletion, we make multiple imputation via fully conditional specification, exploiting information at all hierarchical levels. The proposed approach turns out to be effective. We found that some of the teacher beliefs and practices are significantly related to student ratings.

Abstract *Il presente lavoro analizza la relazione tra le valutazioni dei corsi universitari fornite dagli studenti e le caratteristiche di docenti e studenti. I dati provengono da un'indagine ad hoc svolta dall'Università di Padova nell'a.a. 2012/13 su convinzioni e pratiche dei docenti universitari. La struttura gerarchica dei dati, con valutazioni raggruppate per insegnamento, richiede l'uso di modelli multilivello. L'indagine presenta un alto tasso di non-risposta, ponendo un serio problema di dati mancanti a livello 2. Si considera un'imputazione multipla basata sull'approccio* fully conditional*, sfruttando anche l'informazione proveniente dalle unità di livello 1. I risultati ottenuti evidenziano l'efficacia del metodo utilizzato. Inoltre, risulta che alcune delle convinzioni e delle pratiche adottate dai docenti sono significativamente correlate alle valutazioni degli studenti.*

Key words: fully conditional specification, multiple imputation, multivariate mixed model

1 Introduction

We analyse student satisfaction, as measured by student evaluation of teaching (SET). The peculiarity of the study lies in the availability of many variables about teacher characteristics and beliefs, and teaching practices. This work exploits data from the University of Padua for academic year 2012/13 about bachelor degree courses. The data set is obtained by merging three different sources: (*i*) the traditional SET survey with 18 items, measured on a ten-point scale (1: low, 10: high); (*ii*) administrative data on students, teachers and didactic activities; (*iii*) an online survey carried out by the PRODID project on teacher beliefs and practices.

Data have a two-level hierarchical structure, with $56,775$ student ratings at level 1 and $1,016$ classes at level 2. The average class size is 79 (min 5, max 442). We are interested in student satisfaction about two key aspects of teaching, i.e. teacher ability to involve students (item D06 of the SET questionnaire) and teacher clarity (item D07).

The analysis is based on the following bivariate two-level linear mixed model for item *m* (*m*: 1 for D06, 2 for D07) recorded on student *i* in class *j*:

$$Y_{mij} = \alpha_m + \boldsymbol{\beta}'_m \mathbf{x}_{ij} + \boldsymbol{\gamma}'_m \mathbf{w}_j + u_{mj} + e_{mij} \qquad (1)$$

where $\mathbf{x}_{ij}$ is the vector of student covariates (level 1), and $\mathbf{w}_j$ is the vector of teacher and class covariates (level 2). Level 1 errors e_{mij} are assumed to be independent across students; level 2 errors (random effects) u_{mj} are assumed to be independent across classes and independent from level 1 errors. We make standard assumptions for the distributions of the model errors, including homoscedasticity (within each outcome) and normality. Therefore, the response vector $\mathbf{Y}_{ij} = (Y_{1ij}, Y_{2ij})'$ has residual variance-covariance matrix $Var(\mathbf{Y}_{ij}) = \boldsymbol{\Sigma}_u + \boldsymbol{\Sigma}_e$, where $\boldsymbol{\Sigma}_u$ and $\boldsymbol{\Sigma}_e$ are the covariance matrices of the errors at level 2 and level 1, respectively.

The survey on teacher beliefs and practices has about fifty percent of missing questionnaires, posing a serious issue of missing data at level 2. An analysis based on listwise deletion would discard the entire set of student ratings for non responding teachers, causing two main problems: (*i*) a dramatic reduction of the sample size, and thus of the statistical power, and (*ii*) possibly biased estimates if the missing mechanism is not MCAR.

2 Multiple imputation of level 2 covariates

In multilevel models, the treatment of missing data requires special techniques. In fact, the data have a hierarchical structure and, thus, missing values can be at any level of the hierarchy. Moreover, missing values can alter the variance components and the correlations. Multiple imputation (MI) is the most flexible approach to missing data. MI has been extended to the multilevel setting to deal with these special issues, following two main approaches (Mistler and Enders, 2017; Grund *et* *al.*, 2018): fully conditional specification, also known as multivariate imputation by chained equations, and joint modelling.

In our case study, the substantive model (1) is multilevel, however missing data are only at level 2. This feature makes the imputation simpler than in the general multilevel setting. Indeed, we can apply standard MI techniques to level 2 data and, then, merge level 1 and level 2 data to obtain complete datasets.

Besides this simplification, the MI step for the data under investigation remains a challenging matter, since we have to deal with a large number of categorical variables having a high percentage of missingness. As stated before, about 50% of the teachers did not respond to the whole questionnaire, thus producing missing values on 10 binary items (teacher practices) and 20 ordinal items (teacher beliefs on a seven-point scale). In particular, the imputation model at level 2 should include all the level 2 covariates and information on level 1 variables, especially on the response variables.

Several strategies to summarize information from level 1 variables can be adopted (Erler *et al.*, 2016; Grund *et al.* 2017). Here, we choose to consider the cluster means as they are rather effective and easy to be implemented in cases where level 1 variables (including the response) are completely observed, as in our case.

We perform multivariate imputation by chained equations using the `mi` command of Stata (StataCorp, 2017). In our case, we use a binary logit as imputation model for the 10 binary items (teacher practices), and a cumulative logit for the 20 ordinal items (teacher beliefs). For all imputation models, we consider the following covariates: the fully observed class and teacher characteristics, the cluster means of level 1 variables (covariates and outcomes), and the cluster size.

3 Results

The bivariate two-level model (1) is fitted by maximum likelihood on 10 imputed data sets, and the results are combined with the standard MI rules. The analysis is conducted using the `gsem` and `mi` commands of Stata (StataCorp, 2017).

We first fit the model without covariates in order to explore the correlation structure of the two outcomes, i.e. teacher ability to involve students and teacher clarity. We find out that the ICC is about 30% for both outcomes. The two outcomes are highly correlated (0.83), especially at level 2 (0.933).

Then, we add the available covariates in the model. These include 6 student characteristics, centered on class averages (gender, age, high school grade, year of enrollment, regular student, number of exams passed in 2012), 8 fully observed covariates at level 2, including teacher and course characteristics (gender, age, role, and involment of the teacher in the course; credits, class size, school and compulsoriness of the course) and 30 further level 2 covariates summarizing teacher practices and beliefs. To ensure parsimony, we select a subset of the 30 practices and beliefs using *leaps and bounds* method proposed by Furnival and Wilson (1974) and implemented in the `gvselect` command of Stata (Lindsey and Sheather, 2010). Specifically, we apply the procedure to each equation of model (1) separately and retain in the final model only those covariates significant for at least one of the two equations according to the AIC criterion. Such a procedure leads to the selection of the following binary indicators of teacher practices: Q01 – *practicals*, Q02 – *exploiting contribution from experts*, Q07 – *using multimedia resources*. As regards teacher beliefs, the following ordinal indicators are retained into the final model: Q12 – *passion for teaching*, Q14 – *usefulness of practicals*, Q17 – *usefulness of student opinions*, Q23 – *usefulness of student-oriented teaching*, Q25 – *need for teaching support*, Q27 – *usefulness of sharing teaching experiences with colleagues*.

To quantify the influence of missing data on the sampling variance of the parameter estimates, we can consider the fraction of missing information (FMI), i.e. the ratio between the sampling variance among imputations and the total sampling variance. For the imputed covariates, the FMI ranges from 0.15 to 0.68, with a median value equal to 0.44. The fraction of missing data is about 0.5; therefore, for the majority of imputed covariates, the trade-off between the sampling error inflation due to MI and its reduction due to sample size increase is favourable.

The main substantive finding is that teacher practices and beliefs from the PRODID survey are significantly related with the SET ratings. In particular, the item *practicals* is negatively related to the outcomes, while *contribution from experts* is positively related. As for teacher beliefs, *passion for teaching* and *usefulness of student opinions* are positively associated with the ratings, while *usefulness of practicals* and *need for teaching support* are negatively associated with the ratings.

An alternative imputation method is joint modelling (e.g. Grund *et al.*, 2017), which allows to impute binary and ordinal data through latent normal variables. We implement this approach using the R package `jomo` (Quartagno and Carpenter, 2017). However, in our case with 10 binary and 20 ordinal variables this approach is not feasible due to the computational burden, unless we treat the ordinal variables as continuous or we previously select a subset of the ordinal variables. The second option is preferable to preserve the original scale of measurement. A thorough comparison between chained equations and joint modelling is the object of our future research.

Multilevel Multiple Imputation in presence of interactions, non-linearities and random slopes

Imputazione Multipla Multilivello in presenza di interazioni, non-linearità e pendenze casuali

Matteo Quartagno and James R. Carpenter

Abstract Multiple Imputation is a flexible tool to handle missing data that has been increasingly used in recent years. One of the conditions for its validity is that the two models used for (i) imputing and (ii) analysing the data need to be compatible. For example, when the partially observed data have a multilevel structure, both models need to reflect this. Choosing an appropriate imputation model is more complicated when data are missing in a variable included in the substantive multilevel analysis model as a covariate with a random slope, an interaction or a non-linear term. We propose an imputation method based on joint modelling of the partially observed variables. We factor this joint model in two parts: a joint multilevel distribution for the covariates, and a conditional multilevel distribution for the outcome given the covariates. We guarantee compatibility by using as the second term the substantive analysis model. We fit this model with a Gibbs sampler, and we use a Metropolis-Hastings step to accept/reject the proposed draws for the missing values, to guarantee that they are actual random draws from the desired distribution. Our proposed imputation approach is theoretically consistent with the substantive model, and we demonstrate the marked improvements this brings by simulation.

Abstract *L'imputazione multipla é uno strumento flessibile per gestire dati mancanti la cui popolarità è aumentata considerevolmente negli ultimi anni. Una delle condizioni necessarie per la sua validità è che i due modelli utilizzati per (i) imputare e (ii) analizzare i dati siano compatibili. Per esempio, quando il dataset parzialmente osservato ha una struttura multilivello, entrambi i modelli devono tenerne conto. Scegliere un modello di imputazione adeguato è più complicato quando i dati sono mancanti in una variabile che è inclusa nel modello d'analisi multilivello di interesse come una covariata con una pendenza casuale, un'interazione o un*

termine non-lineare. Proponiamo qui un metodo di imputazione basato sulla modellizzazione congiunta delle variabili parzialmente osservate. Fattorizziamo questo modello congiunto in due parti: una distribuzione congiunta per le covariate ed una distribuzione condizionata per la variabile risposta date le covariate. Garantiamo la compatibilità usando per questo secondo termine la stessa formulazione del modello d'analisi di interesse. Fittiamo questo modello con un campionatore di Gibbs, ed utilizziamo un passo Metropolis-Hastings per accettare/rifiutare i valori proposti per i dati mancanti, per garantire che siano effettive estrazioni casuali dalla distribuzione desiderata. Mostriamo con simulazioni che questo metodo performa in modo appropriato e supera una strategia di imputazione alternativa.

Key words: Missing Data, Multiple Imputation, Multilevel Model, Random Slope, Interactions, Non-linearities

1 Introduction

Multiple imputation (MI) is a missing data handling method that has become very popular in recent years, particularly in the world of medical and social research. Key reasons for its growing popularity include its flexibility, the possibility to use for the analysis step the same model of substantive scientific interest that we would have used on a fully observed dataset and the chance to make use of auxiliary variables to retrieve some information [8, 3].

A key role in MI is played by the *imputation model*, i.e. the model that is used to impute the missing data. In order for MI to lead to valid inference, this needs to be consistent with the substantive analysis model [2]. For example, if the partially observed dataset has a multilevel structure, this needs to be reflected in the imputation model as well as in the analysis model [6].

Different methods have been proposed recently for multilevel MI [1]. The most flexible of these is Joint Modelling Multiple Imputation (JM-MI), which consists in assuming a joint multivariate normal model for the partially observed data, and in fitting this model with a Bayesian (e.g. Gibbs) sampler to impute the missing data. A multilevel version of JM-MI was first introduced in [9], and later extended to allow for binary and categorical data [5] and for cluster-specific covariance matrices [10]. However, in some circumstances it is not possible to find a simple joint imputation model that is fully compatible with the analysis model; some examples include the imputation of variables that are included in the substantive analysis model as covariates with a random slope, an interaction or a non-linear (e.g. quadratic) term. Using a heteroscedastic imputation model can be useful to deal with random slopes and interactions, as it allows for cluster-specific associations between variables [7]. However, full compatibility is still not guaranteed.

Goldstein et al. (2014) proposed a fully bayesian approach that broadly consists in factoring the joint distribution in two terms: a joint model for the covariates of the analysis model and a conditional model for the outcome given the covariates, that usually corresponds with the substantive analysis model. Although it was proposed as a fully bayesian method, it can be used as a multiple imputation approach compatible with the substantive model. The advantage of this is that it allows auxiliary variables to be included.

The aim of this paper is to introduce substantive model compatible JM-MI, and to compare it with standard JM-MI, when the substantive analysis model includes a random slope, an interaction or a quadratic term. We illustrate the advantage of the newly proposed method by simulations.

2 Methods

Assume we have a partially observed dataset with individuals i nested in clusters j. We intended to collect data on three continuous variables Y, X_1 and X_2, but we end up with some missing data in each of the three variables. The substantive analysis model of scientific interest is a linear mixed model:

$$y_{i,j} = (\beta_0 + u_{0,j}) + (\beta_1 + u_{1,j})x_{1,i,j} + \beta_2 x_{2,i,j} + \varepsilon_{i,j}$$
$$\begin{pmatrix} u_{0,j} \\ u_{1,j} \end{pmatrix} \sim N(\mathbf{0}, \Sigma_u) \qquad \varepsilon_{i,j} \sim N(0, \sigma_e^2) \tag{1}$$

In order to deal with missing data, we can use JM-MI. But what imputation model should we use?

2.1 *JM-Hom: Homoscedastic Joint Modelling Imputation*

One possibility is to assume a 3-variate normal joint model for the three variables:

$$\begin{cases} y_{i,j} = \alpha_0 + v_{0,j} + e_{0,i,j} \\ x_{1,i,j} = \alpha_1 + v_{1,j} + e_{1,i,j} \\ x_{2,i,j} = \alpha_2 + v_{2,j} + e_{2,i,j} \end{cases}$$
$$\begin{pmatrix} v_{0,j} \\ v_{1,j} \\ v_{2,j} \end{pmatrix} \sim N(\mathbf{0}, \Omega_u) \qquad \begin{pmatrix} e_{0,i,j} \\ e_{1,i,j} \\ e_{2,i,j} \end{pmatrix} \sim N(\mathbf{0}, \Omega_e) \tag{2}$$

This model can be easily fitted with a standard Gibbs sampler, creating K different imputed datasets. These are then analysed with (1) to obtain K copies of the parameter estimates that are finally combined with Rubin's rules.

This approach naturally extends to include binary or categorical variables. This is achieved by means of a latent normal variables approach, as outlined in [5].

2.2 JM-Het: Heteroscedastic Joint Modelling Imputation

Because of the presence of a random slope, Model (1) is not compatible with Model (2), i.e. the conditional distribution of Y given X_1 and X_2 derived from (2) is not (1). To overcome this issue, one possibility is to assume instead an heteroscedastic imputation model, similar to (2) but with random cluster-specific covariance matrices following an inverse Wishart distribution:

$$\Omega_{e,j} \sim IW(a,A) \tag{3}$$

This model makes an attempt at modelling cluster-specific associations between variables, by assuming cluster-specific covariance matrices at level 1. However, it is still not a fully compatible approach.

It can be fitted with a similar Gibbs sampler to the one used for model (2).

2.3 JM-SMC: Substantive Model Compatible Joint Modelling Imputation

In order to define an imputation model fully compatible with (1), following along the lines of [4], we can factorise the joint distribution of the three variables in two terms: (i) a joint model for the two covariates and (ii) a conditional model for the outcome given the covariates. This way, we can make sure that the conditional model for the outcome corresponds to (1):

$$\begin{gathered}
\begin{cases} x_{1,i,j} = \alpha_1 + v_{1,j} + e_{1,i,j} \\ x_{2,i,j} = \alpha_2 + v_{2,j} + e_{2,i,j} \end{cases} \\
\begin{pmatrix} v_{1,j} \\ v_{2,j} \end{pmatrix} \sim N(\mathbf{0}, \Omega_u) \qquad \begin{pmatrix} e_{1,i,j} \\ e_{2,i,j} \end{pmatrix} \sim N(\mathbf{0}, \Omega_e) \\
y_{i,j} = (\beta_0 + u_{0,j}) + (\beta_1 + u_{1,j})x_{1,i,j} + \beta_2 x_{2,i,j} + \varepsilon_{i,j} \\
\begin{pmatrix} u_{0,j} \\ u_{1,j} \end{pmatrix} \sim N(\mathbf{0}, \Sigma_u) \qquad \varepsilon_{i,j} \sim N(0, \sigma_e^2)
\end{gathered} \tag{4}$$

In order to impute from this model, an additional Metropolis-Hastings step within the Gibbs sampler is needed to impute the missing X_1 and X_2 values: imputations are drawn from a proposal distribution and accepted or rejected depending on the value of the Metropolis ratio. If using a symmetrical proposal distribution, this is simply the ratio of the likelihood of the model with the new proposed imputed value over the likelihood of the model with the previous imputed value.

This method naturally extends to allow for interactions or non-linearities in the conditional model for the outcome given the covariates in (4). Hence, it is possible to impute compatibly with the analysis model at the only cost of having to know the functional form of the substantive model in advance.

2.4 Software

We fit and impute from all three models (2), (3) and (4) using functions jomo and jomo.smc from our R package jomo, freely available on CRAN. The substantive model (1) is fitted with the R package lme4, and the results are combined with Rubin's rules as implemented in the mitml package.

3 Simulations

To illustrate the improvements that random coefficient compatible multiple imputation brings, in a base-case scenario we generate 1000 multilevel datasets, each constituted of 6000 observations, equally divided in 60 clusters, on three variables Y, X_1 and X_2. X_1 and a latent normal Z are generated from a bivariate normal distribution. X_2 is then created as a binary variable that takes the value 1 when $Z > 0$. The data-generating mechanism for the outcome is the following:

$$y_{i,j} = (0.5 + u_{0,j}) + (1 + u_{1,j})x_{1,i,j} - 0.3x_{2,i,j} + \varepsilon_{i,j}$$
$$\begin{pmatrix} u_{0,j} \\ u_{1,j} \end{pmatrix} \sim N\left(\mathbf{0}, \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}\right) \qquad \varepsilon_{i,j} \sim N(0,1)$$

We assume that the desired analysis model is (1). We fit this model on the fully observed data (FD) and store all the parameter estimates. Then, for the fixed effect parameters β_0, β_1 and β_2 we calculate the mean, the empirical and model based standard errors and the coverage level across 1000 simulations. We additionally report the mean of the three variance components: the random intercept variance σ^2_{u0}, the random slope variance σ^2_{u1} and the residual variance σ^2_e.

We then make around 35% of the data on X_1 and X_2 missing at random conditional on the outcome Y, and we re-analyse the data using the complete records (CR). Finally, we handle missing data with the three different MI strategies presented in the previous section.

We investigate four additional scenarios:

- A scenario where X_2 is 3-level categorical;
- One with an additional continuous variable X_3, highly correlated with X_1, but not included either in the data generating process for Y or in the substantive analysis model (i.e. an auxiliary variable);
- One where Y is generated from a model with a quadratic effect on X_1;
- One where there is an interaction between X_1 and X_2.

3.1 Results

Table 1 shows the base-case simulation results. While Complete Records (CR) estimates are strongly biased, because of the dependence of the missingness mechanism from the outcome Y, all imputation methods are preferable; however, JM-Hom also leads to biased estimates and marked undercoverage for most parameters. Inference on the fixed effect parameters after imputation with JM-Het is affected by smaller biases, and leads to good coverage levels. However, bias is larger in the estimation of the variance components. Finally, JM-SMC leads to unbiased parameter estimates and good coverage levels.

Table 1 Base-case scenario: mean and coverage level of fixed effect parameter estimates and mean of variance component estimates over 1000 simulations. We compare Full Data (FD), Complete records (CR), JM imputation with a homoscedastic (JM-Hom) or heteroscedastic (JM-Het) imputation model and substantive model compatible JM-MI (JM-SMC).

	β_0		β_1		β_2		σ^2_{u0}	σ^2_{u1}	σ^2_e
Method	Mean	Cov	Mean	Cov	Mean	Cov	Mean	Mean	Mean
True value	0.50	0.95	1.00	0.95	-0.30	0.95	1.00	1.00	1.00
FD	0.49	0.94	1.00	0.93	-0.30	0.96	0.99	1.01	1.00
CR	1.08	0.00	0.89	0.82	-0.25	0.72	0.57	0.79	0.92
JM-Hom	0.40	0.88	1.07	0.85	-0.28	0.91	1.12	0.54	1.25
JM-Het	0.44	0.92	1.04	0.92	-0.29	0.94	1.09	0.93	1.05
JM-SMC	0.49	0.94	1.00	0.93	-0.30	0.95	0.99	1.01	1.00

Figure 1 pools the results across all the five simulation scenarios into a single panel. This is in terms of relative bias and coverage level for all the fixed effect parameter estimates. While JM-SMC always leads to negligible bias and coverage very close to the nominal level, JM-Hom and JM-Het are prone to bias in the estimation of some parameters in all scenarios. This is particularly serious for the two scenarios with an interaction and a quadratic effect. CR estimates are again always the most seriously biased, because of the missing data mechanism.

Finally, Figure 2 compares the level-2 variance component estimates from the three MI methods. Once again, JM-SMC is the only method leading to unbiased parameter estimates, while JM-Hom is the worst imputation method. JM-Het consistently overestimates the random intercept variance and gives biased estimates of the random slope variance.

4 Conclusions

We have investigated the behaviour of a new substantive model compatible MI strategy to deal with missing data in a multilevel dataset, and compared it with two existing multilevel imputation strategies. In particular, we have showed that when the analysis model of scientific interest includes a random slope, an interaction or a non-linearity, our proposed new method is the only one able to take this into account during the imputation, leading to correct inference.

The only additional price to pay for using this method, is that the precise functional form of the substantive model needs to be known in advance of the imputation process. Further research will investigate what is the best approach to take when model selection has to be performed along the imputation. Future work will also explore ways to impute level-2, i.e. cluster-level, variables within this framework.

All the imputation models presented in this paper can be fitted with functions jomo and jomo.smc in the R package jomo. This allows for binary and survival outcomes as well.

In conclusion, while standard JM-MI remains a valuable, and more flexible, method for the imputation of simple multilevel dataset, substantive model compatible JM-MI is preferable in presence of partially observed covariates with a random slope, an interaction or a non-linear term.

Monitoring Education Systems. Insights from Large Scale Assessment Surveys

Educational Achievement of Immigrant Students. A Cross-National Comparison Over-Time Using OECD-PISA Data

I risultati scolastici degli studenti immigrati. Un confronto fra nazioni attraverso i dati PISA

Mariano Porcu

Abstract According to the Organization for Economic Cooperation and Development (OECD) a substantial performance differential between students with immigrant background and natives is observed in most countries. On average, immigrants tend to underperform their native peers even after their socio-economic conditions are controlled. In this work we study, in a time span perspective, the gap in school performances between native and immigrant students in five different European countries. Two of them are considered as new destination countries, namely Italy and Spain; the others three are traditional immigration countries (albeit with different migration history): France, United Kingdom, and Germany. We analyze data collected for the OECD Program for International Student Assessment (PISA) surveys of 2009, 2012, and 2015 by fitting in a multilevel setting multiple regressions to simultaneously model students' performances in reading and mathematics. We control for gender, socio-economic background, and immigration status (1st generation or 2nd generation immigrants). Results display that the performance gap between immigrant and native students is narrower in mathematics and that it is far from being bridged over-time. No substantial differences in trend are observed differentiating destination countries as new or traditional.
Abstract *Secondo l'Organizzazione per la cooperazione e lo sviluppo economico (OCSE), nella maggior parte dei paesi si osserva una sostanziale differenza di rendimento scolastico tra studenti con background migratorio e nativi. In media, gli immigrati tendono ad avere performance inferiori a quelle dei loro pari nativi, anche dopo aver controllato rispetto alle condizioni socio-economiche. In questo lavoro, in una prospettiva temporale viene studiato il divario nelle prestazioni scolastiche tra studenti nativi e immigrati in cinque diversi paesi europei. Due di questi sono considerati come paesi di nuova immigrazione, ovvero Italia e Spagna; gli altri tre sono paesi di immigrazione tradizionale (anche se con una storia migratoria diversa): Francia, Regno Unito e Germania. Verranno analizzati i dati raccolti*

nell'indagine PISA del 2009, 2012 e 2015 adattando alle performance in lettura e matematica dei modelli di regressione multilivello controllando rispetto al genere, al contesto socio-economico e allo status migratorio (immigrati di prima generazione o di seconda generazione). I risultati mostrano che il divario di prestazioni tra studenti immigrati e nativi è meno pronunciato in matematica, non si riduce nel tempo e i trend non si differenziano tra i paesi di nuova immigrazione e gli altri.

Key words: Immigration, Educational inequalities, PISA, Multilevel models

1 Introduction

Every year, the hope for a better life or the escape from wars or conditions of economic hardship push millions of people to cross the boundaries between the nations. This has happened since there were boundaries to cross and, perhaps, we can say that the drive to emigrate is itself a characteristic of the human kind.

However, in the last thirty years, the phenomenon has taken on impressive dimensions and is probably the most present issue at stake in the global political agendas. Modern means of transport, the globalization of economies, and the aging of Western populations will make this issue even more pressing in the coming years. So, the integration of immigrants in the hosting countries is crucial both for the economic systems and for a long-term growth of the social welfare.

Indeed, the best way to evaluate how well the immigrants are integrated into a society is certainly not that to compare their performance in the labor market (or in the economy in general) with those of the natives. Reasons for justifying a performance gap between native and immigrants workers are clear: difficulty in using the language of the host country, qualifications or work experience that are not recognized or exploitable are the most important reasons to explain the observed gaps. These motivations, however, should not apply to school performance of their children and the success of immigrant integration policies will be increasingly mirrored by the school performances of no-native students.

According to the Organisation for Economic Cooperation and Development (OECD), on average, in the last two decades, the percentage of 15-year-old students with a migratory background has increased by more than 2 points starting from 2000 OECD [2015, 2012a]. This is a very important evidence for education policies because at the same time a substantial performance differential between students with immigrant background and natives is also observed. On average, immigrants tend to underperform their native peers even after the socio-economic conditions are controlled.

Assessing what are the causes of the observed gaps is very difficult because the social groups of immigrant students are very heterogeneous, educational systems differ among countries, and there are different ways in which resources are distributed and educational policies are defined. Therefore, the contexts in which the immigrant students learn are different both from the historical-political point of view and looking at the governance of the school-system.

In this paper, we will try to assess in a time span perspective the gap in school performances between native and immigrant students in five different European countries. Two of which are considered as new destination countries, namely Italy and Spain. Both have been, for most of the twentieth century, emigration nations and only after the fall of the Iron Curtain they became destinations for migrants from South America, Eastern Europe, Middle East, and Africa. The others three countries have a consolidated albeit different migration history having long been a destination for important migratory flows. On one side, France and United Kingdom experimented incoming flows of migrants that reflected the colonial history of the countries. On the other, Germany rampant industrialization process, has long acted as a magnet for foreign workers since the beginning of the second half of twentieth century. This aim has been pursued by adopting two multilevel regression models which consider students' test scores as Level-1 units and schools as Level-2 units. Differences in student test scores have been analised taking into account a wide range of students and schools socio-economic and cultural characteristics and introducing interaction terms between immigrant status (native, 1st generation or 2nd generation immigrant), country (France, United Kingdom, Germany, Italy and Spain) and waves (2009, 2012, 2015). The approach allowed to capture the effect of having an immigrant background in the five countries across waves.

2 Data

Since the year 2000, the Organisation for Economic Cooperation and Development (OECD) carries on its Program for International Student Assessment (PISA). It is administered every three years to provide comparisons of students' achievement among the participating countries. In this analysis data collected in three rounds of the PISA survey have been considered, say 2015, 2012, and 2009. PISA surveys could be considered as the most comprehensive and accurate international assessment of students's skills in reading, mathematics, and sciences. In addition PISA assesses not only students' competences, but also collects information on their socio-demographic background and on the school context in which their are enrolled. In each round PISA carries on a detailed assessment of each of the three subjects and the 2009 survey marks the return to a focus on reading so that our analysis considers three different subject focuses (nonetheless, in each round the three subjects are, however, considered).

The PISA target population is that of students aged between 15 and 16 years at the time of the survey and who have completed a minimum of 6 years of formal education regardless of the type of institution where they are enrolled. The age of 15-16 represents, for many countries, the transition time from a basic education to a more advanced one. Detailed information on PISA sampling design and procedures are available in a collection of thematic and technical reports at PISA-OECD website [OECD, 2012b, 2014, 2017].

We consider as dependent variables the student's performance in reading and mathematics tests. OECD defines reading literacy as the ability in "[...] understanding, using, reflecting on and engaging with written texts, in order to achieve one's goals, to develop one's knowledge and potential, and to participate in society ..." [OECD, 2012b]. Math literacy is "[...] the extent to which students can use their mathematical knowledge and skills to solve various kinds of numerical and spatial challenges and problems [...]" [OECD, 2017].

In PISA surveys, in order to minimise the assessment burden on each student and to avoid that the scaling of skills would be influenced by the "booklet effect" each student is asked to handle only a part of the whole test in the three domains assessed (reading, maths, science) following a systematic booklet assembly and rotation procedure. For that reason rather than one single measure of achievement, the PISA databases provides 5 plausible values (PV) of student's score in each topic. The use of PV allows to to take into account the uncertainty associated with the estimate of a measure of achievement for each student by reproducing the likely distribution of students' competencies in each topic [Monseur and Adams, 2009, OECD, 2017].

At student level we considered (for each wave) the following information:

- Country of residence (`COUNTRY`): France (FRA), Germany (DEU), Italy (ITA), Spain (ESP), United Kingdom (GBR).
- Immigrant status (`IMMSTAT`): according to OECD-PISA classification we differentiate between immigrant and non-immigrant students based on the information on the country of birth of both their parents; if both parents were born in a country different than the country where the student take on the test, then the student is classified as immigrant. Non-immigrant or natives (`IMMSTAT`$=0$) are the remainder. Among immigrants we distinguish between second-generation (`IMMSTAT`$=1$) and first-generation students (`IMMSTAT`$=2$). Second-generation are immigrant students born in the country of PISA assessment; first-generation students are foreign-born alike their parents.
- Language spoken at home (`LHOMEDIFF`): an additional relevant difference among immigrant students is the language they speak at home. We distinguish between immigrants who speak at home a foreign language (`LHOMEDIF`$=1$) (i.e. different from the PISA assessment language; dialects or regional languages are considered as test language).
- Gender (`GENDER`$=0$: female).
- Parental educational level (`PARED`): highest parental education in years of schooling.
- Parental occupational status (`HISEI`): highest parental occupational status. In PISA surveys, occupational data for both parents are obtained from responses to open-ended questions. Responses are then coded to four-digit ISCO codes (International Standard Classification of Occupations) and mapped to the international socio-economic index of occupational status (ISEI) Ganzeboom and Treiman [2003]. Higher `HISEI` scores indicate higher occupational status.

- Family possession of culture related items (CULTPOSS): the PISA index of family cultural possession is derived from what the students report on the availability of specific household items at home such as classic literature, books of poetry, works of art, musical instruments, etc. Highest values indicate an higher family endowment of culture related items.
- Family possession of educational resources (HEDRES): the PISA index of home educational resources (a desk to study at, a computer, educational software, a dictionary, etc.). Highest values indicate higher availability of educational resources at home.
- The percentage of non native students in the school (SCHNONATIVE).

In PISA databases, the HISEI index is calculated using Principal Component Analysis (PCA). Except for the parental education variable (PARED), the remaining variables as well as the PV are calculated by using a model-based scaling procedures belonging to the family of Item Response Theory (IRT) applied to dichotomous or Likert-type responses to questionnaire items OECD [2017].

3 First findings

In this framework we discuss only the main findings we have observed by applying two multilevel regression models for assessing trends in the divergences in mathematics and reading across the five countries in the three years between students with different immigrant background. Results observed for mathematics and reading are listed in Tables 1 and 2. In the following we rapidly focus the attention only on the estimated effect of the country × year × immigrant status combination. Looking at the effect jointly exerted overtime by the combination of country and immigrant status we considered, both in reading and mathematics, the achievement of a German native in 2009 as the baseline. Figure 1 displays the caterpillar plot of the estimated 44 parameters, each one with its associated confidence interval limits. In total 44 parameters are displayed for reading and 44 for mathematics: $44 = [(\text{countries} \times \text{immigrant status} \times \text{wave}) - 1] = [(5 \times 3 \times 3) - 1]$. Parameters are displayed in ascending order of magnitude. Looking at reading competencies, we can spot that the highest ranks are hold by native or second generation immigrants of Germany, France, and Great Britain (although the only significant difference for these outperforming students are those of natives from Germany in 2015 and from France in 2012). Whenever we consider trends of performances according to immigrant status within each countries, situations are noteworthy differentiated. Figures 2 groups the estimated parameters by immigration status for reading. The caterpillar plots clearly show divergences across countries according to the immigrant backgrounds. In Germany we can observe that performances in reading of natives increase from 2009 to 2015; the same occurs for second generation immigrants while performances of first generation steadily underperform.

4 Conclusion

On the light of the main findings we can state that in general in the traditional immigration countries we see that first generation immigrants steadily lag behind. Nonetheless, we observe similar performances for natives and second generation immigrants: the upper limits of the confidence intervals for second generation overlap with the bottom limits of the confidence intervals estimated for natives (albeit in France differences are sensibly wider).

In Italy and Spain differences in performances according to immigrant status are wider; immigrants underperform and no trends of improvement turn up overtime. Nonetheless, we shall note that in Spain reading performances of second generation immigrants are similar to those of natives in 2015 (likely due to the fact that a large part of the immigrant population in Spain comes from Latin America). In mathematics performances of natives and immigrants are in somewhat less noticeable.

New Perspectives in Time Series Analysis

Generalized periodic autoregressive models for trend and seasonality varying time series

Francesco Battaglia and Domenico Cucina and Manuel Rizzo

Abstract Many nonstationary time series exhibit changes in the trend and seasonality structure, that may be modeled by splitting the time axis into different regimes. We propose multi-regime models where, inside each regime, the trend is linear and seasonality is explained by a Periodic Autoregressive model. In addition, for achieving parsimony, we allow season grouping, i.e. seasons may consist of one, two, or more consecutive observations. Identification is obtained by means of a Genetic Algorithm that minimizes an identification criterion.

Key words: Genetic algorithms, Structural break, Regime change

1 Introduction

Many seasonal time series exhibit an autocorrelation structure which depends not only on the time between observations but also on the season of the year. Moreover, the time series of observations within a given season is usually second order stationary (Hipel and McLeod, 1994). In order to model appropriately these and similar types of time series, Periodic AutoRegressive models (PAR) can be employed. When fitting a PAR model to periodic time series a separate AR model for each season of the year is estimated. These models are appropriate for describing time series drawn from different areas such as economics, hydrology, climatology and

signal processing (e. g. Franses and Paap, 2004; Hipel and McLeod, 1994; Ursu and Turkman, 2012).

In this study we consider a generalization of PAR models with linear trend in two directions. First, the model may follow different regimes in time, and regime changes may occur at any time. The regime changes may affect the linear trend, the seasonal means and the autoregressive parameters. We also allow a discontinuous trend which can identify changes in level. Second, inside each regime the model structure may be different for each seasonal position (e.g. months) or vary more slowly, changing only according to grouped seasons like quarters or semesters.

The number of regimes and change times (or break points) are assumed to be unknown. The problem of their identification can be treated as a statistical model selection problem according to a specified identification criterion (Aue and Horväth, 2013). This approach has been used for identification of structural breaks e.g. in Davis et al (2008) and Lu et al (2010). In these works Genetic Algorithms (GAs) are proposed to solve the selection problem.

To the best of our knowledge, there are no articles that handle the changing parameters and changing trend problem in PAR models simultaneously. We propose a class of GAs to detect the number of regimes of piecewise PAR models and their locations. Our procedure evaluates several regime patterns where the locations that are possibly change times are simultaneously considered. In this way, GAs deal efficiently with the detection of multiple change times. We also allow subset AR models to be selected. Each piecewise subset PAR configuration is evaluated by an AIC identification criterion.

In our paper, since the seasonal effect on means, variances and correlations may show different speed and pattern, we propose to join appropriately season parameters into groups for each of these three features.

The piecewise linear nature of our model makes forecasting very simple.

2 The Model

Suppose that a time series $\{X_t\}$ of N observations is available. The seasonal period of the series is s and is assumed to be known. Assume that there are $m+1$ different regimes, separated by m change times τ_j so that the first regime contains observations from time 1 to $\tau_1 - 1$, the second regime contains data from time τ_1 to $\tau_2 - 1$, the $(j+1)$-th regime contains data from τ_j to $\tau_{j+1} - 1$, and the last regime data from τ_m to N. To ensure reasonable estimates we assume that the minimum regime length is a fixed constant mrl, thus any regime assignment is defined by the set $\{\tau_j, j = 1, \ldots, m\}$ subject to $mrl < \tau_1 < \tau_2 < \ldots < \tau_m < N - mrl$, $\tau_j \geq \tau_{j-1} + mrl, j = 2, \ldots, m$.

The parameters of the model for regime j will be denoted by a superscript (j).

The seasonal effect on means, variances and correlations may show different speed and pattern, thus it seems advisable, for each of these features, to use a different splitting of the year, determined by a different length of the season inside which that feature remains constant. For example, if the seasonal period is s, we may have exactly s different models, one for each seasonal position; or rather only s/c different structures, when c consecutive observations are supposed to belong to the same season. E. g. if $s = 12$ (monthly data) and $c = 3$, the same model works for each quarter, therefore there are only $s/c = 4$ different seasons. This may be useful when the seasonal variation is slow and more detailed models would be redundant.

We allow a different season grouping for means, correlation and variance. We denote by c_M the number of consecutive observations for which the mean remains constant (c_M divides s), and by $ss = s/c_M$ the number of seasons. In an analogue fashion, we denote by c_{AR} the number of consecutive observations for which the AR parameters remain constant, and $sv = s/c_{AR}$ the related number of seasons. E. g. for $s = 12$, if $c_{AR} = 1$, each month has a different set of AR parameters, then the variances of the 12 months may a priori be different. If on the contrary $c_{AR} > 1$, the variances of c_{AR} contiguous observation all are proportional, through the same coefficient, to the residual variances, thus a variance instability is equivalent to a residual variance instability. Therefore, we allow the possibility that, inside each single season for the AR model (containing c_{AR} consecutive observations) the residual variances may change. Thus we must consider sub-seasons composed by c_V observations, where c_V divides c_{AR}, and allow the residual variance to change every c_V observations, in a total number of seasons (concerning the residual variance) equal to $svar = s/c_V$.

A linear trend and a different mean for each season is assumed. The residuals are treated as zero mean and described by an autoregressive model with maximum order p, and parameters varying with seasons. Let k_t denote the season (for the mean) of the t-th observation ($1 \leq k_t \leq ss$) and k_t^* the season for AR structure of the t-th observation, denote by $a^{(j)} + b^{(j)}t$ the linear trend in regime j, by $\mu^{(j)}(k)$ the mean of season k in regime j, and by $\phi_k^{(j)}(i)$ the lag-i autoregressive parameter for the model in season k and regime j. Then for $\tau_{j-1} \leq t < \tau_j$:

$$X_t = a^{(j)} + b^{(j)}t + \mu^{(j)}(k_t) + W_t \ , \ W_t = \sum_{i=1}^{p} \phi_{k_t^*}^{(j)}(i) W_{t-i} + \varepsilon_t$$

where $\tau_0 = 1$ and $\tau_{m+1} = N + 1$.

The innovations ε are supposed independent and zero-mean, with variances $\sigma^2(j,k)$ possibly depending on the regime and season.

As far as subset selection is concerned, we introduce also $m+1$ binary vectors $\delta^1, \ldots, \delta^{m+1}$, which specify presence or absence of autoregressive parameters in each regime as follows: if $\delta^j[p(k_t^* - 1) + i] = 1$ then $\phi_{k_t^*}^{(j)}(i)$ is constrained to zero. In summary, a model is identified by the following:
External parameters (fixed and equal for all models) N, s, maximum order p, maximum number of regimes, and minimum number of observations per regime *mrl*

Structural parameters (determining the model structure)

m	number of change times
$\tau_1, \tau_2, \ldots, \tau_m$	change times or thresholds
$\delta^1, \ldots, \delta^{m+1}$	denote which ϕ's are zero in each regime and season
c_M, c_{AR}, c_V	season grouping parameters subject to constraints: c_M divides s; c_{AR} divides s; c_V divides c_{AR}

Regression parameters to be estimated by Least Squares (LS) or Maximum Likelihood (ML)

$a_1, a_2, \ldots, a_{m+1}$	intercepts
$b_1, b_2, \ldots, b_{m+1}$	slopes
$\mu^{(j)}(k)$	seasonal means, $k = 1, \ldots, ss$; $j = 1, \ldots, m+1$
$\phi_k^{(j)}(i)$	AR parameters, $k = 1, \ldots, sv$; $j = 1, \ldots, m+1$; $i = 1, \ldots, p$ (some of them may be constrained to zero)
$\sigma^2(j,k)$	innovation variances, regime j and season $k = 1, \ldots, svar$.

For estimating trend and seasonal means by LS, note that the intercept and the means are linearly dependent, therefore we assume that the seasonal means sum to zero on one cycle: $\mu^{(j)}(1) + \mu^{(j)}(2) + \ldots + \mu^{(j)}(ss) = 0, \forall j$. Therefore the following equations are estimated:

$$X_t = b^{(j)}t + c(j, k_t) \ , \ \ \tau_j \le t < \tau_{j+1} \tag{1}$$

and then the parameter vector is $\beta' = \{b^{(1)}, b^{(2)}, \ldots, b^{(m+1)}, c(1,1), c(1,2), \ldots, c(1,ss), c(2,1), \ldots, c(2,ss), \ldots, c(m+1,1), \ldots, c(m+1,ss)\}$ with dimension $(m+1) \times (ss+1)$ and the estimates are obtained by least squares. From the $\{\hat{c}(j,k)\}$, the intercepts $\hat{a}^{(j)}$ and seasonal means $\hat{\mu}^{(j)}(k)$ are recovered basing on the above assumption. It follows

$$\hat{a}^{(j)} = \frac{1}{ss} \sum_{k=1}^{ss} \hat{c}(j,k) \ \ , \ \ \hat{\mu}^{(j)}(k) = \hat{c}(j,k) - \hat{a}^{(j)}.$$

Moreover it is possible to prescribe trend continuity by imposing that, if the number of regimes is larger than one, the trend values of two consecutive regimes coincide on the first observation of the second regime. A possible level change at $t = \tau_{j+1}$ is estimated if the trend continuity is not imposed.

Conditioning on thresholds, seasonal arrangement and estimated trend and means, the residual series is computed as $\hat{W}_t = X_t - \hat{a}^{(j)} - \hat{b}^{(j)}t - \hat{\mu}^{(j)}(k_t)$.

For each regime and season a separate autoregressive process is considered:

$$\hat{W}_t = \sum_{i=1}^{p} \phi_{k_t^*}^{(j)}(i) \hat{W}_{t-i} + \varepsilon_t.$$

We denote by $I(j,k)$ the set of times belonging to regime j and season k. The corresponding observations $z_{j,k}$ are selected and the LS estimates of the parameters $\{\phi_k^{(j)}(i), i = 1, \ldots, p\}$ are obtained. As far as subset selection is concerned, the final estimates are obtained via LS constrained optimization, with constraints given by linear system $H\phi = 0$:

$$\hat{\phi} = \phi_{LS} - (Z'Z)^{-1}H'[H(Z'Z)^{-1}H']^{-1}H\phi_{LS},$$

where $\phi_{LS} = (Z'Z)^{-1}Z'z$ are the unconstrained least squares estimates, Z is the $n_{j,k} \times p$ design matrix including lagged observations and H is the constraints matrix that specifies subset models. The residuals $e = z - Z\hat{\phi}$ give the estimate of the innovations for regime j and season k $\{\varepsilon_t, t \in I(j,k)\}$, which allow to obtain $\hat{\sigma}^2(j,k)$. The structural parameters take discrete values and their combinations amount to a very large number. GAs are naturally suitable for the choice of optimal structural parameters.

3 Genetic algorithms

GAs, initially developed by Holland (1975), imitate the evolution process of biological systems, to optimize a given function. A GA uses a set of candidate solutions, called *population*, instead of one single current solution. In GA terminology, any candidate solution is encoded via a numerical vector called *chromosome*. The GA proceeds iteratively by updating the population in rounds, called generations. In each generation, some of the active chromosomes are selected (parents-chromosomes) to form the chromosomes of the next generation (children-chromosomes). The selection process is based on an evaluation measure called *fitness function*, linked to the objective function, that assigns to each chromosome a positive number. Children are formed by recombining (*crossover*) the genetic material of their two parents-chromosomes and perhaps after a random alteration of some of the genes (single digits of the chromosome), which is called *mutation* (see Holland, 1975; Goldberg, 1989, for a detailed description).

A successful implementation of GAs is certainly crucial to obtain satisfactory results. Before a GA can be applied to a problem some important decisions have to be made. The GA methods require a suitable encoding for the problem and an appropriate definition of objective function. In addition operators of selection, crossover and mutation have to be chosen.

Encoding. An appropriate encoding scheme is a key issue for GAs. It must guarantee an efficient coding producing no illegal chromosome and no redundancy. Details of the adopted method may be found in Battaglia et al (2018).

Fitness function. The most natural objective in building statistical models is to minimize an identification criterion such as AIC, BIC, ICOMP, MDL. They all are based on the estimated residual variance $\hat{\sigma}^2(j,k)$ and the total number of estimated parameters: there are $m+1$ parameters for trend, $(m+1) \times ss$ seasonal means, and in regime j there are $p \times sv - |\delta^j|$ autoregressive parameters (where $|x|^2 = \sum_i x_i^2$). So, the total number of estimated parameters is $P = (m+1)(ss+1) + (m+1)p \times sv - |\delta^1| - |\delta^2| - \ldots - |\delta^{m+1}|$.

If continuity constraints on trend are added, the number of parameters decreases by m.

The most obvious generalization of AIC is the NAIC criterion introduced by Tong (1990, p. 379) for threshold models:

$$NAIC = [\sum_j \sum_k AIC_{j,k}]/N = \left[\sum_j \sum_k n_{j,k} \log \hat{\sigma}^2(j,k) + \pi \times P\right]/N,$$

where $AIC_{j,k}$ is identification criterion for series of regime j and season k, $\sigma^2(j,k)$ is the related residual variance, P is the total number of parameters, π is the penalization term (equal to 2 in the original Akaike's proposal). Other alternatives are possible (see Battaglia et al, 2018).

Since the identification criteria are to be minimized, the fitness function is a monotonically decreasing function of the identification criterion. We adopted a negative exponential transformation.
GA operators. For selection we used the "roulette wheel" rule where the probability of a chromosome being selected as a parent is proportional to its fitness. Each selected couple of parents will produce two "children" by methods of crossover and mutation. We implemented uniform crossover — each child receives each gene from one parent or the other randomly with probability $1/2$.

The entire population of chromosomes is replaced by the offsprings created by the crossover and mutation processes at each generation except for the best chromosome, which survives to the next generation. This *elitist* strategy ensures that the fitness will never decrease through generations (Rudolph, 1994).

Our search strategy is in two steps: in the first one the GA tries to determine the best splitting in regimes for complete models, as the chromosome includes only $m, \tau_1, ..., \tau_m$; in the second step we exhaustively enumerate all possible seasons grouping (specified by c_M, c_{AR}, c_V) and subset models (examining $\delta^1, ..., \delta^{m+1}$). This strategy is hybrid, as it combines an exact method with an approximate method, and it is feasible if order p and seasonal period s are not too large.

4 Applications

We briefly summarize the application of our method to the CET series of monthly mean surface temperatures for a location in the Midlands region (see Proietti and Hillebrand, 2017, and references therein). It is a very long and frequently investigated series (we use 2904 observations for years 1772–2013). Many researchers suggest an upward trend since the beginning of the 20th century, due to global warming, and an evolution of seasonal pattern, identified as a precession of Earth's axis of rotation. Four PAR models were fitted to the time series: a *complete* model, with a different AR(2) model for each month and no constraint on the autoregressive parameters; a *subset* model similar to the previous one, but with some AR parameters constrained to zero in order to maximize fitness; a *grouped* subset model where the season are grouped; and finally a *constant* seasonality model, subset as well, where the autoregressive parameters remain equal in each regime. The series plot appears in Figure 1 (left panel).

Two regimes were identified, with change time at July, 1899 (the trend is drawn as a dotted line in the figure). This confirms with clear evidence the suggested trend change at the beginning of the last century. The grouped season model identified the optimal setting $c_M = c_{AR} = 1$, meaning that any grouping of seasons would not increase the fitness, thus the grouped model coincides with the subset model (with other more parsimonious criteria like *BIC* the best grouping results $c_M = 1, c_{AR} = 4, c_V = 2$). The results appear in Table 1: it may be concluded that many autoregressive parameters may be constrained to zero without a sensible loss of fit. Moreover, the smaller fitness of the constant seasons model indicates an evolution in the seasonal pattern; Figure 1 (right panel) reports the monthly means for the two regimes. More applications may be found in Battaglia et al (2018).

Table 1 Models fitted to the CET series

Model	Complete	Subset	Constant seasons
Residual variance	1.696	1.701	1.752
Number of parameters	74	50	30
Fitness	0.594	0.602	0.595

5 Conclusions

In this paper we have proposed models that are able to explain, on one side, regime changes and structural breaks, and on the other side a seasonal behavior that evolves in time.

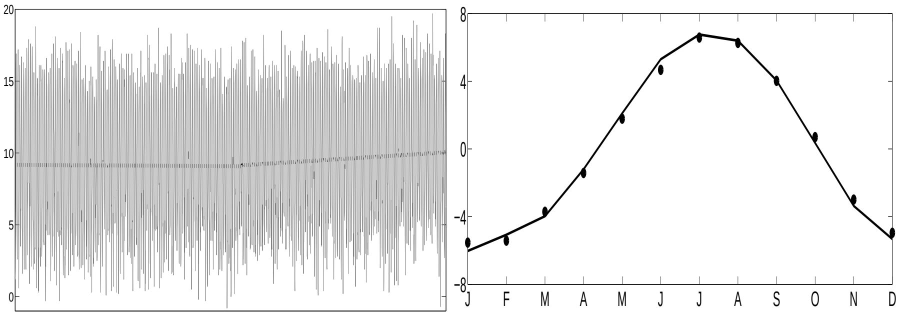

Fig. 1 Left panel: CET series and trend (dotted line). Right panel: monthly means, continuous line: first regime; dotted line: second regime

The complex problem of identifying and estimating such models is solved by GAs. The best model is selected according to a fitness function that is a monotonically decreasing transformation of widely used identification criteria. Experience on real and simulated data suggests that the choice of the fitness function is crucial because a too parsimonious criterion may lead to models that overlook important structure changes.

The results seem to support the usefulness of the proposed methods in detecting relevant changes in the structure of the trend and also possible evolution in the seasonal behavior concerning levels, variance and correlation. The generalized periodic autoregressive models allow a closer analysis of the seasonal behavior, suggesting also the most convenient grouping of seasons in terms of fitness.

Recent Advances in Model-based Clustering

Flexible clustering methods for high-dimensional data sets.

Metodi di cluster analysis flessibili per data set di grandi dimensioni

Cristina Tortora and Paul D. McNicholas

Abstract Finite mixture models assume that a population is a convex combination of densities; therefore, they are well suited for clustering applications. Each cluster is modeled using a density function. One of the most flexible distributions is the generalized hyperbolic distribution (GHD). It can handle skewness and heavy tails, and has many well-known distributions as special or limiting cases. The multiple scaled GHD (MSGHD) and the mixture of coalesced GHDs (CGHD) are even more flexible methods that can detect non-elliptical, and even non-convex, clusters. The drawback of high flexibility is a high parametrization — especially so for high-dimensional data because the number of parameters is depends on the number of variables. Therefore, the aforementioned methods are not well suited for high-dimensional data clustering. However, the eigen-decomposition of the component scale matrix can naturally be used for dimension reduction obtaining a transformation of the MSGHD and MCGHD that is better suited for high-dimensional data clustering.

Key words: Mixture models, generalized hyperbolic distribution, cluster analysis, high dimensional data

1 Background: Model-based clustering

Model-based clustering assumes that a population is a convex combination of a finite number of densities. A random vector $\mathbf{X}$ follows a (parametric) finite mixture distribution if, for all $\mathbf{x} \subset \mathbf{X}$, its density can be written

$$f(\mathbf{x} \mid \boldsymbol{\vartheta}) = \sum_{g=1}^{G} \pi_g f_g(\mathbf{x} \mid \boldsymbol{\theta}_g),$$

where $\pi_g > 0$, such that $\sum_{g=1}^{G} \pi_g = 1$, is the gth mixing proportion, $f_g(\mathbf{x} \mid \boldsymbol{\theta}_g)$ is the gth component density, and $\boldsymbol{\vartheta} = (\pi, \boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_G)$ is the vector of parameters, with $\pi = (\pi_1, \ldots, \pi_G)$. The component densities $f_1(\mathbf{x} \mid \boldsymbol{\theta}_1), \ldots, f_G(\mathbf{x} \mid \boldsymbol{\theta}_G)$ are usually taken to be of the same type. Over the past few years, non-Gaussian model-based clustering techniques have gained popularity. [3] proposed the use of the generalized hyperbolic distribution (GHD), which has the advantage of being extremely flexible because it is characterized by five parameters–the mean, the scale matrix, the skewness, the concentration and the index parameters. Many other distributions, e.g. the Gaussian or the the skew-t distribution, can be obtained as a special or limiting cases. The density of a random variable $\mathbf{X}$ from a generalized hyperbolic distribution is

$$f_{\mathrm{H}}(\mathbf{x} \mid \boldsymbol{\vartheta}) = \left[\frac{\chi + \boldsymbol{\Sigma}(\mathbf{x}, \boldsymbol{\mu} | \boldsymbol{\Sigma})}{\psi + \boldsymbol{\alpha}'\boldsymbol{\Sigma}^{-1}\boldsymbol{\alpha}}\right]^{\frac{\lambda - \frac{p}{2}}{2}} \frac{(\psi/\chi)^{\frac{\lambda}{2}} K_{\lambda - \frac{p}{2}}\left(\sqrt{[\psi + \boldsymbol{\alpha}'\boldsymbol{\Sigma}^{-1}\boldsymbol{\alpha}][\chi + \boldsymbol{\Sigma}(\mathbf{x}, \boldsymbol{\mu} | \boldsymbol{\Sigma})]}\right)}{(2\pi)^{\frac{p}{2}} |\boldsymbol{\Sigma}|^{\frac{1}{2}} K_\lambda(\sqrt{\chi\psi}) \exp\{(\boldsymbol{\mu} - \mathbf{x})'\boldsymbol{\Sigma}^{-1}\boldsymbol{\alpha}\}}, \tag{1}$$

where $\boldsymbol{\Sigma}(\mathbf{x}, \boldsymbol{\mu} \mid \boldsymbol{\Sigma}) = (\mathbf{x} - \boldsymbol{\mu})'\boldsymbol{\Sigma}^{-1}(\mathbf{x} - \boldsymbol{\mu})$ is the squared Mahalanobis distance between $\mathbf{x}$ and $\boldsymbol{\mu}$, K_λ is the modified Bessel function of the third kind with index λ, and $\boldsymbol{\vartheta}$ denotes the parameters. The parameters have the following interpretation: λ is an index parameter, χ and ψ are concentration parameters, $\boldsymbol{\alpha}$ is a skewness parameter, $\boldsymbol{\mu}$ is the mean, and $\boldsymbol{\Sigma}$ is the scale matrix.

Let $Y \sim \mathrm{GIG}(\psi, \chi, \lambda)$, where GIG indicates the generalized inverse Gaussian distribution [1], and the density is given by

$$h(y \mid \boldsymbol{\theta}_g) = \frac{(y/\eta)^{\lambda - 1}}{2\eta K_\lambda(\omega)} \exp\left\{-\frac{\omega}{2}\left(\frac{y}{\eta} + \frac{\eta}{y}\right)\right\}. \tag{2}$$

Consider Y and a random variable $\mathbf{V} \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma})$. Then, a generalized hyperbolic random variable $\mathbf{X}$, see (1), can be generated via

$$\mathbf{X} = \boldsymbol{\mu} + Y\boldsymbol{\alpha} + \sqrt{Y}\mathbf{V}, \tag{3}$$

and it follows that $\mathbf{X} \mid Y \sim \mathcal{N}(\boldsymbol{\mu} + y\boldsymbol{\alpha}, y\boldsymbol{\Sigma})$.

Note that the parameterization used in (1) requires the constraint $|\boldsymbol{\Sigma}| = 1$ to ensure identifiability, but this constraint is not practical for clustering applications. Therefore, an alternative parameterization, setting $\omega = \sqrt{\psi\chi}$ and $\eta = \sqrt{\chi/\psi}$, is used with $\eta = 1$ (see [3]). Under this parametrization the density of the generalized hyperbolic distribution is

$$f_{\mathrm{H}}(\mathbf{x} \mid \boldsymbol{\vartheta}) = \left[\frac{\omega + \boldsymbol{\Sigma}(\mathbf{x}, \boldsymbol{\mu}|\boldsymbol{\Sigma})}{\omega + \boldsymbol{\alpha}'\boldsymbol{\Sigma}^{-1}\boldsymbol{\alpha}}\right]^{\frac{\lambda - \frac{p}{2}}{2}} \frac{K_{\lambda - \frac{p}{2}}\left(\sqrt{[\omega + \boldsymbol{\alpha}'\boldsymbol{\Sigma}^{-1}\boldsymbol{\alpha}][\omega + \boldsymbol{\Sigma}(\mathbf{x}, \boldsymbol{\mu}|\boldsymbol{\Sigma})]}\right)}{(2\pi)^{\frac{p}{2}} |\boldsymbol{\Sigma}|^{\frac{1}{2}} K_{\lambda}(\omega) \exp\{-(\boldsymbol{\mu} - \mathbf{x})'\boldsymbol{\Sigma}^{-1}\boldsymbol{\alpha}\}}. \tag{4}$$

Details of this alternative parameterization, as well as maximum likelihood parameter estimates are given by [3]. Parameter estimation for the mixture of generalized hyperbolic distributions model can be carried out via the expectation-maximization (EM) algorithm [4].

1.1 Multiple scaled generalized hyperbolic distribution

The index and concentration parameters, λ and ω are unidimensional, i.e. they are the same for every dimension. Basing on the idea of [5], [8] proposed the multiple scaled GHD, where $\boldsymbol{\lambda}$ and $\boldsymbol{\omega}$ are p-dimensional vectors, i.e., they can vary in each dimension. To introduce the multiple scaled distribution we need to define the normal variance-mean mixture. The distribution of a p-dimensional random variable $\mathbf{X}$ is said to be a normal variance-mean mixture if its density can be written in the form

$$f(\mathbf{x} \mid \boldsymbol{\mu}, \boldsymbol{\Sigma}, \alpha, \boldsymbol{\theta}) = \int_0^\infty \phi_p\left(\mathbf{x} \mid \boldsymbol{\mu} + w\alpha, f(w)\boldsymbol{\Sigma}\right) h\left(w \mid \boldsymbol{\theta}\right) dw, \tag{5}$$

where $\phi_p\left(\mathbf{x} \mid \boldsymbol{\mu} + w\alpha, w\boldsymbol{\Sigma}\right)$ is the density of a p-dimensional Gaussian distribution with mean $\boldsymbol{\mu} + w\alpha$ and covariance matrix $f(w)\boldsymbol{\Sigma}$, and $h\left(w \mid \boldsymbol{\theta}\right)$ is the density of a univariate random variable $W > 0$ that has the role of a weight function [2, 6]. This weight function can take on many forms, when the density of W follow a generilized inverse Gaussian distribution, $f_t(\mathbf{x} \mid \boldsymbol{\mu}, \boldsymbol{\Sigma}, \nu)$ follows the density of the GHD. [5] show that a multi-dimensional weight variable

$$\boldsymbol{\Sigma}_{\mathbf{W}} = \operatorname{diag}\left(w_1^{-1}, \ldots, w_p^{-1}\right)$$

can be incorporated into (5) via an eigen-decomposition of the symmetric positive-definite matrix $\boldsymbol{\Sigma}$, setting $\boldsymbol{\Sigma} = \boldsymbol{\Gamma}\boldsymbol{\Phi}\boldsymbol{\Gamma}'$. Following [7] the formulation of the GHD in (4) can be written as a normal variance-mean mixture where the univariate density is GIG, i.e.,

$$\mathbf{X} = \boldsymbol{\mu} + W\alpha + \sqrt{W}\mathbf{V}, \tag{6}$$

where $\mathbf{V} \sim \mathrm{N}(\mathbf{0}, \boldsymbol{\Sigma})$ and W has density

$$h(w \mid \omega, 1, \lambda) = \frac{w^{\lambda - 1}}{2K_\lambda(\omega)} \exp\left\{-\frac{\omega}{2}\left(w + \frac{1}{w}\right)\right\}, \tag{7}$$

for $w > 0$, where ω and λ are as previously defined. From (6) and (7), it follows that the generalized hyperbolic density can be written

$$f(\mathbf{x} \mid \boldsymbol{\mu}, \boldsymbol{\Sigma}, \alpha, \omega, \lambda) = \int_0^\infty \phi_p \left(\mathbf{x} \mid \boldsymbol{\mu} + w\alpha, w\boldsymbol{\Sigma}\right) h(w \mid \omega, 1, \lambda) dw. \tag{8}$$

The density of a multiple scaled generalized hyperbolic distribution (MSGHD) is

$$f_{\text{MSGHD}}(\mathbf{x} \mid \boldsymbol{\mu}, \boldsymbol{\Gamma}, \boldsymbol{\Phi}, \alpha, \omega, \lambda) = \\ \int_0^\infty \cdots \int_0^\infty \phi_p \left(\boldsymbol{\Gamma}'\mathbf{x} - \boldsymbol{\mu} - \Delta_{\mathbf{w}}\alpha \mid \mathbf{0}, \Delta_{\mathbf{w}}\boldsymbol{\Phi}\right) h_{\mathbf{w}}(w_1, \ldots, w_p \mid \boldsymbol{\omega}, \mathbf{1}, \boldsymbol{\lambda}) dw_1 \ldots dw_p, \tag{9}$$

where $\boldsymbol{\omega} = (\omega_1, \ldots, \omega_p)'$, $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_p)'$, $\mathbf{1}$ is a p-vector of 1s, and

$$h_{\mathbf{W}}(w_1, \ldots, w_p \mid \boldsymbol{\omega}, \mathbf{1}, \boldsymbol{\lambda}) = h(w_1 \mid \omega_1, 1, \lambda_1) \times \cdots \times h(w_p \mid \omega_p, 1, \lambda_p).$$

Then, a mixture of MSGHDs (MMSGHDs) has density

$$f(\mathbf{x} \mid \boldsymbol{\vartheta}) = \sum_{g=1}^{G} \pi_g f_{\text{MSGHD}} \left(\mathbf{x} \mid \boldsymbol{\mu}_g, \boldsymbol{\Gamma}_g, \boldsymbol{\Phi}_g, \alpha_g, \omega_g, \lambda_g\right). \tag{10}$$

Details of maximum likelihood parameter estimates and EM-algorithm are given by [7].

1.2 Mixture of Coalesced Generalized Hyperbolic Distributions

The generalized hyperbolic distribution is not a special or limiting case of the MSGHD under any parameterization with $p > 1$. [7] proposed a coalesced generalized hyperbolic distribution (CGHD) that contains both the generalized hyperbolic distribution and MSGHD as limiting cases. The CGHD arises through the introduction of a random vector

$$\mathbf{R} = U\mathbf{X} + (1 - U)\mathbf{S}, \tag{11}$$

where $\mathbf{X} = \boldsymbol{\Gamma}\mathbf{Y}$, $\mathbf{Y} \backsim \text{GHD}(\boldsymbol{\mu}, \boldsymbol{\Sigma}, \alpha, \omega_0, \lambda_0)$, $\mathbf{S} \backsim \text{MSGHD}(\boldsymbol{\mu}, \boldsymbol{\Gamma}, \boldsymbol{\Phi}, \alpha, \omega, \lambda)$, with $\boldsymbol{\Sigma} = \boldsymbol{\Gamma}\boldsymbol{\Phi}\boldsymbol{\Gamma}'$, and U is an indicator variable such that

$$U = \begin{cases} 1 & \text{if } R \text{ follows a generalized hyperbolic distribution, and} \\ 0 & \text{if } R \text{ follows a MSGHD.} \end{cases}$$

It follows that $\mathbf{X} = \boldsymbol{\Gamma}\boldsymbol{\mu} + W\boldsymbol{\Gamma}\alpha + \sqrt{W}\boldsymbol{\Gamma}\mathbf{V}$, where $\boldsymbol{\Gamma}\mathbf{V} \backsim \text{N}_p\left(\mathbf{0}, \boldsymbol{\Gamma}\boldsymbol{\Phi}\boldsymbol{\Gamma}'\right)$, $\mathbf{S} = \boldsymbol{\Gamma}\boldsymbol{\mu} + \boldsymbol{\Gamma}\alpha\Delta_{\mathbf{w}} + \boldsymbol{\Gamma}\mathbf{A}$, where $\boldsymbol{\Gamma}\mathbf{A} \backsim \text{N}_p\left(\mathbf{0}, \boldsymbol{\Gamma}\Delta_{\mathbf{w}}\boldsymbol{\Phi}\boldsymbol{\Gamma}'\right)$, and the density of $\mathbf{R}$ can be written

$$f_{\text{CGHD}}(\mathbf{r} \mid \boldsymbol{\mu}, \boldsymbol{\Gamma}, \boldsymbol{\Phi}, \alpha, \omega, \lambda, \omega_0, \lambda_0, \varpi) \\ = \varpi f_{\text{GHD}}\left(\mathbf{r} \mid \boldsymbol{\mu}, \boldsymbol{\Gamma}\boldsymbol{\Phi}\boldsymbol{\Gamma}', \alpha, \omega_0, \lambda_0\right) + (1 - \varpi) f_{\text{MSGHD}}\left(\mathbf{r} \mid \boldsymbol{\mu}, \boldsymbol{\Gamma}, \boldsymbol{\Phi}, \alpha, \omega, \lambda\right), \tag{12}$$

where $f_{\text{GHD}}(\cdot)$ is the density of a generalized hyperbolic random variable, $f_{\text{MSGHD}}(\cdot)$ is the density of a MSGHD random variable, and $\varpi \in (0,1)$ is a mixing proportion. Note that the random vector $\mathbf{R}$ would be distributed generalized hyperbolic if $\varpi = 1$ and would be distributed MSGHD if $\varpi = 0$.

Parameter estimation can be carried out via a generalized expectation-maximization (GEM) algorithm [4].

2 Dimension reduction

The mixture of GHDs, MSGHDs, and CGHDs are extremely flexible and give good clustering performance; however, the flexibility is obtained increasing the number of parameters. This makes the methods unsuitable for high-dimensional data sets. The problem can be solved considering that the singular value decomposition of the scale matrix $\boldsymbol{\Sigma} = \boldsymbol{\Gamma}\Psi\boldsymbol{\Gamma}'$ naturally leads to dimension reduction using $p \times q$ $\boldsymbol{\Gamma}$ and $q \times q$ diagonal $\boldsymbol{\Phi}$ with $q < p$. The random variable $\mathbf{Y}$ is defined as

$$\mathbf{Y} = \boldsymbol{\Gamma}^{*}\mathbf{X} + \varepsilon, \tag{13}$$

with $\mathbf{X} \sim \text{GHD}(\boldsymbol{\mu}, \boldsymbol{\Sigma}, \alpha, \omega, \lambda)$, and $\varepsilon \sim N(0, \Psi)$ where Ψ is a q dimensional diagonal matrix. Using (11) and (13) It follows that

$$\mathbf{Y} = \boldsymbol{\Gamma}^{*}\boldsymbol{\mu} + \boldsymbol{\Gamma}^{*}w\alpha + \boldsymbol{\Gamma}^{*}\sqrt{w}\mathbf{V} + \varepsilon, \tag{14}$$

and

$$\mathbf{Y} \sim GHD(\boldsymbol{\Gamma}^{*}\boldsymbol{\mu}, \boldsymbol{\Gamma}^{*}\alpha, (\boldsymbol{\Gamma}^{*}\boldsymbol{\Phi}(\boldsymbol{\Gamma}^{*})' + \Psi), \lambda, \omega). \tag{15}$$

Similarly if $\mathbf{X} \sim \text{MSGHD}(\boldsymbol{\mu}, \boldsymbol{\Sigma}, \alpha, \omega, \lambda)$,

$$\mathbf{Z} \sim MSGHD(\boldsymbol{\Gamma}^{*}\boldsymbol{\mu}, \boldsymbol{\Gamma}^{*}\alpha, \omega, \lambda, \boldsymbol{\Phi} + \Psi). \tag{16}$$

Define $\tilde{\boldsymbol{\Phi}} := \Psi + \boldsymbol{\Phi}$, a $q \times q$ diagonal matrix. The mixture models obtained using the new proposed density function will be defined as low-dimension mixture of GHDs (LMGHDs) and lo- dimension mixture of MSGHDs (LMMSGHDs) respectively. Using the same procedure used in Section 1.2 we can obtain the lowdimension mixture of CGHDs (LMCGHDs). The parameters that maximize the likelihood for each model can be estimated using the EM-algorithm.

A Comparison of Model-Based and Fuzzy Clustering Methods

Un Confronto tra Metodi di Clustering di tipo Model-Based e Fuzzy

Marco Alfó, Maria Brigida Ferraro, Paolo Giordani, Luca Scrucca, and Alessio Serafini

Abstract Model-based and fuzzy clustering methods represent widely used approaches for soft clustering. In the former approach, it is assumed that the data are generated by a mixture of probability distributions where each component represents a different group or cluster. Each observation unit is ex-post assigned to a cluster using the so-called posterior probability of component membership. In the latter case, no probabilistic assumptions are made and each observation unit belongs to a cluster according to the so-called fuzzy membership degree. The aim of this work is to compare the performance of both approaches by means of a simulation study.

Abstract *I metodi basati sugli approcci model-based e fuzzy rappresentano i piú comuni approcci di soft clustering. Nel primo approccio si assume che i dati siano generati da una mistura di distribuzioni di probabilitá nella quale ciascuna componente individua un gruppo. Key words: Cluster analysis, Model-based approach, Fuzzy approach

1 Introduction

In the last years, model-based and fuzzy clustering methods have received a great deal of attention. The two classes of methods are very different from a theoretical point of view. In the model-based framework, probabilistic assumptions are made. The data are generated by a mixture of known probability distributions (usually Gaussian). Each component of the mixture describes a cluster and, therefore, each cluster can be mathematically represented by a parametric distribution. In practice, the observation units are allocated to clusters via the so-called posterior probabilities of component membership and, for each observation unit, the cluster assignment is carried out by looking at the maximum posterior probability. In the fuzzy approach to clustering, the clusters are no longer represented in terms of parametric distributions. The observation units belong to the clusters according to the so-called membership degree, taking values in [0,1]. From a practical point of view, it is quite obvious that such two classes of clustering methods share similar features. Both of them produce a soft partition of the observation units and the posterior probability of component membership may play a role similar to the membership degree. Nevertheless, as far as we know, a thorough comparison between model-based and fuzzy clustering methods has never been carried out except for a few limited cases (see, e.g., [6, 10]). The aim of this work is to fill this gap by comparing the performances of four clustering methods, two from each class, in a simulation experiment.

2 Model-based clustering

Model-based clustering is a popular family of unsupervised learning methods for data classification. Such methods assume that the data are generated by a statistical model and try to recover it from the data. Let $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n) \in \mathbb{R}^p$ be a random sample of *i.i.d.* observations, where p denotes the number of variables. The random vector $\mathbf{x}_i$ is assumed to arise from a finite mixture of probability density functions:

$$f(\mathbf{x}_i; \boldsymbol{\theta}) = \sum_{k=1}^{g} \pi_k f(\mathbf{x}_i | \boldsymbol{\theta}_k), \tag{1}$$

where π_k, $k = 1, \ldots, g$, such that $\pi_k > 0$ and $\sum_{k=1}^{g} \pi_k = 1$, are the mixing proportions, g is the number of components, $f(\mathbf{x}|\boldsymbol{\theta}_k)$ is the component density $(k = 1, \ldots, g)$

and $\boldsymbol{\Phi} = (\pi_1, \pi_2, \ldots, \pi_g, \boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \ldots, \boldsymbol{\theta}_g)$ is the parameter vector [20]. Each mixture component density belongs to a specific parametric class and represents a group or cluster. Even thought it is not necessary that each mixture component density arises from the same parametric distribution family, we will focus only on the case where the parametric distribution family is the same for each mixture component.

Maximum likelihood estimation of model parameters in $\boldsymbol{\Phi}$ is done by applying the Expectation-Maximization (EM) algorithm [11]. It is an iterative procedure to estimate the parameters of a finite mixture model by maximizing the expected value of the complete data log-likelihood by alternating two different steps. The Expectation step (E-step) computes the expected value of the complete data log-likelihood, and the Maximization step (M-step) maximises the expected value previously computed with respect to $\boldsymbol{\Phi}$. The log-likelihood can be derived as follows:

$$\ell(\boldsymbol{\Phi}) = \log \prod_{i=1}^{n} \sum_{k=1}^{g} \pi_k f(\mathbf{x}_i|\boldsymbol{\theta}_k) = \sum_{i=1}^{n} \log \sum_{k=1}^{g} \pi_k f(\mathbf{x}_i|\boldsymbol{\theta}_k). \tag{2}$$

Suppose to have an unobservable process $\mathbf{z} = (\mathbf{z}_1, \ldots, \mathbf{z}_n)$. We refer to this new dataset $(\mathbf{x}, \mathbf{z})$ as the complete data with density $f(\mathbf{x}, \mathbf{z}|\boldsymbol{\theta})$. The complete data log-likelihood is given by

$$\ell_c(\boldsymbol{\Phi}) = \log \prod_{i=1}^{n} f(\mathbf{x}_i, \mathbf{z}_i|\boldsymbol{\theta}) = \sum_{i=1}^{n} \log\{f(\mathbf{z}_i|\boldsymbol{\theta}) f(\mathbf{x}_i|\mathbf{z}_i, \boldsymbol{\theta})\}. \tag{3}$$

The E-step computes the expected value of the complete-data log-likelihood in (3) with respect to the missing part:

$$Q(\boldsymbol{\Phi}|\boldsymbol{\Phi}^t) = \mathbb{E}_{\boldsymbol{\Phi}^t}[\ell_c(\boldsymbol{\Phi})] = \mathbb{E}_{\boldsymbol{\Phi}^t}\left[\sum_{i=1}^{n} \log f(\mathbf{z}_i|\boldsymbol{\theta}^t) f(\mathbf{x}_i|\mathbf{z}_i, \boldsymbol{\theta}^t)\right]. \tag{4}$$

The M-step maximises equation in (4), such that:

$$\boldsymbol{\Phi}^{t+1} = \arg\max_{\boldsymbol{\Phi}} Q(\boldsymbol{\Phi}|\boldsymbol{\Phi}^t). \tag{5}$$

The procedure is iterated until some convergence criterion is satisfied. The EM algorithm guaranteesthat the observed log-likelihood is nondecreasing and, under fairly general conditions, the sequence converges to at least a local maximum [19]. Further details can be found in, e.g., [19, 20].

2.1 Finite mixtures of Gaussian densities

Due to its flexibility and mathematical tractability, the most popular model for clustering postulates that the data follow a Gaussian mixture distribution, i.e. $f(\mathbf{x}_i, |z_{ik} = 1, \boldsymbol{\theta}_k) \sim \mathcal{N}(\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k)$ [15]. The finite mixture of Gaussian densities is then given by

$$f(\mathbf{x}_i;\boldsymbol{\theta}) = \sum_{k=1}^{g} \pi_k \phi(\mathbf{x}_i|\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k), \tag{6}$$

where $\boldsymbol{\theta} = \{\pi_1, \pi_2, \ldots, \pi_{k-1}, \boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_k, \boldsymbol{\Sigma}_1, \ldots, \boldsymbol{\Sigma}_k\}$ denotes the parameter set for the finite mixture model and $\phi(\mathbf{x}_i|\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k)$ the underlying component-specific density function with parameters $\boldsymbol{\mu}_k$, $\boldsymbol{\Sigma}_k$, $k = 1, \ldots, g$.

Thus, model in (6) generates ellipsoidal clusters centred at the mean vector $\boldsymbol{\mu}_k$, with $\boldsymbol{\Sigma}_k$ controlling the other geometrical properties of each cluster. Parsimonious parametrisations of the cluster covariance matrices can be obtained through the eigendecomposition $\boldsymbol{\Sigma}_k = \lambda_k \mathbf{D}_k \mathbf{A}_k \mathbf{D}_k^\top$ [4, 9], where λ_k is a scalar controlling the volume of the ellipsoid, $\mathbf{A}_k$ is a diagonal matrix controlling its shape and $\mathbf{D}_k$ is an orthogonal matrix controlling the orientation of the ellipsoid. Such an eigendecomposition generates a class of models with different geometrical properties. For some covariance parametrisations a closed formula for the M-step in the EM algorithm can be obtained [9]. The estimation for each of the 14 different models resulting from the eigendecomposition of the within clusters covariance matrices is implemented in the R package **mclust** [23].

The number of clusters and the parametrisation of the covariance matrices are selected using selection criteria, such as the Bayesian information criterion (*BIC*) [14, 22].

2.2 Finite mixtures of t densities

In [21], a heavy-tailed alternative to the component-specific density (6) is proposed by replacing the Gaussian distribution with a *t* distribution as follows:

$$f(\mathbf{x}_i;\boldsymbol{\theta}) = \sum_{k=1}^{g} \pi_k f_t(\mathbf{x}_i|\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k, \nu_k), \tag{7}$$

where $\boldsymbol{\theta} = \{\pi_1, \pi_2, \ldots, \pi_{k-1}, \boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_k, \boldsymbol{\Sigma}_1, \ldots, \boldsymbol{\Sigma}_k, \nu_1, \ldots, \nu_k\}$ and $f_t(\mathbf{x}_i|\boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k, \nu_k)$ is the multivariate *t* distribution with mean $\boldsymbol{\mu}_k$, covariance matrix $\boldsymbol{\Sigma}_k$ and ν_k degrees of freedom. As in the Gaussian case, the EM algorithm is employed for maximum likelihood estimation of $\boldsymbol{\theta}$ [2, 21]. In the present context, a parsimonious parametrization can be based on the same eigendecomposition of the covariance matrices as in the Gaussian case and constraining the degrees of freedom to be equal or not across groups [1]. This produces a class of finite mixture models with *t*-distributed components called *tEIGEN*. The *tEIGEN* family is implemented in the R package **teigen** [1, 2].

3 Fuzzy clustering

As opposed to the model-based framework, no probabilistic assumptions are made in the fuzzy approach to clustering. The complexity of the clustering process is managed in terms of fuzziness [24]. The observation units are assigned to the clusters according to the so-called fuzzy membership degree, taking values in [0,1]. This is inversely related to the dissimilarity between the observation units and the cluster prototype. A membership degree approaching 1 implies that the observation unit is close to the corresponding prototype and therefore it can be clearly assigned to the cluster. In the literature, there exist several fuzzy clustering methods. Among them, the most common one is the Fuzzy *k*-Means (F*k*M) algorithm [5]. In the following subsections, we will recall the F*k*M algorithm and the closely related Gustafson-Kessel variant [12]. The algorithms are implemented in the R package **fclust** [13].

3.1 Fuzzy k-Means

The Fuzzy *k*-Means (F*k*M) clustering algorithm [5] aims at grouping *n* observation units in *k* clusters by solving the following constrained optimization problem:

$$\begin{array}{lll} \min\limits_{\mathbf{U},\mathbf{H}} J_{FkM} & = \sum_{i=1}^{n} \sum_{k=1}^{g} u_{ik}^{m} d^2 \left(\mathbf{x}_i, \mathbf{h}_k\right), & \\ \text{s.t.} & u_{ik} \geq 0, \quad i=1,\ldots,n, \quad k=1,\ldots,g, & \\ & \sum_{k=1}^{g} u_{ik} = 1, \quad i=1,\ldots,n. & \end{array} \tag{8}$$

In (8), the term u_{ik} denotes the membership degree of observation unit i to cluster k, as a generic element of the matrix $\mathbf{U}$ of order $(n \times g)$. The row-wise sum of $\mathbf{U}$ is equal to 1. Furthermore, $\mathbf{h}_k = \left[h_{k1}, \ldots, h_{kp}\right]$, the k-th row of the prototype matrix $\mathbf{H}$ of order $(g \times p)$, is the prototype for cluster k, $k = 1, \ldots, g$. Finally, $d^2\left(\mathbf{x}_i, \mathbf{h}_k\right)$ is the squared Euclidean distance between observation unit i and prototype k, while $m > 1$ is the fuzziness parameter which tunes the level of fuzziness of the obtained partition. The higher the values of m, the fuzzier the partition with membership degrees tending to $\frac{1}{k}$. When m is close to 1, the F*k*M solution approaches that of the standard (non-fuzzy or hard) *k*-means [18] with membership degrees equal to either 0 or 1. The standard choice is $m = 2$.

The solution of (8) is carried out through an iterative optimization algorithm by updating the elements of $\mathbf{U}$ as follows

$$u_{ik} = \frac{1}{\sum_{k'=1}^{g} \left(\frac{d^2(\mathbf{x}_i, \mathbf{h}_k)}{d^2\left(\mathbf{x}_i, \mathbf{h}_{k'}\right)} \right)^{\frac{1}{m-1}}}, \quad i=1,\ldots,n, \quad k=1,\ldots,g, \tag{9}$$

and the rows of $\mathbf{H}$ as

$$\mathbf{h}_k = \frac{\sum_{i=1}^{n} u_{ik}^{m} \mathbf{x}_i}{\sum_{i=1}^{n} u_{ik}^{m}}, \quad k=1,\ldots,g. \tag{10}$$

In order to select the optimal number of clusters, several cluster validity indexes can be adopted. A popular choice is the Fuzzy Silhouette index [8].

3.2 Gustafson-Kessel variant of FkM

The major limitation of the F*k*M algorithm is that the obtained clusters are defined to be spherical. Therefore, F*k*M may be inadequate whenever the clusters have different geometrical shapes. In such cases, the so-called Gustafson-Kessel variant of the F*k*M algorithm can be applied, hereinafter GK-F*k*M [12]. The main difference between F*k*M and GK-F*k*M is that, in the latter, a Mahalanobis-type dissimilarity is considered, that is, $d^2\left(\mathbf{x}_i, \mathbf{h}_k\right)$ is replaced by

$$d_M^2\left(\mathbf{x}_i, \mathbf{h}_k\right) = \left(\mathbf{x}_i - \mathbf{h}_k\right)^\top \mathbf{M}_k (\mathbf{x}_i - \mathbf{h}_k), \tag{11}$$

with $\mathbf{M}_k$ symmetric and positive definite. The GK-F*k*M can then be formulated as

$$\begin{array}{lll} \min\limits_{\mathbf{U},\mathbf{H},\mathbf{M}_1,\ldots,\mathbf{M}_g} & J_{GK-FkM} & = \sum_{i=1}^n \sum_{k=1}^g u_{ik}^m d_M^2\left(\mathbf{x}_i, \mathbf{h}_k\right), \\ \text{s.t.} & & u_{ik} \geq 0, \quad i = 1, \ldots, n, \quad k = 1, \ldots, g, \\ & & \sum_{k=1}^g u_{ik} = 1, \quad i = 1, \ldots, n, \\ & & |\mathbf{M}_k| = \rho_k > 0 \quad k = 1, \ldots, g. \end{array} \tag{12}$$

As the cost function is linear with respect to the matrices $\mathbf{M}_k$, a trivial solution with $\mathbf{M}_k = \mathbf{0}, k = 1, \ldots, g$ would be obtained. To avoid it, $\mathbf{M}_k$ must be constrained. A way to do it is to consider volume constraints such that the determinant of $\mathbf{M}_k$ is positive. Note that the most common choice is $\rho_k = 1$, $k = 1, \ldots, g$.

An iterative solution of (12) can be found by updating $\mathbf{U}$ and $\mathbf{H}$ according to (9) and (10) provided that d^2 is replaced by d_M^2 and $\mathbf{M}_k$ by

$$\mathbf{M}_k = [\rho_k |\mathbf{V}_k|]^{\frac{1}{n}} \mathbf{V}_k^{-1}, \quad k = 1, \ldots, g, \tag{13}$$

where $\mathbf{V}_k$ is the fuzzy covariance matrix for cluster k given by

$$\mathbf{V}_k = \frac{\sum_{i=1}^n u_{ik}^m (\mathbf{x}_i - \mathbf{h}_k)(\mathbf{x}_i - \mathbf{h}_k)^\top}{\sum_{i=1}^n u_{ik}^m}, \quad k = 1, \ldots, g. \tag{14}$$

To avoid possible numerical problems for updating $\mathbf{M}_k$, a computational improvement has been proposed in [3] where the condition number of $\mathbf{M}_k$ is constrained to be higher than a prespecified threshold. Note that this condition is similar to that imposed to covariance matrices in finite mixture models with either Gaussian or t components [16, 17].

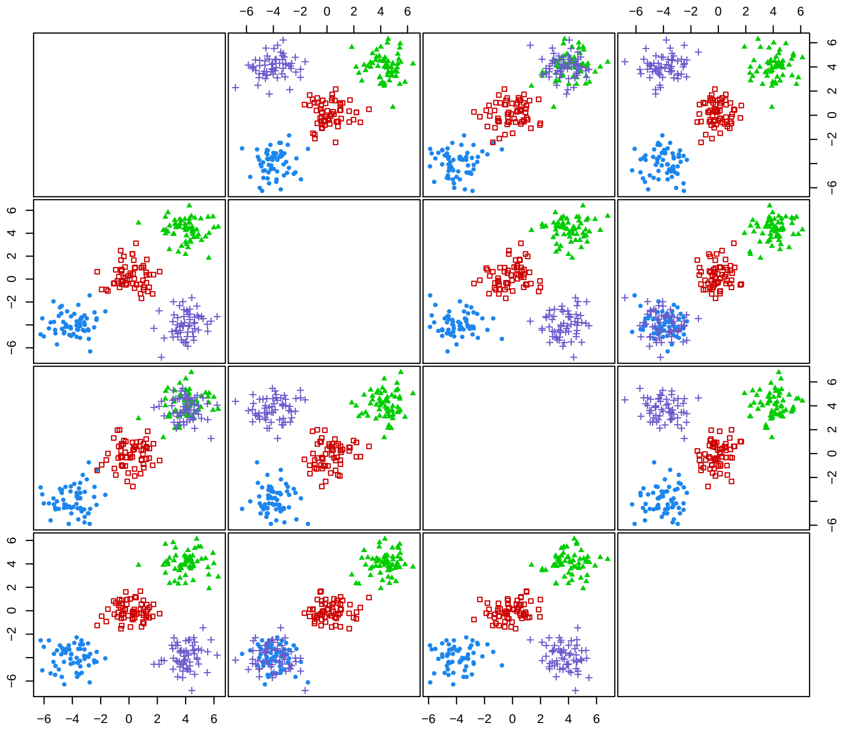

Fig. 1 Example of simulated data

4 Simulation study

A simulation study has been carried out to compare the previously described clustering methods. Simulated data sets have been generated randomly in a full factorial design; an example of generated data is displayed in Figure 1. In the simulation study, the focus lies on assessing the performance of the methods in recovering the cluster structure and checking whether the design variables influence the differential performance of the methods. The results will be presented at the meeting.

Covariate measurement error in generalized linear models for longitudinal data: a latent Markov approach

Roberto Di Mari*[1], Antonio Punzo[1], and Antonello Maruotti[2,3]

Abstract

One common approach to handle covariate measurement error in Generalized Linear Models (GLM) is classical error modeling. In the past 20 years, classical error modeling has been brought to (Non-Parametric) Maximum Likelihood (NPML) estimation, by means of finite mixture modeling: the supposedly continuous true score is modeled as a discrete (multinomial) static latent variable, and is handled as a part of the model. Nonetheless, the true score is not allowed to vary over time: if the true score has own underlying dynamics, these are either unaccounted for or mistaken for measurement error, or possibly both. The aim of the present paper is to formulate a joint model for the outcome variable, the covariate observed with error (measurement model), and the true score model that accounts for the underlying dynamics in the true score. The true score and its dynamics are modeled non-parametrically as a first-order latent (hidden) Markov chain. Estimation is done extending the NPML approach, in a full maximum likelihood environment with a well-know modification of the EM algorithm (forward-backward algorithm). From an applied researcher perspective, our methodology can safely handle both the case where the latent underlying characteristic is stable over time, as well as providing a suitable framework even when changes across measurement occasions are substantial. Within a GLM framework, it is demonstrated, by means of extensive simulation studies, that this is crucial to get correct estimates of the regression coefficients, as well as good coverages. In the real-data application, the effect of heart rate on the occurrence of cardiovascular diseases in a sample of Chinese elderly patients is measured. Modeling the true (unobserved) heart rate and its dynamics - which, in elderly patients, are likely to be non negligible - will be showed to allow a correct assessment of risk factors of cardiovascular diseases occurrence.

KEY-WORDS: covariate measurement error, errors–in–variables, longitudinal data, generalized linear models, latent Markov models.

1 Introduction

In all areas of scientific research, being able to collect high quality measures in order to assess a given phenomenon of interest is crucial. Unaccounted measurement error due to poor measures can severely distort the analysis, leading to unreasonable substantial conclusions.
A relevant type of measurement error is covariate measurement error - or errors in variables. Covariate measurement error issues have long history in epidemiological studies. For instance, Cotton et al. (2005) show how measurement error can affect diagnosis of developmental dyslexia in children with reading difficulties. Kipnis et al. (2003) find that dietary intake assessed with error in a biomarker study produces a severely attenuated estimate of disease relative risk. Guo & Little (2011) report, in pre-menopause women, a negative effect of carotenoids on progesterone, estimated to be zero if measurement error is not accounted for.
The two most common approaches for covariate measurement error modeling are classical error models - known also as error calibration models - and regression calibration models (for an extensive review, see Carroll et al., 2006). In the past 20 years, Aitkin (1996, 1999) and Aitkin & Rocci (2002) among other, have provided a way to bring classical error modeling to maximum likelihood estimation, allowing the user to make no parametric assumption on the true score. That is, nonparametric maximum likelihood (NPML) handles the distribution of the true score as a part of the model non-parametrically, by using finite mixture models (for a recent review, see for instance Alfó & Viviani, 2016. Whereby remaining in a fully ML setup, this approach, in many practical situations, can be more convenient than assuming normality of the true score - as is commonly done in the regression calibration literature. Nonetheless, the true score is not allowed to vary over time. If the true character has own underlying dynamics, these are either unaccounted for or mistaken for measurement error (Alwin, 2007), or possibly both.
Separating unreliability from change in the true score is possible if the true score dynamics are modeled. Quasi Simplex models, or Quasi Autoregressive/Markov Simplex models (Alwin, 2007) are used in survey methods literature to address the issue of changes in the true-score distribution (see, for instance, Uhrig & Watson, 2017). The model is fitted in a confirmatory factor-analytic Structural Equation Modeling (SEM) framework, by assuming a continuous dynamic latent variable with Gaussian error (one-factor model). A similar approach in epidemiology can be found in Sánchez et al. (2009), who study the effects of in-utero lead exposure on child development.
The aim of this work is to formulate a joint model for the outcome variable, the covariate observed with error (measurement model), and the true score model that accounts for the underlying dynamics in the true score. The true score and its dynamics are modeled non-parametrically as a first-order latent (hidden) Markov chain (Bartolucci et al., 2012; Collins & Lanza, 2010; Rabe-Hesketh & Skrondal, 2008; J. K. Vermunt et al., 1999; Wiggins, 1973; Zucchini et al., 2016). Model estimation is done in a fully maximum likelihood environment, with a well-know modification of the EM algorithm (Baum et al., 1970; Welch, 2003).
Our approach is closely related to Aitkin & Rocci (2002)'s, in that we make no distributional assumption on the true score, whereby the key novelty is in modeling the true-score

dynamics. From an applied researcher perspective, our methodology can safely handle both the case where the latent underlying characteristic is stable over time, as well as providing a suitable framework even when changes across measurement occasions are substantial. Within a generalized linear modeling (GLM) framework, we demonstrate that this is crucial to get correct estimates of the regression coefficients, as well as good coverages. Although confirmatory factor-analytic/SEM methodologies allow for dynamics in the true score, estimation relies on identifying restrictions (for instance on the true score variance) and distributional assumptions (normality of each regression errors), which might be restrictive in certain practical situations. In the methodology we propose, we need no identifying restrictions, and we handle non-parametrically a possibly continuous underlying latent variable, modeling it as a dynamic discrete trait (Catania & Di Mari, 2018; Di Mari & Bakk, 2017; J. Vermunt & Magidson, 2004).

We illustrate the proposed methodology by analyzing data from the Chinese Longitudinal Healthy Longevity Survey, where a sample of n Chinese old patients is observed T times, and information on cardiovascular diseases for each person is reported alongside demographics and well-known risk factors, among which heart rate. The aim is to measure the effect of heart rate on the occurrence of a cardiovascular disease, controlling for demographic characteristics and dietary habits.

The structure of the paper is as follows. In Section 2 we will give details on the modeling specification, and describe how the model parameters can be estimated with our latent Markov approach (Section 2. In Section 4 we will summarize the results from the simulation study and the empirical application.

2 Outcome, measurement and error components in common error correction modeling

Let Y_t, W_t and $\mathbf{Z}_t$ be respectively the outcome variable, a continuous covariate corresponding to the true score X_t and a k-vector of error–free covariates, for $t = 0, \dots, T$. In addition, we let $\mathbf{Y}$ be the full vector of outcomes, $\mathbf{Z}$ the full set of available covariates, and $\mathbf{W}$ the full vector of covariate values with corresponding true scores $\mathbf{X}$, observed for the $T+1$ time occasions. We assume that, given the true score, Y_t and W_t are conditionally independent - non–differential measurement error model.

As it is typical in GLM context, we assume Y_t to have distribution belonging to the exponential family, with the following linear predictor

$$\eta_t(\boldsymbol{\theta}) = \alpha + \beta\,\mathrm{X}_t + \boldsymbol{\gamma}'\,\mathbf{Z}_t, \tag{1}$$

where $\eta_t(.)$ is an appropriate link function, $\boldsymbol{\gamma}$ and β are respectively k-vector and scalar regression coefficients, α is an intercept term and $\boldsymbol{\theta} = \{\alpha, \beta, \boldsymbol{\gamma}\}$.

Equation (1) defines the outcome model in terms of its linear predictor.

As for the classical measurement error model, we assume

$$\mathrm{W}_t = \mathrm{X}_t + \xi_t, \tag{2}$$

where $\xi_t \sim N(0, \sigma^2_{\mathrm{W}})$. The classical additive model can be also applied to variables transformed in log-scale, in order to model multiplicative rather than additive error.

The true score and its dynamics can be modeled extending the usual assumption of (conditional) normality of the true score (given the exogenous covariates $\mathbf{Z}_t$; Aitkin & Rocci, 2002), by assuming the score follows an AR(1) process, such that

$$\begin{aligned} \mathrm{X}_0 &= \epsilon_0 + \boldsymbol{\lambda}' \mathbf{Z}_0, \\ \mathrm{X}_t &= \mathrm{X}_{t-1}\, \rho + \boldsymbol{\lambda}' \mathbf{Z}_t + \epsilon_t. \end{aligned} \tag{3}$$

For convenience, we define the transformed true score $\mathrm{X}_0^* = \mathrm{X}_0 - \boldsymbol{\lambda}' \mathbf{Z}_0$, $\mathrm{X}_t^* = \mathrm{X}_t - \boldsymbol{\lambda}' \mathbf{Z}_t$, and $\boldsymbol{\gamma}^* = \boldsymbol{\gamma} + \beta\lambda$. By dropping the stars, the measurement model is now transformed as

$$\mathrm{W}_t = \mathrm{X}_t + \boldsymbol{\lambda}' \mathbf{Z}_t + \xi_t, \tag{4}$$

and the linear predictor of the outcome model becomes

$$\eta_t(\boldsymbol{\theta}) = \alpha + \beta\, \mathrm{X}_t + \boldsymbol{\gamma}' \mathbf{Z}_t\,. \tag{5}$$

We can now express, using Aitkin & Rocci (2002)'s notation, the following joint model for $(\mathrm{Y}_t, \mathrm{W}_t, \mathrm{X}_t \,|\, \mathbf{Z}_t)$

$$P(\mathrm{Y}_t, \mathrm{W}_t, \mathrm{X}_t \,|\, \mathbf{Z}_t) = P(\mathrm{Y}_t \,|\, \mathrm{X}_t, \mathbf{Z}_t) m(W_t |\, \mathrm{X}_t, \mathbf{Z}_t) \pi(X_t), \tag{6}$$

where $P(\mathrm{Y}_t \,|\, \mathrm{X}_t, \mathbf{Z}_t)$ is the density or pmf of the outcome, $m(W_t |\, \mathrm{X}_t, \mathbf{Z}_t)$ is the measurement model density, and $\pi(X_t)$ is the true score density.
We can now define the following joint marginal distribution for (Y_t, W_t)

$$P(\mathrm{Y}_t, \mathrm{W}_t, \mathrm{X}_t \,|\, \mathbf{Z}_t) = \int P(\mathrm{Y}_t \,|\, \mathrm{X}_t) m(W_t |\, \mathrm{X}_t) \pi(X_t) dX_t, \tag{7}$$

Let $\{(\mathrm{Y}_{it}, \mathrm{W}_{it}, \mathbf{Z}_{it})\}_n = \{(\mathrm{Y}_{1t}, \mathrm{W}_{1t}, \mathbf{Z}_{1t}), \ldots, (\mathrm{Y}_{nt}, \mathrm{W}_{nt}, \mathbf{Z}_{nt})\}$ be a sample of n independent observations, observed for $t = 0, \ldots, T$ time points. The sample log-likelihood - corresponding to the model of Equation (7) for $t = 0, \ldots, T$ - can be defined as

$$\ell(\boldsymbol{\theta}) = \sum_{i=1}^{n} \log \left\{ \int P(\mathbf{Y}_i \,|\, \mathbf{X}_i, \mathbf{Z}_i) m(\mathbf{W}_i \,|\, \mathbf{X}_i, \mathbf{Z}_i) \pi(\mathbf{X}_i) d\, \mathbf{X}_i \right\}, \tag{8}$$

where

$$P(\mathbf{Y}_i, |\, \mathbf{X}_i, \mathbf{Z}_i) m(\mathbf{W}_i \,|\, \mathbf{X}_i, \mathbf{Z}_i) = \prod_{t=0}^{T} P(\mathrm{Y}_{it} \,|\, \mathrm{X}_{it}, \mathbf{Z}_{it}) m(W_{it} |\, \mathrm{X}_{it}, \mathbf{Z}_{it}), \tag{9}$$

due to local independence of the distributions of outcome and the covariate measured with error across time given the true score. The assumption on the distribution of X_t involves also assumptions on its dynamics. With a relatively simple AR(1) specification, estimating the model parameters by maximixing the (log) likelihood of Equation (8) requires evaluating an integral over a $(T + 1)$-dimensional space. This can be done by using a (nonlinear) filtering algorithm, known in the time series literature (Heiss, 2008), which is based on the sequential application of Gaussian quadrature rules (see also Bartolucci et al., 2014).

3 Handling covariate measurement error with latent Markov modeling

The idea underlying the NPML approach (Laird, 1978; Lindsay, 1983a,b) is that finding the MLE of $\pi(\cdot)$, say $\widehat{\pi}(\cdot)$, involves a standard convex optimization problem and, as long as the model likelihood is bounded, $\widehat{\pi}(\cdot)$ is concentrated over at most as many support points as the number of sample units, and is uniquely identified by locations and related masses. We let S, with $S \leq n$, be the state space of the concentrated distribution at time t, X_{it}^{s} be the realized discretized true score for the i-th observation at time t corresponding to the s-th location x_s, with time–varying mass π_{st}, for $s = 1, \dots, S$, at time t. We propose to model the time–varying masses by using the properties of first–order homogeneous Markov chains. In particular, by letting $\boldsymbol{\delta} = \{\delta_s\}_S$ be the common initial probabilities, where $\delta_s = P(\mathrm{X}_{i0}^{s} = s)$, and $\mathbf{Q}$ the common transition matrix, with elements $\{\mathrm{q}_{rs}\}$, where $\mathrm{q}_{rs} = P(\mathrm{X}_{t}^{s} = \mathrm{x}_s \,|\, \mathrm{X}_{t-1}^{s} = \mathrm{x}_r)$ with $1 < s \leq S$, and $1 < r \leq S$, we can approximate the log likelihood function of Equation (8) as follows

$$\ell(\boldsymbol{\theta}) \approx \sum_{i=1}^{n} \log \left\{ \prod_{t=0}^{T} \sum_{s=1}^{S} P(\mathrm{Y}_{it} \,|\, \mathrm{X}_{it}^{s}, \mathbf{Z}_{it}) m(\mathrm{W}_{it} \,|\, \mathrm{X}_{it}^{s}, \mathbf{Z}_{it}) \pi_{st} \right\}, \tag{10}$$

where, thanks to the properties of Markov chains, $\pi_{s0} = \delta_s$, and π_{st} is the s-th element of the vector $\boldsymbol{\pi}_t = \boldsymbol{\delta}' * \mathbf{Q}^t$.

The elements of the initial state probabilities and the transition probabilities can be parametrized according to logistic parametrizations as follows

$$\log \frac{P(X_0 = s)}{P(X_0 = 1)} = \beta_{s0}, \tag{11}$$

with $1 < s \leq S$, for the initial state probability, and

$$\log \frac{P(\mathrm{X}_t = s | X_{t-1} = r)}{P(\mathrm{X}_t = 1 | X_{t-1} = r)} = \gamma_{0s} + \gamma_{0rs}, \tag{12}$$

with $1 < s \leq S$, and $1 < r \leq S$ for the transitions probabilities. We take the first category as reference - setting to zero the related parameters. For the transition model, this means that parameters related to the elements in the first row and column of the transition matrix are set to zero.

Iterative procedures, like the EM algorithm (Dempster et al., 1977) can be used to maximize Equation (10) in order to estimate the model parameters in one step. However, when using the standard EM, the time and storage required for parameter estimation of latent Markov models increase exponentially with the number of time points (Vermunt, Langeheine, & Böckenholt, 1999). For this reason, the forward–backward algorithm (Baum et al., 1970; Welch, 2003) is typically implemented: this is a special version of the standard EM in which the size of the problem increases only linearly with the number of time occasions (Zucchini et al., 2016).

4 Results and conclusions

We have assessed the proposed latent Markov approach for parameters estimation of generalized linear models with covariate(s) measured with error under a broad set of scenarios, resulting from combinations of different sample size (100, 500 and 1000 for each time point, with $T = 5$), measurement error size ($\sigma^2_{\mathrm{W}} = (1, 1.5, 2)$), and size of the effect of the true score on the outcome $\beta = (1, 1.5)$, for both continuous and dichotomous outcome variables. We have generated the continuous true score from a continuous dynamic model. We found that our latent Markov approach with a number of states between 3 and 5 is enough to approximate the continuous underlying distribution of the true score. The results have showed that the proposed method yields correct parameter estimates in all conditions, except for small sample size (100 observations), as well as good coverages.
In the empirical application on the Chinese Longitudinal Healthy Longevity Survey data, we were able to find, modeling the true (unobserved) heart rate and its dynamics, risk factors for the cardiovascular disease occurrence consistent with the medical literature.

Statistical Modelling

A regularized estimation approach for the three-parameter logistic model

Un approccio regolarizzato per la stima del modello logistico con tre parametri

Michela Battauz and Ruggero Bellio

Abstract The three-parameter logistic model is an item response theory model used with dichotomous items. It is well known that the parameters of the model are weekly identifiable and that the maximization of the likelihood, which is performed using numerical algorithms, is prone to convergence issues. In this paper, we propose the use of a penalized likelihood for the estimation of the item parameters. In particular, the penalty term shrinks the guessing parameters towards a known constant. Cross-validation is used to select such constant and the amount of shrinkage, though estimation via an empirical Bayes approach is also considered. The method is both simple and effective, and it is illustrated by means of a simulation study and a real data example.

Abstract *Il modello logistico con tre parametri è uno dei modelli item response theory usato con item dicotomici. In letteratura è noto che i parametri del modello sono debolmente identificabili e che la massimizzazione della verosimiglianza, che è condotta attraverso algoritmi numerici, è soggetta a problemi di convergenza. In questo articolo, si propone l'uso di una verosimiglianza penalizzata per la stima dei parametri del modello. In particolare, il termine di penalizzazione regolarizza le stime dei parametri di guessing verso una costante nota. L'ammontare di regolarizzazione viene determinato attraverso la validazione incrociata, e in alternativa mediante un approccio Bayesiano empirico. Il metodo è pratico ed efficace, e viene illustrato attraverso uno studio di simulazione e un esempio con dati reali.*

1 Introduction

The Three-Parameter Logistic (3PL) model is an Item Response Theory (IRT) model used with dichotomous responses. This model can be used for multiple-choice items, which are expected to have a non-zero probability of giving a correct response even at very low achievement levels. However, the parameters of this model are weekly identifiable [6] and the algorithms used for the maximization of the likelihood function frequently encounter convergence problems. A possible resolution is provided by regularization by means of penalized likelihood estimation [3, 10]. In particular, this paper studies the inclusion in the likelihood function of a penalty term that shrinks the guessing parameters towards a known constant. Despite a natural choice for this constant would be $1/k$, where k is the number of response options, we follow a data-driven approach for the selection of this value and of the amount of shrinkage. More specifically, the selection is performed by cross-validation [3]. An alternative route based on empirical Bayes estimation is also considered.

The paper is organized as follows. Section 2 introduces the model and the estimation methods, Section 3 shows an application to achievement data and Section 4 presents the results of a simulation study. Finally, Section 5 contains some concluding remarks.

2 Models and methods

In a 3PL model, the probability of a positive response to item j is given by

$$p_{ij} = \Pr(X_{ij} = 1|\theta_i; a_j, b_j, c_j) = c_j + (1 - c_j)\frac{\exp\{a_j(\theta_i - b_j)\}}{1 + \exp\{a_j(\theta_i - b_j)\}}, \tag{1}$$

where θ_i is the ability of person i, a_j is the discrimination parameter, b_j is the difficulty parameter, and c_j is the guessing parameter. Here, $i = 1, \dots, n$ and $j = 1, \dots, J$, so that n is the sample size and J the number of items. A convenient parameterization of the model, suitable for estimation, is the following

$$p_{ij} = c_j + (1 - c_j)\frac{\exp(\beta_{1j} + \beta_{2j}\theta_i)}{1 + \exp(\beta_{1j} + \beta_{2j}\theta_i)}, \tag{2}$$

with

$$c_j = F(\beta_{3j}) = \frac{\exp(\beta_{3j})}{1 + \exp(\beta_{3j})}. \tag{3}$$

Let β be the vector containing all item parameters. The marginal maximum likelihood method [1], which is a commonly used estimation method of IRT models, requires the maximization of the following log likelihood function for β

$$\ell(\beta) = \sum_{i=1}^{n} \log \int_{\mathbb{R}} \prod_{j=1}^{J} p_{ij}^{x_{ij}} (1-p_{ij})^{1-x_{ij}} \, \phi(\theta_i) d\theta_i, \tag{4}$$

where $\phi(\cdot)$ denotes the standard normal p.d.f.

The penalized log likelihood function considered here is given by

$$\ell_p(\beta) = \ell(\beta) + J(\beta_3), \tag{5}$$

where β_3 is the vector containing all the guessing parameters, and $J(\beta_3)$ is a quadratic penalty term

$$J(\beta_3) = -\frac{1}{2\sigma^2} \sum_{j=1}^{J} (\beta_{3j} - \mu)^2, \tag{6}$$

proportional to the log p.d.f. of the normal distribution with mean μ and standard deviation σ. Note that to constrain the guessing parameters c_j towards a constant c, it is necessary to choose μ so that $c = F(\mu)$, with F defined in (3). Another option would take a penalty derived from a beta distribution for c_j.

2.1 Parameter tuning by cross-validation

A relevant issue is the choice of the tuning parameters μ and σ. The first proposal is to adopt a typical approach followed for regularized regression [10], namely

i. Estimate the item parameter for fixed values of the tuning parameters μ and σ;
ii. Select the tuning parameters by minimizing some error rate computed by cross-validation [3].

Step i. above is simply performed, for example by recourse to IRT software which allows for the introduction of a penalty term for 3PL models. Step ii. requires the definition of a suitable cross-validation error, here taken as minus the log likelihood of the validation set evaluated at the parameter estimates.

2.2 Empirical Bayes

An alternative method consists in treating μ and σ as parameter estimated by an empirical Bayes approach. In particular, we implement this method by treating β_3 as normal random effects, and then jointly estimate $(\beta_1, \beta_2, \mu, \sigma)$ after integrating them out from joint likelihood function of the data and β_3. Here the Laplace approximation is employed to carry out the latter integration, a strategy greatly simplified by the usage of automatic differentiation software [8].

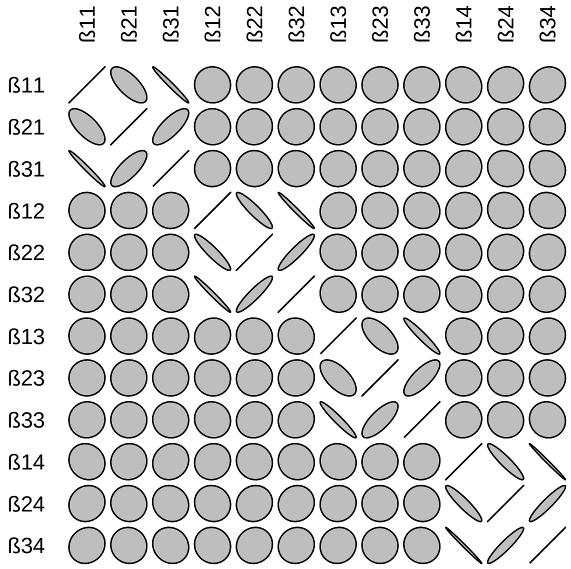
3 A real data example

The proposed methodology was applied to achievement data collected on students attending the third year of vocational high school in Italy. In particular, we used the mathematics test that was administered during the final exam. The sample is composed of 3843 students. Only multiple-choice items were included in the analysis. These were 14 items, all with four response options. All analyses were performed using the `R` software [7].

We started the analysis from ordinary (unpenalized) maximum likelihood estimation. Figure 1 visualizes the estimated correlation matrix among item parameter estimators for the first four items. The estimates were obtained with the `R` package `mirt` [2], and the `R` package `ellipse` [5] was used to obtain the plot.

The correlation matrix is nearly singular, since the estimated guessing parameter of each item $\widehat{\beta}_{3j}$ is negatively correlated with the estimated easiness parameter $\widehat{\beta}_{1j}$, and it is positively correlated with the estimated discrimination parameter $\widehat{\beta}_{2j}$. At times, such correlations are very high (in either direction), so that it is not surprising that parameter estimation may become cumbersome. Some sort of regularization is surely helpful.

Fig. 1 Estimated correlation matrix among item parameter estimators for the first four items.



The function mirt to fit an IRT model in the mirt package has an option parprior to introduce the penalty for the guessing parameters, which turned out to be very handy to apply the methodology endorsed here. The tuning parameters were selected by choosing among a set of candidate values. In particular, $F(\mu)$ was selected in the set $\{0.1, 0.15, 0.2, 0.25\}$, whereas for σ a set formed by 100 values between 0.2 and 5 was considered. The selection was performed by means of 10-fold cross-validation.

Fig. 2 Left: cross-validation error as a function of $1/\sigma$, for given μ. Right: estimates of guessing parameters, as a function of $1/\sigma$, for given μ.

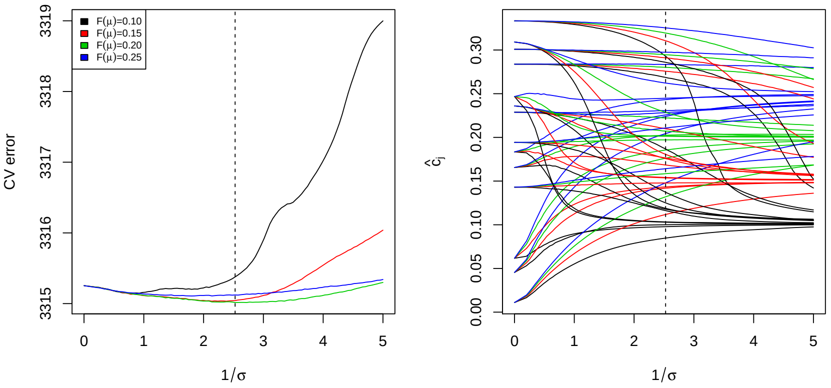


Figure 2 shows the results obtained for this data set. On the left panel of the figure, the cross-validation error is plotted against the reciprocal of σ. Thus, higher values on the x-axis correspond to larger amounts of shrinkage. The different colors refer to different values of $F(\mu)$. The vertical dashed lines indicate the point at which the cross-validation error is smallest. This corresponds to the values $\mu = F^{-1}(0.20)$ and $1/\sigma = 2.5$. The right panel of the figure shows the estimates of the guessing parameters at different levels of shrinkage. For all the values of μ, the smallest value of the cross-validation score is attained for σ values away from 0, pointing to the need of some shrinkage for the guessing parameters.

The estimation based on empirical Bayes has been carried out by means of the Template Model Builder (TMB) R package [9], which allows to define a C++ template used to estimate the random effects model of interest. The use of the package resulted in a rather efficient implementation, the key point being the explicit integration of the ability parameters within the C++ template by means of efficiently-coded Gaussian quadrature.

For the data set of interest, the empirical Bayes method provides estimated tuning parameters equal to $1/\widehat{\sigma} = 4.4$ and $\widehat{\mu} = F^{-1}(0.22)$, implying a higher amount of shrinkage for the guessing parameters with respect to cross validation. The estimates of the remaining item parameters were instead quite similar for the two penalized methods.

The overall message of this example is that, even for a large sample of subjects, the estimation of the guessing parameter is challenging, and penalized maximum likelihood estimation improves the inferential results. The need of some regularization may become more striking for smaller sample sizes, where numerical problems may hamper the estimation routines of IRT software.

4 A simulation study

A small-scale simulation study has been performed to assess the performance of the various methods. In particular, the focus was on a relatively small scale setting, with $n = 500$ subjects and $J = 30$ items. Two different choices for the guessing parameters were considered. In the first setting, we took all the c_j parameters as constant and equal to 0.2, whereas for the second setting we took as guessing parameters the estimates obtained from a large scale educational assessment, with values of c_j ranging between 0.04 and 0.33, with an average value of 0.16. The real data set was employed also to set the values for the other item parameters, for either setting.

Three different methods were considered, given by ordinary maximum likelihood estimation (MLE) as implemented in the `mirt` package, and the two penalized estimation methods with tuning parameters estimated by cross validation (CV) and empirical Bayes (EB), respectively. Table 1 and 2 summarize the result of 100 simulated datasets. In particular, the tables report the average over the three groups of parameters of Root Mean Squared Error (RMSE), the squared root of the average of squared bias (B), and the average of Median Absolute Error (MAE).

Table 1 Summary of simulation results for Setting 1 (equal guessing parameters).

Method	Easiness β_1			Discrimination β_2			Guessing c		
	RMSE	B	MAE	RMSE	B	MAE	RMSE	B	MAE
MLE	0.76	0.19	0.44	0.59	0.18	0.25	0.15	0.02	0.14
CV	0.23	0.03	0.14	0.26	0.03	0.15	0.04	0.01	0.01
EB	0.20	0.02	0.13	0.23	0.02	0.15	0.03	0.01	0.02

The tables points to some interesting results. First, the ordinary unpenalized estimation performs rather poorly in both settings, with unacceptably large variability for all the parameters, thus confirming that this method is essentially useless for datasets of this size. For Setting 1, the two penalized methods perform an excellent adjustment, with negligible bias and greatly reduced variability for all the parameters. This is the setting more relevant to the adopted penalty, so that the good performances are not surprising. For Setting 2, as expected, the two penal-

Table 2 Summary of simulation results for Setting 2 (different guessing parameters).

Method	Easiness β_1			Discrimination β_2			Guessing c		
	RMSE	B	MAE	RMSE	B	MAE	RMSE	B	MAE
MLE	0.70	0.21	0.37	0.53	0.18	0.23	0.14	0.04	0.10
CV	0.32	0.24	0.23	0.29	0.14	0.17	0.07	0.08	0.06
EB	0.30	0.28	0.25	0.24	0.16	0.17	0.08	0.07	0.07

ized methods perform less well, with bias similar to that of the MLE. At any rate, the two penalized estimators have overall better performances, and they represent a clear improvement over the MLE, with shrinkage offering a good level of protection against the large fluctuations affecting ordinary MLE. Finally, the differences between the two penalized methods are generally minor, though the method based on cross-validation seems to be slightly preferable in the most challenging setting.

5 Conclusion and ongoing research

This paper presents a procedure for the estimation of the 3PL model based on a penalized likelihood approach. The application shows that by penalizing the likelihood the error rate of prediction, assessed through cross-validation, is reduced. Even if IRT models are not usually fitted to predict new observations, the procedure can be viewed as a regularization method to obtain a model closer to the data generating process. The simulation study suggests that the penalized estimation represents a notable improvement over ordinary maximum likelihood when the guessing parameters are constant, while the improvement is less substantial when the guessing parameters exhibit large variation. A further finding is that the results obtained via cross validation are generally similar to those obtained by an empirical Bayes approach.

In the Bayesian literature [6], the prior for the guessing parameters is usually a distribution with mean equal to the reciprocal of the number of response options for the items. Despite this seems a sensible choice, the application of the proposed approach typically leads to the selection of a different value of the mean, a fact that seems worth mentioning.

The method introduced here is very practical, since it only requires the introduction of a simple penalty term in the ordinary log likelihood function for MML estimation of a 3PL model. More sophisticated approaches could be considered, such as model-based shrinkage aiming to reduce the bias of guessing parameter estimators [4]. Some investigation in this direction appears worth considering. The introduction of flexible assumptions for the ability parameters, which may be recommendable in some instances [11], appears instead more challenging.

It should be noted that this is a preliminary study. The use of regularization techniques for the estimation of the 3PL model is still under investigation by the authors. Future research will involve more extensive simulation studies to achieve a better understanding of the performance of the procedure, and the consideration of further regularization methods, targeting better inferential properties.

Statistical modelling and GAMLSS
Modellazione statistica attraverso i GAMLSS

Mikis D. Stasinopoulos and Robert A. Rigby and Fernanda De Bastiani

Abstract This paper reflects on the impact and future development of the generalized additive models for location scale and shape, GAMLSS. GAMLSS application is illustrated with an analysis of a real discrete data set.
Abstract *Questo lavoro discute le potenzialit attuali e future dei modelli GAMLSS (generalized additive models for location scale and shape) attraverso l'analisi di un dataset con risposta discreta e modellata attraverso un modello 'zero inflated beta negative binomial'.*

Key words: Beta negative binomial, Flexible.regression, Zero inflated beta negative binomial

1 Introduction

The generalized additive models for location scale and shape (GAMLSS) was introduced by [17]. It has been applied to a variety of different scientific fields including: actuarial science, [7], biology, [6], economics, [26], environment, [24], genomics, [10], finance, [9], [3], fisheries, food consumption, management science, [1], marine research, medicine, [18], meteorology, and vaccines. GAMLSS have also become standard for centile estimation, e.g. [25], [23], [15].

WHO, [27] and [28], use GAMLSS for centile estimation to produce growth charts for children. Their charts are used by more than 140 countries as the stan-

dard charts monitoring the growth of children. The Global Lung Function Initiative (GLFI), [http://www.lungfunction.org, [16]] use GAMLSS to provide a unified worldwide approach to monitoring lung function, by obtaining centiles for lung function based on age and height.

Section 2 discussed GAMLSS within the general framework of statical modelling. Section 3 defines GAMLSS and show one of its application. In the conclusions we discuss the future of GAMLSS.

2 What is GAMLSS

GAMLSS was built around the basic principals of statistical modelling which can be summarized as: i) all models are *wrong* but some are useful (attributed to Gorge Box); ii) statistical modelling is an *iterative* process where, after fitting an initial model, assumptions are checked, followed by refitting models until an appropriate model is found; iii) a simple model is preferable to a more complicated one if both explain the data adequately (*Occam's Razor*) and iv) "no matter how beautiful your theory, no matter how clever you are or what your name is, if the model disagrees with the data, it is wrong"[1].

GAMLSS, is a general framework for *univariate* regression where we assume that the response variable depends on many explanatory variables. This dependance can be linear, non-linear or smooth non-parametric. For example, in the classical linear regression model (LM) the mean of the response variable is a linear function of the explanatory variables. In the generalized linear models (GLM), [14], a monotonic function of the mean, called the linear predictor, is a linear function of the explanatory variables. Non linear relationships between the response variable and the explanatory variables, within both LM and GLM, are dealt with by using nonparametric smoothing functions, giving additive models (AM) and generalized additive models (GAM) respectively. The generalized additive models (GAM) introduced by [5] and popularized by [29], have made the smoothing techniques within a regression framework available to a wide range of practitioners.

GAMLSS is an extension of the LM, GLM and GAM and has two main features. Firstly, in GAMLSS the assumed distribution can be any parametric distribution. Secondly, all the parameters (not only the location e.g. the mean) of the distribution can be modelled as linear or smooth functions of the explanatory variables. As a result the shape of the distribution of the response variable is allowed to vary according to the values of the explanatory variables. The GAMLSS models are an example of a "Beyond Mean Regression" model, [11]. and because of their explicit distributional assumption the response variable they also also part of the "distributional regression" modelling approach, [2].

GAMLSS allows a variety of smooth functions of explanatory variables including the ones which employ a quadratic penalty in the likelihood. The basic ideas of

[1] paraphrasing Richard Feynman famous quote

GAMLSS, have been implemented in **R** in a series of packages, [19], where residual based diagnostics facilities are also provided.

3 The GAMLSS framework

The response variable observations $\mathbf{Y} = (Y_1, Y_2, \ldots, Y_n)$ are assumed independent with

$$\mathbf{Y} \sim D(\mu, \sigma, \nu, \tau) \tag{1}$$

where D is any (up to four distribution) distribution and where usually μ is the location parameter (e.g. the mean), σ is the scale parameter (e.g. the variance), ν and τ are the shape parameters (e.g. skewness and kurtosis). A GAMLSS model allows the modelling of all the parameters of the distribution as linear i.e. $\mathbf{X}_k \boldsymbol{\beta}_k$ or smooth term functions $s_{kj}(x_{kj})$, for example:

$$\begin{aligned}
g_1(\mu) &= \eta_1 = \mathbf{X}_1\beta_1 + \sum_{j=1}^{J_1} s_{1j}(\mathbf{x}_{1j}) \\
g_2(\sigma) &= \eta_2 = \mathbf{X}_2\beta_2 + \sum_{j=1}^{J_2} s_{2j}(\mathbf{x}_{2j}) \\
g_3(\sigma) &= \eta_3 = \mathbf{X}_3\beta_3 + \sum_{j=1}^{J_3} s_{3j}(\mathbf{x}_{3j}) \\
g_4(\sigma) &= \eta_4 = \mathbf{X}_4\beta_4 + \sum_{j=1}^{J_4} s_{4j}(\mathbf{x}_{4j})
\end{aligned} \tag{2}$$

where $\mathbf{X}_k$ is a known design matrix, $\beta_k = (\beta_{k1}, \ldots, \beta_{kJ'_k})^\top$ is a parameter vector of length J'_k, s_{kj} is a smooth nonparametric function of variable X_{kj} the $\mathbf{x}_{kj}$'s are vectors of length n, and $g_k(.)$ known monotonic link function relating a distribution parameter to a predictor η_k, for $k = 1, 2, 3, 4$ and $j = 1, \ldots, J_k$.

Stasinopoulos et al. [21] provide a variety of examples using GAMLSS. Here we use the example given by [20] pages 12-22. The data consists of 4406 observations, on the following variables: `visits`, number of physician office visits (the response variable), `hospital`, number of hospital stays, `health`, a factor indicating health status, `chronic`, number of chronic conditions, `gender`, a factor, `school`, number of years of education, `insurance`, a factor indicating whether the individual is covered by private insurance. The data are available from the **AER** package under the name NMES1988. There are more than 30 available discrete count distributions in the **gamlss** package. After a stepwise selection procedure the following model using a zero inflated beta negative binomial, *ZIBNB*, distribution was chosen:

$Y \sim \texttt{ZIBNB}(\hat{\mu}, \hat{\sigma}, \hat{\nu}, \hat{\tau})$,

$$\begin{aligned}
\log(\hat{\mu}) = {} & 0.980 + 0.382\sqrt{\text{hospital}} + 0.332\sqrt{\text{chronic}} \\
& +0.025\text{school} + 0.255(\text{if health=poor}) \\
& -0.313(\text{if health=excellent}) - 0.112(\text{if gender=male}) \\
& +0.123(\text{if insurance=yes}) \\
\log(\hat{\sigma}) = {} & -1.7026 - 0.208\sqrt{\text{chronic}} + 0.394(\text{if health=poor}) \\
& -0.345(\text{if health=excellent}) + 0.197(\text{if gender=male}) \\
\log(\hat{\nu}) = {} & -2.679 + 0.966\sqrt{\text{hospital}} \\
\log[\hat{\tau}/(1-\hat{\tau})] = {} & -1.077 - 0.744\sqrt{\text{chronic}} - 1.546(\text{if insurance=yes}),
\end{aligned} \tag{3}$$

Figure 1 shows the worm plot and the rootogram of the fitted final model both indicating the the fit is adequate except for the extreme right tail.

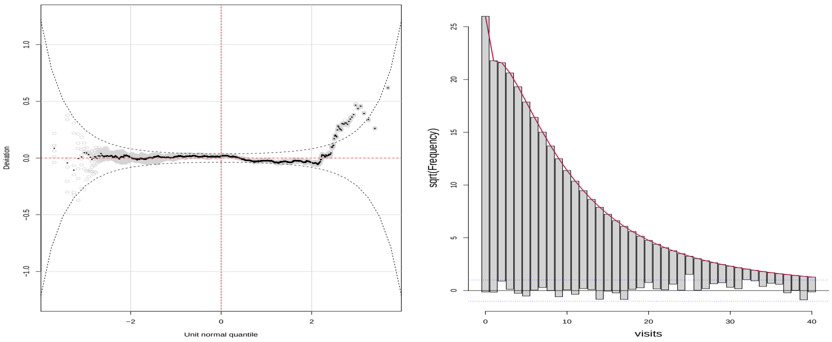

Fig. 1 Worm plot (a) and rootogram of the randomised quantile residuals for the final *ZIBNB* models. .

4 Conclusions

The GAMLSS models are especially useful for continuous response variables if they are negatively skew, highly positively skew, platykurtic, or leptokurtic. For discrete responses, if there exist over-dispersion or under-dispersion, excess or shortage of zero values and long tails. The GAMLSS models allows **any** parametric distribution for the response variable. The current implementation in the **gamlss** package in `R` allows the user to choose from more than 100 distributions with up to four parameters, allowing changes in modelling the location, the scale and shape of the distribution. A boosting and a Bayesian versions of GAMLSS exist in `R` packages , see [8, 13] and [22] respectively. There are alternative approaches to GAMLSS for quantile or centile estimation: for continuous response variable quantile regression, [12], can be used. In quantile regression there are less assumption than GAMLSS and for this reason more difficult to check the model. For mean (and variance) estimation the generalized estimation equation (GEE) [4] also can be used.

At this moment of time the following work is under way for the development and enhancement of GAMLSS:

- A second book on GAMLSS with the title "Distributions for Modelling Location, Scale and Shape: Using GAMLSS in R" is in its final draft.
- Robust methods of GAMLSS model are developed.
- Alternative model selection techniques are explored.
- Time series modelling techniques within GAMLSS are investigated.

The GAMLSS model provide a very general framework for regression type of modelling but it flexibility it is also its burden. More automated procedures would help its spread and its popularity

Young Contributions to Statistical Learning

Introducing spatio-temporal dependence in clustering: from a parametric to a nonparametric approach.

Introduzione di dipendenza spazio-temporale nel problema di clustering: da un approccio parametrico a un approccio non-parametrico

Clara Grazian, Gianluca Mastrantonio and Enrico Bibbona

Abstract A huge literature about clustering spatial time data exists. The problem has been studied both in a parametric and in a nonparametric setting. There are several problems in defining a proper clustering procedure, depending on the type of relationship between the clusters. From a parametric point of view, a classic approach is to introduce mixture models and studying the posterior distribution of the mixture weights. We propose a mixture model where the mixing probabilities are time specific and are assumed to follow a Logistic-Normal distribution. We introduce dependence between the vectors of mixing probabilities by means of a Gaussian processes representation. We briefly propose a nonparametric extension of this approach.
Abstract *Esiste un'estesa letteratura riguardante problemi di clustering temporale e spaziale. Il problema è stato studiato sia in ambito parametrico che nonparametrico. I problemi principali delle procedure di clustering spazio-temporali dipendono dal tipo di dipendenza tra i cluster stessi. Da un punto di vista parametrico, l'approccio classico è quello di assumere un modello mistura e studiare la distribuzione a posteriori dei pesi della mistura. In questo articolo proponiamo ancora un modello mistura dove i pesi dipendono dal tempo e dove si assume che seguano un modello logistico-normale. La dipendenza temporale tra i cluster è introdotta attraverso una rappresentazione in base a processi gaussiani. Nell'articolo proponiamo brevemente anche un'estensione nonparametrica dell'approccio.*

1 Introduction

There is more and more interest in spatial data, i.e. data where the response variable is measured at spatial locations or data where the response variable is defined as a set of spatial coordinates. This is due to the increased ability to store and collect this type of data.

A central problem in the analysis of spatial data is spatial clustering, which groups similar spatial objects into classes. Standard applications are the identification of land areas for usage purposes in agricultural sciences or weather patterns in environmental sciences. The goal of spatial clustering may be multiple, focusing on the study of the characteristics of each cluster and on a better understanding and description of the data and, ultimately, influencing policies in public health and environment. Due to its huge usefulness in applied sciences, spatial clustering has been a very active subject, with many contributions from different fields.

In this work, we will focus on the problem of modelling spatial coordinates (or transformation of them) and, in particular, clustering them through time. Direct applications of this may be seen in the modelling of wind directions [16], ocean streams [8], identification of three-dimensional protein structures [12] and animal movements [3].

The problem of clustering in this settings relates to the description of structural changes in the time series. For instance, it is generally assumed that the animal behaviour changes according to a natural cycle in the observational period, for example the resting/feeding cycle, or to out-of-ordinary situations, such as the assault of a predator or changement in human activities.

The joint distribution of the coordinates, or of an appropriate transformation of them, can be seen as a mixture process where the mixture components are the different behaviours or regimes. It is generally assumed that the switching between regimes is temporally structured [17], and sometime also spatially, as in [2], often ruled by a non-observed Markov process leading to the class of hidden Markov models (HMMs) [25].

In this paper, we propose a mixture-type model, as the hidden Markov model, but with a higher level of flexibility given by the assumption that the vector of probabilities is marginally distributed as a Logistic-Normal model (*LogitN*) [1] and the structured temporal dependence is induced via a coregionalization over a multivariate Gaussian process [10]. This is not the first proposal where a structured dependence is introduced over vectors *LogitN* distributed, however, as we will show, our proposal is more general since it focuses on the dependence structure of the probabilities vectors rather than that of the Gaussian process, as in [22] and [4].

The rest of the paper is organized as follows: Section 2 provides the notation and gives some preliminaries, Section 3 describes the proposed method; Section 4 focuses on a real application on data of animal movement. Section 5 concludes the paper.

2 Notation and preliminaries

Suppose the data are indexed by temporal indices $(t_1,\dots,t_T)' \equiv \mathscr{T}$, assuming that t_1 is the starting observational time and t_T the ending observational time, by allowing that $t_i - t_{i-1} = c_i$ which may vary depending on i.

Let, then, $\mathbf{s}_{t_i} = (s_{t_i,1}, s_{t_i,2})' \in \mathbb{R}^2$ be spatial location at time t_i with $\mathbf{s} = (\mathbf{s}_{t_1},\dots,\mathbf{s}_{t_T})'$.

A standard transformation considered when analysing spatial coordinates is looking at the projections of $\mathbf{s}_{t_i}$ on the x- and y- axes of the cartesian coordinates system centred on $\mathbf{s}_{t_{i-1}}$, say $\mathbf{r}_{t_i} = (r_{t_i,1}, r_{t_i,2}) \in \mathbb{R}^2$ and then defining

$$\mathbf{y}_{t_i} = \frac{\mathbf{r}_{t_i}}{d(t_{i+1},t_i)}.$$

The variable $\mathbf{y}_{t_i}$ contains all the sufficient information to recover the trajectory without loosing any significant property. In particular, the sign of $y_{t_i,1}$ provides information about the fact that the movement is on the same direction of the previous one, while the sign of $y_{t_i,2}$ indicates if it turns to the right or to the left. Moreover, $||\mathbf{y}_{t_i}||$ represents the step-length and $\theta_{t_i} = \text{atan2}(y_{t_i,2}, y_{t_i,1})$ the turning angle of the movement, respectively.

A standard clustering methodology is to introduce information indicating the cluster membership as a latent variable $\mathbf{z} = \{z_t\}_{t\in\mathscr{T}}$, with $z_t \in \{1,2,\dots,K\} \equiv \mathscr{K}$, and K the total number of clusters.

The data are assumed to come from a mixture-type model based on bivariate Gaussian densities:

$$f(\mathbf{y}|\mathbf{z}\{\xi_k,\Omega_k\}) = \prod_{t\in\mathscr{T}} f(\mathbf{y}_t|\xi_{z_t},\Omega_{z_t})$$

where

$$\mathbf{y}_t|\xi_{z_t},\Omega_{z_t} \sim N_2(\xi_{z_t},\Omega_{z_t})$$

i.e. given the latent variables $\mathbf{z}_t$, the observations $\mathbf{y}_t$ are independent. The hidden Markov models (HMMs) [5] assume the latent variables follow the Markov rule

$$\Pr(z_{t_i} \mid z_{t_1},\cdots,z_{t_{i-1}}) = \Pr(z_{t_i} \mid z_{t_{i-1}})$$

and, in particular,

$$z_{t_i}|z_{t_{i-1}},\{\pi_{k,k'}\}_{k,k'\in\mathscr{K}} \sim \sum_{k\in\mathscr{K}} \pi_{z_{t_{i-1}},k}\delta_k.$$

Although HMMs are widely used ans easy to implement, the Markov structure may be too restrictive. For instance, the assumption that the probabilities of switching cluster is fixed and independent from time is difficult to accept in all the contexts. In some works, see for example [19], [17], [13] and [11], problems like these are tackled using covariates that model probabilities, but not always these are available and may not be enough for describing the complexity of reality. [18] proposes a mixture model where the latent spatial process is allowed to evolve dynamically over time.

We proposed to consider a more complex model where the mixing probabilities follow a *LogitN* model; this has been proposed by [1] as a distribution for independent compositional data, i.e. vectors of positive proportions with a constant sum. Beyond the obvious fact that it can model data which are positive and less than a constant, the constant-sum constraint induces some more insidious characteristics which will be described in the next Section.

3 The model

We propose to introduce a dependence on time of the vector of probabilities, instead of using a HMM

$$z_t|\pi_t \sim \sum_{k=1}^{K} \pi_{t,k}\delta_k,$$

where $0 \leq \pi_{t,k} \leq 1$, $\sum_{k=1}^{K} \pi_{t,k} = 1$. The probability vector π_t is then defined with the logistic transformation of real valued variables

$$\pi_{t,k} = \frac{e^{\omega_{t,k}}}{1+\sum_{j=1}^{K} e^{\omega_{t,j}}}, k = 1,\dots,K \tag{1}$$

with the last element defined as

$$\pi_{t,K} = \frac{1}{1+\sum_{j=1}^{K-1} e^{\omega_{t,j}}}.$$

It has to be noticed that adding a constant c to each $\omega_{t,k}$ produces the same vector of probabilities, and then an identifiability constraint is needed; without loss of generality, we set to zero the K^{th}.

In this way, it is possible to model the latent variable ω_t. In particular, we propose to define it as

$$\omega_t = (\mathbf{I}_{K-1} \otimes \mathbf{X}_t)\beta + \mathbf{A}\eta_t \tag{2}$$

where $\mathbf{I}_d$ is the identity matrix of dimension $d \times d$, $\mathbf{X}_t$ is a set of p covariates changing over time and β the corresponding coefficients such that each $\omega_{t,k}$ shares the same set of covariates but different coefficient β. $\mathbf{A}$ is the term introducing dependence among the vectors $\omega_{.,k} = \{\omega_{t,k}\}_{t\in\mathscr{T}}$, while η_t is the error term such that it is defined as a Gaussian process, i.e. $\eta_{.k} \sim GP(\mathbf{0}, C_k(\cdot;\psi_k))$ where C_k models the structured dependence. Consequently, the covariance between ω_t and $\omega_{t'}$ is given by $\Sigma_{t,t'} = \mathbf{A}\mathbf{C}_{\eta,|t-t'|}\mathbf{A}'$.

We say that marginally the vector of probabilities π_t follows a logit-normal model [1], i.e. $\pi_t \sim LogitN(\mu_t, \Sigma)$, where $\mu_t = (\mathbf{I}_{K-1} \otimes \mathbf{X}_t)\beta$ and $\Sigma = \mathbf{A}\mathbf{A}'$.

The nature of a compositional vector, in particular its property to sum to a constant term, implies a lack of interpretability since the correlations are not completely free to vary in $(-1,1)$. We propose a different parametrisation to deal with this problem.

Instead of modelling ω_t, we propose to introduce another variable

$$\gamma_t = (\mathbf{I}_K \otimes \mathbf{X}_t)\beta + \mathbf{A}^* \eta_t$$

in similar way than ω_t, with the difference that all the K variables are defined, i.e. $\mathbf{I}_K$ is the identity matrix of dimension $K \times K$, $\mathbf{A}$ is a $K \times K$ matrix introducing dependence among the $\gamma_{.,k} = \{\gamma_{t,k}\}_{t \in \mathscr{T}}$ while η_t is the error term such that $\eta_{.k} \sim GP(\mathbf{0}, C_k^*(\cdot;\psi_k^*))$. Then, γ_t has covariance matrix given by

$$\Sigma^* = \mathbf{A}^*(\mathbf{A}^*)'.$$

Therefore, it is possible to define a different vector of probabilities with elements

$$\pi_{t,k}^* = \frac{\exp(\gamma_{t,k})}{\sum_{j=1}^{K} \exp(\gamma_{t,j})}.$$

It is evident, however, that the model is not identifiable. Notice that π_t^* follows a marginal distribution different from π_t, with a different temporal dependence.

However, if we let

$$\omega_{t,k} \coloneqq \gamma_{t,k} - \gamma_{t,K}$$

we create a link between the two parametrizations that induces

$$\mathbf{A} = [\mathbf{A}^*]_{1:(K-1),1:K} - [\mathbf{A}^*]_{K,1:K},$$

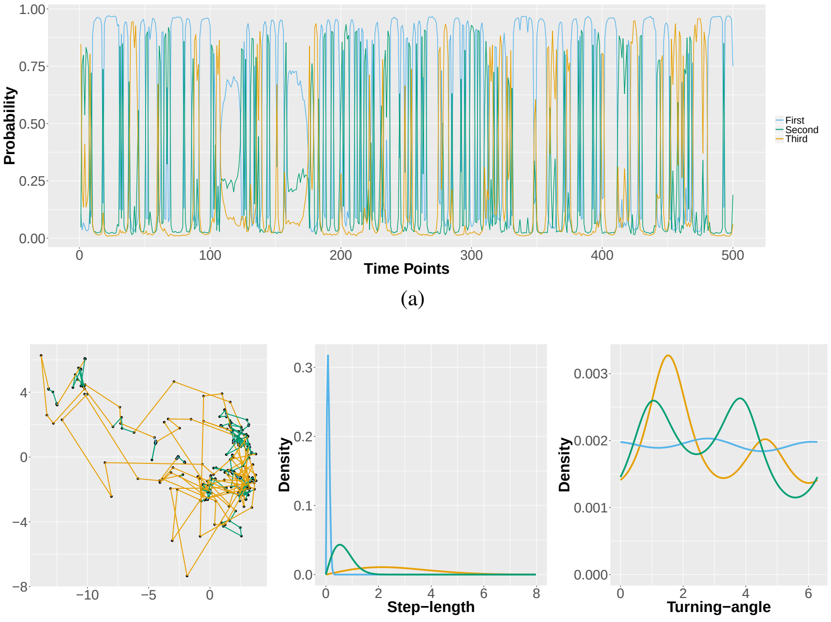
and, consequently,

$$[\Sigma^*]_{1:(K-1),1:(K-1)} + \mathbf{1}_{K-1}[\Sigma^*]_{K,K}\mathbf{1}'_{K-1} - [\Sigma^*]_{1:(K-1),K}\mathbf{1}'_{K-1} - \mathbf{1}_{K-1}[\Sigma^*]'_{1:(K-1),K}.$$

Given this link, it follows that $\pi_{t,k} = \pi_{t,k}^*$ for any $k = 1,\cdots,K$ and $t = 1,\cdots,T$, with the advantage to be able to define a covariance structure on the variables γ_t which induces the desired covariance structure on the corresponding π_t.

There are several interesting issues to highlight at this point. First, our proposed model given in (2) generalizes most of the models available in the literature where transformations as in (1) are used to define probabilities vectors. For instance, the proposal of [15] is obtained by assuming $\eta_t \equiv \mathbf{0}_{K-1}$. The model of [18] is obtained letting η_t be a spatio-temporal process with autoregressive temporal increments and a diagonal $\mathbf{A}$. We can also reduce to the proposals of [24], [14] and [21]. On the other hand, models using the cokriging, such as the ones of [20], can not be expressed with our formulation. However, one may notice that the complexity of our approach is reduced with respect to the cokriging.

Secondly, computational issues often arise for models based on Gaussian processes. We make use of the approach proposed by [7], i.e. a scalable nearest-



(a)

(b) (c) (d)

Fig. 1: Real data: (a) probabilities time series; (b) observed trajectory; (c) posterior estimates of step-length; (d) posterior estimates of turning-angle

neighbour Gaussian process (NNGP) which may be seen as a hierarchical sparse prior and allows for efficient MCMC algorithms to be performed without storing or decomposing large covariance matrices. While [7] empirically shows that 25 neighbours are needed to obtain an approximation close to the complete model, the temporal nature of the data analysed in this paper allow us to use just one neighbour, with a even highest level of saving of computational time.

4 Real Data

Data on 6 free-ranging Maremma sheepdogs positions are recorded by tracking collars every 30 minutes. The behaviour of the dogs is unknown because there is minimal supervision by their owners and the animals are allowed to range freely.

We select a time series of 500 points of one dog and characterize the hidden behaviours using the model proposed above; in Figure 1 (b) we show the observed trajectories, i.e. the observed coordinates.

We estimate model with values of K in $[2,3,\dots,10]$ and, using DIC_5 [6], we select the best model as the one with three components. The three behaviours can be easily characterized looking at the distribution of step-length and turning-angle, Figure 1 (b) and (c). In the first behaviour, the dog has low speed and the distribution of the angle is almost circular uniform, i.e. it moves randomly. In the second one, the speed increases and the direction has two modes with same height, one at $\pi/2$ and one at $3\pi/2$, meaning that it changes direction clockwise and anticlockwise with the same probability. In the last one, the speed is high and it changes direction mainly anticlockwise. From Figure 1 (a) we can see the temporal series of the probabilities and we appreciate that behaviour one is the one that has more temporal stabilities, i.e. it has high values for a long time-period. In Figure 1 (b) we see where the behaviours are spatially localized. The third one occurs in all spatial domain, while the other two behaviours are on the top left (where the house of the owner is localized) and the right part of the map (where there is the livestock).

5 Conclusion

In this work, we propose a model to perform clustering for spatial data, based on a new parametrization of the logit-normal process, with parameters allowing an easier interpretability.

However, the possibility to use this model derives from the knowledge of the exact number of clusters. The nonparametric extension of a mixture model is the Dirichlet process (DP) [9], a stochastic process defined over a measurable space whose random paths are probability measures with probability one. The hierarchical Dirichlet process (HDP), proposed by [23], is an extension of the DP that makes possible to have processes sharing the same set of atoms. In the original construction of the HDP the random vectors $\pi_{j.}$ and $\pi_{k.}$ for any $j \neq k$ are independent. The nonparametric extension of the work proposed in this paper, which will be the subject of further research, focuses on how to introduce dependence in hierarchical Dirichlet processes.

Bayesian inference for hidden Markov models via duality and approximate filtering distributions

Inferenza bayesiana per modelli di Markov nascosti via dualità e filtraggio approssimato

Guillaume Kon Kam King, Omiros Papaspiliopoulos and Matteo Ruggiero

Abstract Filtering hidden Markov models is analytically tractable only for a handful of models (e.g. Baum-Welch and Kalman filters). Recently, Papaspiliopoulos & Ruggiero (2014) proposed another analytical approach exploiting a duality relation between the hidden process and an auxiliary process, called dual and related to the time reversal of the former. With this approach, the filtering distributions are obtained as a recursive series of finite mixtures. Here, we study the computational effort required to implement this strategy in the case of two hidden Markov models, the Cox-Ingersoll-Ross process and the K-dimensional Wright-Fisher process, and examine several natural and very efficient approximation strategies.

Abstract *Il filtraggio dei modelli di Markov nascosti è un problema trattabile analiticamente solo per un numero limitato di modelli (p.es. i filtri di Baum-Welch e Kalman). Papaspiliopoulos & Ruggiero (2014) hanno proposto un nuovo approccio che sfrutta una relazione di dualità tra il processo nascosto ed un processo ausiliario, detto duale e legato alla reversibilità del segnale. Con questo approccio la soluzione del problema di filtraggio assume la forma di una mistura finita valutata mediante una ricorsione. Qui studieremo il costo computazionale richiesto per implementare tale strategia nel caso di due modelli di Markov nascosti, i cui segnali evolvono come un processo di Cox-Ingersoll-Ross e come una diffusione K-dimensionale di Wright-Fisher; analizzeremo diverse strategie di approssimazione.*

Key words: Optimal filtering, duality, Wright-Fisher, hidden Markov models

1 Introduction to optimal filtering using a dual process

Consider a hidden stochastic process and some noisy observations of this process. As new data arrives, obtaining the distribution for the last hidden state given all the values observed previously is called filtering the hidden process. Let the series $\{Y_k, 0 \geq k \geq n\}$ be the sequence of observations, denoted $Y_{0:n}$ for $Y \in \mathscr{Y}$, and let the Markov chain $\{X_k, 0 \geq k \geq n\}$, similarly denoted $X_{0:n}$, be the unobserved stochastic process. We assume $X_{0:n}$ to be the discrete-time sampling of a homogeneous continuous-time Markov process X_t. We also assume that X_t has state-space $\mathscr{X}$, transition kernel $P_t(x, dx')$ and initial distribution $\nu(\mathrm{d}x)$. The observations relate to the hidden signal by means of conditional distributions assumed to be given by the kernel $F(x, \mathrm{d}y)$ and we let $F(x, \mathrm{d}y) = f_x(y)\mu(\mathrm{d}y)$ for some measure $\mu(\mathrm{d}y)$. The filtering distributions, which are the target of inference, are $\mathscr{L}(X_n|Y_{0:n})$, denoted $\nu_n(\mathrm{d}x)$. Define now an update and prediction operator acting on probability measures ν:

$$\text{update:} \qquad \phi_y(\nu)(\mathrm{d}x) = \frac{f_x(y)\nu(\mathrm{d}x)}{p_\nu(y)}, \qquad \text{with } p_\nu(y) = \int_\chi f_x(y)\nu(\mathrm{d}x) \quad (1)$$

$$\text{prediction:} \qquad \psi_t(\nu)(\mathrm{d}x') = \int_\chi \nu(\mathrm{d}x)P_t(x, \mathrm{d}x') \quad (2)$$

Then, the filtering distributions can be obtained by repeated applications of the update and prediction operators, as the recursion: $\nu_0 = \phi_{Y_0}(\nu)$ and $\forall n > 0, \nu_n = \phi_{Y_n}(\psi_{t_n - t_{t-1}}(\nu_{n-1}))$ (see for instance [1]). An explicit solution to the filtering problem is seldom available, except in two notorious cases: unobserved Markov chains with a discrete state-space, and Gaussian unobserved Markov chains with Gaussian conditional distribution. [2] extended the class of models for which an explicit solution is available by exploiting a duality relation between the unobserved Markov chain and a pure death stochastic process. In order to describe this, assume that Θ_t is a deterministic process and that $r : \Theta \to \Theta$ is such that the differential equation: $\mathrm{d}\Theta_t/\mathrm{d}t = r(\Theta_t)$ with $\Theta_0 = \theta_0$ has a unique solution for all θ_0. Let $\lambda : \mathbb{Z}_+ \to \mathbb{R}_+$ be an increasing function, $\rho : \Theta \to \mathbb{R}_+$ be a continuous function, and consider a two-component Markov process (M_t, Θ_t) with state-space $\mathscr{M} \times \Theta$, where Θ_t evolves autonomously according to the previous differential equation, and when at $(M_t, \Theta_t) = (\mathbf{m}, \theta)$, the process jumps down to state $(\mathbf{m} - \mathbf{e}_j, \theta)$ with instantaneous rate $\lambda(|\mathbf{m}|)\rho(\theta)m_j$. We say that (M_t, Θ_t) is *dual* to X_t with respect to a family of functions h, e.g.

$$\mathbb{E}^x\left[h(X_t, \mathbf{m}, \theta)\right] = \mathbb{E}^{\mathbf{m},\theta}\left[h(x, M_t, \Theta_t)\right], \quad \forall x \in \chi, \mathbf{m} \in \mathscr{M}, \theta \in \Theta, t \geq 0.$$

where $\mathbb{E}^x\left[f(X_t)\right] = \mathbb{E}\left[f(X_t)|X_0 = x\right] = \int_\chi f(x')P_t(x, \mathrm{d}x')$ and the duality functions are such that $h : \chi \times \mathscr{M} \times \Theta \to \mathbb{R}_+$, $\Theta \subseteq \mathbb{R}^l$. The dual process (M_t, Θ_t) is separated into a deterministic component Θ_t and a pure death process M_t, whose rates are subordinated to the deterministic process. The transition probabilities of the dual process are denoted $p_{\mathbf{m},\mathbf{n}}(t,\theta) = \mathbb{P}\left[M_t = \mathbf{n} | M_0 = \mathbf{m}, \Theta_0 = \theta\right], \forall\, \mathbf{n}, \mathbf{m} \in \mathscr{M}^2, \mathbf{n} \leq \mathbf{m}$. The duality property is key to the computability of the filters, as it allows to replace the expectation with respect to realisations of the original stochastic process in the prediction operation (Eq. (2)) by an expectation over realisations of the pure death component of the dual process, which involves finite sums.

The transition probabilities can be found by exploiting the duality relation ([2]):

$$p_{\mathbf{m},\mathbf{m}-\mathbf{i}}(t,\theta) = \gamma_{|\mathbf{m}|,|\mathbf{i}|} C_{|\mathbf{m}|,|\mathbf{m}|-|\mathbf{i}|}(t) p(\mathbf{i}; \mathbf{m}, |\mathbf{i}|) \tag{3}$$

with:

$$\gamma_{|\mathbf{m}|,|\mathbf{i}|} = \left(\prod_{h=0}^{|\mathbf{i}|-1} \lambda_{|\mathbf{m}|-h} \right), \text{ and } C_{|\mathbf{m}|,|\mathbf{m}|-|\mathbf{i}|}(t) = (-1)^{|\mathbf{i}|} \sum_{k=0}^{|\mathbf{i}|} \frac{e^{-\lambda_{|\mathbf{m}|-k} t}}{\prod_{0 \leq h \leq |\mathbf{i}|, h \neq k} (\lambda_{|\mathbf{m}|-k} - \lambda_{|\mathbf{m}|-h})} \tag{4}$$

and $p(\mathbf{i}; \mathbf{m}, |\mathbf{i}|)$ is the hypergeometric probability mass function.

We also define the following notion of *conjugacy*, by assuming that $\mathscr{F}_0 = \{h(x,\mathbf{m},\theta)\pi(\mathrm{d}x), \mathbf{m} \in \mathscr{M}, \theta \in \Theta\}$ is a family of probability measures such that there exist functions $t : \mathscr{Y} \times \mathscr{M} \to \mathscr{M}$ and $T : \mathscr{Y} \times \Theta \to \Theta$ with $\mathbf{m} \to t(y,\mathbf{m})$ increasing and such that $\phi_y(h(x,\mathbf{m},\theta)\pi(\mathrm{d}x)) = h(x, t(y,\mathbf{m}), T(y,\theta))\pi(\mathrm{d}x)$. The filtering algorithm proposed in [2] can be summarised by the two following relations. For the family of finite mixtures $\bar{\mathscr{F}}$ $\{\sum_{\mathbf{m}\in\Lambda} w_{\mathbf{m}} h(x,\mathbf{m},\theta)\pi(\mathrm{d}x) : \Lambda \subset \mathscr{M}, |\Lambda| < \infty$, $\sum_{\mathbf{m}\in\Lambda} w_{\mathbf{m}} = 1\}$, the update operation acts as:

$$\phi_y \left(\sum_{\mathbf{m}\in\Lambda} w_{\mathbf{m}} h(x,\mathbf{m},\theta)\pi(\mathrm{d}x) \right) = \sum_{\mathbf{n}\in t(y,\Lambda)} \hat{w}_{\mathbf{m}} h\left(x, \mathbf{n}, T(y,\theta)\right) \pi(\mathrm{d}x) \tag{5}$$

with $t(y,\Lambda) = \{\mathbf{n} : \mathbf{n} = t(y,\mathbf{m}), \mathbf{m} \in \Lambda\}$, and $\hat{w}_{\mathbf{m}} \propto w_{\mathbf{m}}$ and for $\mathbf{n} = t(y,\mathbf{m})$, $\sum_{\mathbf{n}\in t(y,\Lambda)} \hat{w}_{\mathbf{n}} = 1$. This updates the signal given the new data by means of the Bayes theorem. The prediction operation acts as:

$$\psi_t \left(\sum_{\mathbf{m}\in\Lambda} w_{\mathbf{m}} h(x,\mathbf{m},\theta)\pi(\mathrm{d}x) \right) = \sum_{\mathbf{n}\in G(\Lambda)} \left(\sum_{\mathbf{m}\in\Lambda, \mathbf{m}\geq\mathbf{n}} w_{\mathbf{m}} p_{\mathbf{m},\mathbf{n}}(t,\theta) \right) h\left(x, \mathbf{n}, \theta_t\right) \pi(\mathrm{d}x) \tag{6}$$

where $G(\Lambda) = \{\mathbf{n} \in \mathscr{M} : \mathbf{n} \leq \mathbf{m}, \mathbf{m} \in \Lambda\}$, propagating the current filtering distribution by means of the signal transition kernel. As such, filtering a hidden Markov model using the duality relation consists in recursive operations on finite mixtures of distributions, where the number of components remains finite and the components remain within the same family of distributions. At each new observation, the mixture distribution is shifted towards the data, then until the next observation, the mixture progressively forgets the past information and drifts back towards the prior distribution.

2 Implementation of the dual filtering algorithm

The filtering algorithm resulting from the method presented above is similar to the Baum-Welch filter and it alternates update and prediction steps. The update step shifts each component and modifies its weight, while the prediction step lets all the components propagate some of their mass towards the components close to the prior. We illustrate this dual filtering algorithm (Eq. (1)) for two stochastic processes: the Cox-Ingersoll-Ross (CIR) process and the Wright-Fisher (WF), presented in full details later. For these two models, the number of mixture components in the filtering distributions evolves as $|\Lambda_n| = \prod_{i=1}^{K}(m_{0,i} + 1 + \sum_{i=1}^{n} Y_i)$, where K is the dimension of the latent space and $\mathbf{m}_0 = m_{0,1:K}$ is the initial state.

The prediction step is much costlier than the update step, as at each iteration it involves computing the transitions from all elements of Λ_i to those reachable by a pure death process in $G(\Lambda_i)$. It is possible to contain the cost of the prediction operation by storing the transition terms $p_{\mathbf{m},\mathbf{n}}$, which will be used multiple times during the successive iterations. However, the rapid growth in the number of those terms (proportional to $|G(\Lambda_n)|^2$) does not permit saving all of them in memory. Yet, the $p_{\mathbf{m},\mathbf{n}}$ are themselves a product of a number of terms which grows only quadratically with the sum of all observations and can be saved (Eq. (4) and the hypergeometric coefficients expressed as a product of binomials coefficients). Another technical difficulty is that the sum with terms of alternated sign in (4) is susceptible to both over and underflow. We compute it using the `Nemo` library for arbitrary precision computation ([3]).

Although considerable efficiency gains are achieved by storing the transition terms, further improvements may be obtained by a natural approximation of the filtering distributions. Indeed, the filtering distributions contain a number of components that grows quickly as new observations arrive, but the complexity of the hidden signal does not necessarily increase accordingly. Hence, if the prior is reasonable and the posteriors appropriately concentrated, there is no reason for the number of components with non negligible weight to explode. Indeed, simulation studies show that the number of components representing 99% of the weight of the mixture saturates as new observations arrive (Eq. (2)). This suggests that some components may be deleted from the mixtures, speeding the computations, without loosing much in terms of precision. We envision three strategies for pruning the mixtures:

- prune all the components who have a weight below a certain threshold, which is an attempt at controlling the approximation error at a given step. This approach will be referred to as the *fixed threshold strategy*.
- retain only a given number of components, hopefully chosen above the saturation number (see Eq. (2)). This is an attempt at controlling the computation budget at each time step. This approach will be referred to as the *fixed number strategy*.
- retain all the largest components needed to reach a certain amount of mass, for instance 99%. This is an adaptive strategy to keep the smallest possible

number of components under a certain error tolerance level. This approach will be referred to as the *fixed fraction strategy*.

In Algorithm 1, the pruning is performed just after the update step. This choice is dictated by two reasons: first, after the update step the mixture should be more concentrated because information from the new observation was just incorporated, leading to a smaller number of components with non negligible weight. Then, as the prediction step is the most computationally expensive, reducing the number of components before predicting entails the maximum computational gain. After pruning, we renormalise all the remaining weights so that they sum to 1. As the pruning operation occurs at each time step, the level of approximation on a given filtering distribution results from several successive approximations.

Algorithm 1: Optimal filtering algorithm using the dual process, with the option of pruning.

3 Filtering two stochastic processes

For illustration we consider two stochastic processes, a 1-dimensional Cox-Ingersoll-Ross process and a 3-dimensional Wright-Fisher process, which we filter using the strategy outlined above. The dimension of the state space of the pure death process is dependent on the dimension of the signal, therefore the number of components in the filtering distributions for the WF process is much greater than for the CIR process, rendering the inference computationally more challenging. The one-dimensional CIR process has the following generator: $\mathscr{A} = (\delta\sigma^2 - 2\gamma x)\frac{d}{dx} + 2\sigma^2 x\frac{d^2}{dx^2}$. with $\delta, \gamma, \sigma > 0$ and stationary distribution $\mathrm{Ga}(\delta/2, \gamma/\sigma^2)$. A conjugate emission density is: $Y_t|X_t \sim \mathrm{Po}(X_t)$. The duality function can be found in [2]. We simulate a CIR process starting from $X = 3$ with $\delta = 3.6$, $\gamma = 2.08$, $\sigma = 2.8$. which corresponds to a stationary distribution $\mathrm{Gamma}(1.8, 0.38)$. Furthermore, we simulate 10 observations at each time, with 200 time steps separated by 0.011 seconds. For the inference, we use as a prior for the stationary distribution a $\mathrm{Gamma}(1.5, 0.15625)$ which corresponds to $\gamma = 2.5$, $\delta = 3.$, $\sigma = 4.$ and $m_0 = 0$.

The Wright-Fisher model is a K-dimensional diffusion, whose generator is $\mathscr{A} = \frac{1}{2}\sum_{i=1}^{K}(\alpha_i - |\alpha|x_j)\frac{\partial}{\partial x_i} + \frac{1}{2}\sum_{i,j=1}^{K} x_i(\delta_{ij} - x_j)\frac{\partial^2}{\partial x_i \partial x_j}$. and its stationary distribution is a Dirichlet(α). A conjugate emission density is: $f_x(Y) = \prod_{i=1}^{J}\left(|\mathbf{n}_i|!\prod_{k=1}^{K}\frac{x_k^{n_{ki}}}{n_{ki}!}\right)$. The duality function can also be found in [2]. We simulate two datasets using a discrete time and finite population Wright-Fisher model of dimension $K = 3$ initialised at random from a Dirichlet(0.3, 0.3, 0.3) with $\alpha = (0.75, 0.75, 0.75)$ and a population size of 50000. 15 observations are collected at each observation time. There are 10 observation times with a time step of 0.1 second for the first dataset and 20 observation times with a time step of 0.004 second for the second dataset. As a prior, we use a uniform distribution Dirichlet(1,1,1). The two different time steps for the WF model are intended to explore two regimes, one for which the time between observations is large, such that information from previous data is almost forgotten (the predictive distribution has almost moved back to the prior) and one for which that time is very short. In these two regimes, the number of components with non negligible weights is expected to be very different. Notably, in the second regime the impact of the successive approximations is expected to be stronger. Fig. 1 shows that in all the studied cases, the filtering distributions are centred around the signal. For the WF model with the short time step, the filtering distributions do not evolve fast enough to follow the signal exactly, but this is to be expected given the rapid rate at which new observations arrive. Considering how the weights are distributed among the components of the filtering distribution, we observe that the mass is mostly concentrated on a number of components several orders of magnitude smaller than the total number of components. This observation suggests that many components may be deleted with a minimal loss of precision.

To quantify this loss of precision by pruning, we compute the Hellinger distance between the exact and the approximate filtering distributions obtained by pruning: $d_H(f_1, f_2) = \frac{1}{2}\int_{\chi}(\sqrt{f_1} - \sqrt{f_2})^2$. As there is one filtering distribution per observation time, to compare two sets of filtering distributions we consider the maximum over time of the distance between the distributions at each time, i.e. $\sup_n(d_H(\nu_{n,\mathrm{exact}}, \nu_{n,\mathrm{approx}}))$. The numerical evaluation of the distances is done using standard quadrature and simplicial cubature rules from the R package `SimplicialCubature`. Parallel to the loss of precision due to the approximation, we consider the gain in efficiency by measuring the computing time needed

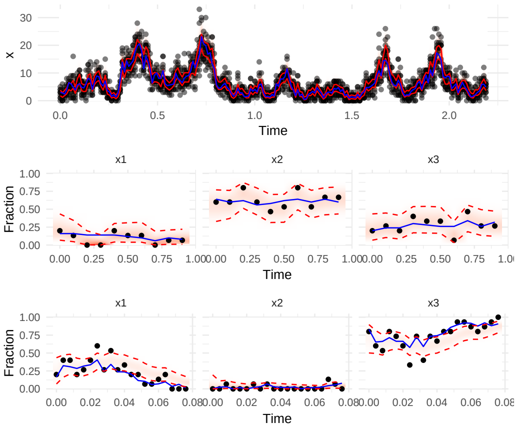

Fig. 1: Hidden signal, data and 95% credible intervals of the filtering distribution for the three datasets. The hidden signal is denoted by the blue line, the data by the black dots and the credible bands by the red dashed lines. Top: CIR, centre: WF, bottom: WF with short time step. For the WF model, each panel corresponds to one marginal, and the data plotted is the proportion of the 15 multinomial observations which are from the corresponding type.

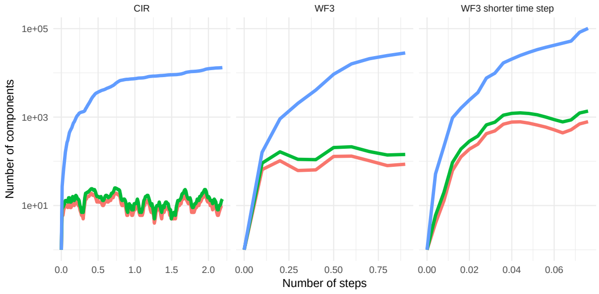

Fig. 2: Number of components (in log scale) in the filtering distributions as a function of the iteration number. Left: CIR, centre: WF, right: WF with short time step. The blue line denotes the total number of components in the filtering distributions, the green line denotes the number of components carrying 99% of the mass and the red 95%.

to filter the whole dataset. Fig. 3 shows that the approximation strategies afford a reduction in computing time by 5 orders of magnitude for the CIR process, or by 2 to 3 orders of magnitude for the three-dimensional WF process. The fixed fraction strategy is noticeably slower in the case of the WF process with the shorter time step because the mass is spread over more components, as was also apparent on Fig. 2. For all strategies and all processes, it seems possible to find a compromise between accuracy and computing time where increasing the computational effort starts yielding diminishing returns. Except in the case of the CIR model where the fixed threshold strategy seems to slightly outperform the others, no strategy seems to offer a fundamentally better precision/cost ratio than the others.

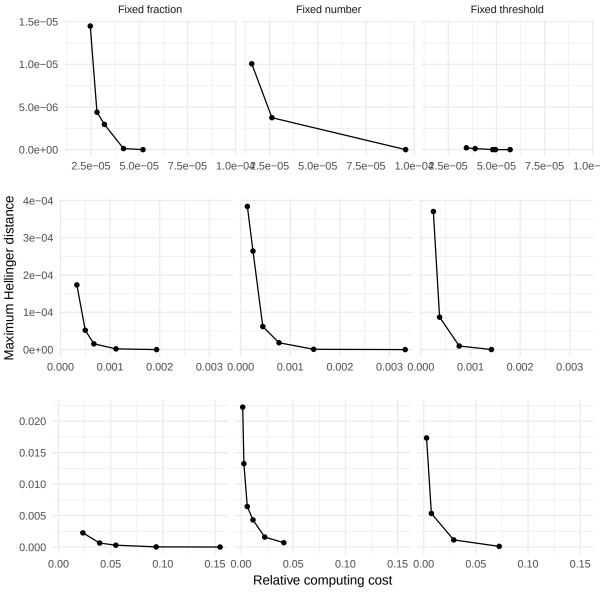

Fig. 3: Approximation error versus computational effort. The computation time is given relative to the time needed for obtaining the exact filtering distributions. The top level represents the CIR process, the middle represents the WF process and the bottom represents the WF process with the shorter time step. Fixed fractions tested are 0.8, 0.9, 0.95, 0.99, 0.999. The fixed numbers tested are 5, 10, 25 for the CIR process, 10, 25, 50, 100, 200, 400 for the WF processes. The fixed thresholds are 0.01, 0.005, 0.001, 0.0005, 0.0001 for the CIR orocess and 0.01, 0.005, 0.001, 0.0001 for the WF processes.

The results presented here are a preliminary study on the computational costs of filtering strategies based on duality. A more thorough investigation of these and other aspects involved in this type of filtering are currently ongoing work.

K-means seeding via MUS algorithm

Inizializzazione del K-means tramite l'algoritmo MUS

Leonardo Egidi, Roberta Pappadà, Francesco Pauli, Nicola Torelli

Abstract K-means algorithm is one of the most popular procedures in data clustering. Despite its large use, one major criticism is the impact of the initial seeding on the final solution. We propose a modification of the K-means algorithm, based on a suitable choice of the initial centers. Similarly to clustering ensemble methods, our approach takes advantage of the information contained in a co-association matrix. Such matrix is given as input for the MUS algorithm that allows to define a pivot-based initialization step. Preliminary results concerning the comparison with the classical approach are discussed.

Abstract *L'algoritmo K-medie è una delle procedure di raggruppamento più utilizzate. Tuttavia, una delle maggiori criticità di tale metodo riguarda l'impatto della scelta dei semi iniziali sulla configurazione finale. In questo lavoro viene proposta una variante del K-medie basata su una scelta opportuna dei semi iniziali. In linea con i cosiddetti 'metodi di insieme', l'approccio considerato sfrutta l'informazione contenuta in una matrice di co-associazione. Tale matrice viene utilizzata dall'algoritmo MUS per definire i semi iniziali dei gruppi sulla base di unità pivotali. Vengono discussi alcuni risultati preliminari riguardanti il confronto con l'approccio classico.*

1 Introduction

The goal of cluster analysis is to group a given collection of objects in such a way that instances in the same cluster are as similar as possible, according to a suitable "similarity" criterion (see, e.g., [5]). One of the most popular and widely used clustering techniques is K-means algorithm (see [7] and the references therein). For a given dataset of n observations $\mathbf{Y} = (y_1, \dots, y_n)$, with $y_i \in \mathscr{Y} \subset \mathbb{R}^d,\ i = 1, \dots, n$, K-means seeks to find a partition of the data into K clusters $\mathscr{S} = \{S_1, \dots, S_K\}$ so as to minimize

$$\phi(\mathscr{S}) = \sum_{k=1}^{K} \sum_{y_i \in S_k} ||y_i - \mu_k||^2,$$

where μ_k is the k-th cluster center. The algorithm begins with K randomly initialized centers, and assigns each point to the nearest center; then, the clusters' centers are recomputed and the partition updated; such process is iterated until a stable configuration is reached. In many instances, the number of clusters K is specified in advance, and the optimal solution is sought conditional on such value. Also the distance adopted is set in advance, depending on the nature of the data and user subjective preferences. Initial seeding is a more technical issue, usually less discussed, whose impact on the final result is often neglected. Nonetheless, the choice of the initial group centers may strongly affect the clustering solution. As already mentioned, the classical approach in K-means clustering uses a random seeding in the first step of the procedure. In practice, multiple random seeds are considered, and the final K-means solution is chosen as the one that minimizes the objective function. An alternative seeding technique is proposed by [1], among others. Many extensions of the classical approach have been explored in the literature (for a complete review see [7]). As it is discussed in [7], classical approaches have been challenged by using ensembles methods.

Clustering ensembles methods ([9, 10]) explore the idea of the so-called evidence accumulation in order to summarize the information coming from multiple clusterings into a pairwise *co-association* matrix, regarded to as a similarity matrix ([8, 6]). Such matrix is constructed by taking the co-occurrences of pairs of units in the same cluster among the total number of partitions, and then used to deliver the final consensus clustering. This kind of matrix has been estimated in [4] and used in the context of the label switching problem in Bayesian estimation of finite mixture models. In particular, the algorithm of Maxima Units Search (MUS), introduced in [4] and further developed in [3], has proved to be useful in extracting some specific units–one for each mixture component–called pivots, from a large and sparse similarity matrix representing an estimate of the probability that pairs of units belong to the same group.

Here the main idea is to exploit the use of the pivots detected by the MUS algorithm, which are determined as the observations that are "as far away from each other as possible" according to the co-association matrix, as group centers in the initialization step of K-means procedure, where such units.

Section 2 briefly reviews the MUS procedure for the identification of pivotal units from a given set of data, and outlines the proposed approach. In Section 3 the performance of the presented algorithm is preliminarily investigated by means of a small simulation study. Section 4 presents some final remarks.

2 Seeding via MUS algorithm

Consider H distinct partitions of a set of n d-dimensional statistical units into K groups determined by some clustering technique. It is possible to map them into a $n \times n$ co-association matrix C with generic element $c_{i,j} = n_{i,j}/H$, where $n_{i,j}$ is the number of times the pair (y_i, y_j) is assigned to the same cluster with respect to the clustering ensemble. Units which are very distant from each other are likely to have zero co-occurrences; as a consequence, C is a square symmetric matrix expected to contain a non-negligible number of zeros.

The main task of the MUS algorithm is to detect submatrices of small rank from the co-association matrix and extract those units $y_{i_1}, \dots, y_{i_K}$ such that the $K \times K$ submatrix of C with only the $i_1, \dots, i_K$ rows and columns has few, possibly none, nonzero elements off the diagonal (that is, this submatrix is identical or nearly identical). Practically, the resulting units—hereafter pivots—have the desirable property to be representative of the group they belong to. From a computational point of view, the issue is non-trivial and involves a global search row by row; as n, K and the number of zeros within C increase, the procedure becomes computationally demanding. Given that the pivots correspond to well separated units in the data space, they can represent an alternative approach to the random seeding in K-means setting. A similar idea has been discussed in [1], where the initial centers are chosen on the basis of suitable weights assigned to data points.

Although K-means clustering is one of the most popular algorithms due to its simplicity and low computational burden, one major criticism is the impact of the choice of the initial centers on the final solution. However, limited work has been developed for improving the seeding of the centers. A modified version of K-means could benefit from a pivot-based initialization step. In particular, the starting point is performing multiple runs of the classical K-means with K fixed, and build the co-association matrix of data units. Such matrix is given as input for the MUS procedure, yielding the pivots regarded to as cluster centers. Intuitively, such approach represents a careful seeding which may improve the validity of the final configuration. According to the general K-means method, steps 1a—1c of the `MUS`K-means algorithm summarized below collapse in a single step, where the initial centers are chosen uniformly at random from the data space $\mathscr{Y}$. The remaining steps coincide with those of the classical K-means version.

MUSK-means:

1a Perform H classical K-means algorithms, and obtain then H distinct data partitions, with initial centers chosen uniformly at random.

1b Build the co-association matrix C, where $c_{i,j} = n_{i,j}/H$, with $n_{i,j}$ the number of times the pair (y_i, y_j) is assigned to the same cluster among the H partitions.

1c Apply the MUS algorithm to the matrix C and find the pivots $y_{i_1}, \dots, y_{i_K}$. For each group, set the initial center $\mu_k = y_{i_k}$.

2 For each k, $k = 1, \dots, K$, set the cluster S_k to be the set of points in $\mathscr{Y}$ that are closer to μ_k than they are to μ_j for all $j \neq k$.

3 For each k, $k = 1, \dots, K$, set μ_k to be the center of mass of all points in S_k: $\mu_k = \frac{1}{|S_k}|\sum_{y \in S_k} y$, where $|S_k|$ is the cardinality of S_k.

4 Repeat Steps 2 and 3 until $\mathscr{S}$ no longer changes.

3 Simulation results

A preliminary simulation study is carried out in order to explore the performance of the methodology proposed in Sect. 2. One of the drawbacks of K-means is its inefficiency in distinguishing between groups of unbalanced sizes. For this reason, two different scenarios in which the classical approach may fail to identify the ‘natural’ groups are considered in the following. In particular, the two simulated datasets reproduce two clusterings in two dimensions, with three and two groups, respectively. For illustration purposes, the results from a single simulation are shown in Fig. 1. The left panel (top) displays the first simulated scenario, where the input data consist of three clusters drawn from bivariate Gaussian distributions with 20, 100 and 500 observations, respectively. The partitions obtained from the classical K-means algorithm using multiple random seeds and from MUSK-means are plotted in the top central and right panel of Fig. 1, respectively. As can be seen, classical K-means tends to split the cluster with the highest density in two separate clusters; conversely, the cluster composition identified by MUSK-means shows a greater agreement with the true partition, and the final centers are close to the pivotal units used for the seeding. The second configuration (see the bottom panel of Fig. 1) consists of data with ‘two-sticks’ shaped groups of 30 and 370 observations, respectively. Classical K-means fails in recognizing the true pattern, and the final centers both belong to the largest cluster. Clustering based on our pivotal units seems to correctly identify the simulated groups, since two well separated pivots are identified and set as initial group centers.

In order to evaluate and compare the performance of classical K-means and MUSK-means, a common measure of the similarity between two partitions, namely,

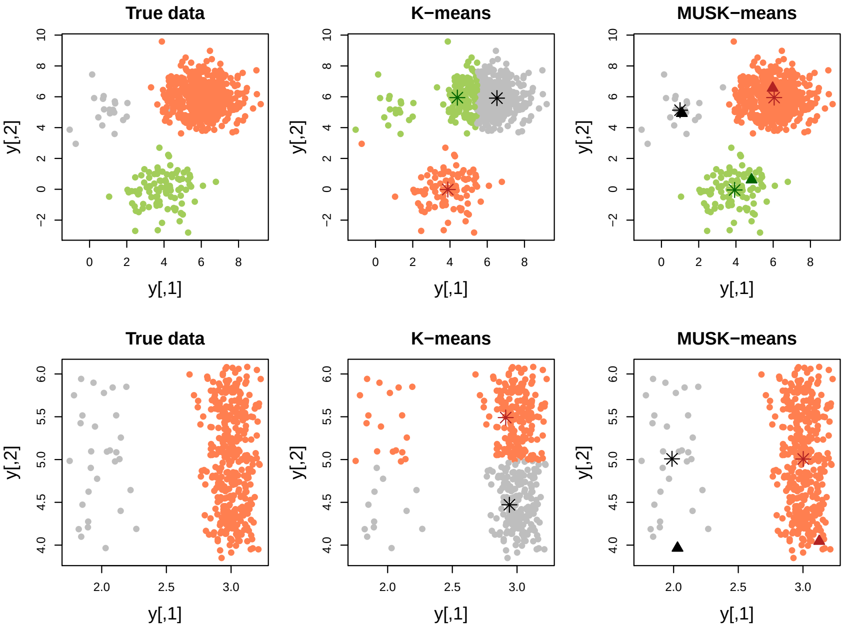

Fig. 1: From left to right. Input data generated from a mixture of three Gaussian distributions (620 samples) (top) and 'stick' data (400 samples) with two groups (bottom) of unequal sample sizes; clustering solutions obtained via classical K-means and MUSK-means algorithms. Each cluster identified is shown in a different color, with final group centers and pivots marked via asterisks and triangles symbols, respectively.

the Adjusted Rand Index (ARI), is computed at each iteration between the resulting clustering and the true data partition. The number of replications in the simulation study is set equal to 1000. Fig. 2 shows the comparison in terms of ARI, for the first scenario considered. As may be noted, MUSK-means gives overall good results; in fact, it yields higher values for 60% of the replications, whereas the two procedures yield the same value of the index in 36% of cases. Concerning the second scenario characterized by 'two-sticks' data, the ARI for K-means is always approximately equal to 0; the same index for MUSK-means is about zero in 43% of cases, while for the remaining 57% it outperforms classical K-means giving an ARI equal to 1, denoting a perfect agreement with the true partition.

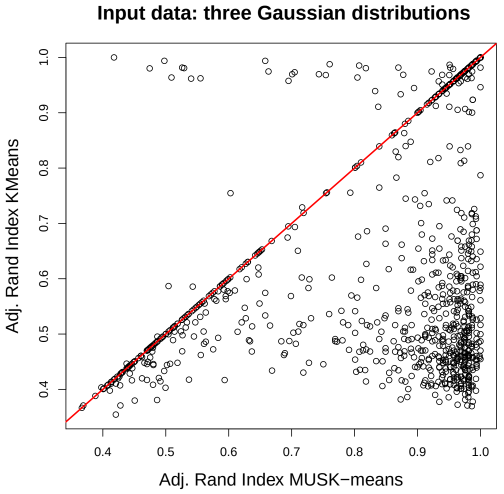

Fig. 2: Comparison between the ARI obtained via classical K-means and `MUS`K-means algorithms for the input Gaussian data over 1000 replications.

4 Discussion

We propose a modified K-means algorithm which exploits a pivotal-based phase seeding. Despite the limited study, preliminary results seem to be promising in terms of clusters' identification. It is worth noting that the proposed algorithm is in general computationally more demanding that the standard procedure, and the complexity grows with the size of the dataset. On the other hand, similarly to clustering ensemble, our method takes advantage of the construction of a co-association matrix, whose information has been only partially exploited so far. Further work is needed to investigate the use of such matrix and the pivotal units for inferring the optimal number of groups.

Advances in Discrete Latent Variable Modelling

A joint model for longitudinal and survival data based on a continuous-time latent Markov model

Un modello congiunto per dati longitudinali e di sopravvivenza basato su un processo Markoviano latente in tempo continuo

Alessio Farcomeni and Francesco Bartolucci

Abstract A shared-parameter approach for jointly modeling longitudinal and survival data is proposed, which allows for time-varying random effects that enter both in the longitudinal and survival processes. The distribution of these random effects is modeled according to a continuous-time hidden Markov chain, so that latent transitions may occur at any time point. Our formulation allows for: (*i*) informative drop-out with precise time-to-event outcomes, while existing approaches are all based on drop-out at longitudinal measurement times and (*ii*) completely non-parametric treatment of unequally spaced intervals between consecutive measurement occasions (even not in the presence of drop-out). For maximum likelihood estimation we propose an algorithm based on coarsening. The resulting estimator is studied by simulation. The approach is illustrated by an application to data about patients suffering from mildly dilated cardiomyopathy.

Abstract *Si propone un modello congiunto per dati longitudinali e di sopravvivenza. La distribuzione degli effetti casuali condivisi è modellata sulla base di un processo latente in tempo continuo e spazio degli stati discreto. La formulazione proposta permette di prevedere (i) drop-out informativo in presenza di tempo-a-evento precisamente misurato, mentre gli approcci attualmente disponibili sono basati su indicatori al momento della misurazione del dato longitudinale, e (ii) un trattamento non-parametrico per il caso di intervalli non-omogenei tra occasioni di misura, anche in assenza di drop-out. Per la stima di massima verosimiglianza sviluppiamo un algoritmo basato sul coarsening. Lo stimatore risultate é valutato per simulazione. L'approccio é illustrato tramite una applicazione a dati su pazienti cardiomiopatia dilatativa di grado lieve.*

1 Introduction

Informative drop-out in longitudinal studies is often treated by linking a model for time to drop-out and one for the longitudinal outcome. Many models devised for informative drop-out assume that subject-specific parameters are time-constant. This is a limitation as unobserved factors affecting the outcomes and the relationship between longitudinal and survival outcomes might evolve over time in an unpredictable way, especially when the follow-up is relatively long. One exception is [1], who propose a discrete-time event-history approach based on latent Markov models [2], which naturally accommodate time-dependent unobserved heterogeneity. Nevertheless, the approach in [1] has two limitations: (*i*) the event-history component models drop-out, by a conditional logit model, as occurring within a time interval, therefore ignoring precise follow-up time information; (*ii*) latent transitions, as common in latent Markov models, are based on a discrete-time stochastic process and hence transitions may only occur at visit times. In terms of interpretation, assuming that transitions may occur only at certain time occasions is rather unrealistic and the explicit use of an hazard function is preferable to that of a conditional logit model.

In order to overcome the above limitations, we propose a shared-parameter model characterized by the following features. First of all the time-varying unobserved heterogeneity is accounted for by a continuous-time discrete-state hidden Markov model [5], parameterized by an initial probability vector and an infinitesimal transition matrix. In this respect our approach can be seen as a complete generalization of the relevant work by [3], which is limited to $k = 2$ and to missing-at-random data. Second, for the survival time we assume a Weibull model with hazard function depending on the (entire) trajectory of the continuous-time latent variable. A latent class model (with time-constant subject-specific parameters) is obtained whenever the infinitesimal transition matrix is constrained to have all elements equal to 0.

For model fitting we introduce a novel method that provides maximum likelihood estimates. The approach is based on a time discretization, in a certain number of windows of arbitrary length, and on an extension of the Baum-Welch recursions. It converges in an accurate and stable way. This algorithm also represents an advance in the literature about estimation of continuous hidden Markov models in general, with respect to computational demands, ease of implementation, and stability.

In the following we illustrate in some detail the assumptions of the proposed model, then we describe the approach to parameter estimation and, finally, we outline an application based on data about patients suffering from Mildly Dilated CardioMyopathy (MDCM).

2 Shared-parameter continuous-time latent Markov and survival models

Consider a sample of n individuals and for individual i, with $i = 1,\dots,n$, let $T_i = \min(T_i^*, C_i)$ be the survival time taken as the minimum between the true event time T_i^* and the censoring time C_i. Furthermore, let Δ_i be the corresponding event indicator defined by $\Delta_i = I(T_i^* \leq C_i)$, where $I(\cdot)$ is the indicator function equal to 1 if its argument is true and to 0 otherwise. The outcome $Y_i(t)$, which arises from a natural exponential family, is repeatedly observed at arbitrary time points t_{ij}, $j = 1,\dots, j_i$, where j_i is the number of observations; also let $Y_{ij} = Y_i(t_{ij})$. We assume that the longitudinal process is associated with T_i^*, namely with the true event time, but, as customary in survival analysis, is independent of the censoring time C_i. In general, realizations of random variables are denoted by small letters, so that, for instance, t_i is the observed value of T_i and δ_i is the observed value of Δ_i.

We denote by w_i a row vector of (time-fixed) baseline covariates to be used in modeling the survival process. For the longitudinal process, we denote by $x_i(t)$ a vector of predictors at time t and we also let $x_{ij} = x_i(t_{ij})$, $j = 1,\dots, j_i$.

The proposed model is based on two equations. Specifically, the model for the longitudinal outcome is formulated along the usual lines of mixed-effects models and the model for the time-to-event outcome is based on a subject-specific hazard function as in Cox-type models. More formally, we assume that

$$\begin{aligned} g(\mu_{ij}) &= \alpha_i(t_{ij}) + x'_{ij}\beta, \quad j = 1,\dots, j_i, \\ h(t_i^*) &= h_0(t_i^*)\exp\{\alpha_i(t_i^*)\phi + w'_i\psi\}, \end{aligned}$$

where $g(\cdot)$ is a link function of the conditional expectation of Y_{ij} denoted by μ_{ij} and $h(\cdot)$ is the hazard function, with $h_0(\cdot)$ being a baseline hazard. In this paper we will assume a Weibull parametric form for $h_0(\cdot)$, that is, $h_0(t) = \nu t^{\nu-1}$, resulting in an Accelerated Failure Time (AFT) model for the survival part. Other parametric choices, or even a non-parametric specification, are possible. We assume that $\alpha_i(t)$ follows a time-continuous Markov process, whereas β and ψ are fixed parameter vectors for the covariates, and ϕ is a parameter for the effect of the latent process on the survival process. Note that several generalizations, including the case of more than one parameter being time-dependent according to the latent process, are straightforward. Regarding the distribution of Y_{ij}, our model has the same degree of flexibility as generalized linear models. It is worth also stressing that the hazard function depends on the *entire* trajectory of the random effect $\alpha_i(t)$, and not only on $\alpha_i(t_{ij})$.

Unlike usual formulations, random intercepts are assumed to be time varying. This greatly enhances model flexibility. In particular, as already mentioned, we assume that the random effects follow a continuous-time (discrete-state) Markov chain [5], with state-space $\{\xi_1,\dots,\xi_k\}$ having elements collected in the column vector ξ. We assume that the transition function of the latent chain satisfies the Chapman-Kolmogorov equations, and specify its Q-matrix based on positive off-diagonal elements q_{uv} for $u, v = 1, \dots, k$ and $v \neq u$. By definition, the diagonal elements are given by $-q_u$, with $q_u = \sum_{v=1, v\neq u}^{k} q_{uv}, u = 1, \dots, k$. Accordingly, for the longitudinal outcome transitions from time t to time $t+s$ are collected in the $k \times k$ matrix $\Pi_s = e^{sQ}$, where e denotes the *matrix exponential* operator, that is, $e^{sQ} = \sum_{n=0}^{\infty} \frac{s^n Q^n}{n!}$. Note that irregularly spaced time occasions are directly accommodated, and hence our model also generalizes [3] simply by restricting it to the first equation. We also define the *jump matrix* R as a matrix with off-diagonal elements $r_{uv} = q_{uv}/q_u$, and collect initial probabilities π_u in the column vector π.

The latent process captures the time-varying unobserved heterogeneity linking the longitudinal and survival outcomes. The shared-parameter formulation is in the spirit of copula models [6]. We also recall that, according to this process, the sojourn time in each state u has an exponential distribution with parameter q_u, denoted as $\text{Exp}(q_u)$, whereas the probability of moving at the end of the sojourn time to state v is equal to the suitable element of the jump matrix R.

3 Estimation

It is straightforward to check that the complete likelihood of our proposed model depends on the entire trajectory of the continuous-time latent process, through the integrals involved in the time-to-event component. This makes it hard to efficiently compute the observed likelihood: the classical Baum-Welch recursion is not directly applicable, even after their extension to continuous time processes, due to lack of certain conditional independence statements. To derive inference we build a sequence of equally spaced windows corresponding to time fixed points $\bar{t}_1, \dots, \bar{t}_M$, with $\bar{t}_1 = 0$. The first window spans the time interval from $\bar{t}_1$ to $\bar{t}_2$, the second from $\bar{t}_2$ to $\bar{t}_3$, and so on. These time points are chosen so that each observation time t_{ij} corresponds to one of them. Let $\bar{y}_{im}$ denote the observation at time $\bar{t}_m$ for individual i, which may be missing for certain time occasions, $\bar{x}_{im}$ be the corresponding vector of covariates, and $\bar{U}_{im}$ the corresponding latent variable. Also let $\bar{y}_{i,\leq m}$ be vector of observations available until time $\bar{t}_m$.

The following forward recursion can now be used. Consider the joint density $f_{im}(u) = f(\bar{y}_{i,\leq m}, t_i \geq \bar{t}_m, \bar{U}_{im} = u)$ referred the observation availably until time $\bar{t}_m$ for individual i, latent state at the same time occasion, and for the event that the individual survives time $\bar{t}_m$. We have that $f_{i1}(u) = \pi_u f(\bar{y}_{i1}|\bar{U}_{i1} = u), \quad u = 1, \dots, k$, and $f_{im}(v) = f(\bar{y}_{im}|\bar{U}_{i1} = v) \sum_{u=1}^{k} \pi_{v|u} f_{i,m-1}(u) S_{m-1}(\bar{t}_m, u), \quad m = 1, \dots, m_i, v = 1, \dots, k$, where, in general, we have $S_m(\bar{t}, u) = \exp\{-H_m(\bar{t}, u)\}$ with

$$H_m(\bar{t}, u) = \int_{\bar{t}_m}^{\bar{t}} \exp(\xi_u \phi + w_i' \psi) \nu t^{\nu-1} dt = \exp(\xi_u \phi + w_i' \psi)(\bar{t}^{\nu} - \bar{t}_m^{\nu}), \quad u = 1, \dots, k,$$

$f(\bar{y}_{im}|\bar{U}_{i1} = v)$ is set equal to 1 if the observation is not available at time t_m, and m_i be largest value of m such that $\bar{t}_m \leq t_i$. For individual i we have the contribution to the likelihood given by $f(y_i, t_i, d_i) = \sum_{u=1}^{k} f_{im_i}(u) h(t_i)^{\delta_i} S_{m_i}(u, t_i)$. Regarding the transition probabilities $\pi_{v|u}$, note that these are the elements of the $k \times k$ matrix $\mathit{\Pi}_a$ obtained as $\exp(aQ)$, where $a = \bar{t}_{m+1} - \bar{t}_m$ is the length of each time window.

The log-likelihood function to be maximized is then $\ell(\theta) = \sum_{i=1}^n \log f(y_i, t_i, d_i)$. In order to maximize this function we also need a backward recursion. In particular, let $g_{im}(u) = f(\bar{y}_{i,>m}, t_i, \delta_i | t_i > t_m, U_{im} = u)$. For $m = m_i$ have that $g_{im_i}(u) = h(t_i)^{\delta_i} S_{m_i}(t_i, u)$ and $g_{im}(u) = S_m(\bar{t}_{m+1}, u) \sum_{v=1}^k \pi_{v|u} g_{i,m+1}(v) f(\bar{y}_{i,m+1}, U_{i,m+1} = v)$ for $m < m_i$. From this recursion we can obtain two posterior distributions used to update the parameters π and $\mathit{\Pi}_a$. In particular, we have that

$$p(U_{im} = u | y_i, t_i, \delta_i) = \frac{f_{im}(u) g_{im}(u)}{f(y_i, t_i, d_i)}, \quad m = 1, \ldots, m_i,\ u = 1, \ldots, k.$$

Moreover, we have that

$$p(U_{im} = u, U_{i,m+1} = v | y_i, t_i, \delta_i) = \frac{f_{im}(u) S(u, \bar{t}_{m+1}) \pi_{uv} f(\bar{y}_{i,m+1}, U_{i,m+1} = v) g_{i,m+1}(v)}{f(y_i, t_i, d_i)}, \\ m = 1, \ldots, m_i - 1,\ u, v = 1, \ldots, k.$$

Then, we update these parameters as $\pi_u = \frac{1}{n} \sum_{i=1}^n p(U_{i1} = u | y_i, t_i, \delta_i)$, $u = 1, \ldots, k$, and

$$\pi_{uv} = \frac{\sum_{i=1}^n \sum_{m=1}^{m_i - 1} p(U_{im} = u, U_{i,m+1} = v | y_i, t_i, \delta_i)}{\sum_{i=1}^n \sum_{m=1}^{m_i - 1} \sum_{\bar{v}=1}^k p(U_{im} = u, U_{i,m+1} = \bar{v} | y_i, t_i, \delta_i)}, \quad u, v = 1, \ldots, k.$$

The infinitesimal transition matrix Q is obtained from $\mathit{\Pi}_a$ by inverting $\exp(aQ)$.

To update the other parameters, we explicit the expected value of the complete log-likelihood. In particular, regarding the third component about the survival process we have

$$\mathrm{E}\{\ell_3(\theta)\} = \sum_{i=1}^n \mathrm{E}\left\{ \delta_i \log h_0(t_i | U_{im_i}) - \sum_{m=2}^{m_i} H_{m-1}(\bar{t}_m, U_{i,m-1}) - H_m(t_i, U_{im_i}) \right\}.$$

Regarding the derivative of $\ell(\theta)$ with respect to the model parameters, let τ denote any of the elements of θ apart from those involved in the latent process; we apply the general rule

$$\ell(\theta) = \sum_{i=1}^n f(y_i, t_i, d_i)^{-1} \frac{\partial f(y_i, t_i, d_i)}{\partial \tau}.$$

4 Application to MDCM data

We illustrate now the proposed approach using an original study on a cohort of patients affected by MDCM, a primary myocardial disease characterized by left ventricular systolic dysfunction and dilation. For more details on the pathology, see [4].

Prognostic measurements were taken at basal time for $n = 642$ patients, who were followed-up until urgent heart transplant or death occurred. There were 212 events during follow-up, which lasted up to 25 years. If censoring (administrative or due to the event) did not occur, measurement of longitudinal biomarkers were taken at visits scheduled at months 6, 12, 24, 48, 72, 96, and 120. Hence each patient has a maximum of 8 longitudinal measurements, with 79 patients having complete records.

The longitudinal outcome is the New York Hearth Association (NYHA) classification, a direct measure of discomfort caused by the disease. Specifically, for each subject at each follow-up occasion we measure an indicator of being in NYHA class III or IV, indicating the presence of strong limitations to physical activity, and the occurrence of dyspnea and discomfort during ordinary activities or even at rest. For the longitudinal model we parameterize probability of high NYHA class as a function of $t > 0$ (indicating medical treatment according to international guidelines), an indicator of history of heart disease in the family, and the left ventricular Ejection Fraction (EF). The latter is a measure of the proportion of blood that is pumped out of the left ventricle at each heart beat.

It is natural to expect that a continuous-time model is more appropriate for the data at hand than any model assuming latent transitions occurring at visit times. In fact, latent states shall be interpreted as patients' frailty beyond that summarized by the predictors, and changes in disease status (and hence propensity to event and/or change of NYHA class) obviously can occur at any time point and not necessarily on the day of the visit by the doctor. Further, a strong dependence between NYHA class and the event is expected, with patients in NYHA classes III or IV being at higher risk of death.

For interpretability reasons, EF has been centered at 30 (which is believed to be a significant threshold, where EF < 30 indicates patients at risk of heart failure).

For our model fitting procedure we evaluate several values for M, and end up fixing $M = 200$, which is well above values guaranteeing stability of estimates. Using the Bayesian information criterion we select $k = 3$. In order to estimate standard errors we perform a non-parametric bootstrap procedure based on $B = 1000$ replicates. In Table 1 we report parameter estimates for the manifest distribution, along with an indication of significance at the 5% level.

The estimate of Q is better understood after computation of the time-specific transition matrix. For this purpose, we report Figure 1 where the inhomogeneous transition matrix at each time t is reported.

The results indicate an important role of all predictors, with the exception of history of hearth disease for survival. Comparing $k = 1$ with $k > 1$, it is clear that taking into account unobserved heterogeneity leads to a more clear identification of the roles of EF and family history for NYHA classification. The effect of family history doubles when passing from $k = 1$ to $k = 3$, while the effect of each percentage point of EF is almost three times larger. Hence, based on our results, doctors should probably pay more attention to EF and family history than expected when assessing

Table 1 *MDCM data: parameter estimates for the manifest distribution, different values of k. An asterisk indicates statistical significance at the 5% level.*

		k

	ξ_2	-	-0.164	-1.446*	-2.182*
	ξ_3	-	-	2.891*	-1.481*
	ξ_4	-	-	-	2.902*
	$t > 0$	1.047*	2.289*	0.920*	0.847*
	history	0.611*	0.724*	1.169*	1.126*
	EF	0.056*	0.094*	0.134*	0.137*
survival	ϕ	0.000	-0.475*	-0.314*	-0.310*
	history	-0.125	0.031	-0.019	-0.001
	EF	-0.058*	-0.048*	-0.049*	-0.058*
	ν	0.799*	0.781*	0.762*	0.789*

prognosis to high NYHA classes. The estimate of ϕ is negative and significant in all cases, indicating as expected that subjects with, for instance, dyspnea during ordinary activities are at higher risk of death than patients without clear signs of heart insufficiency.

When $k = 3$ three clearly separate groups of patients are identified. Even when they have the same history, EF and timing configuration, patients might be different due to unobserved factors. A group of patients (about 30% at baseline time) is at a very low risk. From Figure 1 it can be observed that this group of patients is slightly stable, with low probability of transitions to different states during follow-up. A second group (about 60%) is at slightly larger propensity to high MDCM at baseline. These patients are very likely to change state during follow-up, with many switchings to an even higher risk (especially in the period 15-40 months from time zero) and the rest switchings to the low risk first latent state (possibly due to successful medical treatment). Finally, a third group of patients is at very high risk of high NYHA class at baseline time. Most of them remain at high risk during follow-up, but a slight proportion switches to better propensity states; surprisingly more often to state 1 than to state 2. This might be due to increased medical attention given to high risk patients.

Modelling the latent class structure of multiple Likert items: a paired comparison approach

Modellazione della struttura a classi latenti di item multipli su scala Likert: un approccio basato sul confronto a coppie

Brian Francis, Lancaster University, UK

Abstract The modelling of the latent class structure of multiple Likert items measured on the same response scale can be challenging. The standard latent class approach is to model the absolute Likert ratings, where the logits of the profile probabilities for each item have an adjacent category formulation (DeSantis et al., 2008). We instead propose modelling the relative orderings, using a mixture model of the *relative* differences between pairs of Likert items. This produces a paired comparison adjacent category log-linear model (Dittrich et al., 2007; Francis and Dittrich, 2017), with item estimates placed on a (0,1) "worth" scale for each latent class. The two approaches are compared using data on environmental risk from the International Social Survey Programme, and conclusions are presented.
Abstract *La modellazione della struttura a classi latenti di item multipli misurati sulla stessa scala Likert pu essere problematica. Lapproccio classico a classi latenti si basa sulla modellazione dei punteggi assoluti tramite una formulazione per categorie adiacenti dei logit delle probabilit dei vari profili di risposta per ciascun item (De Santis et al, 2008). In questo contributo si propone, invece, di modellare gli ordinamenti degli item tramite un modello mistura specificato sulle differenze relative tra coppie di item. Il modello risultante un modello log-lineare per categorie adiacenti basato su confronti a coppie (Dittrich et al, 2007; Francis and Dittrich,2017), dove le stime degli item sono poste su una scala di merito (0, 1) per ogni classe latente. I due approcci vengono confrontati e debitamente commentati utilizzando dati relativi al rischio ambientale, provenienti dallInternational Social Survey Programme.*

Key words: latent class, ordinal data, multiple Likert items, paired comparisons

Brian Francis

1 Introduction

Collections of multiple Likert items in questionnaires are very common, and are usually used to measure underlying constructs. Scale from the Likert items can be built either through simply adding the item score or through using an IRT model such as a graded response model to build a score. This approach assumes that there is a single underlying construct to the items. The current paper, in contrast, takes a different view. It proposes that there is a latent class structure to the Likert items, with different classes having different patterns of high and low responses. In this approach, score building is not the aim; instead the aim is to understand the various patterns of responses that might exist in the population.

The standard latent class approach to multiple ordinal indicators essentially constructs a polytomous latent class model (Linzer and Lewis, 2011), and constrains the latent class profile probabilities, imposing a linear score ordinal model on them (Magidson and Vermunt, 2004; DeSantis et al., 2008). This results in a latent class adjacent category ordinal model. The method however uses the *absolute* responses, and this has been criticised by some authors, as they state that each respondent has their own way of interpreting the Likert scale. Such interpretation may itself be culturally determined, or may depend on other covariates such as age, gender and so on. For example younger people and males may be more likely to express a firm opinion, using the end categories of a unipolar Likert scale, than older people and females. The alternative is to take a relative approach. While one method of doing this is to standardise the items for each respondent, subtracting the respondent mean. This is unsatisfactory as it ignores the categorical nature of the data. In this paper we instead develop a paired comparisons approach, which produces a worth scale for each latent class, ranking the items in order of preference. The paper compares the two methods and discusses the advantages and disadvantages of each method.

Some common notation is introduced which will be used to develop both models. The Likert items are assumed to be measured on the same response scale with identical labelling; it is assumed that there are H possible ordered response categories taking the values $1,\ldots,H$ for each of the J Likert items indexed by j, and with N respondents indexed by i. $y_{ij}; \quad y_{ij} \in 1,2,\ldots,H$ is defined to be the (ordinal) response given by respondent i to item j. A set of H indicators for each item and respondent with the indicator z_{ijh} taking the value 1 if $y_{ij} = h$ and 0 otherwise.

2 The ordinal latent class model

We first introduce the ordinal latent class model, which models the absolute responses. Let y_{ij} be the ordinal response of respondent i to item j. It is assumed that there are K latent classes. The item response vector for respondent i is

$$\mathbf{y_i} = (y_{i1}, y_{i2}, \cdots, y_{iJ}),$$

Then the ordinal latent class model is defined by:

$$
\begin{aligned}
P(\mathbf{y_i}) &= \sum_{k=1}^{K} \pi(k) P(\mathbf{y_i}|\mathbf{k}) \\
&= \sum_{k=1}^{K} \pi(k) \prod_{j} P(y_{ij}|k) \qquad \text{under conditional independence.}
\end{aligned}
$$

We write

$$
P(y_{ij}|k) = \prod_{h=1}^{H} p_{jkh}^{z_{ijh}}
$$

where p_{jkh} is the probability of observing the ordinal response h for indicator j given membership of latent class k - these are sometimes called the latent class profile probabilities.

Ordinality is imposed by using an adjacent categories ordinal model and we parameterise the model through regression parameters on the logit scale, which separates out the intercept parameter β_{jh} and the class specific parameters β_{jkh} for each item and response category.

$$
\begin{aligned}
\text{logit}(p_{jkh}) &= \beta_{jh} + \beta_{jkh} \\
&= \beta_{jh} + h\beta_{jk} \qquad \text{under a linear score model}
\end{aligned}
$$

The likelihood L is then given by

$$
L = \prod_{i} \sum_{k=1}^{K} \pi(k) P(\mathbf{y_i}|\mathbf{k}).
$$

Model fitting is usually carried out by using the EM algorithm - details are given in Francis et al. (2010) and Aitkin et al. (2014). Determination of the optimal number of classes is commonly achieved by choosing that model which minimises an information criterion, although a wide variety of other methods have been proposed. We have used the BIC in this paper.

3 The latent class ordinal paired comparison model

An alternative to the absolute latent class approach is to work on a **relative scale**. This perhaps is of greater interest. We take a paired comparison approach, using the difference in the ordinal likert responses. This allows the development of a “worth” scale between 0 and 1 awith items placed on this scale. The sum of the item scores is defined to be 1. This section proceeds by developing the ordinal paired comparison model, and then extends that model by adding a mixture or latent class process to the model.

3.1 The ordinal paired comparison model

This model starts by constructing a set of paired comparisons - taking all possible pairs of items and comparing them in turn (Dittrich et al., 2007). For respondent i and for any two items $j = a$ and $j = b$, let

$$x_{i,(ab)} = \begin{cases} \quad h \text{ if item } a \text{ preferred by } h \text{ steps to item } b & = y_{ia} - y_{ib} \\ \quad 0 \qquad\quad \text{if Likert ratings are equal} & = 0 \\ -h \text{ if item } b\text{preferred by } h \text{ steps to item } a & = y_{ia} - y_{ib} \end{cases}$$

The probability for a single PC response $x_{i,(ab)}$ is then defined by

$$p(x_{i,(ab)}) = \begin{cases} \mu_{ab} \left(\frac{\pi_a}{\pi_b}\right)^{x_{i,(ab)}} & : \text{ if } x_{i,(ab)} \neq 0 \\ \mu_{ab}\, c_{ab} & : \text{ if } x_{i,(ab)} = 0 \end{cases}$$

The πs represent the worths or importances of the items, c_{ab} represents the probability of no preference between items a and b and μ_{ab} is a normalising quantity for the comparison ab. Over all items, we now form a pattern vector $\boldsymbol{x}_i$ for observation i with $\boldsymbol{x}_i = (x_{i,(12)}, x_{i,(13)}, \ldots, x_{i,(ab)}, \ldots, x_{i,(J-1,J)})$ and count up the number of responses n_ℓ with that pattern. The **probability** for a certain pattern ℓ is

$$p_\ell = \triangle^* \prod_{a<b} p(x_{ab})$$

where $\triangle^*$ is a constant (the same for all patterns). A log-linear model can now be constructed with observed counts n_ℓ. The **expected counts for a pattern** ℓ **are** defined as $\boxed{m_\ell = n p_\ell}$ where n is the total number of respondents defined by $n = n_1 + n_2 + \cdots + n_\ell + \cdots + n_L$ and where L is the number of all possible patterns.

Taking natural logs, the **log expected counts** are obtained by

$$\ln m_\ell = \alpha + \sum_{a<b} x_{ab}(\lambda_a - \lambda_b) + \mathbf{1}_{x_{ab}=0}\, \gamma_{ab}$$

For $x_{ab} = \quad h$ this is $\quad h(\lambda_a - \lambda_b)$, for $x_{ab} = -h$ this is $h(-\lambda_a + \lambda_b)$ and for $x_{ab} = \quad 0$ this is γ_{ab}.

To show that this is an adjacent categories model, the log odds of a pair for any two adjacent categories on the ordinal scale can be examined - say h and $h+1$. Then, as $m_\ell = np_\ell$, we have

$$\begin{aligned} \ln\left(\frac{m_\ell(h)}{m_\ell(h+1)}\right) &= \ln(\mu_{ab}) + h(\lambda_a - \lambda_b) - \ln(\mu_{ab}) - (h+1)(\lambda_a - \lambda_b) \\ &= \lambda_a - \lambda_b \end{aligned}$$

which is true for any h as long as h or $h+1$ are not zero.

The worths π_j are calculated from the λ_j through the formula

$$\pi_j = \frac{\exp(2\lambda_j)}{\sum_{j=1}^{J}\exp(2\lambda_j)}$$

.

3.2 Extending the model to incorporate latent classes

As before, we assume that there are K latent classes with different preference patterns (the lambdas). The likelihood L becomes:

$$\mathrm{L} = \prod_{\ell}\Big(\sum_{k=1}^{K} q_k \; n \; p_{\ell k}\Big) \quad \text{where } \sum_{\ell} p_{\ell k} = 1 \quad \forall\, k \text{ and } \sum_{k} q_k = 1.$$

$$\ln p_{\ell k} = \alpha + \sum_{a<b} x_{ab}(\lambda_{ak} - \lambda_{bk}) + \mathbf{1}_{x_{ab}=0}\, \gamma_{ab}$$

λ_j is replaced in the model byλ_{jk}, and we now have to additionally estimate the q_k. q_k is the probability of belonging to class k (the mass points or class sizes). Again, we use the EM algorithm to maximise the likelihood, and use the BIC to determine the number of classes. Typically, we need to use a range of starting values to ensure an optimal solution.

4 An Example

Six question items on the topic of environmental danger were taken from the 2000 sweep of the International Social Survey Programme , which focused on issues relating to the environment. As part of this survey, the respondents assessed the environmental danger of a number of different activities and items. The question is reproduced below; each question used the same response scale. The six Likert items are:

c air pollution caused by **c**ars (`CAR`)

t a rise in the world's **t**emperature (`TEMP`)

g modifying the **g**enes of certain crops (`GENE`)

i pollution caused by **i**ndustry (`IND`)

f pesticides and chemicals used in **f**arming (`FARM`)

w pollution of **w**ater (rivers, lakes, ...) (`WATER`)

with the response scale for each of the items as follows:

In general, do you think *item* is

4. extremely dangerous for the environment
3. very dangerous
2. somewhat dangerous
1. not very dangerous
0. not dangerous at all for the environment

Table 1 BIC values from fitting latent class models (a) the standard ordinal LC model and (b) the ordinal PC LC model

	(a) standard ordinal LC model		(b) Ordinal PC LC model	
	absolute		relative	
No. of classes K	BIC	no of parameters	BIC	no of parameters
1	24207.04	24		
2	22680.48	31	6823.11	26
3	22153.75	38	6359.56	32
4	22112.70	45	6204.76	38
5	22097.07	52	6303.71	44
6	22084.99	59		
7	22083.33	66		

Both absolute and relative latent class models are fitted to this data. The standard ordinal latent class model (absolute) was fitted using Latent Gold 5.1 (Vermunt and Magidson, 2013), and the paired comparison ordinal latent class model (relative) was fitted using an extension to the `prefmod` package in R (Hatzinger and Maier, 2017). Both approaches used 20 different starting values to ensure that the global maximum of the likelihood was reached. Table 1 shows the BIC values for both models, for a range of values of K. It can be seen that the standard latent class approach needs either six or seven classes (six classes is chosen here), whereas the paired comparison latent class model gives a minimum BIC for $K = 4$. The smaller number of classes found for the paired comparison approach is perhaps to be expected, as the standard approach needs to model both the absolute level of the Likert responses as well as the differences.

We examine the mean Likert rating for each of the items within each of the latent classes for the standard ordinal latent class model. In contrast, the worths provide the interpretation of the latent classes in the paired comparison LC model. Both plots are shown in Figure 1, which are oriented so that greater dangerousness (or greater danger worth) is towards the top of the plots.

It can be seen that for the standard ordinal latent class model, the first three classes - Class 1 (51%), Class 2 (24%) and Class 3 (12%) - all show little difference between the items, but differ according to their absolute level. The three remaining classes, in contrast, show considerable differences between the items. The paired comparison solution gives a similar story. The largest class shows little difference between the items, with the three remaining classes showing large differences in

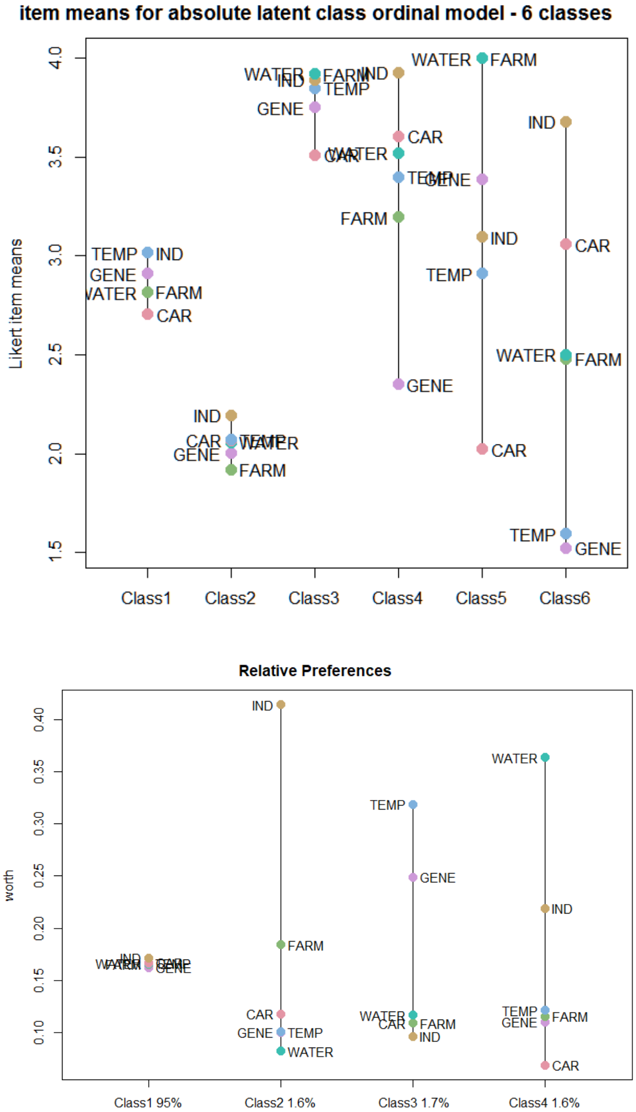

Fig. 1 Item worths for (top) standard ordinal LC model and (bottom) ordinal paired comparison LC model

dangerousness between items. Although the item rankings show some minor differences between the two methods, the results are similar.

5 Discussion and conclusions

This paper has demonstrated that the paired comparison ordinal model can be useful to understand the relative ordering of items in multiple Likert responses when the absolute level of the response is not of interest. The method leads to simpler models, which makes interpretation simpler. There are however some restrictions in using the model. The most important is that all Likert items must be measured on the same response scale. Differences between Likert items only make sense when this is true, and the paired comparison method relies on that. The PC method as currently implemented also assumes equidistance between the Likert categories, and further work is needed to relax this assumption.

Dealing with reciprocity in dynamic stochastic block models

Analisi della reciprocità in modelli dinamici basati su blocchi stocastici

Francesco Bartolucci, Maria Francesca Marino, Silvia Pandolfi

Abstract For directed relations among a set of nodes with a longitudinal structure, we introduce a dynamic stochastic block model where the blocks are represented by a sequence of latent variables following a Markov chain. Dyads are explicitly modeled conditional on the states occupied by both nodes involved in the relation. We mainly focus on reciprocity and propose three different parameterizations in which: (i) reciprocity is allowed to depend on the blocks of the nodes in the dyad; (ii) reciprocity is assumed to be constant across blocks; and (iii) reciprocity is ruled out. Inference on the model parameters is based on a variational approach. An approximate likelihood ratio test statistic based on the variational approximation is also proposed. This allows us to formally test for both the hypothesis of no reciprocity and that of constant reciprocity with respect to the latent blocks. The proposed approach is illustrated by a simulation study and two applications.

Abstract Si propone un modello dinamico a blocchi stocastici per dati relazionali longitudinali. I blocchi sono identificati da una sequenza di variabili latenti distribuite secondo una catena di Markov. Oggetto dell'analisi è ogni singola diade, la cui distribuzione viene modellata condizionatamente ai blocchi di appartenenza di ciascuno dei nodi coinvolti nella relazione. Particolare enfasi viene posta sullo studio della reciprocità tra i nodi, proponendo tre diverse parametrizzazioni in cui: (i) la reciprocità varia al variare dei blocchi di appartenenza dei nodi, (ii) il livello di reciprocità è constante, (iii) la reciprocità è assente. Per fare inferenze sui parametri del modello si propone l'utilizzo di un approccio variazionale, che rappresenta anche la base per lo sviluppo di un test basato sul rapporto di verosimiglianza ap-

1 Introduction

Dynamic Stochastic Block Models (SMBs) [5, 6] represent an important tool of analysis in the dynamic social network literature when the focus is on discovering communities and clustering individuals with respect to their social behavior. According to this specification, nodes in the network can be clustered into k distinct blocks, corresponding to the categories of discrete latent variables which evolve over time according to a first-order Markov chain. The probability of observing a connection between two nodes at a given occasion only depends on their block memberships at the same occasion.

Extending the proposal in [6], we develop an SBM for dynamic directed networks, observed in discrete time, in which the main element of analysis is the *dyad* referred to each pair of nodes. Our main assumption is that of conditional independence between the dyads, given the corresponding latent variables, rather than between univariate responses. This leads to a more flexible specification which does not rely on restrictive assumptions about the reciprocity between nodes. To provide a deeper insight into reciprocity effects, we propose to parametrically specify every dyadic relation by means of a conditional log-linear model. This allows us to effectively distinguish between main and reciprocal effects and improve interpretability of the results. Furthermore, the proposed approach allows us to formulate three different hypotheses: (i) reciprocity may depend on the blocks to which the units involved in the relation belong; (ii) reciprocity is constant across blocks; (iii) reciprocity is absent. Inference on the model parameters is pursued via a variational approach based on a lower bound for the intractable likelihood function. This lower bound also allows us to derive an approximate Likelihood Ratio (LR) test for inferential purposes on the reciprocity parameters.

The reminder of this paper is structured as follows. Section 2 describes the standard dynamic SBM and details the proposed dyadic formulation. In Section 3 we describe the variational approach for model inference. The simulation study and applications are outlined in Sections 4 and 5, respectively. For a detailed description of the proposed approach we remind the reader to [1].

2 Dynamic stochastic block models

Let $Y_{ij}^{(t)}, i, j = 1, \ldots, n, j \neq i$, denote a binary response variable which is equal to 1 if there exists an edge from node i to node j at occasion t, with $t = 1, \ldots, T$, and is equal to 0 otherwise; $y_{ij}^{(t)}$ is used to denote a realization of $Y_{ij}^{(t)}$. We focus on directed networks without self-loops, so that $Y_{ij}^{(t)}$ may differ from $Y_{ji}^{(t)}$ and $Y_{ii}^{(t)}$ is not defined. Moreover, let $\mathbf{Y}^{(t)}$ be the binary adjacency matrix recorded at occasion t, which summarizes the relations between nodes at this occasion and let $\mathscr{Y} = \{\mathbf{Y}^{(1)}, \ldots, \mathbf{Y}^{(T)}\}$ be the set of all network snapshots taken across time occasions.

Standard dynamic SBMs [5, 6] assume that network nodes belong to one of k distinct blocks, which are identified by the node- and time-specific latent variables $U_i^{(t)}$. These are defined on the finite support $\{1, \ldots, k\}$ and are assumed to follow a Markov chain with initial probability vector $\boldsymbol{\lambda} = \{\lambda_u, u = 1, \ldots, k\}$ and transition probability matrix $\boldsymbol{\Pi} = \{\pi_{u|v}, u, v = 1, \ldots, k\}$. A further crucial assumption of dynamic SBMs is that of *local independence*: given the latent variables $U_i^{(t)}$ and $U_j^{(t)}$, the responses $Y_{ij}^{(t)}$ are conditionally independent and follow a Bernoulli distribution with success probability only depending on the blocks of the nodes at occasion t.

We extend the previous formulation by relaxing the local independence assumption and directly accounting for reciprocal effects. For this aim we let $\mathbf{D}_{ij}^{(t)} = (Y_{ij}^{(t)}, Y_{ji}^{(t)})'$ denote the random vector corresponding to the dyad involving nodes i and j at occasion t, with $i = 1, \ldots, n-1$, $j = i+1, \ldots, n$, and $t = 1, \ldots, T$. Conditional on $U_i^{(t)} = u_1$ and $U_j^{(t)} = u_2$, we denote the dyad probabilities by

$$\psi_{y_1 y_2 | u_1 u_2} = p(\mathbf{D}_{ij}^{(t)} = \mathbf{d} \mid U_i^{(t)} = u_1, U_j^{(t)} = u_2),$$

with $u_1, u_2 = 1, \ldots, k$, $y_1, y_2 = 0, 1$, and $\mathbf{d} = (y_1, y_2) \in \{(0,0), (0,1), (1,0), (1,1)\}$. To put emphasis on reciprocity, we use the following log-linear parametrization:

$$\psi_{y_1 y_2 | u_1 u_2} \propto \exp\left[\alpha_{u_1 u_2} y_1 + (\alpha_{u_1 u_2} + \beta_{u_1 u_2}) y_2 + \rho_{u_1 u_2} y_1 y_2\right],$$

where $\beta_{uu} = 0$, for $u = 1, \ldots, k$, $\alpha_{u_1 u_2} = \alpha_{u_2 u_1} + \beta_{u_2 u_1}$, $\beta_{u_1 u_2} = -\beta_{u_2 u_1}$, and $\rho_{u_1 u_2} = \rho_{u_2 u_1}$, for all $u_1 \neq u_2$, to ensure identifiability.

Different versions of the proposed model specification may be obtained by imposing constraints on the $\rho_{u_1 u_2}$ parameters. In particular, under the hypothesis

$$H_I : \rho_{u_1 u_2} = 0, \quad u_1, u_2 = 1, \ldots, k, u_1 \leq u_2,$$

the model directly reduces to the standard dynamic SBM in [6], denoted by M_I, and based on the local independence between the responses $Y_{ij}^{(t)}$. Constant reciprocity effects correspond to the following hypothesis leading to model M_C:

$$H_C : \rho_{u_1 u_2} = \rho, \quad u_1, u_2 = 1, \ldots, k, u_1 \leq u_2.$$

The unconstrained model, with free $\rho_{u_1 u_2}$ parameters, will be denoted by M_U.

3 Variational inference

Let $\mathscr{U} = \{U_i^{(t)},\ i = 1,\dots,n,\ t = 1,\dots,T\}$ denote the overall set of latent variables in the model; based on the assumptions introduced so far, the observed network distribution is obtained by marginalizing out all these latent variables from the joint distribution of $\mathscr{Y}$ and $\mathscr{U}$. This would require the evaluation of a sum over $k^{Tn(n-1)/2}$ terms that, therefore, becomes quickly cumbersome as n, the number of nodes in the network, increases. We then rely on a variational approximation of the intractable likelihood function for making inference on the model parameters.

3.1 Parameter estimation

Let $\boldsymbol{\theta}$ denote the vector of all free model parameters. Following the approach suggested in [5] and [6], we estimate model parameters by a Variational Expectation Maximization (VEM) algorithm [3]. Let $p(\mathscr{U} \mid \mathscr{Y})$ denote the posterior distribution of $\mathscr{U}$ given the observed data $\mathscr{Y}$ and let $Q(\mathscr{U})$ denote its approximation. The VEM algorithm maximizes the following lower bound of the log-likelihood function:

$$\begin{aligned}\mathscr{J}(\boldsymbol{\theta}) &= \log p(\mathscr{Y}) - KL[Q(\mathscr{U}) \,||\, p(\mathscr{U} \mid \mathscr{Y})]\\ &= \sum_{\mathscr{U}} Q(\mathscr{U}) \log p(\mathscr{Y},\mathscr{U}) - \sum_{\mathscr{U}} Q(\mathscr{U}) \log Q(\mathscr{U}),\end{aligned} \qquad (1)$$

where $KL[\cdot \,||\, \cdot]$ stands for the Kullback-Leibler distance. In particular, we use the class of approximate distributions assuming conditional independence between the latent variables in the network given the observed data, namely $Q(\mathscr{U}) = \prod_{i=1}^n \prod_{t=1}^T q(u_i^{(t)}; \boldsymbol{\tau}_i^{(t)})$, where $q(\cdot; \boldsymbol{\tau}_i^{(t)})$ denotes a multinomial probability distribution with parameters 1 and $\boldsymbol{\tau}_i^{(t)} = \{\tau_{iu}^{(t)},\ u = 1,\dots,k\}$. Consequently, function $\mathscr{J}(\boldsymbol{\theta})$ defined in (1) can be rewritten as the sum of the following components:

$$\begin{aligned}\mathscr{J}_1(\boldsymbol{\theta}) &= \sum_{i=1}^n \sum_{u=1}^k \tau_{iu}^{(1)} \log \lambda_u + \sum_{i=1}^n \sum_{t=2}^T \sum_{u=1}^k \sum_{v=1}^k \tau_{iu}^{(t-1)} \tau_{iv}^{(t)} \log \pi_{v|u},\\ \mathscr{J}_2(\boldsymbol{\theta}) &= \sum_{i=1}^{n-1} \sum_{j=i+1}^n \sum_{t=1}^T \sum_{u=1}^k \sum_{v=1}^k \tau_{iu}^{(t)} \tau_{jv}^{(t)} \log p(y_{ij}^{(t)}, y_{ji}^{(t)} \mid U_i^{(t)} = u, U_j^{(t)} = v),\\ \mathscr{J}_3(\boldsymbol{\theta}) &= \sum_{i=1}^n \sum_{t=1}^T \sum_{u=1}^k \tau_{iu}^{(t)} \log \tau_{iu}^{(t)}.\end{aligned}$$

To obtain parameter estimates, the VEM algorithm alternates two separate steps until convergence: the E-step and the M-step. At the E-step, we maximize $\mathscr{J}(\boldsymbol{\theta})$ with respect to $\boldsymbol{\tau}_i^{(t)}, i = 1,\dots,n, t = 1,\dots,T$, under the constraint that these quantities are non-negative and $\sum_u \tau_{iu}^{(t)} = 1$. In the M-step, we maximize $\mathscr{J}(\boldsymbol{\theta})$ with respect to $\boldsymbol{\theta}$. Closed form solutions are available for the initial and the transition probabilities of the hidden Markov chain:

$$\lambda_u = \frac{\sum_{i=1}^n \tau_{iu}^{(1)}}{n}, \quad \pi_{v|u} = \frac{\sum_{i=1}^n \sum_{t=2}^T \tau_{iu}^{(t-1)} \tau_{iv}^{(t)}}{\sum_{i=1}^n \sum_{t=2}^T \tau_{iu}^{(t-1)}}.$$

The remaining model parameters are estimated by a standard Netwon-Raphson algorithm for log-linear models.

Two further relevant issues concern the selection of the optimal number of blocks k and the clustering of nodes. Regarding the first aspect, we rely on an Integrated Classification Likelihood (ICL) approach [2]; moreover, nodes may be assigned to one of the k blocks according to a maximum-a-posteriori rule based on the estimated parameters of the multinomial distribution $\hat{\boldsymbol{\tau}}_i^{(t)}$.

3.2 Testing for reciprocity

Reciprocity plays a central role when dealing with directed networks. To test for the absence of reciprocity in the network we propose an approximate LR test based on the lower bound of the likelihood function, $\mathscr{J}(\boldsymbol{\theta})$. Let $\hat{\boldsymbol{\theta}}_I$, $\hat{\boldsymbol{\theta}}_C$, and $\hat{\boldsymbol{\theta}}_U$ denote the vectors of parameters estimated under models M_I, M_C, and M_U, respectively, with the first model incorporating hypothesis H_I and the second incorporating hypothesis H_C. The proposed test is based on the statistic

$$R_I = -2\left[\mathscr{J}(\hat{\boldsymbol{\theta}}_I) - \mathscr{J}(\hat{\boldsymbol{\theta}}_U)\right].$$

We compare the observed value of this test statistic against a χ^2 distribution with a number of degrees of freedom equal to the number of free parameters in $\boldsymbol{\rho}$, that is, $k(k+1)/2$. In fact, we consider R_I as an approximation of the LR statistic $-2\left[\ell(\hat{\boldsymbol{\theta}}_I) - \ell(\hat{\boldsymbol{\theta}}_U)\right]$ that, under suitable regularity conditions, has null asymptotic distribution of this type.

For a more detailed analysis we also consider the decomposition $R_I = R_C + R_{CI}$, where

$$\begin{aligned} R_C &= -2\left[\mathscr{J}(\hat{\boldsymbol{\theta}}_C) - \mathscr{J}(\hat{\boldsymbol{\theta}}_U)\right], \\ R_{CI} &= -2\left[\mathscr{J}(\hat{\boldsymbol{\theta}}_I) - \mathscr{J}(\hat{\boldsymbol{\theta}}_C)\right], \end{aligned}$$

with R_C being the approximate LR test statistic for testing the constant reciprocity assumption H_C and R_{CI} begin the approximate LR test statistic for testing H_I against H_C. To perform the test, the first statistic is compared against a χ^2 distribution with $k(k+1)/2-1$ degrees of freedom and the second against a χ^2 distribution with one degree of freedom only.

4 Simulation study

To assess the properties of the approximate LR test statistics under different scenarios, we performed an intensive simulation study. We randomly drew $1,000$ samples from a two state ($k = 2$) dynamic SBM for $n = 20, 50, 100$ units observed at $T = 10$ different time occasions. The initial probability vector $\boldsymbol{\lambda}$ has elements 0.4 and 0.6 and the transition matrix $\boldsymbol{\Pi}$ has diagonal elements equal to 0.7 and 0.8. For the parameterization of the dyad probabilities, we set $\boldsymbol{\alpha} = (-2, -3, -1)'$, $\beta_{12} = 0$, and different values for the reciprocity parameter ranging from -2.5 to 2.5.

To evaluate the performance of the proposed inferential procedure, for each simulated scenario we considered the distribution of the approximate LR test statistics R_I and R_{CI}, which allow us to compare the independence model (M_I) against the unconstrained model (M_U) and the constant reciprocity model (M_C), respectively. Results are reported in Tables 1 and 2. The tables also report the simulated type I error probability/power of the above test statistics.

Table 1 *Mean $(\bar{R}_I)$, variance $(Var(R_I))$, and simulated type I error probability/power of the test statistic R_I (p) under different scenarios.*

	$n = 20$			$n = 50$			$n = 100$		
ρ	$\bar{R}_I$	Var(R_I)	p	$\bar{R}_I$	Var(R_I)	p	$\bar{R}_I$	Var(R_I)	p
-1.50	35.76	200.22	0.993	229.01	1167.33	1.000	922.82	5912.34	1.000
-1.00	21.15	109.27	0.975	129.17	557.34	1.000	523.86	2605.36	1.000
-0.50	7.53	28.92	0.737	42.13	178.39	1.000	167.06	728.66	1.000
-0.25	2.89	9.25	0.272	12.71	49.36	0.922	47.97	192.24	1.000
0.00	1.00	2.02	0.052	0.93	1.83	0.045	1.02	2.07	0.052
0.25	3.15	13.70	0.297	14.68	57.46	0.957	57.44	260.67	1.000
0.50	10.65	46.61	0.861	62.66	275.15	1.000	251.68	1130.22	1.000
1.00	45.71	220.82	1.000	293.87	1574.97	1.000	1180.30	7741.51	1.000
1.50	114.84	598.56	1.000	736.43	4668.70	1.000	2977.89	29305.76	1.000

Results confirm our conjecture that, when simulating data from model M_I, both approximate test statistics have a distribution reasonably close to a χ^2 distribution, leading to the rejection of H_I in about 5% of the simulated samples. On the other hand, under the homogeneity assumption for the reciprocity effects, we observe that the power increases as much as ρ deviates from 0. Moreover, the power of the test increases as the sample size n increases.

We also explored the performance of the proposed method for clustering units across time. For this aim, we evaluated the agreement between the estimated and the true latent structure in terms of adjusted rand index [4], obtaining rather encouraging results in comparison to alternative approaches.

Table 2 *Mean $(\bar{R}_{CI})$, variance $(Var(R_{CI}))$, and simulated type I error probability/power of the test statistic R_{CI} (p) under different scenarios.*

5 Empirical applications

5.1 Newcomb Fraternity network

The network at issue consists of 14 network snapshots on preference rankings (coded from 1 to 16) from 17 students. Data were collected longitudinally over 15 weeks between 1953 and 1956 among students living in an off-campus (fraternity) house at the University of Michigan. For the purpose of the analysis, we considered the binary socio-matrices $\mathbf{Y}^{(t)}$ derived from these data that are freely available as part of the R package `networkDynamic`. In each network snapshot, $Y_{ij}^{(t)} = 1$ if student i states a ranking for student j equal to 8 or less at time occasion t.

For these data, we estimated the proposed dynamic SBM with $k = 1,\dots,5$, considering the different model specifications corresponding to different hypotheses on reciprocity. The ICL criterion leads to selecting $k = 3$ latent blocks, regardless the chosen model specification. This criterion also identified M_C as the optimal model specification.

Based on the LR test statistic with $k = 3$, we observe that R_I is statistically significant and, therefore, leads to prefer M_U to M_I. A significant test statistic is also observed when comparing M_I against M_C, again with a p-value smaller than 0.001. On the other hand, we conclude that the assumption of constant reciprocity, H_C, cannot be rejected based on the observed data because $p(\chi^2_5 > R_C) = 0.102$, confirming the result based on the comparison of the ICL values.

The parameter estimates suggest the presence of significant mutual relations between students, irrespective to the cluster they belong to ($\hat{\rho} = 1.044$). Regarding the remaining parameters, we observe that students in block 1 are likely to declare a non-reciprocated friendship with nodes belonging to the same block ($\hat{\alpha}_{11} = 1.203$), while null within-group relations are mainly observed for students belonging to block 2 ($\hat{\alpha}_{22} = -1.069$). A non-significant value is observed for α_{33}. Regarding the estimated initial and transition probabilities of the hidden Markov chain, cluster 2 is the most likely at the beginning of the observation period ($\hat{\lambda}_2 = 0.48$). Moreover, estimated transitions show quite persistent hidden states.

5.2 Enron email network

The second example is based on a dynamic network derived from the Enron corpus, consisting of a large set of email messages that was made public during the legal investigation concerning the Enron corporation. The dataset concerns 184 Enron employees; we considered communications recorded between April 2001 and March 2002 and we built an email network for each month, so that the dynamic network has 12 time points. In this application, $Y_{ij}^{(t)} = 1$ if user i sent at least one email message to user j during the t-th month of the analyzed time window, with $i = 1,\ldots,183$, $j = i+1,\ldots,184$, and $t = 1,\ldots,12$.

We estimated a dynamic SBM with a varying number of blocks ($k = 1,\ldots,7$). ICL values lead to selecting a model with $k = 6$ hidden states for all considered parameterizations. Based on the same index, we selected the unconstrained model M_U, with reciprocity parameters depending on the latent blocks. Even in this case, we may validate the results by comparing the values of the approximate LR statistics. From this comparison, when $k = 6$, we observe that the hypothesis of absence of reciprocity, H_I, is strongly rejected by both tests based on R_I and R_{CI}. Moreover, the observed value of the test statistic R_C allows us to confirm that the unconstrained model has to be preferred to the other model specifications, due to a very low p-value. Accordingly, in this application, we conclude that reciprocal relations are statistically significant, and that they depend on the latent blocks of the nodes.

Causality patterns of a marketing campaign conducted over time: evidence from the latent Markov model

Effetti causali di una campagna di marketing protratta nel tempo attraverso un modello con processo di Markov latente

Fulvia Pennoni, Leo Paas and Francesco Bartolucci

Abstract Many statistical methods currently employed to evaluate the effect of a marketing campaign in dealing with observational data advocate strong parametric assumptions to correct for endogeneity among the participants. In addition, the assumptions compromise the estimated values when applied to data in which the research expects endogeneity but this is not realized. Based on the recent advances in the literature of causal models dealing with data collected across time, we propose a dynamic version of the inverse-probability-of-treatment weighting within the latent Markov model. The proposal, which is based on a weighted maximum likelihood approach, accounts for endogeneity without imposing strong restrictions. The likelihood function is maximized through the Expectation-Maximization algorithm which is suitably modified to account for the inverse probability weights. Standard errors for the parameters estimates are obtained by a nonparametric bootstrap method. We show the effects of multiple mail campaigns conducted by a large European bank with the purpose to influence their customers to the acquisitions of the addressed financial products.

1 Background

Firms operationalizing relationship marketing strategies often require insights into long-term developments of interactions with customers. Marketing response models have been developed to relate the customer decisions to the marketing efforts (Manchanda et al., 2004). For example, Li et al. (2005, 2011) propose to assess the consumer financial product portfolios at a bank, by considering key customer lifetime value indicators, such as customer profitability and retention. Latent Markov (LM) models (Bartolucci et al., 2013) have been extensively applied to incorporate switching of customers between segments over time (see, among others, Paas et al., 2007; Schweidel et al., 2011). They have been employed to potentially identify cross-sell opportunities.

In this context, the portfolios development can be influenced by the marketing activities operated by the firm or the bank that may include, among many strategies, also the direct mail channel. This kind of activity is often strategically based on customer characteristics or behaviors. When they are incorporated as covariates in an LM model, endogeneity can occur, since the bank is using the information on, for example, customer demographic characteristics and product ownership when targeting customers for campaigns. Among the models which have been applied to cope with this feature, the Gaussian copulas (Park and Gupta, 2012) and the latent instrumental variable models (Ebbes et al., 2005) are suitable to cope with endogeneity. However, these alternative models need strong assumptions which are not often satisfied. The first one assumes a Gaussian distribution for the errors and non-Gaussian distribution for the endogenous regressors. The latent instrumental variable models assume a discrete component among the endogenous regressors.

We propose an alternative model which is an extension of that proposed by Bartolucci et al. (2016) to address causal effects within observational studies. Consistently with the potential outcome (PO) framework (Rubin, 2005), the causal effects are considered under a counterfactual scenario because individuals cannot be observed under multiple treatments, but only for the treatment they effectively receive. We apply the inverse-probability-of-treatment weighting (IPW), based on the reciprocal of the probability for an individual of receiving the treatment s/he effectively received to alleviate the potential bias due to endogeneity (see also, Skrondal and Rabe-Hesketh, 2014). This accounts for dynamic counterfactuals and sequential endogeneity since treatments at different time occasions may induce different responses. Therefore, we propose to apply a weighted maximum likelihood approach to obtain a consistent estimator for the causal effect of interest.

The remainder of the paper proceeds as follows. In Section 2 we illustrate the proposed causal LM model. In Section 3 we present the empirical application related to a repeated direct mail campaign of an important bank to enlarge the customers' financial product portfolios. In Section 4 we report the results and in Section 5 we offer some concluding remarks.

2 The proposed causal LM model

We consider an observational longitudinal study involving n customers of a firm or a bank. Let $\boldsymbol{Y}_{it}$ be the observed binary vector of responses for customer i, $i = 1, \ldots, n$, at each time occasion t, $t = 1, \ldots, T$, which is a vector indicating the product portfolio of the customer owned at time t. Let $\boldsymbol{X}_{it}$ be a column vector of the available time-varying customer's covariates, some of which may have been selected by the bank to establish the marketing campaign.

Under the potential outcome framework we define a discrete variable to denote the time-varying treatment Z_{it} for customer i and time occasion t that is an ordinal variable with levels in $\{1, \ldots, l\}$. We denote by $H_{it}^{(z)}$ the discrete latent variable that is customer- and time-specific when s/he has received treatment z. Its distribution has support $\{1, \ldots, k\}$ and the support points are discrete finite values as each customer has many potential outcomes which are "potential versions" associated with each marketing intensity z administered at each time occasion. We also allow that the treatment can be absent when the first level of z is set equal to zero. For instance, $H_{it}^{(3)}$ corresponds to the latent state of prospect i at time t if s/he has received the treatment intensity equal to three marketing stimuli up to time t. The time sequence of these variables for customer i is collected in vector $\boldsymbol{H}_i^{(z)} = (H_{i1}^{(z)}, \ldots, H_{iT}^{(z)})'$.

In the following, we denote by lower case letters the realized values of the variables. Accordingly, the time-specific vectors of responses are denoted by $\boldsymbol{y}_{i1}, \ldots, \boldsymbol{y}_{iT}$ and we assume that every customer has a positive probability $p(Z_{it} = z|\boldsymbol{x}_{it})$ of receiving a marketing stimulus at each time period. We also assume that the marketing stimuli at each time period are independent of the potential outcomes given the pre-treatment covariates, that is, $Z_{it} \perp\!\!\!\perp H_{it}^{(z)}|\boldsymbol{X}_{i,t-1}$ for $i = 1, \ldots, n$, $t = 1, \ldots, T$.

The distribution of each $H_{it}^{(z)}$ variable is defined according to a of first-order Markov chain, where the initial probabilities of the latent chain define the potential products portfolios according to the received treatment at the first occasion. These are modeled by the following baseline-category logit model because the latent states do not show a precise order:

$$\log \frac{p(H_{i1}^{(z)} = h)}{p(H_{i1}^{(z)} = 1)} = \alpha_h + \boldsymbol{d}(z)'\boldsymbol{\beta}_h, \quad h = 2, \ldots, k. \tag{1}$$

In the previous expression, α_h is the state specific intercept, $\boldsymbol{\beta}_h = (\beta_{h2}, \ldots, \beta_{hl})'$ is a column vector of $l-1$ parameters, and $\boldsymbol{d}(z)$ is a column vector of $l-1$ zeros with the $(z-1)$-th element equal to 1 if $z > 1$. The element β_{hz} of $\boldsymbol{\beta}_h$ for $z > 1$, corresponds to the effect at the first occasion of the z-th treatment with respect to the effect of the first level of the treatment ($z = 1$). This coefficient is the average effect of the corresponding treatment for the population of interest at the beginning of the campaign.

A similar parameterization, which is not reported here, is employed for the transition probabilities. The parameters referred to the distribution of every observed response variable conditional to the POs identify the products owned by customers at each time occasion and they are useful to cluster the customers into homogenous segments. If required, the latter assumption may be relaxed in different ways (see Bartolucci et al., 2013, for further details).

In order to introduce the IPW estimator, we estimate the following multinomial logit model

$$\log \frac{p(Z_{it} = z|\boldsymbol{x}_{it-1})}{p(Z_{it} = 1|\boldsymbol{x}_{it-1})} = \eta_z + \boldsymbol{x}'_{it-1}\boldsymbol{\lambda}_z, \quad z = 1, \dots, l, \quad t = 1, \dots, T,$$

where η_z and $\boldsymbol{\lambda}_z$ are the intercept and the regression parameters referred to each treatment level. On the basis of the parameter estimates, we compute the customer weights referred to each time period as

$$\hat{w}_{it} = n\frac{1/\hat{p}(z_{it}|\boldsymbol{x}_{it-1})}{\sum_{i=1}^{n} 1/\hat{p}(z_{it}|\boldsymbol{x}_{it-1})}, \quad i = 1, \dots, n, \quad t = 1, \dots, T,$$

and the overall individual weights are provided by products of the weights concerning each year of the campaign

$$\hat{\boldsymbol{w}}_i = \prod_{t=1}^{T} \hat{w}_{it} \quad i = 1, \dots, n.$$

Given the observed data, model estimation is performed by maximizing the weighted log-likelihood

$$\ell(\boldsymbol{\theta}) = \sum_{i=1}^{n} \hat{\boldsymbol{w}}_i \log \ell_i(\boldsymbol{\theta}), \quad \ell_i(\boldsymbol{\theta}) = \log p(\boldsymbol{y}_{i1}, \dots, \boldsymbol{y}_{iT}|z_{it}),$$

where $\boldsymbol{\theta}$ is the overall vector of parameters. This log-likelihood is maximized by using a modified version of the Expectation-Maximization (EM) algorithm (Baum et al., 1970; Dempster et al., 1977). The algorithm is based on the complete data log-likelihood $\ell^*(\boldsymbol{\theta})$ which involves the weighted frequencies of each latent states (see also Bartolucci et al., 2013, for details). The steps of the algorithm are the following:

- **E-step**: it computes the conditional expected value of each frequency involved in the complete data log-likelihood. It requires to compute the posterior probabilities of the latent variable given the weights, the observed responses, and the treatment sequence;
- **M-step**: it maximizes the complete-data log-likelihood where the frequencies are obtained by the corresponding expected values calculated at the E-step.

A non-parametric bootstrap algorithm (Davison and Hinkley, 1997) is employed to obtain the standard errors for the model parameters. We resample customers, with their observed pre-treatment covariates and outcomes, a suitable number of times; then we estimate the model for each generated sample in accordance with the estimated customer's time-varying weights. The number of latent states is selected by the Bayesian Information Criterion (BIC; Schwarz, 1978).

3 Application

We analyze a sample of 49,967 customers aged 18 years and older, provided by a large anonymous European bank that conducted a multiple direct mail campaign over a long period of time. We evaluate the effectiveness of the efforts made by the bank in terms of developments of the customers's portfolios. The following products could be affected by the marketing campaign: *loans, credit cards, checking accounts, investment products, mortgages, savings accounts, and a paid phone service enabling customers to gain insights into their account balances*.

Direct mail was the dominant channel for making product offers to customers in the 2000-2003-period to which the data refer. Table 1 shows the proportions of customers involved in each year of the campaign. We consider four treatment levels varying from none to more than six mails sent to each customer. As shown in Table 1, the sequential treatments have been administered according to an increasing intensity to the customers.

Direct mail intensity	2001	2002	2003
none	0.317	0.237	0.186
1-2	0.311	0.323	0.248
3-5	0.222	0.211	0.245
≥ 6	0.150	0.229	0.321

Table 1 *Observed proportions of direct mail intensity by year.*

The available time-varying covariates influencing the treatment probability are the following: customer's age, money s/he has transferred each year on the account, number of transactions made annually, and annual bank' profits on each customer. It is important to note that the endogeneity arises mainly because the customer selection to which address the campaign made by the managers is not done by randomized methods. Instead the bank's managers choose by simple common sense or by employing logistic regression models or tree-based algorithms.

4 Results

The BIC index favors the model with seven latent states when we estimate the causal LM model for a number of latent states ranging from 1 to 8. The model-based approach defines the following customer segments corresponding to the latent states and characterized on the basis of the conditional response probabilities given the latent states:

1. "none" (0%)
2. "checking account only" (40%)
3. "savers'segment" (5%)

4. “investors” (23%)
5. “phone service customers” (11%)
6. “loans customers” (16%)
7. “actives” (5%)

where the reported percentages are referred to the proportion of customers in the corresponding segment after the first year of the campaign. In this way, we also identify a segment (denoted with 1) as that of individuals which have churned the bank during the first period.

In Table 2 we show the estimated initial probabilities which are averaged according to the intensity of the treatment (see Table 1). They are obtained by considering the estimated average treatment effect on the initial segments as in equation (1). From these results we notice that if the campaign is not conducted, or it is conducted with a low mail intensity, there is a higher probability for a customer to be allocated in segment 2 “checking account only” at the beginning of the period respect to a more intensive campaign. Note that, except for segment 2, all the probabilities referred to intensities (3-5) and (≥ 6) are higher than those of lower treatment levels. This indicates that the treatment enhances the probability to be more active at bank, especially to become “investor” (segment 4).

	Latent state (h)						
Direct mail intensity	1	2	3	4	5	6	7
none	0.00	0.48	0.21	0.03	0.10	0.04	0.15
1-2	0.00	0.44	0.22	0.04	0.10	0.04	0.15
3-5	0.00	0.38	0.25	0.05	0.11	0.05	0.15
≥6	0.00	0.18	0.30	0.11	0.13	0.07	0.21

Table 2 *Estimated initial probabilities for each treatment level under the causal LM.*

	Latent state (h)						
$\bar{h}$	1	2	3	4	5	6	7
1	1.000	0.000	0.000	0.000	0.000	0.000	0.000
2	0.072	0.808	0.030	0.000	0.056	0.020	0.015
3	0.017	0.031	0.894	0.000	0.042	0.003	0.014
4	0.023	0.000	0.000	0.967	0.006	0.000	0.004
5	0.011	0.005	0.001	0.000	0.976	0.000	0.009
6	0.004	0.014	0.004	0.000	0.004	0.972	0.002
7	0.009	0.006	0.005	0.001	0.006	0.000	0.974

Table 3 *Estimated transition probabilities of the causal LM model with 7 latent states.*

In Table 3 we report the estimated transition probabilities for customers in the highest treatment level (intensity ≥6 mails). The other three tables concerning the transition probabilities of the latent states of lower mails intensity are not reported here. Based on all relevant tables, we notice that when treatment is intensive, the customers in segment 2 “checking account only” show a relative high probability to switch towards the segments in which customers own multiple products, that is, 5.6% for switching into latent state 4 “investment inclined customers”, 2.0% for switching into segment 6 “loan customers”, and 1.5% for switching into segment 7 of “active customers”.

From the other estimated matrices relative to a low mail intensity or no treatment at all, we notice that mainly for the customers in segment 5 “loan customers ” and 6 “mortgage customers” there is a higher probability to switch into segment 1 of “inactive customers” or segment 2 of “checking account only” compared to those observed in Table 3.

5 Conclusions

The findings gained by the results illustrated in Section 4 provide a number of salient managerial implications. We provide a short summary through the following three advices:

- ensure that each customer receives at least one direct mailing each year to reduce churn probabilities;
- perform an intensive campaign towards customers in segment 6 “lenders” to reduce the probability of terminating the usage of the loan at the same bank;
- send at least six direct mails each year to customers in segment 2 “checking account only”, to enhance their probability to switch into the more active states, emphasizing the loan and the online phone service, as the acquisition of these financial products is most strongly influenced by the direct mail channel.

Direct mail mostly affects forward switching probabilities for customers with only a checking account (segment 2) into multiple segments not characterized by high ownership of savings accounts and mortgages. This leads to two additional suggestions: (*i*) assess through experiments whether innovative direct mailings can enhance switching probabilities forward that are currently low. Also, other channels can be employed to assess whether these low transition probabilities can be affected (e.g., the personal sales channel); (*ii*) find how the direct mail channels or other marketing communication channels can be employed to effectively market mortgages.

The innovative approach we propose to address endogeneity has important features which may help managers to make better decisions on how many direct marketing mailings each individual customer should receive. Therefore, the proposed causal LM model may be fruitfully applied in many other potential marketing contexts over that illustrated in the applicative example.

Complex Spatio-temporal Processes and Functional Data

Clustering of spatio-temporal data based on marked variograms

Clustering di dati spazio-temporali basato su marked variograms

Antonio Balzanella and Rosanna Verde

Abstract This paper deals with the clustering of data generated by spatio-temporal point processes. The interest on this topic is motivated by the recent availability of spatio-temporally indexed data in several applicative fields like seismology, climatology, economics, social sciences. The data we analyse is a collection of instantaneous events, each occurring at a given spatial location. We introduce a strategy which finds a partition of the individuals into homogeneous clusters considering the space-time interactions. We transform the spatio-temporal point process into two marked point processes, considering the times as marks of the spatial point process and the locations as marks of the times. This allows to use the marked variograms to describe the second-order characteristics of the individuals, in time and space. We propose a k-means like algorithm which uses the marked variograms as cluster representative and performs the allocation to clusters evaluating the contribution of each individual to the definition of the marked variograms. This allows to get clusters of individuals which are homogeneous in terms of space-time interactions.
Abstract *Il presente articolo è incentrato sulle tecniche di clustering per dati generati da processi di punto spazio-tempo. L'interesse sulla tematica è dovuto alla crescente disponibilità di dati spazio-tempo in ambiti applicativi quali la sismologia, la climatologia, le scienze economiche, le scienze sociali. La tipologia di dati che si propone di analizzare è una collezione di eventi istantanei verificatisi, ciascuno, in una specifica locazione spaziale. In tale contesto, si propone una strategia di clustering finalizzata all'individuazione di una partizione degli individui in cluster omogenei, considerando le interazioni spazio-tempo. Si propone di trasformare il processo di punto spazio-tempo in due processi di punto marcati nei quali si considera il tempo, come marcatore di un processo di punto spaziale e lo spazio, come marcatore di un processo di punto temporale. Ciò consente di utilizzare i var-*

iogrammi marcati per descrivere le caratteristiche di secondo ordine degli individui nel tempo e nello spazio. Nella strategia proposta, i variogrammi marcati vengono utilizzati come centroidi di un algoritmo di tipo k-means che effettua l'allocazione ai cluster sulla base del contributo di ciascun individuo alla definizione della struttura di variabilità spazio-temporale sintetizzata dai variogrammi marcati. Tale approccio consente di ottenere cluster di individui che sono omogenei in termini di interazioni spazio-tempo.

Key words: clustering, spatio-temporal point process, mark variogram

1 Introduction

In this paper we deal with the statistical analysis of a collection of data generated by a spatio-temporal point process. Single observations are instantaneous events, each occurring at a given spatial location with a given associated time stamp. Typical applications are the analysis of seismic events, the monitoring of crimes or diseases.

Recent proposals in [2][4] provide, a review of the statistics for analysing such kind of data and new methods for exploring the spatio-temporal data structure by means of suitable second-order statistics.

We focus on clustering the data points into homogeneous groups keeping into consideration their spatio-temporal interactions.

Consistently with [4], we transform the spatio-temporal point process into two marked point processes. We can consider the times as marks of the spatial point process of point locations and the locations as marks of the times.

For evaluating the second-order characteristics of the two marked point processes, we use the mark variograms. The latter, provide a measure of the data interaction over the whole geographic area, for the considered time window.

In this paper, we propose a decomposition of the mark variograms into a set of local measures of spatio-temporal interaction (LMSTI), which allow to evaluate the contribution of each data point to the definition of the mark variogram.

Since we use two mark variograms for evaluating the second order characteristics of the spatio-temporal point process, we will associate each data point to two LMSTI, the first one uses the time as mark, the second one uses the location as mark.

Our idea, is to describe each data point through the two mark LMSTI and to perform a *k*-means like algorithm on this new data description. This allows to get clusters of data points which interact similarly with the other data points, accounting both for the space and time dimension.

2 Main notations and definitions

We consider a spatio-temporal point process $X = \{(s_1,t_1),\ldots,(s_i,t_i),\ldots,(s_n,t_n)\}$, where $s_i \in D \subseteq \Re^2$ is a spatial location and $t_i \in T \subseteq \Re^+$ the corresponding time. We assume that the point process is orderly, that is, coincident points cannot occur.

Similarly to [4], the random process X can be transformed into two mark point processes X_t and X_s using, respectively, the time and the locations as marks.

This allows to use the classic mark variogram [3] for measuring the interactions in the two processes. In particular, if we consider the time, as mark, the variogram γ_{sp} is:

$$\gamma_{sp}(h) = \frac{1}{2}\mathbf{E}\left[(t_i - t_j)^2 \ \mid t_i, t_j \in T\right] \tag{1}$$

where $h = \left\|s_i - s_j\right\|$.

Similarly, if we consider the spatial location as mark, the variogram γ_{ti} is:

$$\gamma_{ti}(v) = \frac{1}{2}\mathbf{E}\left[(s_i - s_j)^2 \ \mid s_i, s_j \in D\right] \tag{2}$$

where $v = \left\|s_i - s_j\right\|$.

Similarly to the classic variogram used in geostatistics ([1]), the mark variogram gives information on the correlations in the marked point process.

In order to estimate $\gamma_{sp}(h)$ we can use the expression in [4]:

$$\hat{\gamma}_{sp}(h) = \frac{\sum_{s_i,s_j \in D} \frac{1}{2}(t_i - t_j)^2 k_e(\left\|x_i - x_j\right\| - h)}{\sum_{s_i,s_j \in D} k_e(\left\|x_i - x_j\right\| - h)} \tag{3}$$

where k_e is is a one-dimensional kernel function with bandwidth e.

Similarly, $\gamma_{ti}(v)$ can be estimated by:

$$\hat{\gamma}_{ti}(v) = \frac{\sum_{t_i,t_j \in T} \frac{1}{2}(s_i - s_j)^2 k_g(\left\|t_i - t_j\right\| - v)}{\sum_{t_i,t_j \in T} k_g(\left\|t_i - t_j\right\| - v)} \tag{4}$$

where k_g is a one-dimensional kernel function with bandwidth g.

In order to introduce our clustering algorithm, we associate to each data point two functions which measure the interaction of the data point (s_i,t_i) with the other data points. The two functions Δ^i_{sp} and Δ^i_{ti} are obtained by decomposing the mark variograms γ_{sp} and γ_{ti}:

$$\Delta^i_{sp}(h) = \sum_{s_j \in D} \frac{1}{2}(t_i - t_j)^2 k_e(\left\|x_i - x_j\right\| - h) \tag{5}$$

$$\Delta^i_{ti}(v) = \sum_{t_j \in T} \frac{1}{2}(s_i - s_j)^2 k_g(\left\|t_i - t_j\right\| - v) \tag{6}$$

where $h = \|s_i - s_j\|$ and $v = \|s_i - s_j\|$.

3 Clustering of local measures of spatio-temporal interaction

By means of Δ^i_{sp} and Δ^i_{ti} we get a new description of the observed data points which we use in a k-means like algorithm for obtaining a partitioning P of the data points (s_i, t_i) into K clusters C_k (with $k = 1, \ldots, K$).

In order to reach our aim, we propose to minimize the following objective function:

$$J(P, L) = \sum_{k=1}^{K} \sum_{(s_i,t_i)\in C_k} d^2(\Delta^i_{sp}(h); \overline{\Delta^k_{sp}}(h)) + d^2(\Delta^i_{ti}(v); \overline{\Delta^k_{ti}}(v)) \tag{7}$$

where:

$\overline{\Delta^k_{sp}}(h)$ and $\overline{\Delta^k_{ti}}(v)$ are the prototypes of the cluster C_k;
L is the matrix of prototypes;
$d^2(.)$ is the squared euclidean distance.

The minimization of the objective function is performed by an iterative algorithm which starts from an initial random partitioning of the data points and, then, alternates a representation step and an allocation step until a stable value of $J(P, L)$ is reached.

In the representation step, the prototype $\overline{\Delta^k_{sp}}$, $\overline{\Delta^k_{ti}}$ of each cluster are computed by:

$$\overline{\Delta^k_{sp}} = \frac{\sum_{(s_i,t_i)\in C_k} \Delta^i_{sp}}{|C_k|} \tag{8}$$

$$\overline{\Delta^k_{ti}} = \frac{\sum_{(s_i,t_i)\in C_k} \Delta^i_{ti}}{|C_k|} \tag{9}$$

that is, they are the average of the LMSTI functions allocated to a cluster and can be seen as a summary of the spatio-temporal interaction structure in each cluster.

In the allocation step, the data points (s_i, t_i) are allocated to the cluster C_k, if the squared Euclidean distance between LMSTI functions Δ^i_{sp} and Δ^i_{ti} and the cluster prototype $\overline{\Delta^k_{sp}}$, $\overline{\Delta^k_{ti}}$ is minimum, through the following rule:

$$d^2\left(\Delta^i_{sp}(h); \overline{\Delta^k_{sp}}(h))\right) + d^2\left(\Delta^i_{ti}(v); \overline{\Delta^k_{ti}}(v))\right) < \\ d^2\left(\Delta^i_{sp}(h); \overline{\Delta^{k'}_{sp}}(h))\right) + d^2\left(\Delta^i_{ti}(v); \overline{\Delta^{k'}_{ti}}(v))\right) \quad \forall k \neq k' \tag{10}$$

Since the centroids of each cluster are the average of the allocated items, similarly to the classic k-means, the optimized criterion decreases with the iterations until it reaches a stable value.

4 Preliminary results on real data

In this section, we introduce some preliminary results on real data. The dataset collects earthquakes in Japan from 1926 to 2005. The dataset contains 948 epicenters of earthquakes with a magnitude higher than 4.5. The data was obtained from `http://users.jyu.fi/~penttine/ppstatistics/data/Earthquakes_Fig_6_21.txt`. We consider D as a planar rectangle of side lengths $a = 543km$ and $b = 556km$, and a time interval T of length 12000 days.

We show in figure 3 the results of the partitioning into $K = 4$ clusters of the dataset of seismic events.

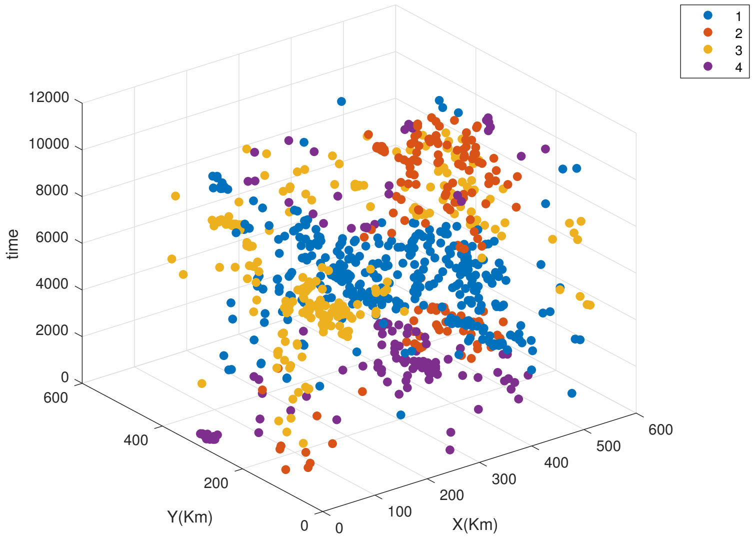

Fig. 1 Partitioning of the seismic events into $K = 4$ clusters.

Still, we show the LMSTI functions and the their average (cluster prototype) for each cluster and for the space and time domain in fig.

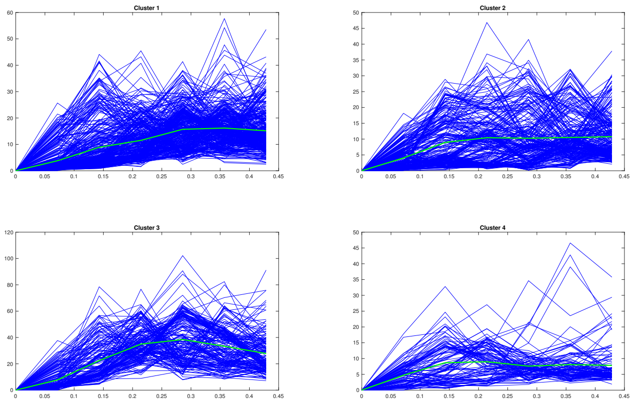

Fig. 2 LMSTI functions and cluster centroid in Space domain

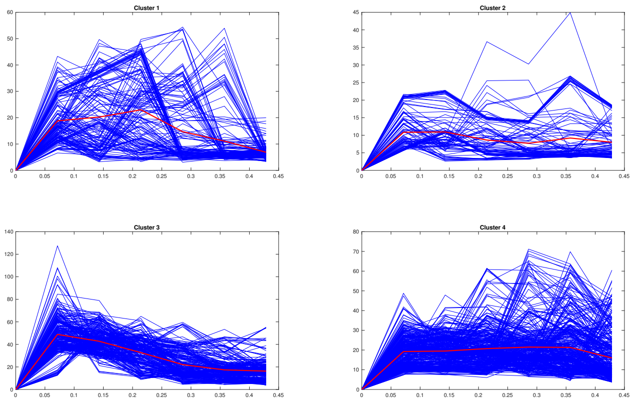

Fig. 3 LMSTI functions and cluster centroid in Time domain

Space-time earthquake clustering: nearest-neighbor and stochastic declustering methods in comparison

Clustering spazio-temporale di terremoti: i metodi nearest-neighbor e di declustering stocastico a confronto

Elisa Varini, Antonella Peresan, Renata Rotondi, and Stefania Gentili

Abstract Earthquakes do not occur randomly in space and time; rather, they tend to group into clusters that can be classified according to their different properties, presumably related to the specific geophysical properties of a seismic region. Two methods for detection of earthquake clusters are considered in order to take advantage of different descriptions of the seismic process and assess consistency with the obtained clusters: the former is based on "nearest-neighbor distances" between events in space-time-energy domain; the latter is a stochastic method based on a branching point process, named Epidemic-Type Aftershock-Sequence (ETAS) model, which provides different plausible clustering scenarios by simulation. Both methods allow for a robust data-driven identification of seismic clusters, and permit to disclose possible complex features in the internal structure of the identified clusters. We aim at exploring the spatio-temporal features of earthquake clusters in Northeastern Italy, an area recently affected by low-to-moderate magnitude events, despite its high seismic hazard attested by historical destructive earthquakes.

Abstract *I terremoti non avvengono in modo casuale nello spazio-tempo, tendono piuttosto a raggrupparsi in cluster che possono essere classificati secondo le loro diverse proprietà, verosimilmente legate alle specifiche proprietà geofisiche della regione dove essi accadono. Due metodi per l'individuazione di cluster di terremoti sono stati presi in esame al fine di benificiare di descrizioni diverse del processo sismico e valutare la coerenza dei cluster ottenuti: il primo è un metodo basato sulla distanza "nearest-neighbor" tra coppie di eventi nel dominio spazio-tempo-energia; il secondo è un metodo stocastico basato su un modello di processi di punto di tipo branching noto come modello ETAS (Epidemic-Type Aftershock-Sequence)*

che, attraverso tecniche di simulazione, è in grado di fornire diversi scenari plausibili di raggruppamento in clusters. Entrambe i metodi consentono una identificazione robusta dei cluster sismici, fondamentalmente guidata dai dati, e permettono di studiare la complessità nella struttura interna dei cluster stessi. Analizziamo le caratteristiche spazio-temporali dei cluster di terremoti avvenuti nell'Italia nord-orientale, un'area ad alta pericolosità sismica, come attestato da alcuni forti terremoti storici, e con una sismicità di magnitudo medio-bassa negli ultimi decenni.

Key words: earthquake clustering, simulation, stochastic declustering, ETAS model, nearest-neighbor distance

1 Some methods for earthquake clustering

Earthquake clustering is a prominent feature of seismic catalogs, both in time and space. Several methodologies for earthquake cluster identification have been proposed in the literature with at least a twofold scope: (1) characterization of the clustering features and their possible relation to physical properties of the crust; (2) declustering of earthquake catalogs which, by removing events temporally and spatially dependent on the mainshocks, allows for spatio-temporal analysis of the background (independent) seismicity. Nevertheless the application of different (de)clustering methods may lead to diverse classifications of earthquakes into main events and secondary events; consequently, the definition of mainshock is not univocal, but strictly related to the different physical/statistical assumptions underlying each method. Therefore we consider different declustering techniques to investigate classification similarities which might provide strong support for some clustering features, and classification differences which might highlight strength and lack of the clustering methods. Two clustering techniques are applied: the nearest-neighbor approach (Zaliapin and Ben-Zion, 2013) and the stochastic declustering approach (Zhuang et al., 2004). Both methods can be satisfactorily applied to decompose the seismic catalog into background seismicity and individual sequences (clusters) of earthquakes; moreover, they are data-driven and allow studying the internal structure of the clusters.

1.1 Nearest-neighbor method (NN)

Bak *et al.* [2] show that the waiting times between earthquakes in California follow a unified scaling law valid at different time scales (from tens of seconds to tens of years), by varying the magnitude threshold M and the linear size L of the studied area. The unified scaling law is obtained by rescaling the distribution $F(t)$ of the waiting times in such a way that t is replaced by $t10^{-bM}L^{d_f}$ and $F(t)$ by $t^{\alpha}F(t)$. Parameters α, b, and d_f correspond to empirical power laws which establish general relations among frequency, waiting times, magnitude, and epicentre locations of the earthquakes: α is the interval exponent of the Omori-Utsu law, b is the b-value of the Gutenberg-Richter distribution of the magnitude, and d_f is the spatial fractal dimension of the epicentre distribution. Thus the unified scaling law is a combination of scale invariant power functions that can be interpreted as statistical evidence of the self-organized critical behaviour of the earth dynamics, which results into a hierarchical organization of earthquakes in time, space, and magnitude. Based on this concept [1], the nearest-neighbor distance between two events in the space-time-energy domain is defined by:

$$\eta_{ij} = t_{ij}(r_{ij})^{d_f} 10^{-bM_i} \ , \tag{1}$$

where t_{ij} denotes the inter-occurrence time between events i and j ($i < j$), r_{ij} is the spatial distance between their epicentres, M_i is the magnitude of i-th event. Event i^* is the nearest-neighbor of event j if $i^* = argmin_{\{i:i<j\}} \eta_{ij}$; in other words, event j is an offspring of event i^*, and also i^* is the parent of j.

By connecting each event with its nearest-neighbor, one obtains a time-oriented tree where each event has a unique parent and may have multiple offspring. By setting a threshold distance η_0, a link between events i and j is removed if $\eta_{ij} > \eta_0$, for all i and j such that $i < j$. The removal of weak links leads to the identification of clusters of events; in each cluster, we define the largest magnitude event as mainshock, the events preceding the mainshock as foreshocks, and the events following the mainshock as aftershocks.

According to Zaliapin and Ben-Zion [6], the histogram of the distances between every pair of events clearly shows a bimodal distribution that can be approximated as a mixture of two Gaussian distributions, one associated with the Poissonian background activity (independent events) and the other with the clustered populations. Thus, threshold distance η_0 can be chosen as equal to the intersection point of the two estimated Gaussian distributions.

Parameters α, b, and d_f are estimated by the Unified Scaling Law for Earthquakes (USLE) method [3, 5].

1.2 Stochastic declustering method (SD)

The stochastic declustering approach is based on the space-time epidemic-type aftershock sequence (ETAS) model [4], a branching point process controlled by its intensity function $\lambda^*(t,x,y,M \mid \mathscr{H}_t)$ conditional on the observation history $\mathscr{H}_t$ up to time t.

Let (t_j, x_j, y_j, M_j) denote occurrence time, epicentral coordinates and magnitude of j-th event. Under the assumption of stationarity, ergodicity, and independence of the magnitude, the general expression of the conditional intensity function of ETAS model is given by:

$$\lambda^*(t,x,y,M \mid \mathscr{H}_t) = J(M)\lambda(t,x,y \mid \mathscr{H}_t) =$$
$$= J(M)\left[\mu(x,y) + \sum_{\{k:t_k<t\}} k(M_k)g(t-t_k)f(x-x_k,y-y_k \mid M_k)\right] ,$$

which, in the formulation of this study, decomposes into:

$$J(M) = be^{-b(M-M_c)} , \tag{2}$$
$$\mu(x,y) = \nu u(x,y) , \tag{3}$$
$$k(M) = Ae^{-\alpha(M-M_c)} , \tag{4}$$
$$g(t) = \begin{cases} (p-1)c^{p-1}(t+c)^{-p} & \text{for } t>0 \\ 0 & \text{otherwise} \end{cases} , \tag{5}$$
$$f(x,y \mid M) = \frac{(q-1)D^{2(q-1)}e^{\gamma(q-1)(M-M_0)}}{\pi[x^2+y^2+D^2e^{\gamma(M-M_0)}]^q} . \tag{6}$$

where M_c is the magnitude threshold of the catalog; Eq.(2) is the distribution of earthquake magnitude; the background rate in Eq.(3) is assumed to be constant in time; the expected number of events triggered from an event of magnitude M is expressed by Eq.(4); the probability density function of the occurrence times and the location distribution of the triggered events are given by Eqs.(5-6), respectively. It is also worth defining the total spatial intensity $m(x,y) = \lim_{T\to\infty} \int_0^T \lambda(t,x,y \mid \mathscr{H}_t)dt/T$ and the clustering spatial intensity $\gamma(x,y) = m(x,y) - \mu(x,y)$. The model parameters are denoted by ν, A, c, α, p, D, q, and γ.

In ETAS model, background earthquakes independently occur at a Poisson rate constant in time, triggering other events with a spatio-temporal decay modelled by the Omori-Utsu law; triggered events have, in turn, the ability to trigger other events. The following expressions respectively provide the probability that event j is triggered by previous event i, the probability that event j is triggered in general, and the probability that event j is generated by the background process:

$$\rho_{ij} = \frac{k(M_i)g(t_j-t_i)f(x_j-x_i,y_j-y_i \mid M_i)}{\lambda(t_j,x_j,y_j \mid \mathscr{H}_{t_j})} \tag{7}$$
$$\rho_j = \sum_{i:t_i<t_j} \rho_{ij} \tag{8}$$
$$\varphi_j = 1-\rho_j \tag{9}$$

By simulating according to these probabilities, the dataset splits into two subsets which are realizations of the background process and the triggered process, respectively: the former is the declustered catalog and the latter identifies a set of clusters each starting from a background event.

The estimation of ETAS parameters is performed by an iterative algorithm that simultaneously estimates the background rate by a variable kernel method and the model parameters by the maximum likelihood method; then the branching structure is obtained by simulation [7, 8, 9].

2 Case study: Northeastern Italy seismicity

The comparative analysis of earthquake clusters is carried out for a sequence of earthquakes occurred in Northeastern Italy. In this area only low-to-moderate magnitude events have been recorded during the last decades, despite its high seismic hazard attested by at least eight historical destructive earthquakes occurred since 1348, the most recent one being the 1976 May 6 M6.4 earthquake, located in the Julian Prealps. A further aim of the clustering analysis is to provide a quantitative basis to understand the role of moderate size earthquakes in the framework of regional seismicity.

2.1 Data

The Italian National Institute of Oceanography and Experimental Geophysics (OGS) started with the monitoring of seismic activities in the Northeastern area of Italy since 1977. We consider the set of earthquakes reported in the OGS bulletins, occurred from 1977 to 2015, with local magnitude at least $M_c = 2$, and ranging from 11.5°E to 14.0°E in longitude and from 45.5°N to 47.0°N in latitude (Fig. 1).
The dataset is considered as complete except for the early 1990s, when data are missing due to a fire accident [5].

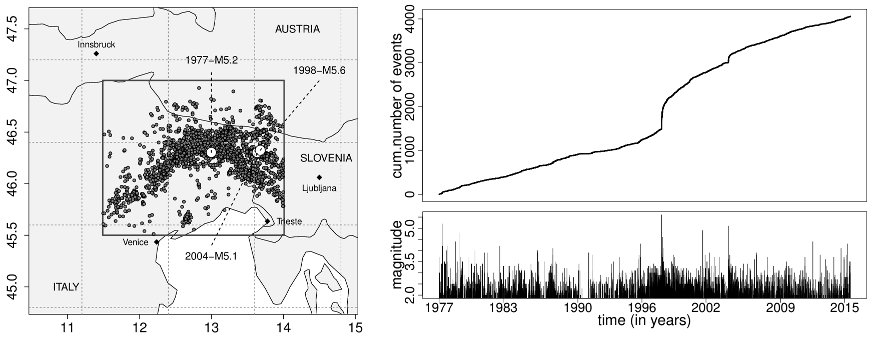

Fig. 1 Epicentres of the earthquakes in the study area: black point if magnitude $M \leq 5$, white points otherwise [left]. Cumulative number of earthquakes versus time (top) and magnitude versus time (bottom) [right].

2.2 Results

NN method univocally splits the dataset into two subsets, a set of background events and a set of triggered events; more details are given in [5]. A tree representation of the identified clusters is provided in order to better highlight the complexity of clusters structure. For example Fig. 2(a) shows the tree of the cluster related to the 1998 earthquake, with magnitude $M5.6$.

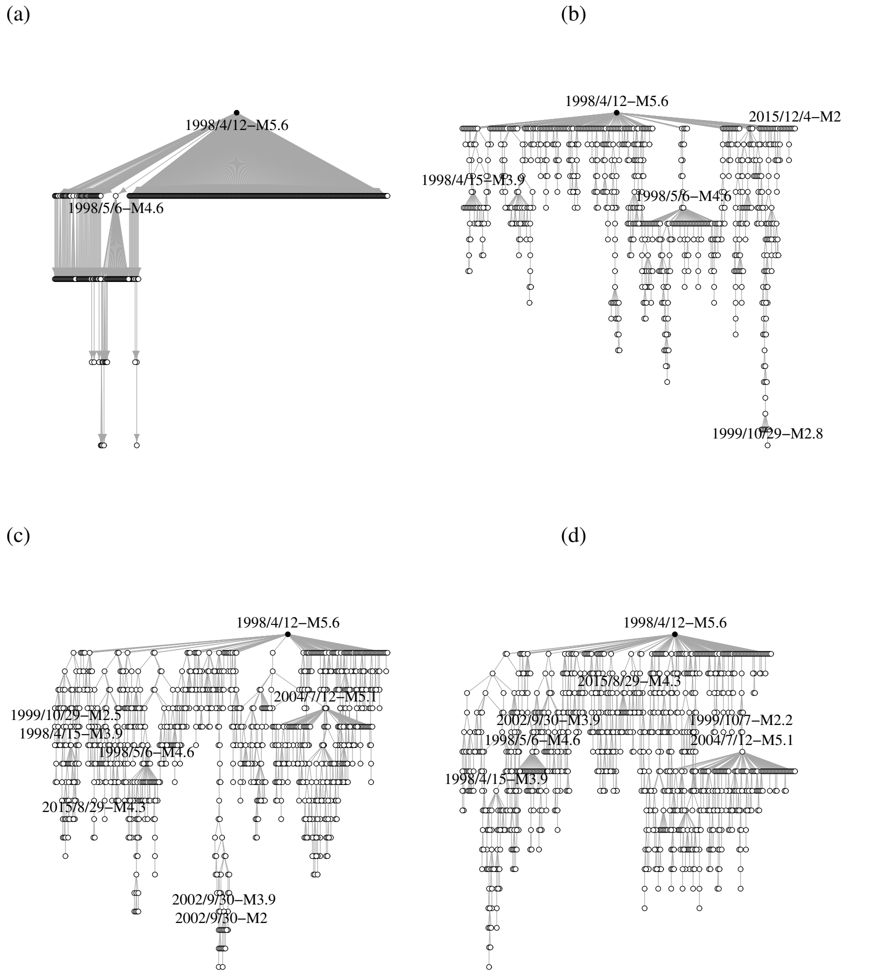

Fig. 2 Cluster trees of the 1998/4/12 earthquake, magnitude M5.6: (a) NN method, (b) SD method, the most probable scenario, and (c-d) SD method, two simulated scenarios, respectively.

As for the SD method, each event j in the dataset is associated with the estimated probability $\hat{\varphi}_j$ ($\hat{\rho}_j$) to be a background (triggered) event. These probabilities provide different clustering scenarios: Fig. 2(b) shows the cluster tree of the 1998 earthquake where each $j-$th event is associated with the most probable ancestor i^* ($i^* = argmax_{i<j}\rho_{ij}$), while Fig. 2(c-d) show the cluster trees of the same earthquake, each derived by simulation according to the estimated background probabilities. For all the spatial coordinates (x,y) in the study area, with reference to SD method, Fig. 3 shows: (a) the estimated background rates $\hat{\mu}(x,y)$, (b) the estimated clustering rate $\hat{\gamma}(x,y)$, (c) the ratio between between estimated clustering rate $\hat{\gamma}(x,y)$ and estimated total rate $\hat{m}(x,y)$, which can be regarded as a smoothed approximation of the triggering probabilities ρ_j. Fig. 3(d) shows the histogram of the estimated background probabilities $\hat{\varphi}_j$, from which the triggering probabilities are given by $\hat{\rho}_j = 1 - \hat{\varphi}_j$: most of the events have high probability of being either background events (21% for $\hat{\varphi}_j \geq 0.9$) or triggered events (42% for $\hat{\varphi}_j \leq 0.1$), and the remaining events have less decisive probabilities (about 37% of the data have background probability ranging from 0.1 to 0.9).

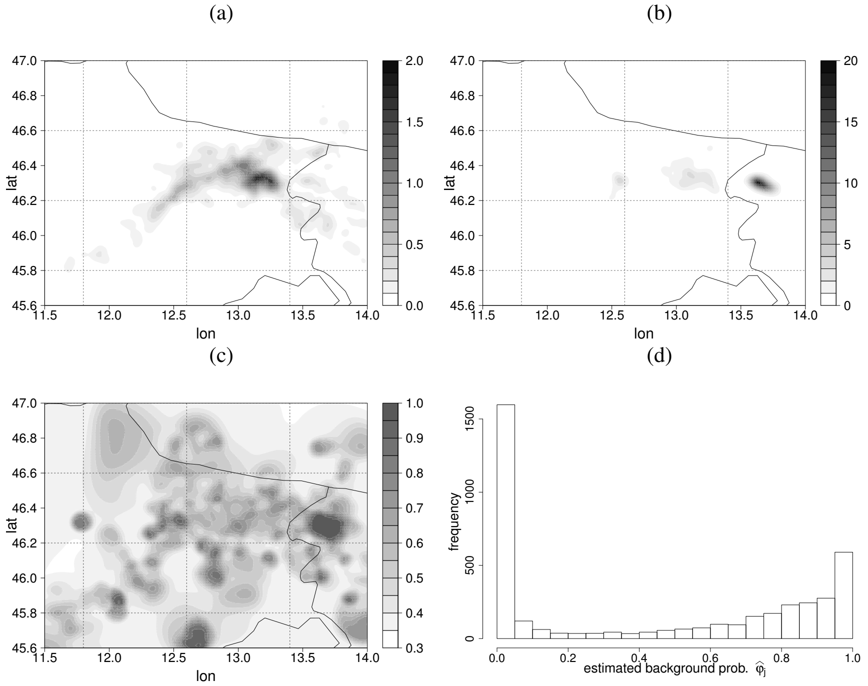

Fig. 3 Estimated background rates (a), estimated clustering rates (b), ratio between estimated clustering rate and estimated total rate (c), and histogram of the estimated background probabilities (d).

A preliminary comparison of results from the two methods shows that the cluster structures produced by NN and SD approaches have comparable trend in terms of spatial extent of seismic clusters. But SD method tends to find some connections between events close in space even if far in time. With reference to 1998 earthquake (Fig. 2), its NN-cluster includes only 480 earthquakes while SD-clusters have more than 900 earthquakes, on average; this is due to the presence in the SD-clusters of earthquakes occurred years later (e.g. in 2002, 2004, or even 2015).

For large sequences, trees obtained from the SD method show a more complex internal structure than trees obtained by the NN method. To quantify topological differences among trees, the average node depth and average leaf depth are considered. The former is the average number of links that connects each node of the tree root; the latter is similarly defined as the average number of links that connects each leaf (node without descendant) to the tree root. According to these scalar measures of internal complexity of a tree, average node depth and average leaf depth are, respectively, 1.30 and 1.31 for the NN-cluster in Fig. 2(a), 5.59 and 5.59 for the SD-cluster in Fig. 2(b), 5.90 and 6.14 for the SD-cluster in Fig. 2(c), 6.20 and 6.43 for the SD-cluster in Fig. 2(d). Greater complexity of the clusters identified by SD method reflects the multilevel triggering property of the ETAS model; we recall that ETAS model assumes that each event is able to generate offspring.

Advanced spatio-temporal point processes for the Sicily seismicity analysis

Processi puntuali spatio-temporali avanzati per l'analisi della sismicità in Sicilia

Marianna Siino and Giada Adelfio

Abstract Due to the complexity of the generator process of seismic events, we study under several aspects the interaction structure between earthquake events using recently developed spatio-temporal statistical techniques and models. Using these advanced statistical tools, we aim to characterise the global and local scale cluster behaviour of the Easter Sicily seismicity considering the catalogue data since 2006, when the Italian National Seismic Network was upgraded and earthquake location was sensibly improved. Firstly, we characterise the global complex spatio-temporal interaction structure with the space-time ETAS model where background seismicity is estimated non-parametrically, while triggered seismicity is estimated by MLE. After identifying seismic sequences by a clustering technique, we characterise their spatial and spatio-temporal interaction structures using other advanced point process models. For the characterisation of the spatial interactions, a version of hybrid of Gibbs point process models is proposed as method to describe the multiscale interaction structure of several seismic sequences accounting for both the attractive and repulsive nature of data. Furthermore, we consider log-Gaussian Cox processes (LGCP), that are relatively tractable class of empirical models for describing spatio-temporal correlated phenomena. Several parametric formulation of spatio-temporal LGCP are estimated, by the minimum contrast procedure, assuming both separable and non-separable parametric specification of the correlation function of the underlying Gaussian Random Field.

zare il comportamento a piccola e a grande scale degli eventi sismici avvenuti a partire dal 2006 nella Sicilia Orientale. In prima istanza, si caratterizza l'andamento globale della sismicità nell'area di studio utilizzando il modello spazio-temporale ETAS, in cui la sismicità di fondo viene stimata in modo non parametrico mentre la sismicità indotta viene stimata mediante massima verosimiglianza. Dopo aver identificato sequenze sismiche, con un opportuno metodo di clustering, per ciascuna sequenza si studia la struttura di relazione che intercorre tra gli eventi dal punto di vista sia spaziale che spazio-temporale. Per quanto riguarda lo studio delle interazioni spaziali, una versione dei modelli ibridi Gibbs viene proposta per descrivere la struttura di interazione multiscala delle sequenze tenendo conto allo stesso tempo del comportamento attrattivo e repulsivo che intercorre tra i punti. Inoltre, abbiamo considerato la classe dei modelli di tipo log-Gaussian Cox, utili per la descrizione di fenomeni correlati nello spazio e nel tempo. Utilizzando il metodo dei momenti, sono stati stimati e in seguito confrontati diversi modelli parametrici assumendo una struttura di correlazione del processo Gaussiano sottostante sia separabile che non-separabile.

Key words: earthquakes; hybrid of Gibbs process; log-Gaussian Cox processes; minimum contrast method; non-separable covariance function; point process; spatio-temporal pair correlation function

1 Goals of the analysis and description of the study area

To describe and predict seismic events in space and time, a proper characterisation of both the intensity function and the second-order properties of the generator process is a crucial issue. In this work, we give a general overview of advanced statistical models that can be used in the seismic context, showing the structure of the models, the main diagnostic tools and the available code (Siino et al, 2018a,b). In an application example, we aim to characterise under several aspects the interaction structure observed in the Sicily catalogue events using proper point process models.

First, we describe the global complex interaction structure using the space-time Epidemic Type Aftershock Sequence model (Ogata, 1988). Focusing on a local scale, we identify some sequences of events characterising their spatial and spatio-temporal structure. In particular, hybrid of Gibbs point processes (Baddeley et al, 2015) are used to describe the distribution of epicentres that generally exhibit interaction at different spatial scales. On the other hand, the spatio-temporal cluster structure is characterised by spatio-temporal log-Gaussian Cox models (Diggle et al, 2013), where the main issue concerns the specification of the moments of the underlying Gaussian Random Field (GRF). Moreover, in the remain of the paragraph we give a general overview of the study area. It is focused on eastern Sicily: it extends from 36.5° to 39° Lat. N and from 14° to 16° Long. E. East Sicily and South Calabria is the area with greater deformation rate and seismic strain release in Italy. We consider the seismic catalogue since 2006, when the Italian National Seismic

Network was upgraded and earthquake location was sensibly improved. The instrumental seismicity recorded in the period from 2006 to 2016, consists of 12356 events; 4170 events (33.7 %) have M between 2.1 and 3.0, 333 events (2.7 %) have M between 3.1 and 4.0, and just 28 events (0.2 %) have $M > 4$. The most of the events (75.4%) are crustal, with hypocentral depth lower than 30 km (Figure 1).

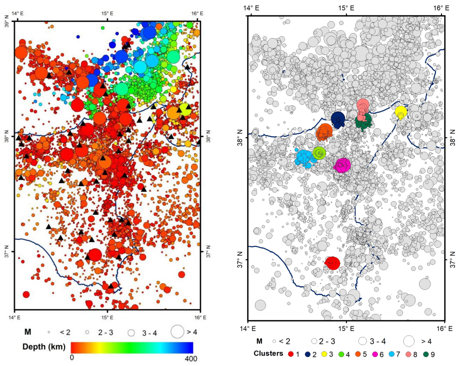

Fig. 1: (left) Seismicity map from 2006 to 2016 period, black triangles indicate the seismic stations. (right) Distribution of the detected sequences.

2 Global scale analysis: Epidemic Type Aftershocks-Sequences model

Let $\mathscr{X}$ be a random countable subset of $\mathbb{R}^2 \times \mathbb{R}^+$ where for a point $(\mathbf{u},t) \in \mathscr{X}$, $\mathbf{u} \in \mathbb{R}^2$ is the location and $t \in \mathbb{R}^+$ is the time of occurrence. In practice, an observed spatio-temporal pattern is a finite set $\{(\mathbf{u}_i,t_i)\}_{i=1}^n$ of distinct points within a bounded spatio-temporal region $W \times T \subset \mathbb{R}^2 \times \mathbb{R}^+$, where usually W is a polygon with area $|W| > 0$ and T a single closed interval with length $|T| > 0$. The space-time point process is defined as a random point pattern, completely characterized by its conditional intensity function (CIF). The CIF of the ETAS model (Ogata, 1988), in time t and location $\mathbf{u}$ conditional to $\mathscr{H}_t$ (the history until t) is defined as the sum of a term describing the long-term variation and one relative to the short-term variation,

$$\lambda_{\boldsymbol{\theta}}(t,\mathbf{u}|\mathscr{H}_t) = \mu f(\mathbf{u}) + \sum_{t_j<t} \frac{\kappa_0 \, e^{(\alpha)\ (m_j-m_0)}}{(t-t_j+c)^p} \left\{||\mathbf{u}-\mathbf{u}_j||^2+d\right\}^{-q} \tag{1}$$

The background activity is characterized by μ, that indicates the general background intensity, and $f(\mathbf{u})$ that is the space density. Instead, for the induced intensity, κ_0 is a constant which measures the aftershocks productivity, c and p are parameters of the modified Omori's law (p characterises the pattern seismicity in the given region indicating the decay rate of aftershocks in time), α measures the influence on the relative weight of each sequence, m_j is the magnitude of the inducing event and m_0 is the completeness threshold of magnitude. The parameters are estimated with the Forward Likelihood-based predictive approach implemented in the `R` package `etasFLP` (Chiodi and Adelfio, 2014). Figure 2 shows the estimated spatial background intensity and the induced one with $m_0 = 2.7$. According to the estimated model (Figure 2), there is quicker decay in space than time since $q > p$, and there is a positive effect of the magnitude of the previous events since $\alpha > 0$.

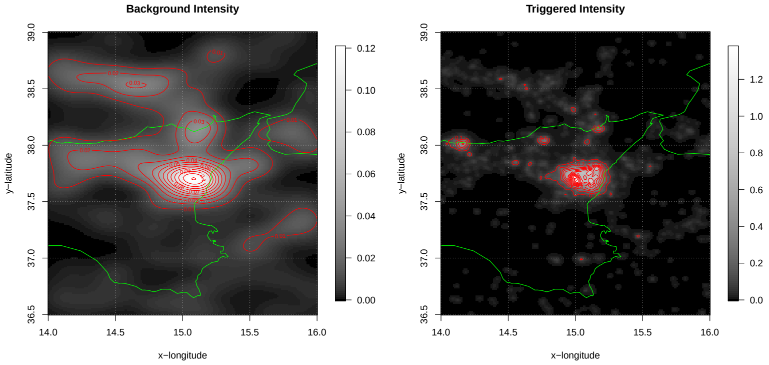

Fig. 2: Estimated background and triggered space intensities, with estimates $\boldsymbol{\theta} = \{0.051, 0.049, 0.005, 1.075, 0.931, 7.510, 1.796\}$ and corresponding standard errors $s.e.(\boldsymbol{\theta}) = \{0.003, 0.017, 0.001, 0.013, 0.113, 1.174, 0.073\}$.

3 Local scale analysis

For the local scale analysis, we report the main results obtained for the cluster 5 of Figure 1 occurred close to the village San Salvatore di Fitalia in 2011. The main-shock event was the 23rd of June 2011 with M=4.5 and 7 km depth. For this sequence, the aims are to characterise the spatial multiscale interaction structure using hybrid models and the spatio-temporal evolution using log-Gaussian Cox models.

3.1 Hybrid of spatial Gibbs process

The class of Gibbs processes $\mathscr{X}$ is determined through a probability density function $f : \mathscr{X} \to [0, \infty)$, where $\mathscr{X} = \{\boldsymbol{\upsilon} \subset W : n(\boldsymbol{\upsilon}) < \infty\}$ is a set of point configurations contained in W. In the literature several Gibbs models have been proposed such as the area-interaction, Strauss, Geyer, hard core processes. However Gibbs processes have some drawbacks when points have a strong clustering and show spatial dependence at multiple scales (Baddeley et al, 2013). Baddeley et al (2013) propose hybrid models as a general way to generate multi-scale processes combining Gibbs processes. Given m unnormalized densities $f_1, f_2, \ldots, f_m$, the hybrid density is defined as $f(\boldsymbol{\upsilon}) = f_1(\boldsymbol{\upsilon}) \times \ldots \times f_m(\boldsymbol{\upsilon})$, respecting some properties. For example, the density of the inhomogeneous hybrid process obtained considering m Geyer components (with interaction ranges $r_1, \ldots r_m$ and saturation parameters $s_1, \ldots, s_m$) is

$$f(\boldsymbol{\upsilon}) = \prod_{i=1}^{n(\boldsymbol{\upsilon})} \beta(\boldsymbol{u}_i) \prod_{j=1}^{m} \gamma_j^{min(s_j, t(\mathbf{u}_i, \boldsymbol{\upsilon} \backslash \mathbf{u}_i; r_j))} \tag{2}$$

where $t(\mathbf{u}_i, \boldsymbol{\upsilon} \backslash \mathbf{u}_i; r_j) = \sum_i \{\mathbf{1} \| \mathbf{u} - \mathbf{u}_i \| \leq r_j\}$. This density indicates that the spatial interaction between points changes with the distances r_j and the parameters that capture this information are the interaction parameters γ_j. Gibbs models can be fitted to data by pseudolikelihood that is function of the Papangelou conditional intensity $\rho_\phi(\mathbf{u}|\boldsymbol{\upsilon})$ at location $\mathbf{u} \in W$ given $\boldsymbol{\upsilon}$, where ϕ are the parameters to estimate (Baddeley et al, 2015). In hybrid models, the conditional intensity is

$$\rho_\phi(\mathbf{u}, ; \upsilon) = \exp\{B(\mathbf{u}) + \theta_1^T V_1(\mathbf{u}, \eta) + \theta_2^T G(\mathbf{u}, \boldsymbol{\upsilon}, \eta)\}, \tag{3}$$

where $B(\mathbf{u})$ is an offset term, $\theta_1^T V_1(\mathbf{u}, \eta)$ is the first-order potential and $\theta_2^T G(u, \boldsymbol{\upsilon}, \eta)$ accounts for the interaction effects. In the following analysis, it will be a combination of Geyer processes, and in this case the irregular parameter η accounts both for an interaction distance r_j and a saturation parameter s_j for each j-th Geyer component. Usually, to assess the goodness-of fit, the estimated models are compared in terms of AIC, spatial raw residuals and number of simulated points under the estimated model (Baddeley et al, 2015). Furthermore, the diagnostic plots based on the residual K- and G-functions are used to decide which component has to be added at each step to the hybrid model (Baddeley et al, 2015). In the `spatstat` package (Baddeley et al, 2015) of R (R Development Core Team, 2005), there are the most of the functions that have been used for fitting, prediction, simulation and validation of Hybrid models. Given a set of points, the first attempt in model estimation is to fit an inhomogeneous Poisson model with intensity depending on the spatial coordinates in which the points do not interact with each other, that is equal to equation (3) where the term $G(\cdot)$ is null. For the selected sequence, the corresponding AIC and the range of the spatial raw residuals of the fitted inhomogeneous Poisson models with a non-parametric spatial trend are in Table 1. In Figure 3a, the residual G-function for the estimated inhomogeneous Poisson model is reported. For distances up to about 200 meters, it wanders substantially outside the limits showing peaks, so there is a positive association between points unexplained by the Poisson model. Therefore, we consider hybrid of Geyer processes, and the main estimation results are in Table 1. Considering the hybrid model, there is an improvement in terms of AIC, of range of raw residuals, and of residual G-function (Figure 3b), it oscillates around zero and it is inside the envelopes indicating that the multiscale interaction structure between the earthquakes is well described by the hybrid model of two Geyer processes.

Table 1: Inhomogeneous Poisson and the hybrid of Gibbs model: AIC, range of spatial raw residuals, vector of irregular parameter η and interaction parameter for each Geyer component γ_j.

Inhom. Poisson model		Inhom. hybrid of Gibbs processes				
AIC	Range res.	Comp.	η	γ	AIC	Range res.

3.2 *Spatio-temporal log-Gaussian Cox process*

The class of log-Gaussian Cox processes (LGCPs) (Møller et al, 1998) is a flexible and relatively tractable class of models for describing correlated phenomena specifying the moments of an underlying Gaussian Random Field (GRF). Considering a spatio-temporal point process as in Section 2, $\mathscr{X}$ is said to be a Cox process driven by Λ (a non-negative and locally integrable stochastic process), if the conditional distribution of the point process $\mathscr{X}$ given a realization $\Lambda(\mathbf{u},t) = \lambda(\mathbf{u},t)$ is a Poisson process on $W \times T$ with intensity function $\lambda(\mathbf{u},t)$. Following the homogeneous specification in Diggle et al (2013), the log-Gaussian Cox process for a generic point in space and time has the following intensity $\Lambda(\mathbf{u},t) = \exp\{\beta + S(\mathbf{u},t)\}$ where S is a Gaussian process with $\mathbb{E}(S(\mathbf{u},t)) = \mu = -0.5\sigma^2$ and so $\mathbb{E}(\exp\{S(\mathbf{u},t)\}) = 1$ and with variance-covariance matrix $\mathbb{C}(S(\mathbf{u},t), S(\mathbf{v},s)) = \mathbb{C}(||\mathbf{u}-\mathbf{v}||, |t-s|) = \sigma^2\gamma(r,h)$ under the stationary assumption, where $\gamma(\cdot)$ is the correlation function of the GRF. Following Møller et al (1998), the first-order product density and the pair correlation function of the log-Gaussian Cox process are $\mathbb{E}(\Lambda(\mathbf{u},t)) = \lambda = \exp(\beta)$ and $g(r,h) = \exp(\sigma^2\gamma(r,h))$, respectively.

To describe the spatio-temporal correlation structure of the selected sequence (Figure 1), we consider several formulation of LGCP models changing the specification of the covariance structure of the underline GRF assuming both separable (exponential structure in space and time) and non-separable parametric specifications (Gneiting and Iaco-Cesare families). Table 2 shows the estimated parameters for each model obtained with the minimum contrast method proposed in Siino et al (2018a). To assess the goodness-of-fit of the estimated models, we use the 95% envelopes of the non-parametric spatio-temporal K-function (Figure 4) and a global test based on Monte Carlo procedure to check if the spatio-temporal point pattern is a realisation of a LGCP with the specified parameters. The fitted models assuming a separable structure and the Gneting families seem to do not describe properly the data because the observed spatio-temporal K-function is outside the envelope, see Figures 4a and 4c. This is confirmed by the global p-values in Table 2. A LGCP model with Iaco-Cesare structure for the underlying GRF describes better the spatio-temporal cluster structure according to Figure 4b and the global p-value that is 0.10 (Table 2). According to the estimates for the selected homogeneous LGCP model, there is a decay of the interaction in space and time governed mainly by the scale parameters α and β.

4 Comments

We propose the use of different models for the analysis of seismic data, focussing both on the global and local scales. In the first case the ETAS model is considered, providing a space-time characterization of the seismic activity in the considered area. For the local scale analysis of the sequence, we consider both Hybrid and LGCP models. Their results are not comparable, since the two model formulation focus on different aspects. In particular, with the hybrid model, we focus on a spatial scale and the multiscale interaction structure is properly described by a hybrid of Geyer processes after taking into account the spatial inhomogeneity with a non-parametric kernel. Moreover, there is evidence of a strong clustering structure for short distances up to 200 meters. On the other hand, by using the LGCP model, spatial and temporal evolution are simultaneously described specifying the moments of a GRF, without assuming a deterministic part in the intensity and considering a homogeneous formulation of the model.

Spatial analysis of the Italian seismic network and seismicity

Analisi spaziale della rete sismica italiana e della sismicità

Antonino D'Alessandro, Marianna Siino, Luca Greco and Giada Adelfio

Abstract Seismic networks are powerful tools for understanding active tectonic processes in a monitored region. Their numerous applications, from monitoring seismicity to characterizing seismogenic volumes and generated seismicity, make seismic networks essential tools for assessing seismic hazard in active regions. The ability to locate earthquakes hypocenters requires a seismic network with a sufficient number of optimally distributed, stations. It is important to assess existing network geometry, to identify seismogenic volumes that are not adequately monitored, and to quantify measures that will allow network improvement. In this work we have studied the spatial arrangement of the stations of the Italian National Seismic Network by means of several Point Pattern techniques The results of the point patter analysis were compare with the spatial distribution of the historical and instrument seismicity and with the distribution of the well know seismogenetic sources of the Italian peninsula. Some considerations have also been made on some models of seismic hazard of the Italian territory. Our analysis allowed us to identify some critical areas that could require an optimization of the monitoring network.

Abstract *Le reti sismiche permettono di misurare e comprendere i processi tettonici attivi in una regione monitorata. Le informazioni acquisite mediante le reti vengono utilizzate per il monitoraggio della sismicità, per la caratterizzazione dei volumi sismogenetici e della sismicità generata, di fatto sono uno strumento essenziale per la valutazione del rischio sismico. Per localizzare gli ipocentri bisogna disporre di una rete sismica con un numero sufficiente di stazioni distribuite in modo ottimale. È importante valutare la geometria della rete esistente, identificare i volumi sismogenetici che non sono adeguatamente monitorati e quantificare le misure che consentiranno il miglioramento della rete. disposizione spaziale delle stazioni della Rete Sismica Nazionale Italiana attraverso diverse tecniche per lo studio dei processi puntuali. I risultati dell’analisi spaziali delle stazioni sono stati confrontati con la distribuzione spaziale della sismicità storica e strumentale e con la distribuzione delle ben note sorgenti sismiche della penisola italiana. Alcune considerazioni sono state fatte anche su alcuni modelli di pericolosità sismica del territorio italiano. La nostra analisi ci ha permesso di identificare alcune aree critiche che potrebbero richiedere un’ottimizzazione della rete di monitoraggio.

Key words: earthquakes; point process; seismic network; spatial correlation

1 Introduction

The Italian seismic network was developed immediately after the Irpinia seismic crisis in 1980. After this disastrous event, the National Seismic Network (NSN) was established. Initially, the NSN consisted of only few stations spread over Italy. In the 90s, the ING (Istituto Nazionale di Geofisica), then became INGV (Vulcanlogia), upgraded progressively the monitoring network leading, in about thirty years, to the current NSN consisting of about 500 seismic stations. Over the years, the spatial and temporal network development continued, depending on the funds availability for the purchase of the instrumentation and the implementation of monitoring nodes. As it is well known, the quality of the estimate of focal parameters depends on the density and geometry of the monitoring stations. Therefore, the development of a seismic network should be carried out according to precise criteria, designed to guarantee a rational development of the monitoring infrastructure. The most correct criterion is to adapt the seismic network, that is to increase the density of monitoring stations, in the areas with the greatest number of seismogenic structures, historical strong earthquakes and with the greater release of seismic energy observed as instrumental seismicity. Unfortunately, the development of the NSN did not follow a precise criterion, uniformly applied to the whole territory. The result is that the quality of the location and the magnitude of completeness is very inhomogeneous and sometimes does not seem to be rational or proportional to the seismic rate (Schorlemmer et al, 2010; D’Alessandro et al, 2011). This clearly can have repercussions on the quality of the seismic monitoring and studies and it is therefore necessary to identify a simple and effective criterion that could be used for the future NSN optimization. In the following, we propose a statistical approach based on the spatial distribution of the NSN, instrumental and historical seismicity, to evaluate the current degree of the network coverage and plan for future optimization.

2 Data description

We integrate seismological, geological and seismic network data in order to address the goals of the analysis, and in this paragraph they are briefly described. We restrict the study window (W) to the Italian peninsula and Sicilian land boundary because only few stations are placed in offshore areas and Sardinia island is not characterised by a high seismicity. As a matter of fact, at this point of the analysis, we want to relate the spatial distribution of the stations with the seismicity and geological information available on the mainland.

More than 500 stations of the National Seismic Network managed by the National Institute of Geophysics and Volcanology and other networks managed by other bodies are used to locate earthquakes, sending data to the central branch in Rome in real time to monitor the seismicity in Italy. The seismic network is composed by 363 stations (Figure 1a).

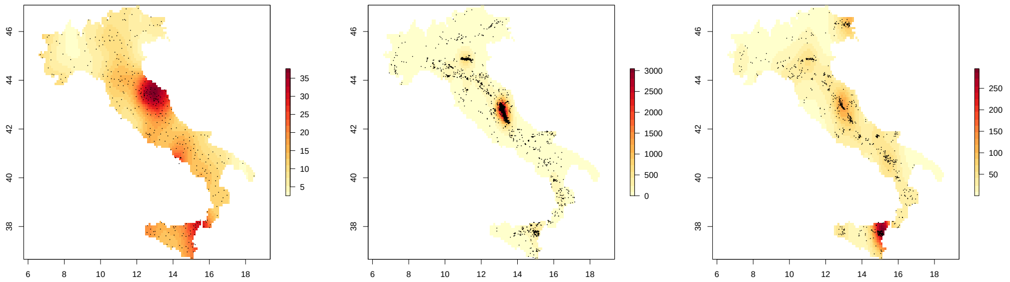
The Italian catalogue contains events since 1985 and we considered the earthquake since 2005, when the network was upgraded and earthquake location was sensibly improved. A subset of the catalogue consisting by 2936 events is analysed, selecting the earthquakes in W with a threshold magnitude equal to 3 and a focal depth less than 50 km (Figure 1b). Furthermore, the historical seismicity is selected starting from the Parametric Catalogue of the Italian Earthquakes, (Rovida et al, 2016) containing 4584 events in the time window 1000-2014; in particular, we select a subset of the events with location, magnitude and depth corresponding to the ones of the catalogue data (Figure 1c).

Additionally, we consider geological information to understand dependence between stations and the sources of earthquakes. The dataset of the Composite Seismogenic Sources (CSS) (Group et al, 2010) is plotted in Figure 2. A composite source represents a complex fault system with an unspecified number of aligned individual seismogenic sources that cannot be separated spatially. In particular for the analysis, we consider the upper edges of the composite sources that for the sake of simplicity are named faults.

The seismic stations, the catalogue events (instrumental seismicity) and the historical seismicity are treated as three spatial point patterns in the region W. Then, we use R (R Development Core Team, 2005) packages for the statistical analysis of spatial patterns of points in two-dimensional space, *spatstat* (Baddeley and Turner, 2005) and *spatstat.local* (Baddeley, 2018).

3 Main results

More formally, a spatial point pattern $\boldsymbol{\upsilon} = \{\mathbf{u}_1, \dots, \mathbf{u}_n\}$ is an unordered set of points in the region $W \subset \mathbb{R}^d$ where $n(\boldsymbol{\upsilon}) = n$ is the number of points, $|W| < \infty$ and $d = 2$. The first-order intensity is assumed inhomogeneous ($\lambda(\mathbf{u})$) and for our point patterns is estimated non-parametrically to understand the spatial trend (Figure 1). The usual kernel estimator of the intensity function is (Baddeley et al, 2015)



(a) Stations (b) Earthquakes (c) historical seismicity

Fig. 1: Kernel estimate of intensity, with smoothing bandwidth selected by Scott’s rule for: (a) the seismic monitoring stations, (b) earthquakes occurred between 2005 and 2018 and (c) the historical seismicity. In (a) and (b), the selected events have a magnitude greater than or equal to 3 and a focal depth less than 50 km. Black points are the events.

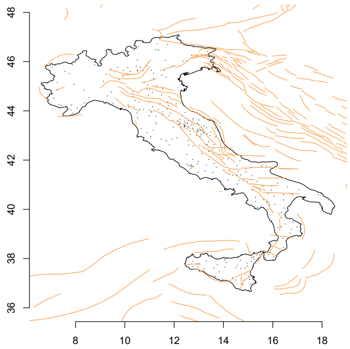


Fig. 2: Faults, upper edges of the composite sources

$$\hat{\lambda}(\mathbf{u}) = 1/e(\mathbf{u}) \sum_{i=1}^{n} k(\mathbf{u} - \mathbf{u}_i, h)$$

where $e(\mathbf{u})$ is the edge corrections and $k(\cdot)$ is a Gaussian density with standard deviation (smoothing bandwidth) equal to h.

From Figure 1a, there is a high concentration of stations in the centre of Italy and in the neighbourhood of the Vesuvio and Etna volcanoes. As for the spatial distribution of instrumental seismicity (Figure 1b), the areas with the higher number of events are in centre of Italy (referring to the Aquila sequence in 2009 and Amatrice-

Norcia-Visso sequence between 2016 and 2018) and in the north centre of Italy for the Emilia sequence in 2012. The historical seismicity (Figure 1c) indicates that most of the seismic activity in Italy is along the alpine and Apennines areas and in Sicily

In this paper, we want to study the relationship between the spatial distribution of the stations with respect to the two types of seismicity (instrumental and historical) under two aspects, their spatial dependence and the global and local characterization. With respect to the first aspect, we compute the inhomogeneous version of the bivariate K-function, to assess if the pair of point patterns are spatially dependent. As it concerns the second aspect, the global and local correlation coefficients are computed to compare the estimated intensities in Figure 1.

Generally for any pair of types i and j, the multitype K-function $K_{ij}(r)$ is the expected number of points of type j lying within a distance r of a typical point of type, i, dividing by the intensity of points of type j. It takes the form

$$K_{ij}(r) = 1/\lambda_j E\left[t(u, r, \mathbf{X}^{(j)})|\mathbf{u} \in \mathbf{X}^{(i)}\right]$$

where $\mathbf{X}^{(j)}$ is the sub-process of points of type j, with intensity λ_j, and $t(\cdot)$ is the the number of points in the point pattern $\mathbf{X}^{(j)}$ that lie within a distance r of the location **u**, but not at **u** itself. If the process of type i points are independent of the process of type j points, then $K_{ij}(r)$ is equal to ϕr^2. Deviations between the empirical value of the curve and the theoretical one suggest dependence between the points of types i and j.

For instance, Figure 3a shows the K-cross where the point pattern of stations is type i and the point patterns of earthquake events from 2005 to 2018 is type j. Clearly the two point patterns are dependent and since the observed cross K-function is below the theoretical value, type j events are farther to type i events than it would be expected under complete spatial randomness. Similarly conclusions can be drawn when the K-cross is computed between the point pattern of the stations (type i) and the point pattern of historical seismicity (type j), see Figure 3a. However, for distances up to 0.5 degree, the two distributions (the station and the historical seismic events) seem to be independent.

As expected, the overall correlation between the intensity of stations with respect to the instrumental seismicity and historical seismicity is positive, the Pearson correlation coefficients are 0.423 and 0.643, respectively.

Moreover, considering the estimated intensities as raster data, we want to check if there are variations of correlation in space. Around each cell of the rasters, we define a focal squared area 5x5 and the correlation between the 25 values of each raster in this square is recorded for the central cell, see Figure 4. Comparing the two plots, it seems that there are more areas with negative correlation between the stations and instrumental seismicity (Figure 4a) than the stations and the historical seismicity (Figure 4b). It would suggest the necessity of a development of the current network, not completely concordant with the spatial seismicity evolution.

Finally, the main interest lies in deciding whether the spatial arrangement of the stations occurs more frequently near faults. The geological information in Figure 2

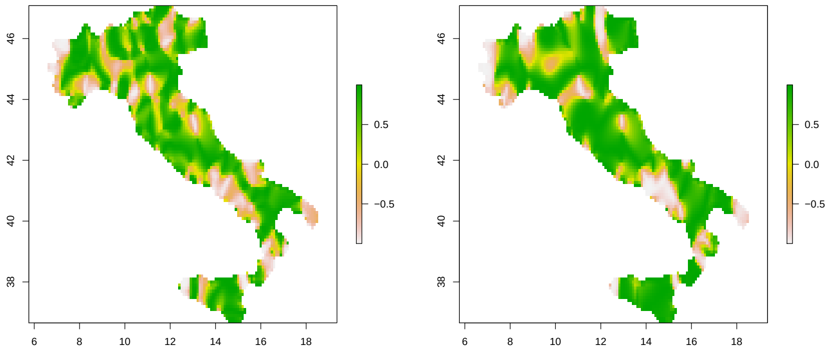
(b)

Fig. 3: (a) The black line is the inhomogeneous bivariate K-function for the seismic station point pattern (type i) and the earthquake events from 2005 and 2018 (type j). (b) The black line is the bivariate inhomogeneous K-function for the seismic station point pattern (type i) and the historical seismicity (type j). In both the plots, the red line corresponds to the theoretical value πr^2.



(a)

(b)

Fig. 4: (a) Local correlation coefficient for the raster objects, between the stations and the instrumental seismicity. (b) Local correlation coefficient for the raster objects, between the stations and the historical seismicity. In both cases, the focal squared area has a dimension 5x5.

is transformed into a spatial variables defined at all locations $\mathbf{u} \in W$, namely $D(\mathbf{u})$ distance to the nearest fault. Assuming an inhomogeneous Poisson model with a parametric log-linear form with respect to the covariate D, we estimate the following intensity

$$\lambda(\mathbf{u}) = exp(\beta_0 + \beta_1 D(\mathbf{u}))$$

where the estimates are $\hat{\beta}_0 = 2.84$ and $\hat{\beta}_1 = -1.69$.

Moreover, we obtain with local inference (Baddeley, 2017) spatially-varying estimates of the parameters of the previous inhomogeneous Poisson process model,

$$\lambda(\mathbf{u}) = exp(\beta_0(\mathbf{u}) + \beta_1(\mathbf{u})D(\mathbf{u}))$$

This approach has the potential to detect and model gradual spatial variation of the parameters that govern the intensity of the stations and the estimates are in Figure 5.

Generally increasing the distance to the nearest fault the station intensity decreases, however according to the spatially varying slope coefficient this reduction is higher in the centre and north-east of Italy.

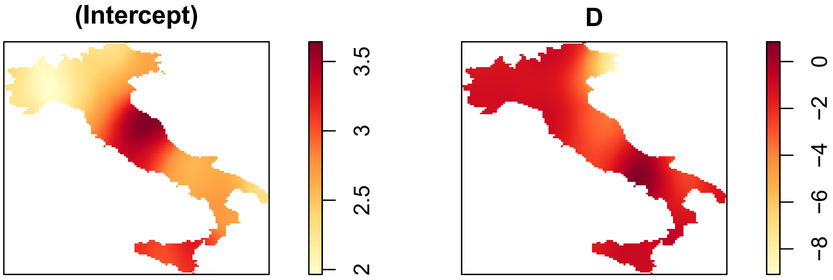


Fig. 5: Spatially varying estimates of intercept (Left) and slope coefficient (Right) from the local likelihood fit of the log-linear model to the seismic station data where the covariate ($D(\mathbf{u})$) is distance to the nearest fault.

4 Conclusions

In this paper we use statistical methods and tools ior the description and characterization of the current degree of the network coverage based on the spatial distribution of the NSN and of the instrumental and historical seismicity, in order to suggest directions for planning future optimization.

As observed from Figure 4, a further upgrade of the network allocation is necessary, in order to get homogeneous and positive correlation in all the Italian area.

In particular, for instance, along the Apennines as well as the West Sicily area, the different correlation between the NSN and instrumental and historical seismicity respectively, suggests the necessity of a network strengthening in those areas.

Clustering Data Streams via Functional Data Analysis: a Comparison between Hierarchical Clustering and K-means Approaches

(*Classificazione di Data Stream con l'Analisi dei Dati Funzionali: un Confronto tra Cluster Gerarchica e Metodo delle K-medie*)

Fabrizio Maturo, Francesca Fortuna, and Tonio Di Battista

Abstract Recently, the analysis of web data, has become essential in many research fields. For example, for a large number of companies, corporate strategies should be based on the analysis of customer behaviour in surfing the world wide web. The main issues in analysing web traffic and web data are that they often flow continuously from a source and are potentially unbounded in size, and these circumstances inhibit to store the whole dataset. In this paper, we propose an alternative clustering functional data stream method to implement existing techniques, and we address phenomena in which web data are expressed by a curve or a function. In particular, we deal with a specific type of web data, i.e. trends of google queries. Specifically, focusing on top football players data, we compare the functional k-means approach to the functional Hierarchical Clustering for detecting specific pattern of search trends over time.

Abstract Recentemente, l'analisi dei dati web é diventata essenziale in molti campi di ricerca. Informazioni sulle ricerche nei motori di ricerca, sul numero di visite, sul tempo trascorso sul sito web, sulla provenienza degli utenti e sul successo di una pubblicitá online, sono essenziali per prevedere vendite future, analizzare le performance passate e monitorare i modelli di acquisto. Tuttavia, lo studio del traffico web presenta alcuni problemi metodologici in quanto questi dati fluiscono continuamente inibendone la totale archiviazione ed ostacolando l'applicazione di tecniche di analisi standard. Questo articolo propone un metodo alternativo di classificazione rispetto a quelli noti in letteratura affrontando situazioni in cui i dati web sono

espressi da una curva o da una funzione. L'analisi é condotta su un tipo specifico di dati web, cioé l'andamento delle ricerche su Google. Nello specifico, concentrandoci sui dati dei migliori giocatori di calcio, l'obiettivo é quello di confrontare l'approccio delle k-medie con quello della cluster gerarchica per dati funzionali al fine di rilevare modelli di comportamento nelle tendenze di ricerca attraverso il tempo.

Key words: clustering football players, data streaming, google query, google trends, FDA

1 Introduction

In recent decades, the analysis of web-data has attracted the attention of many companies dealing with marketing and advertising in the Sports sector, and particularly in the football industry. Due to the massive diffusion of high speed network and internet technology, the analysis of consumers' behavior in surfing the web has become a fundamental data for understanding consumer preferences. Data collected on the web are referred to as data streams, whose main characteristics are that they continuously flow. Since data streams are potentially infinite, the identification of common patterns through clustering techniques become a crucial issue. However, clustering methods suffer from many problems related to the nature of the data, such as clusters robustness over time, the difficulty of exploring data at different portions of the stream, and the computational time-consuming issue. Because each stream can be seen as a function in a continuous domain, i.e. time, this paper proposes to analyze web-data through the functional data analysis (FDA) approach [Ramsay and Silverman, 2005] and discusses the benefits of this method focusing on the clustering data streams problem. The main advantage provided by FDA approach is the drastic dimensionality reduction of data streams, which is gained by converting discrete observations into functions. Moreover, the use of additional functional tools may sometimes reveal crucial information better than the original data [Ramsay and Silverman, 2005, Ferraty and Vieu, 2006, Maturo and Di Battista, 2018, Fortuna and Maturo, 2018, Maturo, 2018, Maturo et al., 2018]. Specifically, in this paper, the FDA approach is proposed for clustering data streams using either hierarchical clustering and K-means approaches. In this study, we focus our attention on a semimetric based on the functional principal components (FPCs) decomposition for both clustering technique. The methodological approach is implemented for analyzing a real data set concerning the Google queries regarding 20 top football players. The final aim of this contribution is to propose the use of functional clustering methods for the analysis of web-queries, and to compare the results of the main two functional clustering approaches.

2 Materials and Methods

The basic idea behind a functional interpretation of web-data is that each stream is a sample from a smooth function of time. Because in real applications curves are observed at a finite set of sampling points, the functional form of a stream, say $X(t)$, can be reconstructed and represented by a basis expansion as follows: $X_i(t) = \sum_{k=1}^{K} a_{ik}\phi_k(t) \quad i = 1,....,n$ where $X_i(t)$ is the reconstructed function for the i-th unit; $\phi_k(t)$ are linearly independent and known basis functions; and a_{ik} are coefficients that link each basis function together in the representation of $X_i(t)$. Various basis systems can be adopted, depending on the characteristics of curves [Ramsay, 1991]. In this work, we consider the least squares approximation with B-splines basis for the functional representation of web-data. To achieve an optimal representation of curves into a function space of reduced dimension, the functional principal component analysis (FPCA) can be adopted [Ferraty and Vieu, 2006]. In particular, let us assume that the observed curves are centered so that the sample mean is equal to zero. Then, for each unit ($i = 1,..,n$), the j-th principal component score is given by $\xi_{ij} = \int_T x_i(t) f_j(t)\,dt$, where the weight functions or loadings $f_j(t)$ are the solutions of the eigenequation where $c(t,s)$ is the sample covariance function and $\lambda_j = Var[\xi_j]$ [Aguilera and Aguilera-Morillo, 2013]. Then, the sample curves admit the following principal component decomposition: $x_i(t) = \sum_{j=1}^{p} \xi_{ij} f_j(t) \quad i = 1,...,n$ where p denotes the total number of functional principal components. By truncating this representation in terms of the first q principal components ($q << p$), we can obtain an approximation of the sample curves whose explained variance is given by $\sum_{j=1}^{q} \lambda_j$. If we assume that the observed functions are expressed in terms of B-splines, then the weight functions $f_j(t)$, admit the following basis expansion: $f_j(t) = \sum_{k=1}^{K} b_{jk}\phi_k(t),\ j = 1,2,...,q$. To identify specific common patterns of data-streams, clustering of functions is carried out in combination with dimension reduction in order to remove the effect of irrelevant functional information. In particular, the distance among functional data is computed using the FPCA method according to the following semi-metric [Ferraty and Vieu, 2006]: $d^{(q)}\left(X_i(t), X_{i'}(t)\right) = \left[\sum_{j=1}^{q} \left(\xi_{ij} - \xi_{i'j}\right)^2 \left\|f_j^{(q)}\right\|\right]^{1/2} \quad i \neq i'$ where $\left\|f_j^{(q)}\right\| = \int_T f_j(t)^2\,dt$, and q denotes the reduced dimensional space at q components [Ferraty and Vieu, 2006, Febrero-Bande and de la Fuente, 2012], chosen according to the criterion of their explained variability.

The basic idea of this unsupervised clustering approach is to find a partition for which the variability within clusters is minimized. The most used algorithm, in this context, is the k-means. Starting from n functional observations, this method aims to assembly units into $G \leq n$ groups, $C_1, C_2, ..., C_G$ so as to minimize the within-cluster sum of squares. The first step of this iterative procedure consists in fixing G initial centroids, $\psi_1^{(0)}(t), ..., \psi_G^{(0)}(t)$. Then, each function is assigned to the cluster whose centroid, at the previous iteration $(m-1)$ is the nearest according to the chosen distance. Once all the functions have been assigned to a cluster, the cluster means are updated as follows: $\psi_g^m(t) = \sum_{x_i(t)\in C_g} \frac{x_i(t)}{n_g}$ where n_g is the number of functions in the g-th cluster, C_g.

Despite this approach could be extended to first and second derivatives or other functions derived from the original ones [Fortuna et al., 2018, Fortuna and Maturo, 2018], in this context, we limit our attention to the original b-spline approximation. Effectively, the aim of this paper is to propose thise approach and compare its results to the agglomerative hierarchical method. In this setting, the classification strategy consists of a series of partitions, which may run from a single cluster containing all the functions (divisive methods), to n clusters, each containing a single function (agglomerative methods). In order to determine which groups should be merged (for agglomerative approach) or divided (for divisive approach), different metrics and linkage methods can be used. In this context, the agglomerative approach with the average linkage method is used. In addition, the gap statistic [Tibshirani et al., 2001] and silhouette plot are adopted for estimating the optimal number of clusters [Kassambara and Mundt, 2017].

3 Application

The proposed method has been applied to the number of queries collected by Google trends over two months (from the beginning of January 2018 to the end of February 2018) regarding the 19 football players with highest market values ($\geq$50 million euros), valued on December 19, 2017 (https://www.transfermarkt.it/); and participation in 2017-2018 UEFA Champions League. Table 1 shows the full list of statistical units considered in the study. Figures 1 and 2 illustrate top player queries over time and the corresponding spline approximation, respectively. Figure 3 presents the functional principal components decomposition: the first three FPCs explain 56.93%, 16.11%, and 8.99% of the total variability, respectively. Figure 4 exhibits the results of the k-means functional clustering of the 19 top players' queries over time whereas Figures 5 and 6 presents the hierarchical clustering findings. According to the gap statistic 7 and silhouette analysis 8, the optimal number of groups is two. Effectively, Figure 4 strongly highlights the presence of two distinct groups: the groups n.1 is characterized by higher variability and elevated levels of queries over time; conversely, the group n.2 presents low variability over time and a minor average level of queries. Table 1 specifies in detail the group membership according to the two different methods. 16 soccer players are distinguished by the same pattern of groups' membership. Only Ronaldo, Hazard, and Kroos change group in passage from k-means to hierarchical clustering.

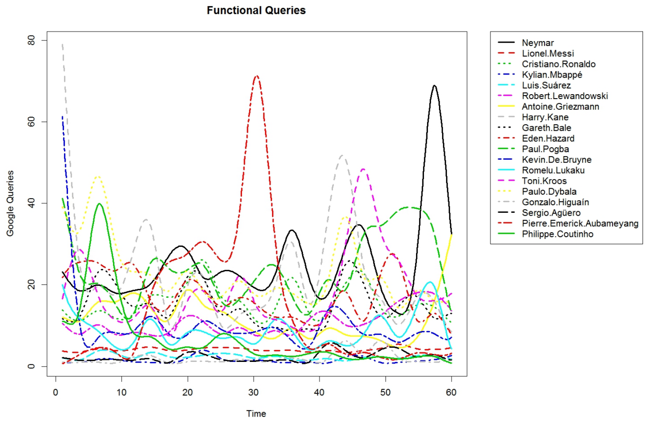

Fig. 2: Spline Approximation of Top Player Queries Over Time

4 Conclusion

The basic idea of this study is to use FDA to analyse datastreaming and in particular the number of queries on search engines. Hence, the originality of this research lies in the application, and in particular we have focused on cluster analysis using the two best known methods: the k-means and hierarchical clustering. Naturally, starting from this idea, many possible developments can be done in the field of functional regression, prediction, and supervised classification. In future research, it would be interesting to analyze in depth what are the reasons that lead to conflicting results between the two types of clustering methods. To achieve this goal, we should

Co-clustering algorithms for histogram data
Algoritmi di Co-clustering per dati ad istogramma

Francisco de A.T. De Carvalho and Antonio Balzanella and Antonio Irpino and
Rosanna Verde

Abstract One of the current big-data age requirements is the need of representing groups of data by summaries allowing the minimum loss of information as possible. Recently, histograms have been used for summarizing numerical variables keeping more information about the data generation process than characteristic values such as the mean, the standard deviation, or quantiles. We propose two co-clustering algorithms for histogram data based on the double *k*-means algorithm. The first proposed algorithm, named ”distributional double Kmeans (DDK)”, is an extension of double Kmeans (DK) proposed to manage usual quantitative data, to histogram data. The second algorithm, named adaptive distributional double Kmeans (ADDK), is an extension of DDK with automated variable weighting allowing co-clustering and feature selection simultaneously.

Abstract *Una delle principali esigenze nell'era dei big-data è quella di rappresentare gruppi di dati attraverso strumenti di sintesi che minimizzano la perdita di informazione. Negli ultimi anni, uno degli strumenti maggiormente utilizzati a tal scopo è l'istogramma. Esso fornisce una sintesi della distribuzione che genera i dati risultando più informativo delle classiche sintesi quali la media, la deviazione standard, o i quantili. Nel presente articolo, si propongono due algoritmi di co-clustering per dati rappresentati da istogrammi che estendono il classico double k-means algorithm (DK). La prima proposta chiamata ”distributional double Kmeans (DDK)”, è un'estensione dell'algoritmo DK a dati ad istogramma. La seconda pro-*

posta, chiamata adaptive distributional double Kmeans (ADDK), è un'estensione dell'algoritmo DDK che effettua la ponderazione automatica delle variabili consentendo di effettuare simultaneamente il co-clustering e la selezione delle variabili.

Key words: Co-clustering, Histogram data

1 Introduction

Histogram data are becoming very common in several applicative fields. For example, in order to preserve the individuals' privacy, data about groups of customers transactions are released after being aggregated; in wireless sensor networks, where the energy limitations constraint the communication of data, the use of suitable synthesis of sensed data are necessary; official statistical institutes collect data about territorial units or administrations and release them as histograms.

Among the exploratory tools for the analysis of histogram data, this paper focuses on co-clustering, also known as bi-clustering or block clustering. The aim is to cluster simultaneously objects and variables of a data set [1, 2, 5, 6].

By performing permutations of rows and columns, the co-clustering algorithms aim to reorganize the initial data matrix into homogeneous blocks. These blocks also called co-clusters can therefore be defined as subsets of the data matrix characterized by a set of observations and a set of features whose elements are similar. They resume the initial data matrix into a much smaller matrix representing homogeneous blocks or co-clusters of similar objects and variables. Refs. [4] presents other types of co-clustering approaches.

This paper proposes at first the DDK (Distributional Double K-means) algorithm whose aim is to cluster, simultaneously, objects and variables on distributional-valued data sets. Then, it introduces the ADDK (Adaptive Distributional Double K-means) algorithm which takes into account the relevance of the variables in the co-clustering optimization criterion.

Conventional co-clustering methods do not take into account the relevance of the variables, i.e., these methods consider that all variables are equally important to the co-clustering task, however, in most applications some variables may be irrelevant and, among the relevant ones, some may be more or less relevant than others.

ADDK and DDK use, respectively, suitable adaptive and non-adaptive Wasserstein distances aiming to compare distributional-valued data during the co-clustering task.

2 Co-clustering algorithms for distributional-valued data

Let $E = \{e_1, \ldots, e_N\}$ be a set of N objects described by a set of P distributional-valued variables denoted by $Y_j \, (1 \leq j \leq P)$. Let $\mathscr{Y} = \{Y_1, \ldots, Y_P\}$ be the set of P

distributional-valued variables and let

$$\mathbf{Y} = \left(y_{ij}\right)_{\substack{1\le i\le N\\ 1\le j\le P}}$$

be a distributional-valued data matrix of size $N \times P$ where the distributional data observed on the Y_j variable for the i-th object is denoted with y_{ij}. Our aim consists in obtaining a co-clustering of $\mathbf{Y}$, i.e, in obtaining simultaneously a partition $\mathscr{P} = \{\mathscr{P}_1, \ldots, \mathscr{P}_C\}$ of the set of N objects into C clusters and a partition $\mathscr{Q} = \{\mathscr{Q}_1, \ldots, \mathscr{Q}_H\}$ of the set of P distributional-valued variables into H clusters.

The co-clustering can be formulated as the search for a good matrix approximation of the original distributional-valued data matrix $\mathbf{Y}$ by a $C \times H$ matrix

$$\mathbf{G} = \left(g_{kh}\right)_{\substack{1\le k\le C\\ 1\le h\le H}}$$

which can be viewed as a summary of the distributional-valued data matrix $\mathbf{Y}$ (see, for example, Refs. [2, 5, 6]).

Each element g_{kh} of $\mathbf{G}$ is also called a prototype of the co-cluster

$$\mathbf{Y}_{kh} = \left(y_{kj}\right)_{\substack{e_i\in\mathscr{P}_k\\ Y_j\in\mathscr{Q}_h}}$$

Moreover, each g_{kh} is a distributional data, with a distribution function G_{kh} and a quantile function $Q_{g_{kh}}$

In order to obtain a co-clustering that is faithfully representative of the distributional-valued data set $\mathbf{Y}$, the matrix $\mathbf{G}$ of prototypes, the partition $\mathscr{P}$ of the objects and the partition $\mathscr{Q}$ of the distributional-valued variables are obtained iteratively by means of the minimization of an error function J_{DDK}, computed as follows:

$$J_{DDK}(\mathbf{G}, \mathscr{P}, \mathscr{Q}) = \sum_{k=1}^{C}\sum_{h=1}^{H}\sum_{e_i\in\mathscr{P}_k}\sum_{Y_j\in\mathscr{Q}_h} d_W^2(y_{ij}, g_{kh}) \tag{1}$$

where the d_W^2 function is the non-adaptive (squared) L_2 Wasserstein distance computed between the element y_{ij} of the distributional data matrix $\mathbf{Y}$ and the prototype g_{kh} of co-cluster $\mathbf{Y}_{kh}$

In order to propose an adaptive version of the DDK algorithm which evaluates the relevance of each variable in the co-clustering process, we still propose the local minimization of the following criterion function:

$$J_{ADDK}(\mathbf{G}, \Lambda, \mathscr{P}, \mathscr{Q}) = \sum_{k=1}^{C}\sum_{h=1}^{H}\sum_{e_i\in\mathscr{P}_k}\sum_{Y_j\in\mathscr{Q}_h} \lambda_j d_W^2(y_{ij}, g_{kh}) \tag{2}$$

where $\Lambda = (\lambda_j)_{j=1,\ldots,P}$ (with $\lambda_j > 0$ and $\prod_{j=1}^{P} \lambda_j = 1$) are positive weights measuring the importance of each distributional-valued variable.

The minimization of the J_{DDK} criterion, is performed iteratively in three steps: representation, objects assignments and distributional-valued variables assignments.

The representation step gives the optimal solution for the computation of the representatives (prototypes) of the co-clusters. The objects assignments step provides the optimal solution for the partition of the objects. Finally, the variables assignments step provides the optimal solution for the partition of the variables. The three steps are iterated until the convergence to a stable optimal solution.

The minimization of the J_{ADDK} criterion, requires a further weighting step which provides optimal solutions for the computation of the relevance weights for the distributional-valued variables.

Representation step in DDK and ADDK

In the representation step, DDK algorithm aims to find, for $k = 1,\dots,C$ and for $h = 1,\dots,H$, the prototype g_{kh} such that $\sum_{e_i \in \mathscr{P}_k} \sum_{Y_j \in \mathscr{Q}_h} d_W^2(y_{ij}, g_{kh})$ is minimal.

According to [3], the quantile function associated with the corresponding probability density function (*pdf*) g_{kh} $(1 \leq k \leq C; 1 \leq h \leq H)$ is:

$$Q_{g_{kh}} = \frac{\sum_{e_i \in \mathscr{P}_k} \sum_{Y_j \in \mathscr{Q}_h} Q_{ij}}{n_k n_h} \tag{3}$$

where n_k is the cardinality of $\mathscr{P}_k$ and n_h is the cardinality of $\mathscr{Q}_h$.

The ADDK algorithm aims to find, for $k = 1,\dots,C$ and for $h = 1,\dots,H$, prototype g_{kh} such that $\sum_{e_i \in \mathscr{P}_k} \sum_{Y_j \in \mathscr{Q}_h} \lambda_j d_W^2(y_{ij}, g_{kh})$ is minimal.

Under the constraints $\prod_{j=1}^{P} \lambda_j = 1$, $\lambda_j > 0$, the quantile function associated with the corresponding probability density function (*pdf*) g_{kh} $(1 \leq k \leq C; 1 \leq h \leq H)$ is computed as follows:

$$Q_{g_{kh}} = \frac{\sum_{e_i \in \mathscr{P}_k} \sum_{Y_j \in \mathscr{Q}_h} \lambda_j Q_{ij}}{n_k \sum_{Y_j \in \mathscr{Q}_h} \lambda_j} \tag{4}$$

Objects assignment step in DDK and ADDK

During the object assignment step of DDK, the matrix of co-cluster prototypes $\mathbf{G}$ and the partition of the distributional-valued variables $\mathscr{Q}$ are kept fixed. The error function J_{DDK} is minimized with respect to the partition $\mathscr{P}$ of objects and each object $e_i \in E$ is assigned to its nearest co-cluster prototype.

Proposition 1. *The error function J_{DDK} (Eq. 1) is minimized with respect to the partition $\mathscr{P}$ of objects when the clusters P_k $(k = 1,\dots,C)$ are updated according to the following assignment function:*

$$P_k = \left\{ e_i \in E : \sum_{h=1}^{H} \sum_{Y_j \in \mathscr{Q}_h} d_W^2(y_{ij}, g_{kh}) = \min_{z=1}^{C} \sum_{h=1}^{H} \sum_{Y_j \in \mathscr{Q}_h} d_W^2(y_{ij}, g_{zh}) \right\}$$

The error function J_{ADDK} is minimized with respect to the partition $\mathscr{P}$ and each individual $e_i \in E$ is assigned to its nearest co-cluster prototype.

Proposition 2. *The error function J_{ADDK} (Eq. 2) is minimized with respect to the partition $\mathscr{P}$ of objects when the clusters $P_k\,(k = 1,\ldots,C)$ are updated according to the following assignment function:*

$$P_k = \left\{ e_i \in E : \sum_{h=1}^{H} \sum_{Y_j \in \mathscr{Q}_h} \lambda_j d_W^2(y_{ij}, g_{kh}) = \min_{z=1}^{C} \sum_{h=1}^{H} \sum_{Y_j \in \mathscr{Q}_h} \lambda_j d_W^2(y_{ij}, g_{zh}) \right\}$$

Variables assignment step in DDK and ADDK

During the variables assignment step of DDK, the matrix of prototypes **G** and the partition of the objects $\mathscr{P}$ are kept fixed. The error function J_{DDK} is minimized with respect to the partition $\mathscr{Q}$ of the distributional-valued variables and each variable $Y_j \in \mathscr{Y}$ is assigned to its nearest co-cluster prototype.

Proposition 3. *The error function J_{DDK} (Eq. 1) is minimized with respect to the partition $\mathscr{Q}$ of the distributional-valued variables when the clusters $Q_h\,(h = 1,\ldots,H)$ are updated according to the following assignment function:*

$$Q_h = \left\{ Y_j \in \mathscr{Y} : \sum_{k=1}^{C} \sum_{e_i \in \mathscr{P}_k} d_W^2(y_{ij}, g_{kh}) = \min_{z=1}^{H} \sum_{k=1}^{C} \sum_{e_i \in \mathscr{P}_k} d_W^2(y_{ij}, g_{kz}) \right\}$$

where $d_W^2(y_{ij}, g_{kz})$ is the squared L^2 Wasserstein distance.

Proposition 4. *The error function J_{ADDK} (Eq. 2) is minimized with respect to the partition $\mathscr{Q}$ of the distributional-valued variables when the clusters $Q_h\,(h = 1,\ldots,H)$ are updated according to the following assignment function:*

$$Q_h = \left\{ Y_j \in \mathscr{Y} : \sum_{k=1}^{C} \sum_{e_i \in \mathscr{P}_k} \lambda_j d_W^2(y_{ij}, g_{kh}) = \min_{z=1}^{H} \sum_{k=1}^{C} \sum_{e_i \in \mathscr{P}_k} \lambda_j d_W^2(y_{ij}, g_{kz}) \right\}$$

Weighting step for ADDK

We provide an optimal solution for the computation of the relevance weight of each distributional-valued variable during the weighting step of the ADDK algorithm.

During the weighting step of ADDK, the matrix of prototype vectors **G**, the partition $\mathscr{P}$ of the objects and the partition $\mathscr{Q}$ of the distributional-valued variables are kept fixed. The error function J_{ADDK} is minimized with respect to the weights λ_j.

Proposition 5. *The relevance weights are computed according to the adaptive squared L_2 Wasserstein distance:*

If we assume that $\prod_{j=1}^{P} \lambda_j = 1$, $\lambda_j > 0$, *the P relevance weights are computed as follows:*

$$\lambda_j = \frac{\left\{ \prod\limits_{r=1}^{P} \left(\sum\limits_{k=1}^{C} \sum\limits_{h=1}^{H} \sum\limits_{e_i \in \mathscr{P}_k} \sum\limits_{Y_r \in \mathscr{Q}_h} d_W^2(y_{ir}, g_{kh}) \right) \right\}^{\frac{1}{P}}}{\sum\limits_{k=1}^{C} \sum\limits_{h=1}^{H} \sum\limits_{e_i \in \mathscr{P}_k} \sum\limits_{Y_j \in \mathscr{Q}_h} d_W^2(y_{ij}, g_{kh})} \tag{5}$$

3 Conclusions

In this paper we have introduced two algorithms, based on the double k-means, for performing the co-clustering of a distributional valued data matrix. The main difference between the two algorithms is that ADDK integrates in the optimization criterion the search for a set of weights which measure the relevance of each variable. In order to evaluate the effectiveness of the proposal, we have made some preliminary test on real and simulated data with encouraging results.

A network approach to dimensionality reduction in Text Mining

Un approccio di rete per la riduzione dimensionale nel Text Mining

Michelangelo Misuraca, Germana Scepi and Maria Spano

Abstract There is an ever-increasing interest in developing statistical tools for extracting information from documental repositories. In a Text Mining frame, a knowledge discovery process usually implies a dimensionality reduction of the vocabulary, via a feature selection and/or a feature extraction. Here we propose a strategy designed for reducing dimensionality through a network-based approach. Network tools allow performing the reduction by considering the most important relations among the terms. The effectiveness of the strategy will be shown on a set of tweets about the 2018 Italian General Election.

Abstract *Lo sviluppo di strumenti statistici per estrarre informazioni da archivi documentali è oggi sempre più importante. Nel Text Mining il processo di knowledge discovery solitamente include uno step di riduzione dimensionale, con procedure di selezione o estrazione dei termini. In questo lavoro si propone una strategia per ridurre la dimensionalità attraverso un approccio di rete. Gli strumenti per lanalisi di rete consentono di operare la riduzione considerando le pi importanti relazioni tra i termini. L'efficacia della strategia è mostrata su un insieme di tweet relativi alle Elezioni Italiane del 2018.*

soning. In each domain in which Statistics can help researchers in finding trends, revealing patterns or explaining relations, there is nowadays an over-availability of data. This massive amount of data required the development of mining techniques for discovering and extracting knowledge, because only a part of the collected data is relevant and informative with respect to the phenomena of interest.

This instance is particularly important when we consider texts. Texts express a wide, rich range of information, but encode this information in a form difficult to automatically process. Aiming at analysing a collection of documents written in natural language, it is then necessary to transform the original unstructured data into structured data. In this framework, the most common algebraic model for representing documents is the so-called *vector space model* [14]: a document is a vector in the (extremely sparse) space spanned by the terms. Because of vector space model, each document contains a lot of noise. Documents are seen as *bag-of-words*, i.e. as an unordered set of terms, disregarding grammatical and syntactical roles. The focus is on the presence/absence of terms belonging to the collection's vocabulary, their characterisation and their discrimination power. To reduce space dimensionality, it is possible to consider feature selection procedures and/or feature extraction methods. Feature selection allows filtering a subset of the original terms, by excluding the less informative and discriminative ones or by considering only the most relevant ones, with respect to a given criterion. Feature extraction performs a reduction of the original space by combining the terms into new entities. One of the main differences is that selection techniques retain the original meaning of terms, where extraction techniques require an additional effort in interpreting the results.

To reduce the dimensionality and save the readability of the results, here we propose a new feature extraction strategy based on network analysis. Network analyses allow visualising the relations among the terms of a collection by recovering the context of use. This paper is structured as follows. In Section 2 the reference literature is reviewed. Section 3 introduces the problem and describes the proposed strategy. In Section 4 the effectiveness of the proposal is showed on a set of tweets about the 2018 Italian General Election. Final remarks and some possible future development of the research are discussed in Section 5

2 Background and related work

In the statistical analysis of large collections of documents, one of the main problems is the high-dimensionality of data. Once we have pre-processed the documents via the *bag-of-words* coding, every single term belonging to the collection's vocabulary represents a dimension in the vector space. The *documents* × *terms* lexical table − obtained by juxtaposing the different document-vectors − is usually a large and very sparse matrix. Since only a part of the terms is actually relevant for expressing the informative content of the documents, the noise in the data has to be eliminated because it leads to unreliable results and significantly increases the computational complexity. Two approaches are used to deal with the problem of dimensionality reduction in Text Mining: *feature selection* and *feature extraction*.

Feature selection methods aim at finding a subset of the original terms, by focusing on their importance in determining the content itself. One of the main advantages of these methods is that the selected features retain the original meaning and provides a better understanding of the results. The most common approach is using a *stop-list*. Typically in a stop-list we can find articles, prepositions, conjunctions and interjection. These terms can be considered unuseful, because they have a very general and weak lexical meaning. In addition, stop-lists may include terms related to the main topics listed in the document collection. On the other hand, many methods have been proposed aiming at selecting the most important terms in a collection [1]. The simplest criterion for term selection is the *document frequency*, i.e. the number of documents in which a term occurs. An alternative is the well-known *tf-idf* [13], which jointly considers the frequency of a term in a document and the document frequency of the term in the collection. Other methods for feature selection such as *term strength* [18], *term contribution* [10] and *entropy-based ranking* [3] are based on the concept of documents' similarity. More recently, other two similar methods for feature selection was proposed: *term variance* [9] and *term variance quality* [5]. Term variance evaluates the quality of terms by computing the variance of each term in the collection. It follows the same idea of document frequency, where terms with low frequency are not important. When class labels are available for a document collection, there are also some supervised methods for term selection. Methods such as *information gain*, *mutual information* and *Chi-square* statistics, have been successfully used in text classification [19].

Feature extraction methods aim at minimising the amount of resources required to describe a large collection of documents. The main task of this approach is to obtain the most relevant information from the original features – through some functional mapping – and represent the information in a lower dimensionality space. The dimensionality reduction is reached by constructing linear combinations of the original features that still describe the document collection with sufficient accuracy. The obvious drawback of feature extraction is that the new features may not have a clear physical meaning, therefore the results are difficult to interpret. In textual data analysis, methods like *principal component analysis* (PCA) [7], *lexical correspondences analysis* (LCA) [8], and *latent semantic analysis* (LSA) [4] are widely used. Although they have been developed in different contexts and with different aims, they are based on a common algebraic frame. A low-rank approximation of the lexical table is obtained via a generalised singular value decomposition. The differences among these techniques are related to the weights assigned to the elements, introducing different orthonormalising constraints. LSA is popular in an information retrieval framework for representing the semantic structures in a collection of documents. LCA is generally used to identify the association structure in the lexical table on factorial maps. More interesting is a non-linear approach to the problem, also known as *manifold learning*, that encompass for example the *isometric feature mapping* (ISOMAP) [16] and the *local linear embedding* (LLE) [12].

3 Problem definition and proposed strategy

Basically, both feature selection and feature extraction are carried out on the $documents \times terms$ lexical table. The vector space model ignores the context in which each term is used. It is possible to get back part of the structural and semantic information by constructing a $terms \times terms$ co-occurrence matrix. In general, each element of this latter matrix is the number of times two terms co-occur in the collection. This data structure can be represented as a network, where each vertex is a term and each edge is an element of the matrix different from 0. In this way, we can visualise both single terms and subsets of terms frequently co-occurring together.

Aiming at reducing the original dimensionality by a feature extraction process, in this paper we propose a community detection based strategy. Differently from the methods described in Sec. 2, our strategy preserves the original meaning of the terms and allows better readability. In a network, a community is a set of similar nodes that can be easily grouped. There is a lack of a universally accepted definition of community, but it is well known that most real-world networks display this kind of structures [6]. It is usually thought as a group where vertices are densely inter-connected and sparsely connected to other parts of the network [17]. From a theoretical viewpoint, community detection is not very different from clustering. Several algorithms have been proposed. Traditional approaches are based on the well-known hierarchical or partitional clustering [15]. Divisive approaches do not introduce substantial conceptual advances with respect to traditional ones. The main difference is that instead of removing edges between pairs of vertices with low similarity, inter-cluster edges are removed. The most popular algorithm for community detection was proposed by Newman and Girvan [11]. This work introduced the concept of *modularity* as a stopping criterion for the algorithm. Here in the follow, we consider the *fast-greedy* algorithm [2]. The advantage of using this algorithm is that the problem of choosing a grouping criterion is overcome by the direct use of modularity as optimisation function.

3.1 Basic notation and data structure

Let $\mathbf{T} = \{\mathbf{d_1}, \ldots, \mathbf{d_n}\} \subset \Re^p$ be a set of n document vectors in a term space of dimension p. This set can be represented as a $terms \times documents$ lexical table, where each element t_{ij} represents the number of occurrences of a term i into a document j $(i = 1, \ldots, p; j = 1, \ldots, n)$. Let transform $\mathbf{T}$ into a binary matrix $\mathbf{B}$, where the generic element b_{ij} is equal to 1 if the term i occurred at least once in document j, 0 otherwise. From the matrix $\mathbf{B}$, we derive the $terms \times terms$ co-occurrence matrix $\mathbf{A}$ by the product $\mathbf{A} \equiv \mathbf{B}\mathbf{B}^{\mathsf{T}}$. The generic element $a_{ii'}$ is the number of documents in which the term i and the term i' co-occur $(i \neq i')$. According to network theory, $\mathbf{A}$ is a $p \times p$ undirected weighted adjacency matrix that can be used to visualise the relations existing among the different terms.

3.2 Network-based feature extraction

On the matrix $\mathbf{A}$, we perform a community detection through a fast-greedy algorithm. This algorithm falls in the general family of agglomerative hierarchical clustering methods. As we said above, it is based on the optimisation of a quality function known as modularity. Modularity is the difference between the observed fraction of edges that fall within the given communities and the expected fraction in the hypothesis of random distribution. Suppose that the vertices of matrix $\mathbf{A}$ can be divided into two communities. The membership to one community or the other one is detected by a variable s, assuming values 1 or -1 respectively. The modularity Q is defined as:

$$Q = \frac{1}{2h} \sum_{ii'} \left[a_{ii'} - \frac{\delta_i \delta_{i'}}{2h} \right] s_i s_{i'} \tag{1}$$

where δ_i is the degree of the i-th term, h is the total number of edges in the network, and s_i represents the membership value of the term i to a community. When we consider G communities, eq. 1 can be expressed in terms of additional contribution ΔQ to the modularity. In matrix form we have:

$$\Delta Q = \frac{1}{4h} \mathbf{s}^{\mathsf{T}} \mathbf{M}^{(g)} \mathbf{s} \tag{2}$$

where $\mathbf{M}^{(g)}$ is the modularity matrix referred to the g-th community ($g = 1, \ldots, G$), and $\mathbf{s}$ is the binary column vector indicating the membership of each term to the community. The fast-greedy algorithm, starting with a state in which each term is the sole member of one of G communities, repeatedly joins communities together in pairs choosing in each step the join that results in the greatest increase in modularity. At the end of the detection process, we obtain a $terms \times communities$ matrix $\mathbf{C}$, a complete disjunctive table where the c_{ig} element is 0 or 1 when a term i belongs or not belongs to a community. The result of the dimensionality reduction is a *documents* × *communities* matrix $\mathbf{T}^{\star} \equiv (\mathbf{T}^{\mathsf{T}}\mathbf{C})\mathbf{D}_G{}^{-1}$, where $\mathbf{D}_G{}^{-1}$ is the diagonal matrix obtained from the column marginal distribution of $\mathbf{C}$. Each cell of $\mathbf{T}^{\star}$ contains the proportion of terms belonging to a community detected in the documents.

4 A study on the 2018 Italian Election campaign

The campaign for the 2018 General Election in Italy was different from the previous ones. In the past, streets were lined with political posters and candidates rallied potential voters around the country. But for the first time, there was no public refund to Italian parties for their campaign spending. Social media offered a less expensive but affordable way to reach voters in a largely unregulated forum.

Twitter is one of the most popular – and worldwide leading – social networking service. It can be seen as a blend of instant messaging, microblogging and texting, with brief content and a very broad audience. The embryonic idea was developed considering the exchange of texts like Short Message Service in a small group of users. We decided to focus our study on the official Twitter accounts of the first ten Italian political parties, considering the Election results. By using the *Twitter Archiver add-on* for Google Sheet, we collected 6094 tweets. We referred only to the last three months of the 2018 Election campaign, from January 1st to March 4th, 2018. We decided not filtering the so-called retweets, so that in the collection some texts were replicated more times. In Table 1, it is possible to see the main characteristics of the dataset. About 50% of the tweets were posted by the official account of the *Lega* party. Some of the parties, such as *Movimento 5 Stelle* and *Partito Democratico*, seemed to be less active on Twitter, but they showed a greater consensus both regarding the average number of *retweets* and *likes*.

Table 1 Statistics on the parties' accounts from January 1st to March 4th 2018

Party	# tweets	% tweets	avg. # retweets	avg. # like
+ Europa	417	6.84	37.8	103.2
Civica Popolare	86	1.41	7.5	13.5
Forza Italia	122	2.00	25.0	38.6
Fratelli d'Italia	789	12.95	7.8	18.3
Insieme	201	3.30	10.7	17.0
Lega	3025	49.64	7.3	14.5
Liberi e Uguali	560	9.19	36.3	75.9
Movimento 5 Stelle	134	2.20	232.7	398.3
Partito Democratico	288	4.73	114.5	227.7
Potere al Popolo	472	7.75	44.2	84.7

The pre-processing was performed in two phases, because of the peculiarity of tweets. Firstly, we stripped URLs, usernames, hashtags, emoticons and RT prefixes, and we normalised the tweets by removing other special characters and any separators than the blank spaces. Secondly, we performed a lemmatisation and tagged each term with the corresponding grammatical category. We decided to consider only the substantives and the adjectives because of their significant content-bearing role. Moreover, we deleted the terms appearing in the collection just one time from the vocabulary. The result of this step was a $documents \times terms$ matrix $\mathbf{T}$ with 6094 rows and 3610 columns, and a $terms \times terms$ co-occurrence matrix $\mathbf{A}$.

We performed the community detection procedure on $\mathbf{A}$ to extract the features. For better highlighting the relationships, we fixed a threshold of 15 co-occurrences and deleted the isolated terms. The greedy algorithm detected 20 communities. The high value of modularity ($Q = 0.83$) reveals the effectiveness of the procedure. In Table 2, the size of each community and the characterising terms are showed.

It is interesting to note that the algorithm identifies the communities related to the different parties' electoral manifestos. For instance, *C1* contains terms emphasising

Table 2 Communities in collection of tweets

ID	Size	Terms
C01	16	*fratello, diritto, futuro, italia, grande, unico, paese, ospite, tutto, europa, libertá, civile, proprio, unione, europeo, piúeuropa*
C02	9	*lavoratore, scuola, grasso, aggiunto, account, libero, uguale, cgil, buono*
C03	13	*italiano, marzo, estero, politico, istruzione, simbolo, elezione, melone, giorgia, semplice, palermo, croce, inciucio*
C04	9	*nuovo, comunitá, diretto, forza, momento, pagina, ordine, ufficiale, facebook*
C05	4	*potere, popolo, pubblico, spesa*
C06	9	*programma, partito, voto, utile, governo, pd, sinistro, ambiente, democratico*
C07	7	*anno, euro, popolare, ultimo, prossimo, casa, mila*
C08	2	*piano, natalitá*
C09	6	*centrodestra, berlusconi, lega, salvini, premier, matteo*
C10	2	*milano, duomo*
C11	4	*intervista, live, capitano, replay*
C12	3	*donna, violenza, uomo*
C13	2	*museo, egizio*
C14	2	*fake, news*
C15	3	*campagna, elettorale, legge*
C16	2	*made, italy*
C17	2	*giulia, bongiorno*
C18	2	*flat, tax*
C19	2	*movimento, stella*
C20	2	*sociale, centro*

the role of Italy in the European Union (e.g. *diritto, futuro, grande, unico, paese, libertá,. . .*) and the name of the party that promotes these aspects (+ *Europa*). Community *C6*, as well as *C9*, contains more trivial terms but specifically related to main opposite coalitions (*Partito Democratico* vs *Lega* and *Forza Italia*). Some of the communities are smaller, containing only a couple of terms, but still very important because they identify key themes of the campaign, such as *flat tax* and *piano natalitá*. The community detection procedure helps in reducing the dimensionality also by automatically identifying collocations and multiword expressions such as *fake news*, *centro sociale*, *made italy*.

By selecting only the terms belonging to the different communities, we obtain a 6094×20 matrix $\mathbf{T}^{\star}$, which can be used for further statistical analyses.

5 Some remarks and future developments

The proposed strategy aims at extracting features from a collection of documents by detecting high-level structures, i.e. communities. Each community is a new feature that retains the meaning of the single terms, and it can be seen as a concept/topic relevant for the domains to which the collection is referred. The strategy is suitable when we deal with short texts, as in the case study, but can also be applied to other kind of documents. One of the advantages of this approach, compared with the other proposal in the literature, is that the dimensionality is reduced by detecting collocations, multiwords and other structure. This reduction can also be seen as the first step for other analyses. Future developments of this work are devoted to automatically set a co-occurrence threshold in the community detection step, and to evaluate alternative similarity indices for measuring the relation strength among terms.

Self Organizing Maps for distributional data

Mappe autorganizzanti per dati distribuzionali

Rosanna Verde and Antonio Irpino

Abstract We present Batch Self Organizing Map (BSOM) algorithms for data described by distributions. As unsupervised classification algorithms, BSOM depend on a suitable choice of a distance measure. Using the $L2$ Wasserstein distance for distributional data and its decomposition, we show how adaptive distances can be exploited in the learning process for describing the structure of the data. Adaptive distances induce a set of relevance weights on the descriptors of the data acting, then, as feature selection method. We present different types of adaptive distances based on different constraints and, using real data, we show the results of the proposed method.
Abstract *Nel presente lavoro proponiamo degli algoritmi di tipo Batch per l'estrazione di Mappe Autorganizzate (BSOM) per dati descritti da distribuzioni. Le BSOM sono da considerarsi degli algoritmi di classificazione non supervisionata basate su un'opportuna scelta di una distanza per confrontare i dati. Utilizzando la distanza $L2$ di Wasserstein per dati distribuzionali che, insieme ad una sua particolare decomposizione, mostriamo come le distanze adattative, nel processo di apprendimento della rete, possano essere sfruttate per una descrizione migliore della struttura dei dati. Le distanze adattative, infatti, inducono una serie di pesi per i descrittori dei dati, che ne valutano la rilevanza nel processo di classificazione. In questo modo, le distanze adattative possono fungere come metodo di selezione dei descrittori. Nel lavoro presentiamo differenti schemi tipi di ditanze adattative basati su diversi vincoli e, utilizzando dei dati reali, mostriamo i risultati del metodo proposto.*

Estimation of coral growth parameters via Bayesian hierarchical non-linear models

Stima dei parametri di crescita di coralli tramite modelli bayesiani gerarchici non lineari

Crescenza Calculli, Barbara Cafarelli and Daniela Cocchi

Abstract In Ecology, the von Bertalanffy growth function (VBGF) is the standard model used to investigate the body growth of marine species. The parameters of this function are usually estimated by a classical method that might induce bias in the results: this method does not allow to distinguish the variability at individual or population level nor to take into account the contribution of environmental factors. A Bayesian hierarchical nonlinear model for estimating the VBGF parameters is proposed in order to overcome the limitations of the traditional method. The proposal improves both the statistical accuracy and the quantification of uncertainties affecting marine species growth. The proposal is assessed through a case study concerning two Mediterranean corals, *Balanophyllia europaea* and *Leptopsammia pruvoti*.

Riassunto *La funzione di von Bertalanffy (VBGF) è il modello standard usato in Ecologia per studiare la crescita degli individui nelle popolazioni marine. I parametri di questa funzione sono comunemente ottenuti tramite un metodo classico che può portare a errori delle stime, oltre a non permettere di modellare la variabilità disgiuntamente a livello di individuo o di popolazione, né di tenere in considerazione il contributo di fattori ambientali. Si propone un modello bayesiano gerarchico non lineare che permette di superare i limiti del metodo tradizionale e di ottenere un guadagno in termini di accuratezza statistica e di quantificazione delle componenti di incertezza che caratterizzano la crescita delle popolazioni marine. La proposta è valutata tramite un caso di studio riguardante due coralli mediterranei, Balanophyllia europaea e Leptopsammia pruvoti.*

1 Introduction

Marine biologists use individual demographic variables (age, oral disk length and body size) for modeling coral peculiarities, as well as their relationships with the environment. Individual coral age is usually obtained from coral body size using reliable growth models. The VBGF is a popular model for predicting the growth of marine organisms linking their lengths to ages by a non-linear relationship [4, 9]. For estimating the VBGF parameters, marine biologists use several methods that do not exploit statistical reasoning as they might. These methods are based on linear transformations of the VBGF, whose parameters are subsequently estimated by OLS. This approach has some limitations. Linear transformations are often proposed without accounting for measurement errors of observed data. Variability, at individual or population level, is neglected, inducing bias in parameter estimates and variance underestimation.

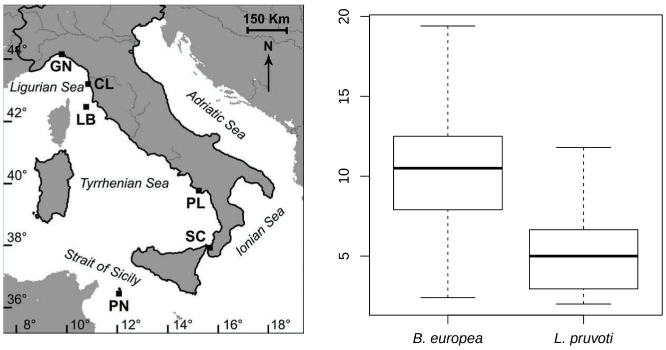
Environmental features at different sites are crucial in affecting coral characteristics. Unfortunately, these features are often unsuitable to this end, since they are measured as synthetic aggregates collected for other purposes: association of site-specific environmental measures to individual species data might be a forcing. The effort for considering environmental information, such as sea temperature, solar radiation, surface ocean acidification and anthropogenic stress, might be costly in terms of modeling and useless when interpreting results. For these reasons, a statistical model with random effects that avoid the explicit consideration of environmental covariates is suitable.

In particular, a feasible approach for estimation of coral growth parameters based on Bayesian hierarchical non-linear mixed effects models is proposed. Hierarchical modeling [2] is equivalent to handle VBGF in a two stage framework, accounting for two different sources of variability: the within-site and the between-site variations. The approach is applied to data of two solitary corals living in the Mediterranean sea, *Balanophyllia europaea* (*B. europaea*) and *Leptopsammia pruvoti* (*L. pruvoti*).

2 Motivating example

In this study, data on two species of solitary Mediterranean corals, *B. europaea* and *L. pruvoti*, are available. Both species live in rocky habitats and are widely distributed in the Mediterranean basin. Their growth and demographic peculiarities have been proved to be sensitive to changes in environmental conditions and, more generally, to the global warming [4, 9].

A dataset of 417 individuals combining 238 specimens of *B. europea* and 179 specimens of *L. pruvoti* is considered. In particular, specimens for the two species were collected during the same time interval (from 9th November 2003 to 30th September 2005) in the same sites as reported in Figure 1a [4, 8]. For each individual the main measurements available are the corallite length (L, in *mm*) which



(a) (b)

n	42	30	34	29	34	30	54	30	32	30	42	30
Mean age (years)	7.4	6.2	5.5	4.1	4.6	8.1	6.9	5.6	6.2	7.8	5.2	7
Mean length (mm)	11.7	4.8	8.3	3.9	9	6.3	9.9	4.4	9.9	6.3	8.8	4.8
R (W/m^2), annual mean	166.95		170.07		172.74		181.48		187.31		192.95	
T (°C), annual mean	19.56		18.02		18.74		19.14		19.54		19.88	

Figure 1b shows differences in terms of length between the the two species. Summary features of the two species and the different environmental site conditions are reported in Table 1 where some differences among sites are appreciable. The measurement of environmental site conditions, even if in principle very stimulating, is currently performed under very general purposes, not directly linked to coral data collection. For this reason, they will not be explicitly considered in the following model.

3 Bayesian hierarchical VBGF modeling

Instead of the standard specification of the VBGF [5], an alternative parameterization [3] is followed to link the age and size of corals:

$$L(t) = L_\infty(1 - e^{-te^{c/L_\infty}}) \tag{1}$$

with

$$c = ln(k)L_\infty \tag{2}$$

where $L(t)$ is the individual length at age t, L_∞ is the asymptotic length and k is the rate at which growth approaches this asymptote [1]. Parameter c can be seen as the part of the length growth accountable for site-specific conditions. This parameterization allows to skip the interaction between coral asymptotic length and growth rate.

A suitable hierarchical model to link coral length and age is proposed among different alternatives [6]. For the i-th observation ($i = 1,\dots,n_j$) in the j-th site, the coral length is modeled as $L_i \sim N(\mu_i, \tau^2)$, where τ^2 is the precision, with

$$\mu_i = L_{\infty_{h,j}}(1 - e^{-t_i e^{c_j/L_{\infty_{h,j}}}}) \qquad h = 1,\dots,H \quad \text{and} \quad j = 1,\dots,J \tag{3}$$

where H is the number of species, J is the number of sites and n_{jh} is the abundance of the h-th species in the j-th site. Since relevant environmental covariates are measured with different timing and reliability with respect to the coral dataset, the second stage of the hierarchy accounts for possible differences in the asymptotic length between sites by random effects, as follows

$$L_{\infty_{h,j}} \sim TN_{(0.1,\infty)}(0, 0.1). \tag{4}$$

The effects expressed in (4) allow different environmental site-specific features together with differences between the two species. Being L_∞ strictly positive, a left truncated normal distribution with large precision has been chosen [10] as the prior distribution for this parameter, while for the c parameter in (2) a vague prior distribution has been chosen. This parameter is assumed to capture the differential growth of species between sites and is specified as

$$c_j \sim N(0.001, 1.00e^{-3}). \tag{5}$$

The model implicitly includes environmental covariates such as the solar radiation, the sea surface temperature or the marine current through the c parameter.
Finally, to complete the Bayesian specification, $\tau \sim U(0, 10)$ has been chosen. Models are implemented by means of the JAGS software [11] via the `R2jags` package of `R` [12] providing a powerful and flexible tool for analyzing grouped data, such as repeated measures data and nested designs.

4 Results

The joint posterior distribution of model parameters is obtained using 72,000 iterations with 3 chains, discarding the first 12,000 of the burn-in phase of the algorithm. Chains were checked for convergence and reasonable mixing by graphical inspection of the trace plots and by means of the Gelman-Rubin convergence diagnostics [7]. Posterior distributions of parameters are summarized in Figure 2. To ease the interpretability of results, distributions are reported distinguishing among sites. Each site panel contains graphical representations of the posterior distributions for the random effect and the asympotic length for the two species.

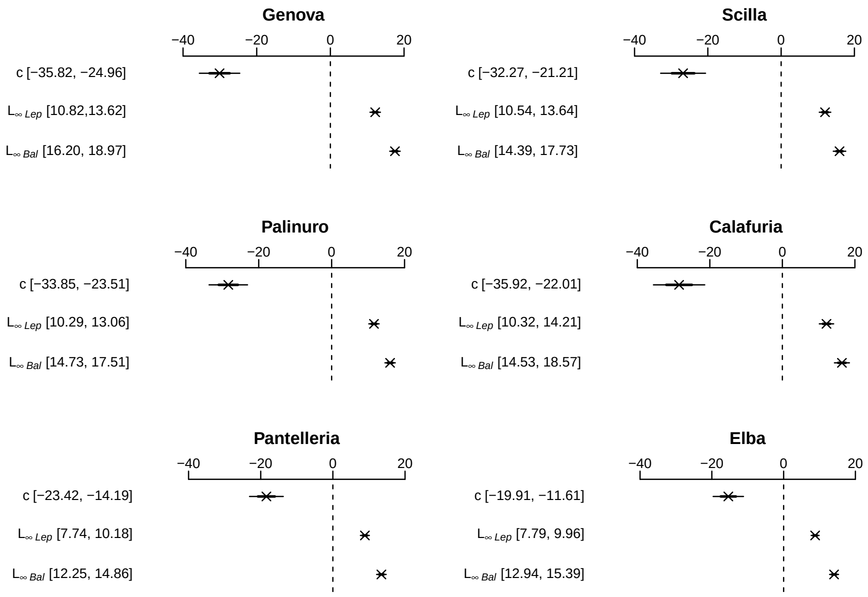

Fig. 2: Syntheses of posterior distributions of VBGF parameters. Crosses represent the means of the marginal posterior distributions; horizontal-bars represent 50% (thicker ones) and 95% (lighter ones) CIs (1 and 2 sd around the mean, respectively). For each parameter, 95% Credibility Intervals extremes are reported in brackets

The combination of species and locations is relevant in affecting L_∞ values. Results suggest a higher overall asymptotic length for *B. europea* than for *L. pruvoti*, confirming the well-known differences between the two species (Figure 1b). Posterior distributions of *c* parameters allow to distinguish among different sites, summarizing the relevant geographical effects on the growth rates of both species. The negative values of *c* are due to the fact that growth rates in (2) are less than 1 for this dataset. Sites that exhibit negative posterior c values closer to 0, tend to have lower L_∞ values with more concentrated posterior distributions. This result witnesses that very different environmental conditions influence coral growth at each site, which however translate into a direct relationship between a favorable situation and growth rate.

5 Conclusions

The examined case study provides a flexible framework that allows biologically meaningful estimates of the VBGF parameters. In particular, the use of Bayesian hierarchical models enables a better evaluation of uncertainty typical of length-at-age data and an innovative description of the relations between species growth and environmental conditions which can be represented by priors in a hierarchical model. The proposed approach demonstrates how to address ecological problems where environmental information is often limited, sparsely sampled or does not suit with collected data. By considering individual and population variation, the growth of two coral species has been estimated accurately and precisely, improving the understanding of their biological characteristics. Furthermore, this approach might be conveniently extended to multi-species models allowing tools to analyze entire communities.

A Hierarchical Bayesian Spatio-Temporal Model to Estimate the Short-term Effects of Air Pollution on Human Health

Un modello bayesiano spazio-temporale gerarchico per stimare gli effetti di breve periodo dell'inquinamento atmosferico sulla salute umana

Fontanella Lara, Ippoliti Luigi and Valentini Pasquale

Abstract We introduce a hierarchical spatio-temporal regression model to study the spatial and temporal association existing between health data and air pollution. The model is developed for handling measurements belonging to the exponential family of distributions and allows the spatial and temporal components to be modelled conditionally independently via random variables for the (canonical) transformation of the measurements mean function. A temporal autoregressive convolution with spatially correlated and temporally white innovations is used to model the pollution data. This modelling strategy allows to predict pollution exposure for each district and afterwards these predictions are linked with the health outcomes through a spatial dynamic regression model.

Abstract *In questo lavoro viene introdotto un modello di regressione spazio-temporale gerarchico per studiare l'associazione spazio-temporale tra i dati sulla salute e l'inquinamento atmosferico. Il modello è stato sviluppato nell'ambito della famiglia esponenziale e consente di modellare condizionatamente le componenti spaziali e temporali in modo indipendente attraverso variabili casuali per la trasformazione (canonica) della funzione media. Per modellare i dati sull'inquinamento viene utilizzata una convoluzione temporale autoregressiva con innovazioni spazialmente correlate e temporalmente indipendenti. Questa strategia di modellizzazione consente di prevedere l'esposizione all'inquinamento per ciascun distretto e, successivamente, queste previsioni sono messe in relazione con le ospedalizzazioni attraverso un modello di regressione spaziale dinamica.*

Key words: Hierarchical model, spatio-temporal model, MCMC

1 Introduction

In the last 30 years, a large number of studies have provided substantial statistical evidence of the adverse health effects associated with air pollution. The statistical literature on health care research is very rich and includes a plethora of models referring to different types of study designs. Most of those studies are usually based on time series models, developed both in single and multisites frameworks (e.g., [1]). However, because air pollution concentrations vary at fine spatio-temporal scales, quantifying the impact of air pollution appeares more as an inherently spatio-temporal problem. Also, despite the availability of large data sets for multiple pollutants, only a few studies consider the joint effects of numerous air pollutants simultaneously [2]. In this paper, we thus propose a hierarchical spatio-temporal regression model, which is able to cope with different spatial resolutions in order to change the support of air pollution data (regressors) to achieve alignment with the health outcome measured at area level.
Considering the air pollution data, we opt for a modelling approach based on assuming the existence of a latent Gaussian variable which may be interpreted as a potential pollution harmful to health in the short period. Then at the process level, we use a dynamic model proposed by [3] which takes into account for spatio- temporal variation using a temporal autoregressive variable with spatially correlated innovations. It is assumed that these innovations follow a Gaussian process with an exponential covariance function. Given such model, we can interpolate the process at unobserved times and/or locations and face the change of support problem (COSP). Afterwards, assessing the effect of air pollution on human health is possible through a regression model that includes lagged exposure variables as covariates.

2 Model Specification

Assume that Y and X are two multivariate spatio-temporal processes observed at temporal instants $t = 1, 2, \ldots, T$ and generic locations, $\mathbf{s} \in \mathscr{D}_y$ and $\mathbf{u} \in \mathscr{D}_x$, respectively. Assume also that X is a predictor of Y, which thus represents the process of interest. For the two different processes, the spatial sites $\mathbf{s}$ and $\mathbf{u}$ can denote the same location but, in general, they need not be the same. Furthermore, both $\mathscr{D}_y$ and $\mathscr{D}_x$ may represent different spatial characteristics and structures. Usually, health data (Y) are collected over time in a fixed study region,$\mathscr{D}_y$, typically in the form of mortality and morbidity counts or hospital admissions, coded according to the type of disease (e.g. cardiovascular, acute respiratory, etc). While pollution concentrations (X) are measured at specific points in time and at a number of monitoring sites across a continuous region $\mathscr{D}_x$ and usually come in the form of geostatistical data.

Let n_y be the number of observed variables for Y and n_x the number of observed variables for X. The most informative case is represented by the isotopic configuration where, for each multivariate process, Y or X, all variables are measured at all their respective sites. In this case, let $\mathbf{Y}(\mathbf{s},t) = [Y_1(\mathbf{s},t), \ldots, Y_{n_y}(\mathbf{s},t)]'$

be the vector of the n_y values of Y at site $\mathbf{s}$ and time t. Equivalently, we write $\mathbf{X}(\mathbf{u},t) = [X_1(\mathbf{u},t),\ldots,X_{n_x}(\mathbf{u},t)]'$ for the vector of the n_x values of X at site $\mathbf{u}$ and time t. The opposite case is the completely heterotopic case where not all the variables can be observed at the same site $-$ this is especially true for X in our study. Without loss of generality, for the sake of simplicity, here we use the notation for the isotopic case. Accordingly, the n_y variables of Y are observed at the same sites $\mathbf{s}_i,\ i = 1,\ldots,N_y$ and the n_x variables of X are observed at sites $\mathbf{u}_r,\ r = 1,\ldots,N_x$.

Let $\tilde{n}_y = n_y N_y$ and $\tilde{n}_x = n_x N_x$. At a specific time t, by using a site ordering, the $(\tilde{n}_y \times 1)$ and $(\tilde{n}_x \times 1)$ dimensional spatial processes are denoted as $\mathbf{Y}(t) = [\mathbf{Y}(\mathbf{s}_1,t)',\ldots,\mathbf{Y}(\mathbf{s}_{N_y},t)']'$ and $\mathbf{X}(t) = [\mathbf{X}(\mathbf{u}_1,t)',\ldots,\mathbf{X}(\mathbf{u}_{N_x},t)']'$. However, the data may also be ordered by variable. In this case, we write $\mathbf{Y}(t) = [\mathbf{Y}_1(t)',\ldots,\mathbf{Y}_{n_y}(t)']'$ and $\mathbf{X}(t) = [\mathbf{X}_1(t)',\ldots,\mathbf{X}_{n_x}(t)']'$, where $\mathbf{Y}_k(t)$ is the the vector of n_y observations for variable Y_k, and $\mathbf{X}_j(t)$ is the the vector of n_x observations for variable X_j.

The model is based on the measurement equations for the conditionally independent variables,

$$Y_k(\mathbf{s},t)|\eta_{y_k}(\mathbf{s},t),\sigma^2_{y_k} \overset{ind}{\sim} F_y(\eta_{y_k}(\mathbf{s},t),\sigma^2_{y_k}), \quad k = 1,\ldots,n_y$$

$$X_j(\mathbf{u},t)|\eta_{x_j}(\mathbf{u},t),\sigma^2_{x_j} \overset{ind}{\sim} F_x(\eta_{x_j}(\mathbf{u},t),\sigma^2_{x_j}), \quad j = 1,\ldots,n_x,$$

where $\sigma^2_{y_k}$ and $\sigma^2_{x_k}$ are dispersion parameters. In general, the distributions F_y and F_x are allowed to be from any exponential family distribution. By choosing appropriate canonical link functions, the specification of the measurement equations are completed with the specification of the following linear predictors

$$g_y\left[\eta_{y_k}(\mathbf{s},t)\right] = \mu_{y_k}(\mathbf{s},t) + \phi_{y_k}(\mathbf{s},t) \tag{1}$$

$$g_x\left[\eta_{x_j}(\mathbf{u},t)\right] = \mu_{x_j}(\mathbf{u},t) + \phi_{x_j}(\mathbf{u},t) \tag{2}$$

where $\mu_{y_k}(\mathbf{s},t)$ and $\mu_{x_j}(\mathbf{u},t)$ are fixed effect terms representing the large-scale spatio-temporal variability of the processes, and $\phi_{y_k}(\mathbf{s},t)$ and $\phi_{x_j}(\mathbf{u},t)$, are random effects introduced to capture any residual spatio-temporal autocorrelation.

The random effects are modelled through the following equations

$$\phi_{x_j}(\mathbf{u},t) = \int_{\mathscr{D}_x} \kappa_{\theta_{x_j}}(\mathbf{u}-\mathbf{u}')\phi_{x_j}(\mathbf{u}',t-1)d\mathbf{u}' + \mathbf{v}_{x_j}(\mathbf{u},t) \tag{3}$$

$$\phi_{y_k}(\mathbf{s},t) = \sum_{j=1}^{n_x}\sum_{l=0}^{L} \beta_{k,j,l}\ \phi_{x_j}(\mathbf{s},t-l) + \mathbf{v}_{y_k}(\mathbf{s},t) \tag{4}$$

where $\kappa_{\theta_{x_j}}(\mathbf{u}-\mathbf{u}') = \rho_{1,x_j}\exp\Big((\mathbf{u}-\mathbf{u}')'\,\Sigma^{-1}_{x_j}\,(\mathbf{u}-\mathbf{u}')\Big)$,
$\Sigma^{-1}_{x_j} = \frac{1}{\rho^2_{2,x_j}}\begin{bmatrix}\cos(\alpha_{x_j}) & \sin(\alpha_{x_j})\\ -d_{x_j}\sin(\alpha_{x_j}) & d_{x_j}\cos(\alpha_{x_j})\end{bmatrix}$, $\alpha_{x_j}\in[0,\frac{\pi}{2}]$, $d_{x_j}>0$, $\theta_{x_j} = \left\{\rho_{1,x_j},\rho_{2,x_j},c_{x_j},\alpha_{x_j}\right\}$, $\beta_{k,j,l}$ is the distributed lag coefficient which relates the jth pollutants at lag l to the kth disease health outcome, $\mathbf{v}_{y_k}(\mathbf{s},t)$ and $\mathbf{v}_{x_j}(\mathbf{u},t)$ Gaussian innovations that are

white in time and correlated in space.
It is worth noting that $\phi_{x_j}(\mathbf{s},t-l)$, in equation (4), is the structured variation in time at space resolution $\mathbf{s}$, $\phi_{x_j}(\mathbf{s},t) = \int_{\mathbf{s}} \phi_{x_j}(\mathbf{u},t)d\mathbf{u}$. In practice one could first define a regular grid, then interpolate the non-observed grid points, and approximate the integral by a Riemann sum. Since the regular grid usually becomes very large, this is computationally expensive, other strategies to approximate the integral can be found in [3].
Model completion requires specific forms for $\mu_y(t)$ and $\mu_x(t)$. The simplest specification of the mean components assumes the form of a linear regression function to take care of the effects of confounders, i.e. $\mu_{x_l}(\mathbf{u},t) = \sum_{i=1}^{c} \sum_{l=0}^{g} \delta_{x_j,il}(\mathbf{u})\, z_i(\mathbf{u},t-l)$, and $\mu_{y_k}(\mathbf{s},t) = \sum_{i=1}^{c} \sum_{l=0}^{g} \delta_{y_k,ij}(\mathbf{s})\, z_i(\mathbf{s},t-l)$, where $z_i(\cdot,t),\ i = 1,\ldots,c$ are observed covariates or components representing seasonal and long-term trends introduced to take care of the effects of unmeasured confounders (see [1] and [4]). Note that the $z_i(\cdot,t)$ could also be smoothed versions of measured confounders represented by natural cubic splines with specified degree of freedom.
The hierarchy of our model is completed by specifying the prior distributions of all hyperparameters. Noninformative conjugate priors are assumed with the expection of the spatial correlation parameters. This model is developed within a state-space framework and full probabilistic inference for the parameters is facilitated by a Markov chain Monte Carlo (MCMC) scheme for multivariate dynamic systems.
The proposed model has an intuitive appeal and enjoys several advantages. For example, it describes the spatial-temporal variability of the disease risk and explicitly defines a non-separable spatio-temporal covariance structure of the process. Also, it allows to study how the disease risk at a specific areal unit reacts over time to exogenous impulses from the same or different areal units. Finally, several general structures that make use of different covariate information, can be easily accommodated in the different levels of the hierarchy.
Fitting our model using the MCMC algorithm is computationally intensive. However, once the statistical model is fitted and assuming that the posterior of the parameters for (3) does not change (see [3] for more details), predictions are computationally a lot cheaper.

3 Application

We illustrate our modelling approach to measure the effect of exposure variables on hospital admissions observed in Lombardia and Piemonte regions (Italy) in 2011. In particular, health data consist of counts of daily hospital admissions for cardiovascular diseases and respiratory diseases. Pollution data refer to daily-average concentration levels of CO, NO_2, PM_{10} and O_3.
To provide more insight on the way in which the disease risks spread out to surrounding districts, Figure 1 below shows maps of raw standardized morbidity ratios obtained by averaging the SMR values across time. The map on the left, shows that, on average, the highest risk areas associated with the cardiovascular diseases

correspond to districts in the Southeastern parts of Lombardia. The map for the respiratory diseases (right) also supports the idea that Lombardia is the most at risk with the highest SMR values observable at the Northern and the Southeastern parts of Milan. In general, the SMR maps show evidence of localised spatial clusters.
The MCMC algorithm was run for $35,000$ iterations. Posterior inference was based on the last $30,000$. Convergence was monitored by inspecting trace plots. Preliminary results show a positive association between air pollutants and hospital admissions. In particular, the peak response of hospital admissions for cardio-respiratory diseases after a positive shock on pollutants occurs after three days and then gradually decreases and dies out in about six days.

A multilevel hidden Markov model for space-time cylindrical data

Un modello multilivello a classi markoviane latenti per dati cilindrici spazio-temporali

Francesco Lagona and Monia Ranalli

Abstract Motivated by segmentation issues in marine studies, a novel hidden Markov model is proposed for the analysis of cylindrical space-time series, that is, bivariate space-time series of intensities and angles. The model is a multilevel mixture of cylindrical densities, where the parameters of the mixture vary at the spatial level according to a latent Markov random field, while the parameters of the hidden Markov random field evolve at the temporal level according to the states of a hidden Markov chain. Due to the numerical intractability of the likelihood function, parameters are estimated by a computationally efficient EM algorithm based on the specification of a weighted composite likelihood. The proposal is tested in a case study that involves speeds and directions of marine currents in the Gulf of Naples.

Riassunto *Motivati da problemi di classificazione in studi marini, proponiamo un nuovo modello a classi markoviane latenti per l'analisi di serie cilindriche spazio-temporali, ovvero serie spazio-temporali bivariate di intensità ed angoli. Il modello è una mistura multi-livello di densità cilindriche, con parametri che variano al livello spaziale secondo un campo markoviano latente, i cui parametri variano nel tempo secondo una catena markoviana latente. A causa dell'intrattabilità numerica della funzione di verosimiglianza, i parametri sono stimati da un algoritmo EM basato sulla definizione di una funzione di pseudo-verosimiglianza composita. Il modello è applicato all'analisi di una serie spazio-temporale contenente le velocità e le direzioni delle correnti marine del golfo di Napoli.*

1 Introduction

A detailed knowledge of coastal currents is crucial for a valid integrated coastal zone management. Among the different available ocean observing technologies, high-frequency radars (HFRs) have unique characteristics, that make them play a key role in coastal observatories. HFR data can be conveniently described as space-time bivariate arrays of angles and intensities that respectively indicate the directions and the speeds of sea currents across space and over time. Data with a mixed circular-linear support are often referred to as *cylindrical* data [1], because the pair of an angle and an intensity can be represented as a point on a cylinder.

The statistical analysis of cylindrical space-time series is complicated by the unconventional topology of the cylinder and by the difficulties in modeling the cross-correlations between angular and linear measurements across space and over time. Additional complications arise from the skewness and the multimodality of the marginal distributions of the data. As a result, specific methods for the analysis of space-time cylindrical data have been relatively unexplored. Proposals in this context are limited to geostastical models, where cylindrical data are assumed conditionally independent given a latent process that varies continuously across space and time [15]. Geostatistical models give good results in open sea areas, where waves and currents can move freely without obstacles. Sea motion in coastal areas provides, however, a different setting. Coastal currents are shaped and constrained by the orography of the site. As a result, coastal circulation is much more irregular than ocean-type patterns and it is inaccurately represented by traditional geostatistical models, which do not incorporate orographic information. The development of a physical model that well represents sea motion in coastal areas can be a formidable task if the orography of the site is irregular. A more practical approach relies on decomposing an observed circulation pattern into a small number of local regimes whose interpretation is easier than the global pattern.

To accomplish this goal, we propose a model that segments coastal data according to finitely many latent classes that vary across space and time and are associated with the distribution of the data under specific, space-time varying, environmental conditions. Specifically, we assume that the joint distribution of the data is well approximated by a multi-level mixture of cylindrical densities. At each time, the parameters of the mixture vary according to a latent Markov field, whose parameters evolve over time according to a latent Markov chain. The idea of using hidden Markov models to segment cylindrical data is not completely novel. Hidden Markov models have been proposed for segmenting cylindrical time series [6] and hidden Markov fields have been proposed to segment spatial cylindrical data [11]. Our proposal integrates these specifications in a space-time setting.

A potential disadvantage of the model is the intractability of the likelihood function. We address estimation issues by relying on composite likelihood (CL) methods [14, 7]. This estimation strategy, on one hand, provides feasible and fast estimation methods. On the other hand, some dependence among observations is lost, resulting in a loss of statistical efficiency. However, consistency of the CL estimators still holds under regularity conditions [9]. Under these conditions, furthermore, CLEs are asymptotically normal with covariance matrix given by the inverse of a sandwich matrix, known as Godambe information [4] rather than the usual Fisher information matrix for maximum likelihood estimators (MLEs). CL methods have been successfully applied in spatial and space-time settings [11, 3].

2 Marine currents in the Gulf of Naples

The Gulf of Naples is a semienclosed marginal basin of the central Tyrrhenian Sea. It is a coastal area characterized by striking environmental contrasts: one of the most intensely urbanized coastlines in the whole Mediterranean, with massive industrial settlements, the very polluted Sarno river mouth, a number of distributed sewage outlets, coexisting with the extremely scenic coastal landscapes of the Sorrento Peninsula, of the Islands of Capri, Procida and Ischia and with unique underwater archaeological treasures (e.g. Baiae and Gaiola). For this reason, the Gulf of Naples has been subject to intense monitoring of its meteorological and oceanographic conditions. In particular, starting in 2004 an HFR system has been installed along its coastline, consisting first of two, and from 2008 of three, transceiving antennas operating at 25 MHz, providing hourly data of the surface current field at 1-km2 horizontal resolution. Such a system has shed light on very rich, multiple-scale surface dynamics and on the mechanisms driving water renewal of individual subbasins of the gulf [8, 13, 2]. Moreover, these data have been exploited in numerical models to enhance their predictive skills through state of the art assimilation schemes [5]. The functioning principle of HFRs is based on resonant backscatter, resulting from coherent reflection of a transmitted electromagnetic wave by ocean surface waves whose wavelength is half of the transmitted electromagnetic wavelength. As a result, every station can provide only the radial component of the surface currents with respect to the antenna location. Two, at least, or even better more stations (to ensure better statistics, to minimize gaps due to physical obstacles or to electromagnetic disturbances, to lower geometric dilution of precision) are needed to combine the radial information to obtain a current vector field. A vector map (or field) decomposes the current's field into the u- and v-components (Cartesian representation) of the sea surface at each observation point of a spatial lattice, where u corresponds to the west–east and v to the south–north current component. Joint modelling of u and v is, however, typically complicated by cross-correlations that vary dramatically in different parts of the spatial domain [12]. We therefore model sea current fields by using polar coordinates. Specifically, the observed current field is represented as a cylindrical spatial series, obtained by computing for each observation site the speed $y = \sqrt{u^2 + v^2} \in [0, +\infty)$ of the current (meters per second) and the direction $x = \tan2^{-1}(u, v) \in [0, 2\pi)$ of the current (radians), where $\tan2^{-1}$ is the inverse tangent function with two arguments and x follows the geographical convention, clockwise from North (0) to East ($\pi/2$). The data that motivated this paper include current speed and direction across a grid of 300 points, observed every hour during March 2009 in the Gulf of Naples.

3 A cylindrical space-time hidden Markov model

The data that motivated this work are in the form of an $n \times T$ array of cylindrical data, say $(\mathbf{z}_{it}, i = 1 \ldots n, t = 1 \ldots T)$, where $\mathbf{z}_{it} = (x_{it}, y_{it})$ is a pair of an angle $x_{it} \in [0, 2\pi)$ and an intensity $y_{it} \in [0, +\infty)$, observed at time t and in the spatial site i. We assume that the temporal evolution of these data is driven by a multinomial process in discrete time $\boldsymbol{\xi} = (\boldsymbol{\xi}_t, t = 1 \ldots T)$, where $\boldsymbol{\xi}_t = (\xi_{t1}, \ldots, \xi_{tK})$ is a multinomial random variable with K classes. We specifically assume that such process is distributed as a Markov chain, whose distribution, say $p(\boldsymbol{\xi}; \boldsymbol{\pi})$, is known up to a vector of parameters $\boldsymbol{\pi}$ that includes the initial probabilities and the transition probabilities of the chain. Conditionally on the value assumed each time by the Markov chain, the spatial distribution of the data at time t depends on a multinomial process in discrete space $\mathbf{u}_t = (\mathbf{u}_{it}, i = 1 \ldots n)$, where $\mathbf{u}_{it} = (u_{it1}, \ldots, u_{itG})$ is a multinomial variable with G classes. We assume that such spatial process is distributed as a G-parameter Potts model, whose parameters depend on the value taken at time t by the latent Markov chain $p(\boldsymbol{\xi}; \boldsymbol{\pi})$. This model depends on $G-1$ sufficient statistics

$$n_g(\boldsymbol{u}_t) = \sum_{i=1}^{n} u_{itg}, \quad g = 1 \ldots G-1,$$

that indicate the frequencies of each latent class across the study area, and one sufficient statistic

$$n(\boldsymbol{u}_t) = \sum_{i=1}^{n} \sum_{j>i: j \in N(i)} \sum_{g=1}^{G_{t-1}} u_{itg} u_{jtg},$$

which indicates the frequency of neighboring sites which share the same class (for each i, $N(i)$ indicates the sets of neighboring sites of i). Precisely, we assume that the joint distribution of a sample $\mathbf{u}_t$, conditionally on $\boldsymbol{\xi}_t$, is known up to an array of class-specific parameters $\boldsymbol{\alpha} = (\alpha_{gk}, g = 1 \ldots G-1, k = 1 \ldots K)$ and a vector of auto-correlation parameters $\boldsymbol{\rho} = (\rho_1, \ldots, \rho_k)$, and given by

$$p(\boldsymbol{u}_t \mid \boldsymbol{\xi}_t; \boldsymbol{\alpha}, \boldsymbol{\rho}) = \frac{\exp\left(\sum_{g=1}^{G_{t-1}} n_g(\boldsymbol{u}_t)\alpha_{gt} + n(\boldsymbol{u}_t)\rho_t\right)}{W(\boldsymbol{\alpha}, \boldsymbol{\rho})}, \tag{1}$$

where

$$\alpha_{gt} = \sum_{k=1}^{K} \xi_{tk} \alpha_{gk}$$

and

$$\rho_t = \sum_{k=1}^{K} \xi_{tk} \rho_k.$$

Our proposal is completed by assuming that, conditionally on the values taken by the Markov chain and the Potts model, the observed cylindrical data are independently distributed according to cylindrical densities, known up to a vector of parameters that depends on the latent class taken by the latent Markov random field at time t in site i. Precisely, we assume that

$$f(\mathbf{z} \mid \boldsymbol{\xi}, \mathbf{u}) = \prod_{i=1}^{n} \prod_{t=1}^{T} f(\mathbf{z}_{it}; \boldsymbol{\theta}_{itg}),$$

where

$$\boldsymbol{\theta}_{itg} = \sum_{g=1}^{G} u_{itg} \boldsymbol{\theta}_g,$$

and $\boldsymbol{\theta}_g$ is the gth entry of a vector of parameters $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \dots, \boldsymbol{\theta}_G)$. Under this setting, we follow [1] and exploit the following parametric cylindrical distribution, namely

$$f(\mathbf{z}; \boldsymbol{\theta}) = \frac{\alpha \beta^{\alpha}}{2\pi \cosh(\kappa)} (1 + \lambda \sin(x - \mu)) y^{\alpha - 1} \exp(-(\beta y)^{\alpha} (1 - \tanh(\kappa) \cos(x - \mu))), \tag{2}$$

known up to five parameters $\boldsymbol{\theta} = (\alpha, \beta, \kappa, \lambda, \mu)$, where $\alpha > 0$ is a shape parameter, $\beta > 0$ is a scale parameter, $\mu \in [0, 2\pi)$ is a circular location parameter, $\kappa > 0$ is a circular concentration parameter, while $\lambda \in [-1, 1]$ is a circular skewness parameter.

The joint distribution of the observed and the latent variables is therefore given by

$$f(\mathbf{z}, \mathbf{u}, \boldsymbol{\xi}; \boldsymbol{\theta}, \boldsymbol{\pi}, \boldsymbol{\alpha}, \boldsymbol{\rho}) = f(\mathbf{z} \mid \boldsymbol{u}; \boldsymbol{\theta}) p(\mathbf{u}; \boldsymbol{\rho}, \boldsymbol{\alpha}) p(\boldsymbol{\xi}; \boldsymbol{\pi}). \tag{3}$$

By integrating this distribution with respect to the unobserved variables, we obtain the likelihood function of the unknown parameters

$$L(\boldsymbol{\theta}, \boldsymbol{\pi}, \boldsymbol{\alpha}, \boldsymbol{\rho}; \mathbf{z}) = \sum_{\boldsymbol{\xi}} \sum_{\boldsymbol{u}} f(\mathbf{z}, \boldsymbol{u}, \boldsymbol{\xi}; \boldsymbol{\theta}, \boldsymbol{\pi}, \boldsymbol{\alpha}, \boldsymbol{\rho}). \tag{4}$$

The maximization of the corresponding complete log-likelihood through an EM algorithm is unfeasible. As a result, we propose to estimate the parameters by maximizing a surrogate function, namely a composite log-likelihood function. Our proposal is based on the specification of a cover $\mathbb{A}$ of the set $S = \{1 \dots n\}$ of the observation sites, i.e. a family of (not necessarily disjoint) subsets $A \subseteq S$ such that $\cup_{A \in \mathbb{A}} = S$. For each subset A, we respectively define $\mathbf{z}_A = (\mathbf{z}_{it}, i \in A, t = 1 \dots T)$, $\mathbf{u}_A = (\mathbf{u}_{it}, i \in A, t = 1 \dots T)$, and

$$L^A(\boldsymbol{\theta}, \boldsymbol{\pi}, \boldsymbol{\alpha}, \boldsymbol{\rho}; \mathbf{z}_A) = \sum_{\boldsymbol{\xi}} \sum_{\boldsymbol{u}_A} f(\mathbf{z}_A, \boldsymbol{u}_A, \boldsymbol{\xi}; \boldsymbol{\theta}, \boldsymbol{\pi}, \boldsymbol{\alpha}, \boldsymbol{\rho}) \tag{5}$$

as the contribution of the data in A to the composite likelihood (CL), where CL=$\prod_{A \in \mathbb{A}} L^A$. This composite likelihood function involves summations over all the possible values that $\boldsymbol{u}_A$ can take. As a result, the numerical tractability of these steps dramatically decreases with the cardinality of the largest subset of the cover $\mathbb{A}$. On the one side, this would suggest to choose a cover with many small subsets. On the other side, a cover that includes a few large subsets is expected to provide a CL function that is a better approximation of the likelihood function. Because summations over $\boldsymbol{u}_A$ become cumbersome for $\mid A \mid \geq 3$, a natural strategy is a cover that includes subsets with 2 elements. When $\mathbb{A}$ include all the subsets of two elements, then composite likelihood reduces to the pairwise likelihood function [14]. In a spatial setting, a pairwise likelihood can be further simplified by discarding all the pairs (i, j) that are not in the neighborhood structure $N(i), i = 1 \ldots n$. This choice provides a computationally efficient EM algorithm, without sacrificing the good distributional properties that are expected by a CL estimator.

Estimation of entropy measures for categorical variables with spatial correlation
Stima di misure di entropia per variabili categoriche con correlazione spaziale

Linda Altieri, Giulia Roli
Department of Statistical Sciences, University of Bologna, via Belle Arti, 41, 40126, Bologna, Italy.

Abstract

Entropy is a measure of heterogeneity widely used in applied sciences, often when data are collected over space. Recently, a number of approaches has been proposed to include spatial information in entropy. The aim of entropy is to synthesize the observed data in a single, interpretable number. In other studies the objective is, instead, to use data for entropy estimation; several proposals can be found in the literature, which basically are corrections of the estimator based on substituting the involved probabilities with proportions. In this case, independence is assumed and spatial correlation is not considered. We propose a path for spatial entropy estimation: instead of intervening on the global entropy estimator, we focus on improving the estimation of its components, i.e. the probabilities, in order to account for spatial effects. Once probabilities are suitably evaluated, estimating entropy is straightforward since it is a deterministic function of the distribution. Following a Bayesian approach, we derive the posterior probabilities of a binomial distribution for categorical variables, accounting for spatial correlation. A posterior distribution for entropy can be obtained, which may be synthesized as wished and displayed as an entropy surface for the area under study.

Riassunto

L'entropia è una misura di eterogeneità ampiamente utilizzata nelle scienze applicate, dove spesso i dati sono georeferenziati. Recentemente, sono stati proposti svariati approcci per includere informazione spaziale nell'entropia, il cui scopo è sintetizzare l'osservato in un numero interpretabile. In altri studi, invece, l'obiettivo è utilizzare i dati per stimare l'entropia di un processo: esistono diverse proposte in letteratura, che sono correzioni dello stimatore basato sulla sostituzione delle probabilità con proporzioni. In questo caso, si assume indipendenza e non è considerata la correlazione spaziale. Proponiamo un nuovo percorso per la stima dell'entropia: invece di intervenire sullo stimatore globale, miglioriamo la stima delle sue componenti, le probabilità, per tenere conto di effetti spaziali. Una volta che le probabilità sono accuratamente valutate, si può stimare direttamente l'entropia, essendo questa una funzione deterministica della distribuzione di probabilità. Con un approccio Bayesiano, deriviamo la distribuzione a posteriori per variabili categoriche spazialmente correlate. Si ottiene quindi una distribuzione a posteriori per l'entropia, che può essere sintetizzata a piacere e diventa un superficie di entropia per l'area di interesse.

Keywords: Spatial entropy, entropy estimation, CAR models, categorical variables

1 Introduction

Shannon's entropy is a successful measure in many fields, as it is able to synthesize several concepts in a single number: entropy, information heterogeneity, surprise, contagion. The entropy of a categorical variable X with $I < \infty$ outcomes is

$$H(X) = \sum_{i=1}^{I} \log(p(x_i)) \log\left(\frac{1}{p(x_i)}\right), \tag{1}$$

where $p(x_i)$ is the probability associated to the i-th outcome (Cover and Thomas, 2006). The flexibility of such index and its ability to describe any kind of data, including categorical variables, motivate its diffusion across applied fields such as geography, ecology, biology and landscape studies. Often, such disciplines deal with spatial data, and the inclusion of spatial information in entropy measures has been the target of intensive research (see, e.g., Batty, 1976, Leibovici, 2009, Leibovici et al., 2014). In several case studies, the interest lies in describing and synthesizing data. This is usually not a simple task: large amounts of data require advanced computational tools, qualitative variables have limited possibilities, and, when data are georeferenced, spatial correlation should be accounted for. When it comes to measuring the entropy of spatial data, we suggest an approach proposed in Altieri et al. (2018), which allows to decompose entropy into a term quantifying the spatial information, and a second term quantifying the residual heterogeneity.

In other cases, though, the aim lies in estimating the entropy of a phenomenon, i.e. in making inference rather than description. Under this perspective, a stochastic process is assumed to generate the data according to an unknown probability function and, consequently, an unknown entropy. One realization of the process is observed and employed to estimate such entropy. The standard approach relies on the so-called 'plug-in' estimator, presented in Paninski (2003), which substitutes probabilities with observed relative frequencies in the computation of entropy:

$$\widehat{H}_p(X) = \sum_{i=1}^{I} \log(\widehat{p}(x_i)) \log\left(\frac{1}{\widehat{p}(x_i)}\right), \tag{2}$$

where $\widehat{p}(x_i) = n_i/n$ is the relative amount of observations of category i over n data. It is the non-parametric as well as the maximum likelihood estimator (Paninski, 2003), and performs well when $I < \infty$ is known (Antos and Kontoyiannis, 2001). For unknown or infinite I, estimator (2) is known to be biased; the most popular proposals at this regard consist of corrections of the plug-in estimator: see, for example, the Miller-Madow (Miller, 1955) and the jack-knifed corrections (Efron and Stein, 1981). Recently, Zhang (2012) proposed a non-parametric solution with faster decaying bias and upper limit for the variance when $I = \infty$. Under a Bayesian framework, the most widely known proposal is the NSB estimator (Nemenman et al., 2002), improved by Archer et al. (2014) as regards the prior distribution. Other approaches, linked to machine learning methods, directly estimate entropy relying on the availability of huge amounts of data (Hausser and Strimmer, 2009). In all these works, independence among realizations is assumed.

Two main limits concern entropy estimation. Firstly, the above mentioned proposals only focus on correcting or improving the performance of (2). Secondly, no study is available about estimating entropy for variables presenting spatial association: the assumption of independence is never relaxed, while spatial entropy studies do not consider inference.

In this paper, we take a perspective to entropy estimation, which moves the focus from the index itself to its components. Entropy, as defined in equation (1), is a deterministic function of the probability mass function (pmf) of the variable of interest. Therefore, once the pmf is properly estimated, the subsequent steps are straightforward. In the case of categorical variables following, e.g., a multinomial distribution, the crucial point is to estimate the distribution parameters. A Bayesian approach allows to derive the pmf of such distribution and can be extended to account for spatial correlation among categories. After obtaining a posterior distribution for the parameters, this is used to compute the posterior distribution of entropy as a transformation. Thus, a point estimator of entropy can be, e.g., the mean of the posterior distribution of the transformation; credibility intervals and other syntheses may be obtained via the standard tools of Bayesian inference. This approach can be used for non-spatial settings as well; in the spatial context, coherently with standard procedures for variables linked to areal and point data, the estimation output is a smooth spatial surface for the entropy over the area under study.

The paper is organized as follows. Section 2 summarizes the methodology for Bayesian spatial regression and shows how to obtain the posterior distribution and the Bayesian estimator of entropy. Then, Section 3 assesses the performance of the proposed method on simulated data for different spatial configurations. Lastly, Section 4 discusses the main results.

2 Bayesian spatial entropy estimation

For simplicity of presentation, we focus on the binary case. Let X be a binary response variable with $x_1 = 1$ and $x_2 = 2$; consider a series of n realizations indexed by $u = 1, \ldots, n$, each carrying an outcome $x_u \in \{1, 2\}$. This may be thought of as a n-variate variable, or alternatively as a sequence of variables $X_1, \ldots X_n$, which are independent, given the distribution parameters and any effects modelling them. For a generic X_u, the simplest model is:

$$X_u \sim Ber(p_u) \tag{3}$$

$$logit(p_u) = z_u^{'}\beta \tag{4}$$

in absence of random effects, where z_u are the covariates associated to the u-th unit.

To the aim of including spatial correlation, consider n realizations from a binary variable over the two-dimensional space, where u identifies a unit via its spatial coordinates. Let us consider the case of realizations over a regular lattice of size $n = n_1 \times n_2$, where u identifies each cell centroid. The sequence $X_1, \ldots, X_n$ is now no longer independent, but spatially correlated. In order to define the extent of such correlation for grid data, the notion of neighbourhood must be introduced, linked to the assumption that occurrences at certain locations are influenced by what happens at surrounding locations, i.e. their neighbours. The simplest way of representing a neighbourhood system is via an adjacency matrix: for n spatial units, $A = \{a_{uu'}\}_{u,u'=1,\ldots,n}$ is a square $n \times n$ matrix such that $a_{uu'} = 1$ when unit u and unit u' are neighbours, and $a_{uu'} = 0$ otherwise; in other words, $a_{uu'} = 1$ if $u' \in \mathcal{N}(u)$, the neighbourhood of area u, and diagonal elements are all zero by default.

In the remainder of the paper, the word 'adjacent' is used accordingly to mean 'neighbouring', even when this does not correspond to a topological contact. The most common neighbourhood systems for grid data are the '4 nearest neighbours', i.e. a neighbourhood formed by the 4 pixels sharing a border along the cardinal directions, and the '12 nearest neighbours', i.e. two consequent pixels along each cardinal direction plus the four ones along the diagonals.

Auto-models provide a way of including spatial correlation, by explaining a response via the response values of its neighbours. They are thus developed by combining a logistic regression model with autocorrelation effects, and are initially developed for the analysis of plant competition experiments and then extended to spatial data in general. Besag (1974) proposed to model spatial dependence among random variables directly (rather than hierarchically) and conditionally (rather than jointly). The autologistic model for spatial data with binary responses emphasises that the explanatory variables are the surrounding array variables themselves; a joint Markov random field is imposed for the binary data. A recent variant of this model, substituting (4) with (5), is proposed by Caragea and Kaiser (2009):

$$logit(p_u) = z(u)'\beta + \sum_{u' \in \mathcal{N}(u)} \eta_{u'}(X_{u'} - \mu_{u'}) \tag{5}$$

where η parametrizes dependence on the neighbourhood and, in the simplest case, $z(u)'\beta = \beta_0$ only includes an intercept. Parameter $\mu_u = \exp(z(u)'\beta)/(1+\exp(z(u)'\beta))$ represents the expected probability of success in the situation of spatial independence.

An analogous rewriting in the form of a CAR model (Cressie, 1993), in absence of covariate information, is

$$\begin{aligned} &logit(p_u) = \beta_0 + \phi_u \\ &\phi \sim MVN_n(0,\Sigma) \\ &\Sigma = [\tau(D - \rho A)]^{-1} \end{aligned} \tag{6}$$

where $\phi = (\phi_1, \dots, \phi_n)'$ is a spatial effect with a structured covariance matrix Σ, which depends on a precision parameter τ and a dependence parameter $\rho \in [-1,1]$ quantifying the strength and type of the correlation between neighbouring units. The symbol A denotes the adjacency matrix reflecting the neighbourhood structure, and D is a diagonal matrix, where each element contains the row sums of A.

The estimation of the parameters for Bayesian spatial logit regression models may proceed via MCMC methods or the INLA approach. We exploit the latter (Rue et al., 2009) and obtain a posterior distribution for the parameters of the probability of success for each grid cell. A synthesis, such as the posterior mean, is chosen in order to obtain an estimate for p_u over each cell. Such estimate is used for the computation of a local estimated entropy value for each pixel:

$$\widehat{H}(X)_u = \hat{p}_u \log\left(\frac{1}{\hat{p}_u}\right) + (1-\hat{p}_u)\log\left(\frac{1}{1-\hat{p}_u}\right). \tag{7}$$

This way, an entropy surface is obtained for estimating the process entropy, whose smoothness may be tuned by the neighbourhood choice, or by the introduction of splines for the spatial effect. Any other surface can be obtained following the same approach for different aims, e.g. for plotting the entropy standard error or the desired credibility interval extremes.

3 Simulation study

To the aim of assessing the performance of the proposed entropy estimator, we generate binary data on a 40×40 grid under two spatial configurations: clustered and random. Figure 1 shows an example of the generated datasets. The underlying model is (6), with a 12 nearest neighbour structure for A, $\tau = 0.1$ and $\rho = \{0.999, 0.001\}$ for the two scenarios, respectively. For each scenario, 200 datasets are generated with varying values for β_0 so that the expectation of p_u in a situation of independence varies between 0.1 and 0.9; values for β_0 differ across replicates but are constant across scenarios, so that the proportion of pixels of each type is comparable.

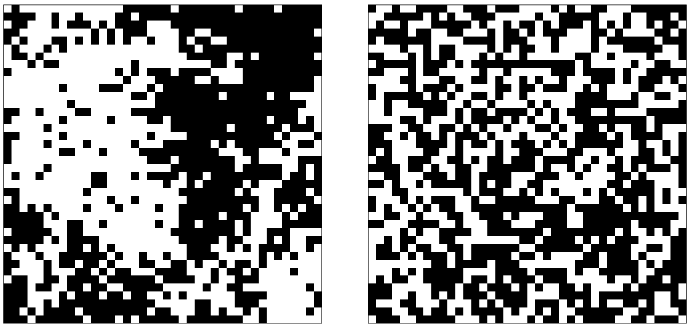

Figure 1: Clustered scenario (left) and random scenario (right) - example with $\beta_0 = 0.57$.

Results show that fitting the model over the generated data leads to good estimates for the p_us. For all replicates on both scenarios, the estimated parameters are very close to the true ones, which are always included within the 95% credibility intervals. The proposed approach is able to produce good estimates for the probabilities of success, ensuring the goodness of the estimates for spatial entropy, which is a function of such probabilities.

Obtaining the entropy surface proceeds as follows. First, the posterior distribution for each p_u is synthesized with its posterior mean. This way, for each scenario and replicate we obtain a single number for $\hat{p}_u$ on every cell. Then, an entropy value is computed over each cell following (7) and a smooth spatial function is produced. An example is shown in Figure 2, where values range from 0 (dark areas in the figure) to $\log(2)$ (white areas). The clustered situation (left panel) shows a smoothly varying surface. By comparing the left panels of Figure 1 and 2, one can see that the entropy surface takes low values in areas where pixels are of the same type: white pixels in the top-left part in Figure 1, and black pixels in the top-right part of Figure 1, correspond to the darker areas of Figure 2 where entropy values are low. In the areas where white and black pixels mix, the entropy surface tends to higher values (whiter areas in Figure 2). The random configuration (right panel of Figure 2) has a constant entropy close to the maximum $\log(2)$; this is expected, as no spatial correlation influences the entropy surface in this scenario. Therefore, such spatial functions properly estimates the entropy of the underlying spatial process.

Thanks to the availablity of the marginal posterior distribution of all parameters, any other useful synthesis is straightforward to compute. An example is shown in Figure 3, where the standard error of the estimate over each cell is plotted. Again, it is possible to appreciate a smooth surface for the clustered scenario, while the value is constant for the random one.

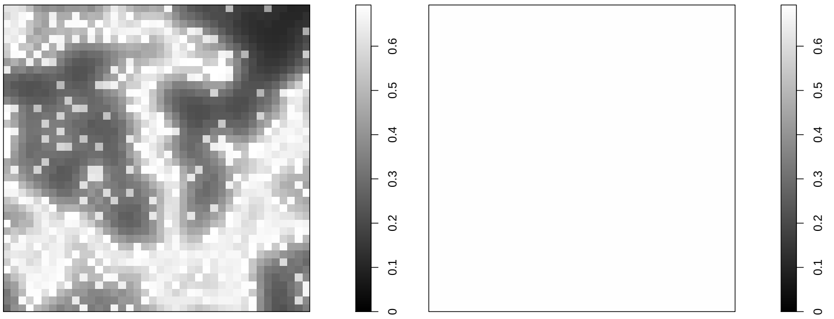

Figure 2: Example of estimated entropy surface for the two scenarios.

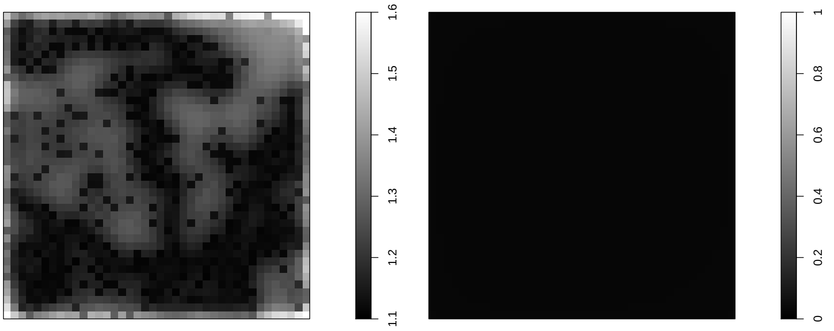

Figure 3: Example of the standard error of the estimate for the two scenarios.

4 Concluding remarks

In this paper, we describe an approach to entropy estimation which starts from rigorous posterior evaluation of its components, i.e. the probabilities. This way, we frame entropy within the theory of Bayesian models for spatial data, thus assembling the available results in this field.

Results from the simulation study enforce the validity of the approach in providing good estimates for the distribution parameters and, consequently, for entropy. The flexibility of the Bayesian paradigm allows to synthesize the posterior distribution of entropy as wished, in order to answer different potential questions.

Our procedure ensures realistic results, since, when the behaviour of a spatial process is under study, the basic hypothesis is that it is not constant but smoothly varying over space. In the same spirit, an appropriate spatial entropy measure is not a single number, rather it has to be allowed to vary over space as a smooth function.

The choice of the INLA approach allows to obtain results in a very reasonable time (minutes) for models including covariates and for very fine grids too, provided the model does not get extremely complicated in terms of random effects.

Innovations in Census and in Social Surveys

A micro-based approach to ensure consistency among administrative sources and to improve population statistics

Un approccio basato sui microdati per garantire la coerenza tra fonti amministrative e per migliorare le statistiche demografiche

Gianni Corsetti, Sabrina Prati, Valeria Tomeo, Enrico Tucci

Abstract According to Istat modernisation programme the Registers Integrated System (RIS) is the core of the data production process. The RIS enables to enlarge the level of the analysis and the quality of the information collected linking at micro level the economic and social phenomena. In this view, the Base Register on Individuals and Households (BRIH) that identifies the usually-resident population will be enriched by the information collected by the other Base Registers (enterprises, addresses, activities) and by the thematic ones (Labour, Educational level, etc.). BRIH will be the common target for Continuous Census and Demographic statistics and for Social Statistics. To improve the accuracy of the population outputs in terms of timeliness, coverage and consistency it has been developed an information system of micro demographic accounting based on a longitudinal statistical register of individuals (Anvis). Anvis let us to continuously monitor population changes by linking the population stock with outflows and inflows. The new system allows us to adopt a multistate demographic approach for longitudinal models and for indicators based on change-of-state probabilities. Moreover, it let us to bring together all the events involving a given individual especially for the analysis of migration and migration trajectories.

Abstract *Secondo il programma di modernizzazione dell'Istat, il Sistema Integrato dei Registri (SIR) è il nucleo del processo di produzione dei dati. Il SIR consente di ampliare il livello delle analisi e la qualità delle informazioni raccolte integrando a*

livello micro i fenomeni economici e sociali. In questa prospettiva, il Registro Base su Individui e Famiglie (RBI), che identifica la popolazione abitualmente dimorante, sarà arricchito dalle informazioni raccolte dagli altri registri di base (imprese, indirizzi, attività) e da quelli tematici (manodopera, livello di istruzione, eccetera.). RBI sarà il punto di riferimento comune sia per il censimento permanente che per le statistiche demografiche e sociali. Per migliorare la qualità delle stime sulla popolazione in termini di tempestività, copertura e coerenza è stato sviluppato un sistema informativo di contabilità micro-demografica basato su un registro statistico longitudinale di individui (Anvis). Anvis ci permette di monitorare continuamente i cambiamenti della popolazione collegando lo stock di popolazione con gli eventi demografici. Attraverso Anvis sarà possibile, inoltre, realizzare analisi longitudinali seguendo l'approccio della demografia multistato e costruire indicatori basati sulle probabilità di cambiamento di stato. Infine, il sistema Anvis riunirà gli eventi riferiti ad un singolo individuo in modo da consentire studi sulle migrazioni e sulle traiettorie migratorie.

Key words: administrative data, population statistics, data integration, longitudinal database.

1 Introduction

This paper presents an overview of some results from the studies which Istat is carrying out in the context of the modernisation of Population and Social statistics. The object is to make the best use of the available administrative sources within the population statistics. New technologies and administrative changes allow to enhance the exploitation and the quality of data collected mainly due to the possibility to integrate different data sources. Istat has been developed a project of engineering and implementing an information system of micro demographic accounting based on a statistical population register of individuals Anvis (ANagrafic VIrtual Statistical database). Anvis makes it possible to continuously monitor population changes by linking the population stock with outflows and inflows. Fundamental requirements in Anvis information system are data integration and longitudinal consistency. For this reason, Istat needs to check and correct the system to improve data quality in terms of timeliness, coverage and consistency with other administrative sources. Italy supports the adoption of a Regulation on Demographic Statistics. We are aiming at improving the features of our systems according to the harmonization principle incorporated in the Regulation. ANVIS ensure the coherence and the consistence among the information requested by the Regulation on demographic statistics (in progress) and the information collected pursuant Regulation (EC) No 862/2007(of the European Parliament and of the Council on Community statistics) on migration and international protection and Regulation (EC) No 763/2008 of the European Parliament and of the Council on population and housing censuses. At the same time Anvis ensure the consistency of the Regulation to our National Legal requirements.

The new system will allows to achieve two research targets:

- A new longitudinal microdata system (MIDEA) for longitudinal models and techniques and demographic indicators based on change-of-state probabilities;
- An integrated system of administrative signals for measuring emigration flow.

2 The new longitudinal microdata system (Mi.DE.A-ANVIS)

The MIcro Demografic Accounting (Mi.DE.A) is a very large-scale linkage study which is going to be build up at Istat by using data of last Population Census and those of current administrative and statistical sources. These include all individual data available from the compulsory registration System (POPREG), such as Vital Events data (births, deaths, migration in or out Italy). Other data will be included in future steps, i.e marriages separations and divorces, or Health data collected by the National Health Service (Cedap, hospital admissions), or Household sample data.

There are some key differences among the MiDEA project and other longitudinal studies conducted in Europe as the Scottish Longitudinal Study (SLS) or as the England and Wales Longitudinal Study (LS). First of all the size of population involved into the Study. MiDEA is designed to include all the individual records captured in the last Population Census, around 60 million of records. Information for these people have been linked with vital events in order to follow the changing through time. In addition new records will be included or withdrawn each year using migration flows.

The ANagrafic VIrtual Statistical database (AN.VIS.) is one of the most relevant outcome of the project. It includes one records for each individual registered as resident according to census and flows data. An important aspect of the ANVISs individual data is the information on other household members (those who live in the same household as resulting at the time of last census or according to the variations collected by population registers).

The db [ANVIS] is a part of the Base Register on Individuals and Households (BRIH) in which individual Information can be merged with information of those living in the same household. Household data provide valuable additional information. In fact is the universe of populations and sub-populations for census and samples social surveys. This opens new opportunities and methodological challenges for the design of sample surveys. In perspective for each individual demographic information will be integrated with other socio-economic also in longitudinal perspective.

The starting point of the MiDEA are the Unit Records of Population Census at census time. The first step was to up-date census data until 31th December 2012 using Population register (POPREG) flows report entries and exits (Births, Deaths, Immigration and Emigration, Administrative adjustments); this process have been repeated for each year in order to up-date data at 31th December 2016 (latest year available at moment).

At the end of each year we match Anvis and POPREG unit records in order to carry out corrections due to underreporting of changes on personal data. However, due to mistakes by the individuals or administrations concerned, errors occur especially related coverage issues of the demographic flows.

At the same time MiDEA-ANVIS ensure the consistency of the Regulation to our National Legal requirements.

The new longitudinal microdata system can improve the accuracy of currently released demographic indicators, especially the ones that are called incidence indicators because they require the calculation of the population at risk.

In the macro approach population at risk is calculated as an average between initial and final population, making uniform distribution hypothesis in the time of reference.

Longitudinal microdata system can link population stock and demographic events in the continuous time, so that it is possible a closer calculation of the population at risk in terms of person-time.

Person-time is an estimate of the actual time-at-risk – in years, months, or days – that all participants contributed to a population in a given reference period. A subject is eligible to contribute person-time only so long as that person does not yet have left population due to emigration or death (Figure 1).

Since ANVIS contains full information for birthdate and dates referred to any migratory events or death, we can use exact dates to calculate person-time.

Figure 1: Exposure to risk of the individuals in a reference year by type of demographic event

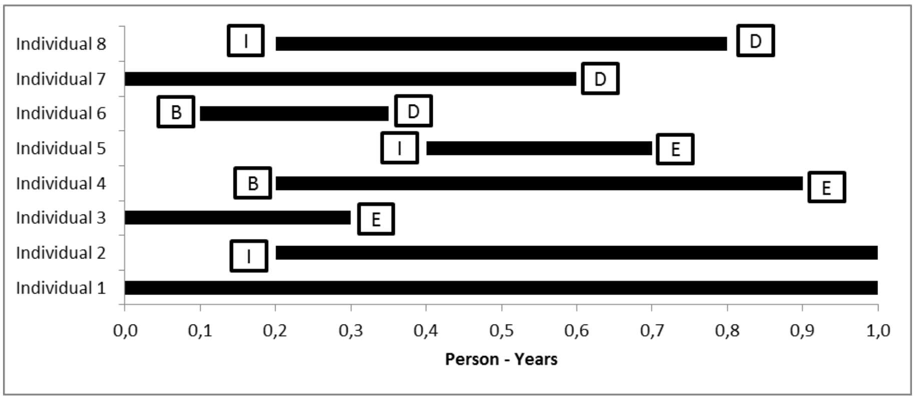

Table 1 shows age-specific death rates per thousand person-year by sex referred to 2016. They are compared with age-specific death rates per thousand inhabitant currently release by Istat and estimated with aggregated data (http://dati.istat.it/?lang=en&SubSessionId=1ca4016d-d5e1-4d13-a15c-a7ec98464094&themetreeid=-200).

Table 1: Age-specific death rates by sex and type of estimation – Year 2016

Age class	Male			Female		
	average population	person-years	relative difference	average population	average population	relative difference
	(A)	(B)		(A)	(B)	
0-4	0.7	0.8	14.3	0.6	0.7	16.7
5-9	0.1	0.1	-	0.1	0.1	-

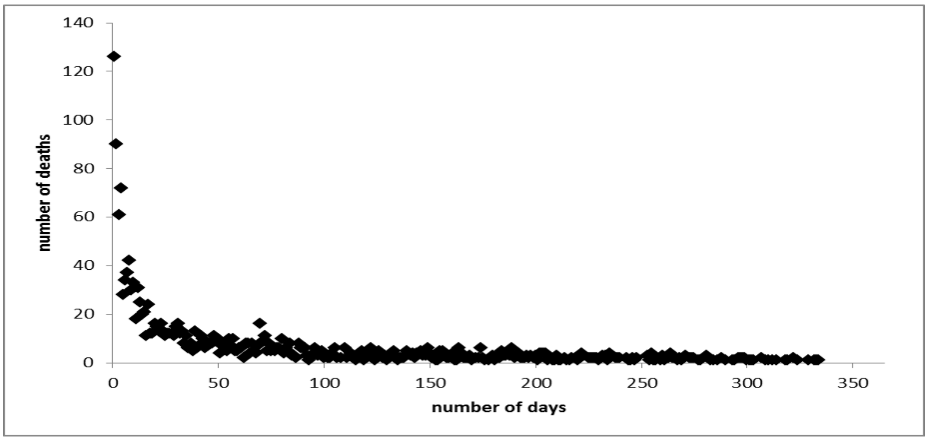
95+	351	345.2	1.7	295.9	292.6	1.1
Total	10.0	10.0	-	10.2	10.2	-

Figure 2: Distribution of deaths in the first year of life by number of days between birth and death – Year 2016



Results are very close but differences increase in the first age class, where the uniform distribution hypothesis in the reference period is highly unlikely, because of the super mortality of the newborns in the very early period after birth, as shown in Figure 2.

This is a first attempt to fully exploit the potential of the new system under construction. Nevertheless we can underline the importance of longitudinal microdata in pursuing the goal of more consistently estimates.

3 Building an integrated system of administrative signals for measuring emigration flow

The necessity for improvements in migration statistics is not an issue that is confined to a single country, with an increased international policy focus on the socio-economic impacts of demographic change. As a dominant driver of population growth, robust estimation of immigration and emigration is key to the production of consistent national and regional population projections for EU countries (Lanzieri, 2007) and the implementation of EU Regulation 862/2007 has provided a statutory basis for greater harmonization of international migration statistics in Europe (Boden and Rees, 2008). However, there is a certain asymmetry between data availability on immigration and emigration, for two main reasons: departures tend to be less well recorded than arrivals and it is difficult to count persons leaving the country from a statistical point of view because of their absence (United Nations, 2010).

In Italy, a total of 410 thousand people emigrated abroad from the Census date (9th October 2011) to 1th January 2016, while around 450 thousand people were deregistered ex officio from the population registers. The latter figure is included in the demographic balance as «deregistration for other reasons» (based on a macro approach) but it is excluded from the migration flows statistics (micro events). Nevertheless, it is likely that a deregistration refers to someone who left the country without informing the administrative accountable office of their departure. Among these 450 thousand, there were almost 300 thousand of deregistration that could be assimilated to emigrations since they are related to individuals that, after the date of cancellation, do not reappear at least for 12 months. In order to classify these deregistration as migrations flows, the date of occurrence of the emigration has to be estimated.

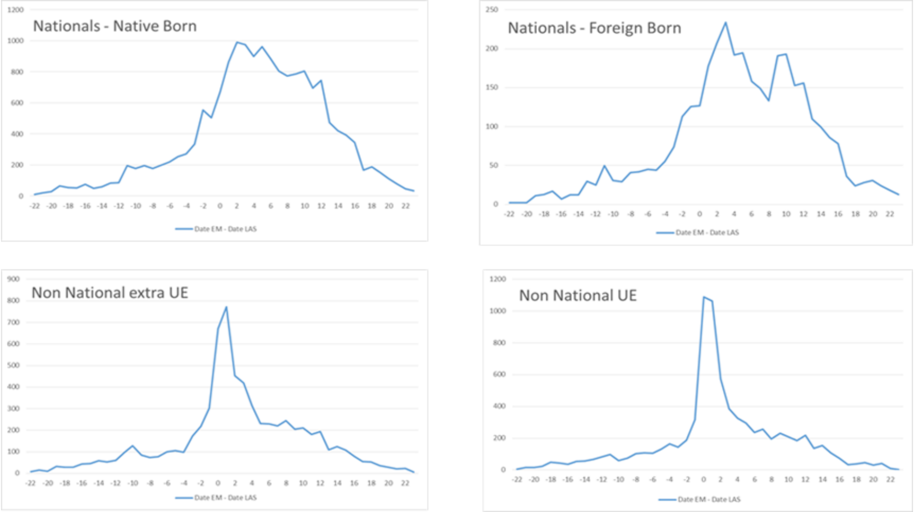
To this aim, we have used the information coming from other administrative sources (Labor and Education registers, Tax Returns register, Earnings, Retired, and Non-Pension Benefits registers, Permits to Stay archive) to derive a monthly Administrative Signal of presence in Italy.

As already mentioned, there have been 409,758 emigrations to abroad (EM) from the Population Census (9th October 2011) to 1th January 2016. Every individual emigration flow has been associated with the respective Last Administrative Signal (LAS) on the territory.

The underlying idea is that there is a relationship between the Date of emigration (Date EM) and the date of the Latest Administrative Signal (Date LAS). In particular, we have made the hypothesis that the difference between the mentioned dates is distributed normally.

Figure 3 shows that for non-nationals, the difference is strongly concentrated around 0 and 1 month, meaning that the majority of foreign citizens leaves the country very soon after they lose the signal of presence in Italy. The variability of the distribution is different for Nationals, meaning that, even without a signal of study or work, they can afford to stay longer in the country before emigrating abroad. In order to consider a deregistration ex officio as an emigration to abroad, the date of occurrence of the emigration (Date EM*) has to be imputed since the date of deregistration ex officio (Date DER) of a person has probably been postponed respect to the date of occurrence of the emigration (Date EM). To this aim, also the individual Date of deregistration ex officio has been associated with the respective Date of latest Administrative Signal on the territory (Date LAS).

Figure 3: Observed differences (in month) between Date of emigration and Latest Administrative Signal by citizenship (CTZ) and country of birth (CTB)



Observed Diff EMLAS distribution (by CTZ and CTB) has been used to estimate the date of occurrence of the emigration (Date EM*) for those deregistration carried out ex officio. In summary, the procedure was as follows:

1. Estimation of normal distribution parameters from observed data (Diff EMLAS = Date EM – Date LAS).
2. Computation of emigration data (Date EM* = Random Normal (Diff EMLAS) + Date LAS) for individuals deregistered ex officio by simulating Diff EMLAS with the normal distributions estimated in the previous step.

Figure 4: Observed differences (in month) between Date of deregistration and Latest Administrative Signal by citizenship (CTZ) and country of birth (CTB)

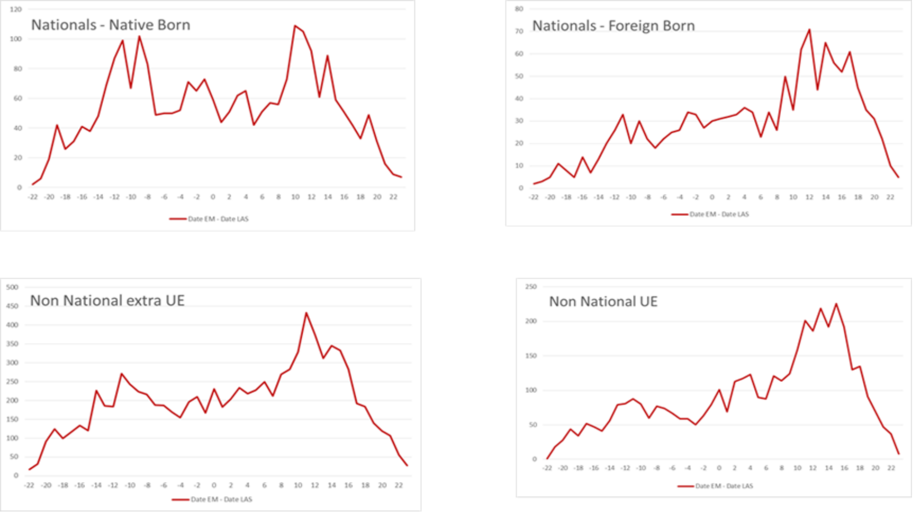


Figure 5: Estimated random normal differences (Diff EMLAS*) and observed ones (Diff DERLAS) by citizenship and country of birth

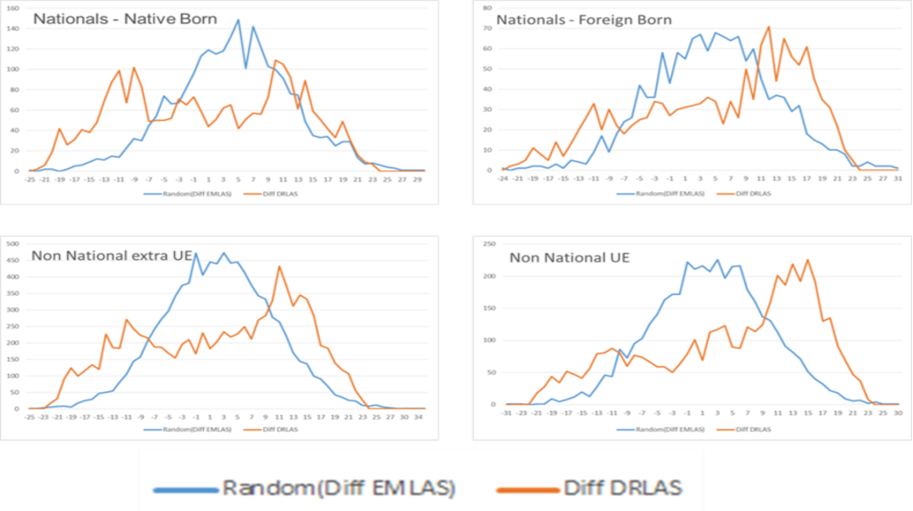

According to a first estimation of the emigration flows, the number of emigrants, almost doubled the number published by the official statistics. The latest figure for 2015, along with the number of immigrants during the same year, produces a negative net migration of -4 thousand while official statistics reported a positive net migration equal to +133 thousand units (Table 2).

An analysis by citizenship reveals that the Non Nationals report the largest impact on the emigration figures (from 45 thousand to 112 thousand). As a result the number of

Non National leaving the country is almost equal the number of Nationals. If we take into consideration that more than 20% of emigrants with Italian citizenship is born abroad, we can conclude that the majority of the people that leave the country has a foreign origin.

Table 2: Immigration, emigration flows and net migration observed and estimated (observed and estimated) by citizenship – Year 2015

Citizenship	***Immigration***	***Emigration***	***Net MIG***	***Emigration****	***Net MIG****
		Observed		***Estimated***	
Nationals	30,052	102,259	-72,207	147,300	-117,248
Non nationals	250,026	44,696	205,330	137,450	112,576
Total	280,078	146,955	133,123	284,750	-4,672

4 Conclusion

There is a lack of longitudinal database in Italy. An integrated period and cohort approach is a pillar of the MiDEA-ANVIS project. In order to produce information useful to the interpretation and the explanation of demographic phenomena, a deep change of strategies in organising basic statistics data is required, overcoming the traditional period approach at favour of cohort one.

Migration is the most difficult component of population change to evaluate, as if there is a comprehensive system which registers migration in our Country, either moves to or from the rest of the world, or moves within the Italian Municipalities.

The traditional concepts of resident or present population are less and less reliable to assess people usually or actually living in a Municipality, due to the increasing mobility of the population and the international migration (an international migrant is defined by the United Nations (UN) as someone who changes country of residence for 12 months or more).

Measuring migration movements of populations in different countries is a challenging task.

Administrative sources are an extremely powerful tool and a potential source of information for emigration statistics. The Italian case provided empirical evidence of the issues to be confronted and the challenges to the use of a data integration for improving the quantity and quality of data on emigration. A coherent and consistent database that contains detailed, up-to-date and accurate information allows to study migration through a longitudinal approach (Return Migration, Circular Migration).

Demographic changes, research questions and data needs: issues about migrations

Cambiamenti demografici, domande di ricerca e necessità informative: considerazioni in tema di migrazioni

Salvatore Strozza and Giuseppe Gabrielli

Abstract After a synthetic introductory analysis on the trends of legal and resident population in Italy according to different sources, such as census, post-census estimations and Municipal Population Registers, the paper aims at focusing on the migratory component of population dynamics. In particular, it underlines the recent changes occurred to foreign immigration (for example, the importance of family reunifications and the growth of asylum seekers) to foreign-origin presence (from first to second generation, and from foreigners to new Italians), as well as to Italian emigration. This background framework will outline new information and research needs to which Italian public statistics system could or should handle considering the gained experience in other European countries (from cross-sectional to longitudinal surveys).

Abstract *Dopo aver proposto un sintetico esame introduttivo sulla determinazione della popolazione legale e residente attraverso i censimenti, la ricostruzione post-censuaria e i registri d'anagrafe, l'attenzione viene focalizzata sul bilancio demografico e sulla sua componente migratoria. In particolare vengono evidenziati i cambiamenti in atto con riguardo all'immigrazione e alla presenza straniera in Italia, ma anche all'emigrazione italiana all'estero. Si tratta del quadro di sfondo per richiamare le necessità informative e di ricerca che dovrebbero o potrebbero trovare risposta nel sistema delle rilevazioni italiane, anche tenendo conto dell'esperienza maturata a livello europeo.*

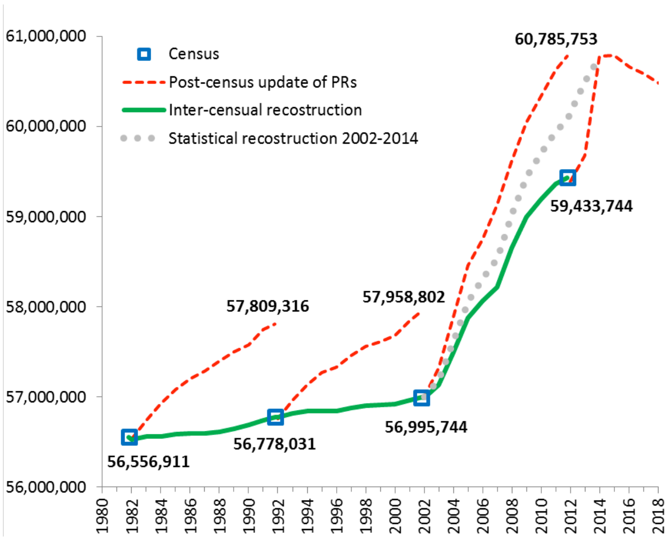
1 Introduction

The contribute has undoubtedly an ambitious title, maybe it is too ambitious compared to what it intends to analyse. It not refers to the general picture of demographic changes in recent decades and to all issues of current and future demographic interest, but it focuses only on the determination over time of the resident population, on the collection and estimation of migration flows and stocks and on some current and future challenges related to migration processes. These challenges may found an answer through information that will be acquired with the new population census strategy [14, 12, 6]. The aim is to recall the main information and research needs that the Italian Statistical System should or could provide on migration issues.

2 Determination over time of the resident population

It is well known that the census resident population is the so-called "de iure" population or “legal” population. Until now, the update of resident population, coming from Municipal Population Registers (MPRs), started from the amount of legal population has been recorded through the last census (Figure 1). Also the re-count of population (the so-called “inter-censual reconstruction”) was provided in previous inter-census period starting from (using as constraints) the legal population of the last two census.

Figure 1: Total resident population by different data collection or estimates, 1980-2018.



Source: own elaborations on Istat data.

The update population of MPRs is always higher than census resident population (1,031,000 people in 1991, 963,000 in 2001 and 1,352,000 in 2011). Synthetically, the difference depends on the over-estimation of resident people by MPRs (due to no deregistration of the people leaving the municipality) and under-count of census resident population (due to the well-known coverage problems of the total survey). A relatively recent novelty is that the ISTAT [11] proposed also a statistical reconstruction estimating the regional population in the period 2002-2014.

The population estimates are the architrave not only of demographic statistics but also of socio-economic statistics. The reduction in the timing of the release of the 2011 census results and of the revision and update times of the registers (resulted in a considerable recovery of people re-registered in 2012-2013) produced a large growth of the resident population. The statistical reconstruction of the population was therefore determined in order to eliminate the perturbations due to administrative issues, being used for the estimates coming from the main sample surveys (starting from the Labour Force Survey) and for the definition of the economic aggregates (starting from National Accounting). The main novelty consists in the correction of the 2001 census resident population based on the results of the Post Enumeration Survey (PES).

In general, it is clear that the decennial census involved a revision of population statistics every 10 years. In other words, the "reconstructed" population replaced the "updated" population about 10 years later. Even no large disparities occurred between the two different estimates (less than 2%), it is likely that 'permanent' Census of Population and Housing should overcome the re-count of population every decennial cycle.

In future, it will be interesting to understand how the "legal population" will be defined. For example: will the usual inhabitants be determined not considering the legal status?

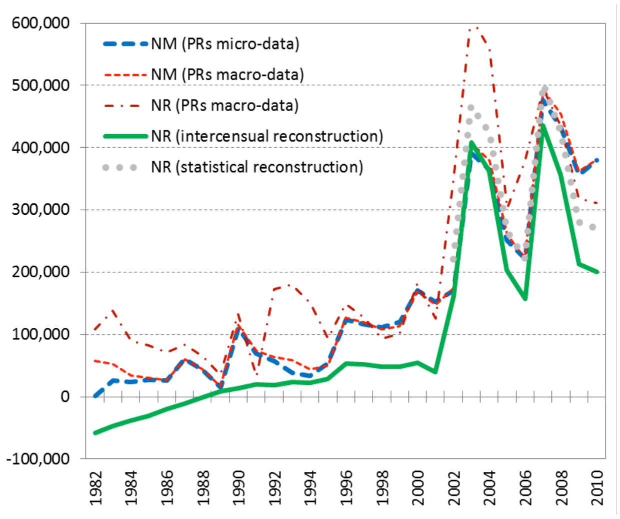
3 Determination over time of the net migration

Differences between the "updated" resident population and the "reconstructed" inter-censual population concerns also the (count or evaluation of) migratory component. Figure 2 shows net migration (NM) and net residue (NR) in the period 1982-2010 according to different data collection or estimates. In particular, net residue comprises all population variations except the natural change (births minus deaths).

The data of inter-censual reconstruction shows lower net migration than the other sources. Net migration turns from negative to positive during 80s, increases during 90s and widespread in the new Millenium. This is the story of the last 30 years but with different levels of the Italian migratory balance with the rest of the world.

During 80s net migration is positive (more than 500,000 people) according to direct estimation coming from the up-data population of MPRs but is negative (for almost 200,000 people) in the inter-censual reconstruction. During 90s, both sources of data show positive values, but the difference between them is of 600,000 of individuals. In the last observed decade the same difference enlarges to almost 800,000, but less important in relative terms.

Figure 2: Net Migration (NM) and Net residue (NR) according to different data collection or estimates, 1982-2010.



Notes: NR = NM plus other variations (excluding natural change); PRs = Population Registers
Source: own elaborations on Istat data.

Migrations become the main component of the demographic dynamics in Italy [7, 19]. In the last decade, the natural increase rate was -0.3 people per year every 1,000 inhabitants, while the net migration was in the range 4.5-5.8 immigrants per year every 1,000 inhabitants, with a significant gap of 1.4 points for every 1,000 inhabitants greater than in the previous two decennial periods (Table 1).

Table 1: Net Migration (NM) and Net Residue (NR) according to different data collection or estimates, 1981-1991, 1991-2001, and 2001-2011 inter-censual periods.

	Phenomenon (source of data)	Absolute values (in thousand)			Rates (per 1,000 inhabit.)		
		1981-91	1991-01	2001-11	1981-91	1991-01	2001-11
A.	NM (PRs micro-data)	404	978	3,350	0.7	1.7	5.8
B.	NM (PRs macro-data)	508	995	3,392	0.9	1.7	5.8
C.	NR (PRs macro-data)	833	1,358	3,953	1.5	2.4	6.8
D.	NR (inter-censual reconstruction)	-198	395	2,601	-0.3	0.7	4.5
E.	NR (statistical reconstruction)	…	…	3,243	…	…	5.6
F.	Difference between B and D	706	600	791	1.2	1.1	1.4

Source: own elaborations on Istat data.

Some scholars have talked about: “Italian migratory crossroads” [17]. Italy has not only become an important immigration country, but it remains a country of emigration of its citizens in the last years (more than during 80s and 90s). Data on registrations and de-registrations from and for/to abroad well show this picture. However, there are statistical uncertainties on the emigration size and sometimes on the sign of the net migration of Italians with foreign countries [18].

The direct data collection of MPRs counts 425,000 registration from abroad and almost 491,000 deregistration for abroad of Italian citizens in the period 2002-2011. Thus the net emigration of Italians is negative but of the small size (-65,000). As the emigration from Italy is generally under-estimated (for different reasons) and postponed (in respect to the effective date of the transfer), it was reasonable to expect a more consistent net emigration coming from indirect inter-censual estimation. Conversely, last two censuses lead to estimate a positive net migration of Italian citizens: arrivals from abroad exceed for 70,000 departures for abroad (Table 2). In particular, this outcome is evident considering Southern regions and Islands. The net immigration is even larger in the inter-censual reconstruction of population (almost 500,000). On the opposite, the net migration is negative of more than 200,000 people according to the Post Enumeration Surveys (PES) [5, 13].

Table 2: Registered and estimated net migration for Italian citizens in the 2001-2011 period, using different evaluations of the population residing at the two censuses (or around this data).

Sources of data	Resident population		Period 2001-2011		Net migration
	2001	2011	Natural increase	Acquisition citizenship	
Population Registers (PRs)*	…	…	…	…	-65
The two censuses (inter-censual recostruction)	55,661	55,406	-709	385	69
The two censuses, the second re-evaluated (statistical recostruction)*	55,653	55,812	-726	393	492
The two censuses, both re-evaluated according to the Post Enumeration Surveys	56,340	55,772	-709	385	-245

Note: (*) Population at the end of the year and/or period 2002-2011.
Source: own elaborations on Istat data. See also [18].

All these simple applications show in synthesis the existing problems to measure migration from and for abroad still in the past decade. In recent years this problem has returned to the center of attention. Enrico Pugliese in his last book [17] underlines that "Having a clear vision of the numerical consistency of the Italian emigrations also allows us to have an idea of its social significance" (p. 23). Thus … "It is not a useless exercise to try to understand if 110,000 people go away or a double or triple number, as some experts believe" (p. 25). Paradoxically, "arrivals (in the destination countries) exceed departures (from Italy)" (p. 27). This is particularly evident in Germany or in the Great Britain, as the author shown. It could depend on the source of data too. Anyway, the difference between the statistics of origin countries and the ones of destination countries exists since long time.

According to ISTAT data of cancellations for abroad, Italians departed toward countries of EU-15, Swiss and Norway were 83 thousands in 2016, equal to 73% of total cancellations. Thus, it is sufficient to look at these destination countries to get a not-exhaustive but general situation. Using Eurostat data, information are missing in 4 out of 16 considered countries: Germany, Greece, Ireland and Portugal. Unfortunately, data about Germany are missing. Looking at the 12 available destination countries in the period 2012-2016, we observe, according to Eurostat, almost 400,000 arrivals (registrations) of Italians in the 12 European countries. At the same time, Istat data register more than 230 departures (de-registrations from Italian MPRs) of Italians directed towards the same 12 European countries. The two sources present an hypothetical under-estimation of 69%. This is just an exercise to underline an existing counting problem of migration from and to abroad.

Can the New Population Census Strategy solve this discrepancy in the next future? Can the linkage between different administrative sources identify possible unregistered (undocumented) migrations and also unregistered return migrations? Can longitudinal data provide further information about the determinants of Italian emigration as the characteristics and the socio-economic conditions of the individuals and their origin families?

4 Foreign presence in Italy: resident and non-resident population

After twenty years of zero population growth (80s and 90s), resident population in Italy increases thanks to immigration. The number of foreign residents has been around 5 million in the last years. Today the information framework is much richer than in the past [16, 20, 10, 4] but there are still several gray areas and questions that cannot be answered. New issues and research questions emerge over time. The Statistical System, starting from the permanent census, should consider it.

ISMU estimation [1] counts almost 6 million of foreign population (resident, not resident and irregular people). They represent the 10% of total population. Irregular migrants represent in the last years a marginal quota (less than 10%) but a significant size (about 500,000) of the phenomena. It is unknown how many people, arrived in Italy from the Mediterranean Sea, enlarged the number of the irregular component or went elsewhere. In other words, now day it is not possible to determine the inclusion paths of (irregular) sea arrivals that can become asylum seekers and refugees in Italy.

Will the ‘permanent’ census overcome this limit? Will the permanent census contribute to estimate them as well as the regular non-resident population? Will it count naturalization of immigrant and of transnational couple descendants?

The National Statistical System has produced more and more reliable and exhaustive statistical information on migrations in the 80s and 90s. Significant improvements have been made to ensure the availability of unreliable information on the foreign population [16, 20, 10, 4], disaggregated on a territorial scale (at least at the provincial level). However, at the end of the last century, there were still numerous limitations and gaps such as [20]: the discrepancy between flows and stock data; the difficulty to define net migrations in the population equation; the lack of many information between two successive census due to the absence of reliable data on immigrants and/or foreigners in the National sample surveys (e.g. education, work, income, housing).

Census of 2001 represents the first and most important and reliable source on foreign (or immigrant) people, not only for the territorial detail (up to sub-municipal level), but above all for the importance of the acquired information [3, 2]. In adding, starting from the new Millenium, labor force (sample) survey became representative also for the foreign component of the population residing in Italy, ad-hoc sample surveys on households with at least one foreign component have been designed and implemented [4], the role of administrative data collections has been re-defined (in particular, residence permits) and record-linkage techniques have been performed.

Now day census data and survey data provide a wide and heterogeneous range of information on people with migration background. However, new requests of information raised and some lacks of information are still present about, in particular: characteristics and settlement process of undocumented arrivals; naturalization and integration processes of 1st and 2nd generations [15, 9, 8]; returning and emigration (that is generally under-estimated).

5 Future challenges related to migration processes

In conclusion, it is interesting to underline (in a schematic way) partial and not exhaustive future challenges related to migration processes. The Municipal Population Registers and Households (Surveys) have always been two reference elements for official statistics. However, this paradigm will be less and less relevant to analyze a more complex and dynamic society. This is particularly evident for migrant families/individuals. It will be increasingly necessary to identify new indicators of habitual residence and of different (non-cohabitant) family forms.

The data sources are increasingly differentiated and articulated (e.g. social data). In the future it will be necessary to link information that are different for definitions, concepts and methods, coming from a plurality of subjects.

It is increasingly necessary in the scientific research to be able to observe individuals according to a longitudinal approach to define the causal relationships of processes. Examples are: 1) the life trajectories of sea arrivals that become asylum seekers and refugees; 2) mobility and return migrations; 3) demographic behavior of migrants and their descendants; 4) processes of integration and naturalization.

The use of big and complex databases and of micro-data (as in the case of ‘permanent’ census), for the analysis of phenomena, has become indispensable. On the other hand, the “Cambridge Analytica” scandal has shown the increasing risks in data acquisition processes and the need of a correct use of information. The right balance between confidentiality of information and access to micro-data for research will be an important challenge. These issue is even more relevant when considering small groups of individuals, for example, by citizenship or by geographical context.

Centralization of data collection guarantees better monitoring and uniformity of statistical information. This is the case, for example, of the next National Register of Resident Population (ANPR). At the same time, given the persistent geographical differences in Italy, it will be increasingly necessary to guarantee analytical information at local level in order to identify local policies: in manner of fact the integration of immigrants regards the specific contexts in which they live.

Towards more timely census statistics: the new Italian multiannual dissemination programme

Verso una produzione censuaria più tempestiva: il nuovo piano di diffusione pluriennale italiano

Simona Mastroluca and Mariangela Verrascina

Abstract Italy is moving towards a new census strategy, integrating information arising from registers and recurring sample surveys. One of the main targets of such approach is the timeliness of the data; the delay in release of census data reduces their value and usefulness for many stakeholders. Therefore, a new Italian dissemination programme has been carried out to ensure a subset of census statistics every year; the contents can evolve overtime as user needs change and the availability of administrative data improves. The annual data dissemination will be supplemented by a larger decennial publication, which will occur for the reference year 2021, the same defined at European level. Meanwhile, Eurostat is working to define a strategy for future censuses founding on a more frequent data supply, especially on population and migration topics. The purpose is a multiannual data collection, essentially relied on administrative data sources starting from the mid-2020s maintaining the traditional decennial data collection that will be done in 2031. It reveals evident similarities with the Italian case.

Abstract *La nuova strategia censuaria italiana si basa sull'integrazione di informazioni provenienti da registri e da indagini campionarie periodiche. Uno dei principali obiettivi è quello di assicurare una maggiore tempestività dei risultati: il ritardo nel rilascio dei dati censuari riduce il loro valore e l'utilizzabilità degli stessi. A tal fine è stato predisposto un nuovo piano di diffusione che prevede, oltre alla tradizionale diffusione decennale riferita al 2021 (lo stesso definito a livello europeo), la produzione annuale di un ridotto set di incroci rimodulabili nel tempo in funzione delle esigenze degli utenti e dei dati amministrativi che via via si rendono disponibili. Contemporaneamente Eurostat sta lavorando alla progettazione dei censimenti futuri che dovranno garantire una fornitura più frequente dei dati a partire dal 2025, soprattutto su temi relativi a popolazione e*

Mariangela Verrascina, Istat, verrasci@istat.it

migrazioni, mantenendo comunque la consueta e più ampia diffusione decennale del 2031. Emerge chiaramente che la strategia europea per i censimenti post-2021 presenta numerose affinità con quella già adottata nel nostro Paese.

Key words: permanent census, data dissemination, European strategy, timeliness

1 The new Italian census strategy

The 2011 Italian general population and housing census has been the last one carried out in a traditional way even if many innovations as the mail out of forms and the self-completed questionnaires collected by a multimode system were planned to achieve a stable and enduring balance between census costs and benefits. Considering the huge amount of data from administrative sources, the reduced budget allocated for the enumerations and a growing need for more frequent census-like data, Italy designed a new census strategy. The systems that would allow annual data production are: the register-based systems, combined approaches based on administrative sources supported by surveys and the rolling census. The expected user need for more frequent information, especially on population topics, is reflected also in Eurostat's plans to develop a redesign of European census statistics after the next census round. A key aspect will be to ensure a complementarity of data to meet key user needs, while avoiding duplication of data collection. The new Italian population and housing Census, that will no longer be decennial but permanent, is based on the Census and Social Surveys Integrated System (CSSIS), a complex statistical process integrating the information arising from registers and surveys. It foresees a two phases Master Sample design consisting of a set of balanced and coordinated sampling surveys. The first phase of Master Sample is based on two different component samples, namely A (Areal) and L (List). The first is designed to satisfy the needs of estimating under-coverage and over-coverage rates of the Population Register at national and local level for different sub-population profiles like sex, age, citizenship. The component L - based on a list sample - has the purpose of thematic integration that is estimating the hypercubes which cannot be obtained using the replaceable information coming from Registers. Census topics have been classified as totally, partially or not replaceable. The first group includes variables for which the administrative sources provide the correspondent proxy information; they are considered complete because they are available for all units in the thematic registers and accurate, having a good level of coverage and quality. Partially replaceable variables are considered complete and accurate only for a subset of the target population; for the others, the topics are unknown or cannot be considered accurate. This is, for example, the case of the educational attainment: the Italian Ministry of Education does not provide information on Post-secondary non-tertiary education or degrees obtained abroad. In the last group (not replaceable variables) there are topics not yet available from administrative sources. Therefore, the Italian permanent census is a combined census using both the information produced by the

Statistical Registers, for replaceable variables, and the CSSIS for the remaining topics. For Population and Housing Census purposes, at the moment three Statistical Registers are under construction: the Population Register, containing the census topics sex, age, place of birth, legal marital status and citizenship, the Employed Register with information on Economic characteristics and the Register of Buildings, including data on buildings and dwellings. Seven years after the last traditional Italian Census, the first survey of the new census project is scheduled for October. The A and the L components involve almost 1400 thousand households and 2800 municipalities with different population size. The Area survey is a totally paperless door-to-door enumeration with CAPI (computer-assisted interview) technique. Questionnaire will be completed by enumerators supported by electronic devices (tablets). The List survey is totally paperless too. Households self-complete web questionnaire (CAWI). First step is the mailing of invitation letters with credential to login the web questionnaires; eventually, all not respondent households up to a specific date will be interviewed by enumerators to get all the forms filled (CAPI). The questionnaire is the same for both the components. It includes not only partially or not replaceable variables, but all the necessary topics to produce hypercubes with the aim of using collected information also to test quality and coverage of data already available in Registers. One of the main targets of the new census strategy is the timeliness of the information; the decennial data dissemination would be supplemented by an annual dissemination programme in order to face the stakeholders' needs.

2 Census data dissemination between tradition and innovation

2.1 **2011 data dissemination programmes**

The 2011 European Census of Population and Housing was the first census exercise based on a common legislation that covered in detail all aspects of census outputs. In particular, an output harmonisation approach was taken: countries were free to produce the required data using any appropriate methods and data sources according to national availability and preference. However, the European data needed to fully meet the standards as defined in the legislation – such as the definitions, breakdowns, cross-tabulations and quality reporting to be applied. The Regulation (EC) 763/2008 defined the variables to be included necessarily in the survey plan and the time required to make the definitive census data and the related metadata available to Eurostat; allowed NSIs flexibility in the choice of data sources that could be used to fulfil the requirements of the data collection. Member States provided the Commission (Eurostat) with final, validated and aggregated data and with metadata, as required by the Regulation, within 27 months of the end of the reference year. The Regulation Annex listed the census topics that should be included and sets the geographical levels for which data on these topics should be available. With a view to standardizing the census output, the Regulation no. 519/2010, concerning the dissemination programme of data and metadata, provided the list of cross-tabulations which, to various territorial details (from national to municipal) and at different classification levels, had to be validated and made available. The list of mandatory core topics present in the hypercubes was that reported in the Framework Regulation, while classifications referred to the Regulation no. 1201/2009 on breakdowns and technical specifications. ISTAT prepared and made available to Eurostat 60 hypercubes (5 at national level, 36 at NUTS2 level, 10 at NUTS3, 5 at LAU2 and 4 at place of work), corresponding to 175 principal marginal distributions; the data dissemination programme focused mainly on regional detail. The Regulation on hypercubes also defined the textual metadata that must be supplied for the census topics. Data were produced in the form of detailed multidimensional cross-tabulations (hypercubes) and accessible via the online Census Hub system, allowing users the flexibility to define tables according to their needs. The dissemination programme defined by Eurostat did not correspond to the Italian programme; in fact, the hypercubes listed in Regulation no. 519/2010 differed from the cross-tabulations characterizing the Italian dissemination in terms of information, breakdowns, definitions, classification details and territorial level. For the Italian dissemination it was necessary to satisfy the information needs of the national users and to guarantee continuity to the time series. Consequently, for the 2011 census, two different dissemination programmes were produced, one defined on the basis of the European Regulations, the other with tables crossings all the variables contemplated by the Italian survey plan, which, in addition to ensure continuity with the past, allow to disseminate information on phenomena of national interest (for example, mobility at municipal level) or for the first time investigated during the census in Italy (for example, the place of birth of parents). The dissemination took place only via the web, through the corporate datawarehouse (I.Stat); there are more than 300 multidimensional tables that users can export. Data were then disseminated for enumeration areas, thematic maps compared with the previous censuses and data in open format (Linked Open Data).

2.2 **EU Programme of the statistical data for the reference year 2021**

A European Task Force composed of 18 EU Member States and 3 Candidate Countries worked for the preparation of the new legislation. The 2021 EU census data collection is based on the existing Framework Regulation (763/2008) that provided the legal basis for the 2011 census, while new implementing regulations have been developed to define in detail the 2021 census: definitions of topics, classifications, programme of cross-tabulations, metadata and quality reports; even if the list of topics and their geographical breakdown cannot be changed. The Regulation no. 2017/543 concerns the technical specifications of the topics and of their breakdowns to be applied for the 2021 data collection. Compared to 2011, a number of changes for 2021 have been introduced to simplify wherever possible definitions and breakdowns and to remove optional categories. Definitions and breakdowns have also been updated to reflect new data needs, changes in society, or to take into account changes in other related statistical exercises. The Regulation no. 2017/712 is on the reference year, the table programme and textual metadata to be applied for the 2021 EU census data collection. The table programme for 2021 retains the richness of the census as a data source and covers the priority issues, while reducing as far as possible the burden on the NSIs. It contains significant reductions in terms of the number of tables, as well as in the dimensionality of the tables. Thus, the simplification of the data (resulting from the 2011 experience and outputs) has implied a reduction in the number and complexity of the cross-tabulations, the removal of cross-tabulations and/or dimensions that were little used in 2011 and a focus on variables that are priorities for users (in particular, data on migration-related variables). The 2011 data transmission programme included 175 principal marginal distributions, while the programme for 2021 is based on 119 smaller datasets. As was the case for 2011, the 2021 data will be disseminated primarily via the Census Hub. The 2021 EU census data collection can be seen as consisting of two areas: the 'main' data collection, as described above, and an additional set of data geo-referenced to a standard 1km² grid. Geographically detailed data from the census are essential for Regional and cohesion policy to plan, develop and evaluate policies. The collection of population data at the 1km² grid level is an area where there is significant user demand and which is undergoing rapid development in many NSIs. The potential value of merging geospatial data with official statistics is to provide better social and environmental information. The 2020 round of censuses would be an important opportunity for the integration of statistical and geospatial data. Only 13 numbers would be collected for each grid square, then disseminated via the Census Hub. This is a new development for the 2021 census, distinct from the main EU census data collection programme. This data collection is not based on Regulation no. 763/2008 but, instead, will use a 'temporary direct statistical action' based on the Regulation on European Statistics.

2.3 **The Italian dissemination programme for the Permanent Census**

Istat is working on the preparation of different dissemination programmes. The proposals start from a critical evaluation of the 2011 Italian programme (complexity of the tables, redundancies, outdated phenomena, requests from stakeholders, etc.), from the analysis of the use of the information available on I.Stat and on other dedicated sites and the results of the survey on information content, tools and dissemination strategies adopted in some foreign countries. The extended dissemination programme, in line with the EU, will have as reference year the 2021. With a view to simplification, the new ten-year programme has been redefined, ie cross-tabulations at regional level have been eliminated (preferring tables with a lower territorial detail), particularly complex cross-tabulations have been simplified but, at the same time, new cross-tabulations have been introduced to study social emerging phenomena. The draft decennial programme proposes around 250 tables, structured on various thematic areas and with different classification details and territorial levels (over 70 municipal tables) that, between tradition and innovation, guarantee the updating of the time series, a fine territorial detail, a high classification detail and new focus (seniors, children, foreigners, inactive people, NEET). Considering then the information available through the Registers and the annual survey (MS) on over one million households, a minimum set of tables at municipal level and possibly sub-municipal for municipalities over a certain demographic threshold has been developed (about 30, reconfigurable over time) to be disseminated from 2019 on an annual basis. The planned municipal cubes concern the areas “Population, Households and Family Nuclei”: population structure by sex, age and citizenship, migrations, educational attainment, current activity status, commuting, type of family nucleus and type of private household. The hypothesis of a uniform base dissemination for all the municipalities and of an additional dissemination depending on the population size is under study; the choice is strictly linked to the sample design that Istat intends to adopt for the Master Sample. From a further analysis carried out on the 2021 national dissemination programme, a new set of tables to be released to the provincial (and big cities) details has been identified, with a periodicity to be defined. The additional tables have variables not included in the annual proposal or more detailed classifications than those foreseen at municipal level. The Permanent Census dissemination can be read from the point of view of the Statistical data (annual, multiannual and decennial dissemination programmes) and of view of the Output presentation (tools to be adopted for the census data dissemination). The starting point is the preparation of predefined tables so the dissemination is made up of tables defined a priori. Then a dissemination differentiated by population size of municipalities should be introduced. The dissemination could be completed with data representation (maps and cartography improved than that used for 2011 census output). All these kinds of output need the use of new technologies and new dissemination tools, that means new approaches to the production and presentation of census data. For example, the following tools could be used: Stories (short analysis designed specifically for web publishing); Summaries (concise articles that illustrate only the main results of an analysis); Infographics (graphical representations of the main results of the analysis with some contextual information or annotations); Video podcasts (video to explain the main results of the analysis); Interactive content (maps, graphs and images that the user can manipulate to highlight areas of interest). Finally, customised analyses could be permitted, by creating a system that allows customised queries in the case users do not find the information they are looking for in the predefined tables or preparing a datawharehouse that allows the cross-tabulation of variables and classifications according to user needs.

3 Strategy for the post-2021 European census

In 2016 representatives of France, Germany, the Netherlands and the UK on the Task Force on future EU censuses drafted jointly with Eurostat a vision for the post-2021 census. This vision was a result of the consultations with key users that showed a growing need for more frequent census-like data. The vision is made possible by the fact that the vast majority of European countries have made, or are planning or considering, major changes to the data sources and methods used for the census; most widely, the increased use of data from administrative sources and a move away from a traditional census enumeration. A fundamental goal for all European countries should be the development of a post-2021 strategy that provides relevant census results for data users. Based on the 2011 data provision, greater relevance for the census can be achieved if countries agree to more frequent and timelier census publications. A good balance will need to be found between the level of detail and accuracy in the publications on the one hand and timeliness of the publications on the other hand. Moreover, it is important to develop a strategy that is appropriate for both countries with and countries without field enumerations. Although many countries have moved or are moving from traditional censuses towards combined and register-based censuses, it is clear that different approaches towards census methodology will remain within Europe. The post-2021 census can be defined in the form of two separate collections. The first of these would be an annual data dissemination based essentially on administrative data sources, to be introduced in the mid-2020s. This annual data dissemination could include occasional modules on particular topics where data were collected at an intermediate frequency (such as every 5 years). The annual data dissemination would be supplemented by a larger decennial data dissemination in the form of the recurring decennial census first to be done in 2031. The initial need identified is to have basic demographic and migration data available on an annual basis; further topics could be added to the developing annual data dissemination. Given this uncertainty on how the annual data dissemination will develop over time, and the need to look ahead for a period of up to 10-15 years in the future, the framework for the post-2021 development will be implemented in a flexible manner. The key features of the new EU census strategy are a census round every ten years supported by annual updates on relevant topics, annual updates starting with a core set of demographic and migration topics with limited cross-tabulations, flexibility regarding the topics of the annual updates and the timetable for increasing the amount of data available, timeliness of the publication of annual census data, data provision of annual updates on a detailed regional level and of annual population counts for a geographical grid (1 km² or smaller if possible), integration of annual census updates into the annual work programmes of the national and European Statistical systems. This implies a convergence and merging with the annual demographic statistics, as well as coherence with other European social statistics developments. The introduction of 1km² grid data already for the round of 2021 (above mentioned) is an important development. There is a growing user need for grid-based data because grid squares are more stable over time than, for example, municipality boundaries. As the production of geo-referenced data is time-consuming and cost-demanding, and the level of experience with geo-referenced census data differs greatly among European countries, a good starting point for annual updates is to begin with annual population counts by 1 km² grids. If that approach succeeds, the annual updates could gradually be extended. Of course future availability of administrative data is not so clear since no one knows what data will be accessible by the mid-2020s. Dissemination within 12 months is a difficult goal to reach for countries with large field data collections, even when (part of) the forms are filled in via internet. For those countries it might be an option to provide provisional results within 12 months and then, later, according to their own dissemination plan, definitive results. For countries with large field data collections it would probably be possible to make use of estimations to reach the 'within 12 months criterion'. The estimations should be precise enough for the European level of analyses made through the Census Hub data. Users said they prefer timely provisional results rather than outdated definitive information. As far as the content of annual census results is concerned, it is important to produce census data on a more detailed regional level, but to achieve good timeliness and policy relevance, the annual census results would have to focus on demographic and related migration variables. The need for some basic explanatory variables must also be considered, although these may prove to be more complex to produce. This implies that the annual updates only concern the Population Census and not the Housing Census and the tables should not be as high-dimensional as the current decennial hypercubes.

4 Summarizing

Thanks to the new Italian census strategy a subset of census statistics will be disseminated every year starting from 2019. A core set of demographic, socio-economic and migration topics with limited cross-tabulations and less detailed disaggregations will be promptly made available to the stakeholders. In 2016 the "Task Force on future EU censuses of population and housing", composed by Eurostat and 18 countries (including Italy), drafted a vision for the post-2021 census providing a framework for the development of census-type population statistics over a period of around 10-15 years, covering the more frequent (annual) statistics to be introduced and expanded after the completion of the 2021 census programme, as well as consideration of the likely needs for a full census programme in 2031. A fundamental goal for all European countries is the development of a post-2021 strategy that provides relevant and timely census results for data users. It means that Italy is realizing in advance what will be applied at European level only from the mid-2020s: it's a big challenge for our country that has to face many innovations in a very short time in order to produce high quality territorial annual census data.

Living Conditions and Consumption Expenditure in Time of Crises

Household consumption expenditure and material deprivation in Italy during last economic crises

Spesa delle famiglie e deprivazione materiale in Italia durante le ultime crisi economiche

Ilaria Arigoni and Isabella Siciliani

Abstract

The severe economic crises affecting Italy during the last decades have had serious effects on the living conditions of residing households. Household disposable income decline was associated with a general decrease of household consumption expenditure, mainly in the period 2011-2013, and a rearrangement of its structure, with a slight increase in the expenditure share on food and non-alcoholic beverages (*foodshare*) whose increase is a well-known symptom of stronger budget constraints. However, economic hardships affected households differently, producing inequality increase and an enlargement of the share of population suffering from material deprivation.

This paper attempts to shed light on extent and the characteristics of the impact on household living conditions of the economic crises in Italy, and tries to describe the most affected subgroups of population. Results are based on the 2007-2013 data of the two main socioeconomic surveys conducted by Istat: the Household Budget Survey (HBS) and the Income and Living conditions Survey (IT-SILC).

The general framework is deepened by modelling separately the share of expenditure on food and non-alcoholic beverages and the material deprivation on a set of pooled data (in order to disentangle the time effect) and by single year.

1 Introduction

Italian economy was first affected by economic crisis in 2008, year of the initial decline of the GDP (-1.1% at constant prices), and then in 2009, when GDP suffered a heavy fall (-5.5%), followed later by other significant drops in 2012 and 2013 (-2.8% and -1.7%, respectively).

This long period of economic crisis, characterizing the last decade, has had serious effects on household living conditions. Average and median household disposable income, at constant prices, has declined, while the general reduction of available economic resources has implied a similar decay of household savings and household consumption expenditure. The latter has been rearranged in its structure, with the share of expenditure on food and non-alcoholic beverages (*foodshare*) gaining a slight increase during the crisis period, perhaps as a symptom of stronger budget constraints.

The main objective of this paper is to shed light on the extent and the characteristics of the impact of the most important economic crises of this century on the living conditions of households residing in Italy, trying to find out the features of the most affected subgroups of population. Analyses embrace the period from 2007, formally considered the pre-crisis year, until 2013, the last year of the GDP decrease. Results are based on data from the two main socioeconomic surveys conducted by Istat: the Household Budget Survey (HBS) and the Income and Living conditions Survey (IT-SILC).

Views expressed in this article represent the opinion of the authors and do not necessarily reflect the official position of the affiliation institution.

After a general portrait of the main changes occurred in household incomes and household consumption expenditures, the paper first focuses on trends of foodshare and severe material deprivation and then on household subgroups most affected by economic crises, taking into account both the foodshare and the breadth of severe deprivation. It is worthwhile highlighting that the severe material deprivation concerns households suffering stronger economic hardships.

The identification of the main characteristics of the most vulnerable subgroups of population is carried out through linear regression models. First, by modelling the foodshare on HBS pooled data 2007-2013, a clearer picture of the factors influencing its variation (predictors) is obtained; more, controlling for household socioeconomic characteristics, the time effect during the crisis period can be isolated. Then, running separate models for each year of the above mentioned period, changes in the relationship between the foodshare and its main predictors may be investigated. In the same way, pooling the IT-SILC data 2007-2013, the household deprivation share is modelled on a set of variables (including time effects) in order to describe its main predictors and figure out, *ceteris paribus*, the impact of the time dimension. Afterwards, separate models are performed for each year, to point out possible changes in the relationship between the breadth of severe deprivation and its predictors.

2 Data and Methodology

As already mentioned above, this paper is based on data from the Household Budget Survey (HBS) and from the Income and Living conditions Survey (IT-SILC, included in the system of European Statistics on Income and Living Conditions - EU-SILC), both carried out by Istat.

The Italian HBS focuses on consumption expenditure behaviours of households residing in Italy. It analyses the evolution of level and composition of household consumption expenditure according to their main social, economic and territorial characteristics. The main focus of the HBS is therefore represented by all expenditures incurred by resident households to purchase goods and services exclusively devoted to household consumption (self-consumptions, imputed rentals and presents are included); every other expenditure for a different purpose is excluded from the data collection (e. g., payments of fees and business expenditures). The Italian HBS represents the informative base for the official estimates of relative and absolute poverty in Italy.

The EU-SILC, set up with the Regulation of the European Parliament no. 1177/2003 and first launched in 2004, is the reference source for comparative statistics on income distribution and social inclusion in the European Union. It provides both cross-sectional and longitudinal annual data on income, poverty, social exclusion and other living conditions.

As far the key indicators analysed in this paper, the foodshare is the ratio of household expenditure on food and non-alcoholic beverages to total household consumption expenditure; according to Engel's Law, "this share in the budget declines as income or total outlay increases". The assertion, made by Engel, is that "foodshare is a good indicator of welfare" (Engel, 1895). More recently, Deaton wrote that "since food is seen as the first necessity, the share of food in total expenditure can be regarded as an (inverse) indicator of welfare. It is also a very convenient indicator, since its definition as a dimensionless ratio renders it comparable over time periods and between geographical locations, at least if the relative price of food does not vary too much. However, the real interest in the food share is that it may be capable of acting as a better indicator of welfare than measures based on income or expenditure alone" (Deaton, 1981). This indicator has been largely used in studies on developing economies; however, considering the severity of the economic crises of the last decade and their tangible effects on the living conditions of households residing in Italy (at macro indicator level), in this paper it is assumed that in the period 2007-2013 the foodshare behaved as a welfare indicator although in the context of an advanced economy such as the Italian one. The foodshare indicator is expressed in percentage values.

The rate of population at risk of poverty or social exclusion (AROPE) is among the main indicators used to measure the status of economic hardship of people living in private households at EU level[2], based on EU-SILC data. It includes the share of population at risk of poverty (with an equivalised income below 60% of the median equivalised income for the population as a whole) or severely material deprived (suffering from at least four out of nine items of deprivation) or living in households with low work intensity. After first economic crisis, in Italy AROPE increased primarily for the worsening of severe deprivation, one of the two indicators considered in this work. The choice of such an indicator depends on its nature of non-relative indicator, that aims at measuring economic and financial difficulties in absolute terms, independently by changes affecting the whole distribution. That is why it is particularly appropriated for across

[2] In fact, for this indicator a precise target has also been chosen within the 2020 Europe strategy (established in 2010) to fight against poverty and social exclusion: that is to lift from this condition at least 20 million people, 2,2 million of which in Italy (see, European Commission 2010 and European Commission 2011).

time analyses. However, the severe deprivation indicator is a synthetic measure covering nine different symptoms of deprivation; once a person overcomes the cut-off threshold of four items, no further distinction is possible. Actually, a severely deprived person could suffer potentially from 4 to 9 symptoms of deprivation; therefore, in order to capture the breadth of severe material deprivation, the Alkire-Foster approach (Alkire and Foster, 2011) has been applied, based on the dual cut-off identification method. Given n individuals and d dimensions, for each dimension j a cut-off z_j is identified to establish if a person i is deprived in j-dimension, and then a cut-off k is used to determine who is multidimensional poor (in the specific case, severely deprived over nine dimensions, using k=4). Once identified the severely deprived, a censored deprivation matrix $\boldsymbol{g_0(k)}$ of n rows and d columns is constructed with the value of deprivation on each dimension only for the severely deprived, while for non-severely deprived individuals all the d values are set to zeros. The measure M_0 (adjusted headcount ratio) is the mean of the elements of the censored deprivation matrix. It can be interpreted as the total deprivations experienced by the severely deprived, divided by the maximum number of deprivations that could possibly be experienced by all people, that is nd:

$$M_o = \frac{\sum_{i=1}^{n}\sum_{j=1}^{d} g_0(k)_{ij}}{nd}$$

One of the properties of the above indicator is the decomposability across population groups and across dimensions, not feasible with the standard severe deprivation indicator. This feature allows to measure the contributions of the several symptoms of deprivation to the overall indicator across time.

In order to outline which subgroups of population suffered most from economic crises, linear regression models have been performed, first on pooled data 2007-2013 and then for each year in the same period; dependent variables are foodshare and the breadth of deprivation, considered as proxy measures of economic hardships. Models, that have run separately on HBS and IT-SILC data, have been based as much as possible on the same set of covariates[3]: place of residence (geographical area and type of municipality); household size and type; number of in-work members; age, level of education attained and activity status of the Reference Person (HBS) or Bread Winner (IT-SILC); house tenure status; quintiles of equivalent household total expenditure (HBS) or of income (IT-SILC). Models based on pooled data have shed light on time effects, while models by single year have enlightened the existence of changes in parameter estimates across time and their strength. Households are units of analysis, being all the variables considered common to all household members.

As far the model based on IT-SILC data, a couple of clarifications are needed. The breadth of deprivation is measured as the percentage share of deprivation, ranging from a minimum of zero, if a household is not deprived at all, to a maximum of 100, if a household is affected by all symptoms of deprivation. In analytical terms, the dependent variable, the household deprivation share (HDS), is the sum of the elements of the censored deprivation matrix divided by the maximum number of dimensions (multiplied by 100) for each row of the matrix[4]:

$$y_i = \frac{\sum_{j=1}^{d} g_0(k)_j}{d} * 100$$

As far the pooled data model, due to the longitudinal structure of the EUSILC survey, in order to deal with repeated measures on the same set of households and the presence of a non-negligible level of intra-class correlation (ICC=0.44) within the same households across time, a linear mixed model[5] with random effect on the intercept has been applied:

$$\left.\begin{aligned} \mathrm{Y}_{it} &= \beta_{0i} + \beta_1 X_{1it} + \cdots + \beta_H X_{Hit} + \lambda_1 \delta_{it} + \cdots + \lambda_{T-1}\delta_{iT-1} + \varepsilon_{it} \\ \beta_{0i} &= \gamma_{00} + u_{oi} \\ \beta_h &= \gamma_{0h} \quad \forall\, h \end{aligned}\right\} \Rightarrow$$

$$y_{it} = \gamma_{00} + \gamma_{01} X_{1it} + \cdots + \gamma_{0H} X_{Hit} + \lambda_1 \delta_{it} + \cdots + \lambda_{T-1}\delta_{iT-1} + u_{0i} + \varepsilon_{it}$$

$\text{with } \mathrm{i} = 1,2, \ldots \mathrm{n} \text{ households}, \; \mathrm{t} = 1,2, \ldots \mathrm{T} \text{ time} - \text{units}, \; \varepsilon_{it} = \text{error term for household } i \text{ and time } t,$
$u_{0i} = \text{ random effect for household } i.$

3 General Framework

In the observed period (2007-2013), two economic crises were registered: the first significant drop in GDP was recorded in 2009 (-5.5% compared to 2008), the second was shown in 2012-2013 (respectively, -2.8% and -1.7% compared to the previous year value).

Household income (at constant prices) in 2009 had, on average, an increase and a trend inversion compared to the previous two years; its first decrease started in fact in 2010, with one-year lag respect to the GDP. That reduction went on until 2013, showing an impoverishment of the average household economic conditions: the overall decrease, since

[3] The choice of the covariates has been based on information common to the two surveys.
[4] The mean value of this dependent variable across all population units provides the adjusted headcount ratio M_0.
[5] The MIXED Procedure included in the SAS package has been used.

2007, was -12.3% (Figure 1). This trend is not reasonably due to a decrease in household size, since for the same period the equivalised income showed the same trend, although with an overall reduction less intense (-10.8%).

During the whole period 2007-2013, household consumption expenditure (at constant prices) had a continuous decline, even sharper than the one observed for household income in the same time interval (for consumptions, the overall decrease since 2007 was -16.7%) and double than the decrease of GDP after 2011 (-8.6% versus -4.4%). Still compared to the GDP, between 2009 and 2011 household consumption expenditure did not confirm the same slight recovery: its lagging behind the economic growth was probably related to the fact that, in light of international uncertainty, households were cautious in their consumption expenditures.

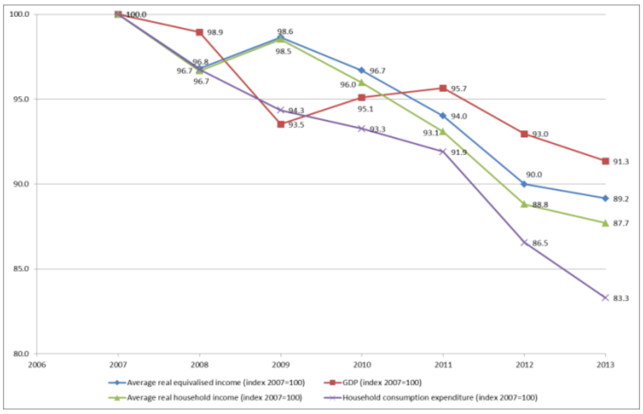

Figure 1 - GDP, household and equivalised income at costant prices, household consumption expenditure at costant prices

After first economic crisis in 2008, in Italy foodshare started increasing slightly since 2010 onwards, to reach the value of 22.4% in 2013 (Figure 2). This trend was quite differentiated within the national borders: in the North there was no dynamic at all; in the Centre, it started later but the foodshare increased from 20.4% in 2011 to 21.5% in 2013, registering the highest percentage increase from 2011 to 2013, considering the three geographical areas; in the South, where the situation is structurally worse than in the rest of the country, the foodshare started increasing since 2010 but more softly than in the Centre.

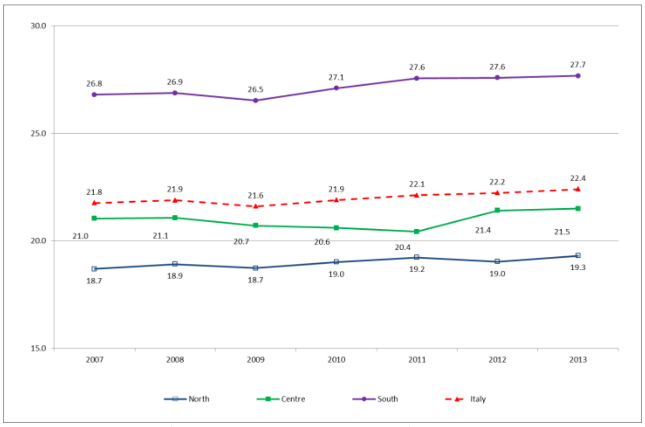

Figure 2 – Share of household expenditure on food and non-alcoholic beverages at national level and by geographical area *(percentage values)*

Focusing on the economic most disadvantaged groups, the share of population AROPE, equal to 26% in 2007, after a slight improve in the following three years, reached in 2011 the value of 28.1% and a peak of 29.9% in 2012 (Figure). Investigating the different components of the AROPE, it is clear that this big raise is due to the growth of severely deprived: the population share suffering from severe deprivation passed from 7.4% in 2010 to 11.1% in 2011, followed by a successive increase to 14.4% in 2012. Until 2010 there was not a significant increase in material deprivation, thanks to the strengthening of workers' income support measures, such as unemployment benefits and salary integration allowances, and thanks to household strategies, set up to tackle the progressive erosion of their purchasing power (drawing assets, saving less or borrowing). With the continuation of the crisis, however, in 2011 there was a strong deterioration of the situation, with an increase in the material deprivation rate, and in 2012 household economic difficulties further widened (Istat, 2014). After this year the severely deprived decreased, but never accounting less than 12%.

Even if in 2011-2012 the severe deprivation widened, it seemed to have become less hard in terms of symptoms of deprivation: in fact, the average number of deprivation items, equal to 4.57 in 2010, dropped to 4.42 in 2011 and 4.36 in

2012 (Figure), and the adjusted headcount ratio (following the Alkire-Foster methodology[6]), that takes into account not only the deprived but also the width of deprivation among the deprived, recorded a smoother increasing trend than the severe deprivation headcount ratio. The latter approach allows also measuring the contribution of the different dimensions to the overall index of severe deprivation, in order to know which one of them influences more the synthetic index, and whether its relevance has changed across time. Looking at the different dimensions (or items) of deprivation, the main contributions before and after 2011 were given by the unaffordability of an annual week holiday away from home (22%) and by the inability to face unexpected financial expenses corresponding to the monthly national at-risk-of-poverty threshold (22%). A little less than a fifth was the contribution of the inability to keep home adequately warm, while the relevance of the unaffordability of an appropriate protein meal every second day increased from 14% in 2010 to 17% in 2011 and 19% in 2012; on the contrary, being in arrears (with utility bills, rent, mortgage or other debts) weakened its significance from 16% in 2010 to 14% in 2011, and even 11% in 2012[7].

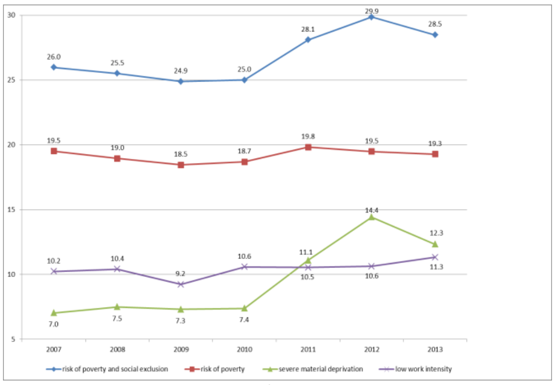

Figure 3 - Population at risk of poverty and social exclusion, at risk of poverty, severely deprived and in low work intensity households *(values per 100 individuals)*

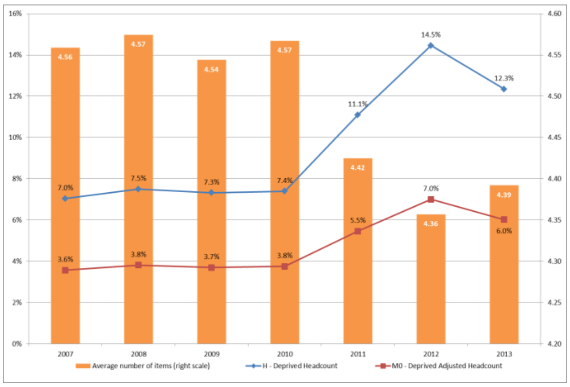

Figure 4 - Population severely deprived, adjusted headcount ratio of severely deprived *(values per 100 individuals)*, average number of items of deprivation

4 Results

As reported above, analyses presented in this paper rely on a twofold strategies to measure household economic hardships during the last economic crises. On one side, it has been hypothesized an expansion of the expenditure share on food and non-alcoholic beverages (FOSH) for stronger budget constraints, on the other a strengthening of material deprivation has been theorized, measured in terms of household deprivation share (HDS). FOSH and HDS dependent variables were regressed separately on a set of common dependent variables describing household place of residence and socioeconomic conditions[8].

[6] For a wider application of the Alkire-Foster methodology to the analysis of multidimensional poverty in the EU Countries. see Alkire and Apablaza, 2017.

[7] Taking into account the headcount ratios, from 2010 until 2012 the items of deprivation showing the biggest increases were: unaffordability of an annual week holiday away from home (40.5% in 2010, +5.94 p. p. in 2011 and +4.41 p.p. in 2012); unaffordability of an appropriate protein meal (7% in 2010, +5.72 p.p. in 2011 and +4.38 in 2012); inability to keep home adequately warm (11.6% in 2010, +6.22 p.p. in 2011 and +3.45 p.p. in 2012); inability to face unexpected financial expenses (33.8% in 2010, +4.43 p.p. in 2011 and +3.91 p.p. in 2012). The increase of the severe deprivation started in 2013 (also due to a more favourable inflation dynamics compared to 2012) concerned mostly the affordability of a protein meal every second day (-3.15 p.p.), the ability to keep home adequately warm (-2.45 p.p.) and the ability to face unexpected financial expenses (-1.91 p.p.) (Istat, 2014).

[8] Namely, covariates are: the natural logarithm of household size (LNHSIZE); the age of the Reference Person (AGERP); the education level attained by the Reference Person, distinguished in low (EDURPLOW), medium (EDURPMEDIUM) and high (EDURPHIGH); the activity status of the Reference Person, grouped in self-employed (ACTRPSELF), employee (ACTRPDEP), retired (ACTRPRET) and other than the mentioned conditions (ACTRPOTHER); the number of household members working (NHHWORKER); the household type, classified in single person less than 65 years (HHTYPE_SPLESS65), single person 65 years and over (HHTYPE_SPLEAST65), couple without children with Reference Person less than 65 years (HHTYPE_CNOCHILDLESS65), couple without children with Reference Person 65 years and over (HHTYPE_CNOCHILDLEAST65), couple with one child (HHTYPE_C1CHILD), couple with two children (HHTYPE_C2CHILDREN), couple with three or more children (HHTYPE_C3CHILDREN), single parent (HHTYPE_SPARENT), other household typologies than the mentioned ((HHTYPE_OTHER); the accommodation tenure status, if rented (HOUSE_RENTED) or owned (HOUSE_OWNED); the equivalent total expenditure/income quintile, from QUINTILE1 (the lowest) to QUINTILE5 (the highest). More, the place of household residence has been introduced in the models, taking into account: the geographical area (North, Centre, South) and the size of municipality (Metropolitan area - Centre (BIGMC), Metropolitan area suburbs and municipalities with 50,001 inhabitants and over (MEDIUMM), other municipalities until 50,000 inhabitants (SMALLM)).

Please note that: as IT-SILC reference person, the main income recipient or Bread Winner (BW) has been used; in order to allow for the remaining curvature in the relationship between the dependent variables and AGERP, the square of AGERP has been also introduced (AGERPSQUARED).

By modelling FOSH and HDS on pooled data 2007-2013, controlling for household socioeconomic characteristics, parameter estimates show a time effect during the crisis period on both dependent variables.

For FOSH variable (Table 1, pooled data), the increase of time effect starts in 2010 (when the estimate is 0.201 higher than in the reference year 2007) to reach the value of 0.728 in 2013.

For households belonging to lower equivalent total expenditure quintiles, residing in the South, with low educated Reference Person and living in a rented accommodation, FOSH variable raises the most. Across time, the relative wider foodshare of households residing in the South rises slightly, especially in 2010 and 2011 (respectively 4.039 and 4.607 compared to 3.474 of year 2007). Since 2010, just after the first economic crisis, the distance between the better-off households of the upper quintile (fifth) and the ones in the first quintile starts increasing monotonically, and in 2013 the parameter for the lowest quintile (first) reaches the value of 9.692.

It is noteworthy mentioning that, while in the pre-crisis time no significant difference has been observed for FOSH variable between households whose reference person is self-employed and households with reference person who is an employee, a retired or another inactive, in the post-crisis phase these latter households show a feebly higher FOSH, in particular for employees from 2010 onwards, while for the retired the rearrangement of the foodshare takes place later, since 2012.

Others factors have contributed, although to a minor extent, to the increase of foodshare among households residing in Italy. As far the level of education attained by the Reference Person, parameter estimates for low and medium educated Reference Person (always significantly different from the reference category of high educated Reference Person, and always positive) reached their peaks in 2009 (respectively, 5.181 and 3.196) and 2011 (5.299 and 2.649), although for medium educated Reference Person the value observed in 2013 is the same as 2011. Looking at the household type, elderly people, single or in a couple, compared to a reference couple with 2 children, just after the first economic crisis, in 2009, worsened their conditions (parameter estimates were, respectively, 3.056 and 2.366), while during the second phase of the crisis, in 2012, they actually showed a feebly higher FOSH, which nevertheless reached values lower than 2009 (2.871 and 2.201). To be mentioned also the behaviour of other household typologies than single person and couples with or without children: since 2009 onwards their conditions slightly deteriorated, although with a lower magnitude (the peak was in 2013, when the parameter estimate was 1.385).

For HDS variable (Table 1, pooled data), again a time effect is observed; in this case, until 2010 time parameters are not significantly different from the reference year 2007, while they show a meaningful increase since 2011 (when HDS is 1.943 percentage points higher than that in 2007) to reach the highest value (3.333) in year 2012.

[a] RP, Reference Person=Bread Winner (BW)

Among the factors associated with a higher HDS, the most important are: residing in the South, living in a household belonging to lower income quintiles, with a low-educated Bread Winner or where the Bread Winner is inactive (other than retired), living in a rented accommodation.

The disadvantage of residing in the South increased monotonically from 2009 onwards: in 2009, a household living in this geographical area had a HDS 2.503 percentage points higher than a household living in the Centre, and this estimate reaches the value of 6.036 in the year 2013. Also the magnitude of low and medium educated Bread Winner effects (always positive compared to high educated BW) increased during the crisis period, especially in 2011 and 2012 (when for low educated Bread Winner the estimate was 5.45, compared to the pre-crisis value of 2.887). Deprivation for low income households increased as well: in 2007, households in the first income quintile had a HDS 5.484 percentage points higher than the ones in the fifth quintile, while in 2013 this estimate was equal to 7.983. When the Bread Winner is self-employed (reference category) households suffer less from deprivation: after the economic crises manifested their effects, the relative disadvantage of inactive (other than retired) Bread Winner widened (6.327 in 2012 and 6.519 in 2013), while the conditions of households whose Bread Winner is an employee or a retired worsened less.

Others factors that have contributed to exacerbate HDS, but to a minor extent than the above mentioned, are firstly: being a single non-elderly person, a single parent or a couple with 3 or more children. However, in these cases the relative magnitude of the effect has changed across the analysed period. In the pre-crisis time, compared to a reference couple with 2 children, being a single person less than 65 years (6.157 in 2008) or a single parent (3.985 in 2008) worsened the HDS more than in the post-crisis time (respectively, 2.604 and 1.841 in 2011). The opposite happened for household with 3 or more children: from a non-significant difference from couple with 2 children in 2008, in 2011 the parameter estimate reached the value of 2.17; from that year onwards the situation for couples with 3 or more children has continued to deteriorate monotonically, up to the estimated effect of 2.474 in 2013. Until 2010, living in metropolis was associated to a slightly major extent of the HDS than in medium towns, while afterwards a minor or not significantly different association has been observed. As far the household size, in the pre-crisis time a positive effect was observed, which surprisingly changed sign in the last year of the considered period. Although further analyses are definitely required, one possible explanation is that in bigger households other than couples with 3 or more children (that have on the contrary a positive estimate in 2013), additional household members are elderly people who are likely to be retired. In this sense, they can contribute to improve household financial resources thanks to the guarantee represented by their pension income (that, for the lower amounts, was linked to the price indexes in the considered period), leading to a lower degree of material deprivation.

5 Concluding remarks

The economic crises of the last decade have had considerable effects on household living conditions in Italy, with a sharp decline, equal to -12.3%, of the average household income, and an even higher decline (-16.7%) for the average household consumption expenditure.

Stronger budget constraints have induced a moderate raise of foodshare and an enlargement of the share of population suffering from severe material deprivation. In particular, main evidences show that households residing in the South, belonging to lower income or expenditure quintiles, having a reference person with a low level of education, living in a rented dwelling and in large households (namely, other household typologies than single person and couples with or without children and couples with three or more children) are the ones hit hardest by the economic crises of the last decades; unfortunately, these population subgroups were already the most disadvantaged in the pre-crisis time.

Network Data Analysis and Mining

Support provided by elderly Italian people: a multilevel analysis

L'aiuto offerto dagli anziani italiani: un'analisi multilivello

Elvira Pelle, Giulia Rivellini and Susanna Zaccarin

Abstract The characteristics of social networks determine the availability of social support, that is the aid individuals gain from their network members. Despite the literature usually investigate the importance of having support, the role of the support provided to alters had not yet received the same attention. In particular, the support elderly provide to their networks members shows an active participation in the social life, that is one dimension of the active ageing. Using data from 2009 edition of "Famiglia e Soggetti Sociali (FSS)" survey carried out by the Italian National Statistical Institute, we propose a Bayesian multilevel model to highlight the determinants of observing a provided support tie by elders to family or non-family members.

Abstract *Le caratteristiche della rete sociale in cui un individuo è inserito determinano la disponibilità di supporto ricevuto dai membri della rete. Sebbene la letteratura si concentri sull'importanza di ricevere aiuto, minore attenzione è dedicata all'analisi dell'aiuto fornito. Per gli anziani, per esempio, l'aiuto dato ai membri della loro rete è segno di un'attiva partecipazione alla vita sociale, che rappresenta una dimensione dell'invecchiamento attivo. Usando i dati 2009 dell'indagine Istat su "Famiglia e Soggetti Sociali" (FSS), si propone un'analisi multilivello per evidenziare le caratteristiche della popolazione anziana (persone di età 65 e oltre) e dei loro alter che influenzano la probabilità di dare aiuto a familiari e non familiari.*

1 Introduction

The characteristics of social networks and their composition determine the availability of social support, which, in turn, is defined as the aid that individuals gain from their network members [15, 5]. Whatever the type of support (emotional, informational and instrumental), a growing number of studies have documented the positive influence of social support and social network on various health outcomes and wellbeing (among others, see [17]). Social interactions have the potential to protect individuals at risk (e.g., encouraging them to develop adjustment to face the difficulties) and promote positive personal and social development; as consequence the exposure to various types of stress diminishes [14, 8] while there is an increasing of the ability of coping with it. Despite the literature usually investigate the importance of having support, especially that received from the personal network, the role of the support provided by ego to alters had not received the same attention. Focusing on elderly people, the support they provide to their networks members can be view as a sign of an active participation in the social life; the latter is one dimension of the active ageing, a multidisciplinary concept that identify both experience and capability of being autonomous in the economic, political and social life [4].

In a familistic country such Italy informal intergenerational transfers are the most important pillar of the national welfare system, replacing formal sources of support [9]. Moreover, recent analyses on the individual potential support ego (PSE) networks in Italy [2] provides evidence to the existence of sources of potential support that extend beyond the family circle.

The aim of this contribution is to study the types of support provided by the elderly to other people, stressing how features of both ego (the elderly) and alters in their network (siblings, children, grandchildren, other relatives, neighbors, friends) affect the form of aid given. Using data from Family and Social Subjects (FSS) survey carried out in 2009 by the Italian National Statistical Institute, in this study we propose a Bayesian multilevel model to highlight the determinants of observing a provided support tie by elders to family or non-family members, controlling also for the kind of PSE-network in which the elders are embedded.

The remain of the article is organised as follow: in Section 2 we present the characteristics of elderly Italian people along with the characteristics of their potential support network. In Section 3 we describe the multilevel approach used to investigate the provided support given by elderly. Section 4 ends the paper with a discussion and some concluding remarks.

2 Individual (ego) characteristics, network typologies and support exchanged

In this work we exploit data drawn from “Family and Social Subjects” (FSS) survey carried out by the Italian National Statistical Institute in 2009. Since 1998, FSS is part of the Multipurpose Survey Program on Italian households and represents the primary statistical source providing information on contacts and provided and received support by Italian individuals. 2009 FSS edition involved 43850 individuals living in about 24000 family units. We focus on Italian individuals aged 65 years and more (n=9202, 21% of the total). Looking at the gender, 57% are females, while 43% are males. Most of elders are in couple (married or unmarried) without cohabiting children (45.9%), while 15.3% are in couple with cohabiting children; 27.8% live as single (without other members), 6.3% are single-parents and 4.8% have other family typologies. More than half of the elders (51.3%) are aged 65-74ys, while the oldest-old (85+) are the 11.6% of the total. With respect to the place of residence, 42.8% of elders live in the North of Italy, 38% in the South or Islands, and the remaining 19.2% in the Center. Looking at the health, 76.7% declare to have good/satisfactory health conditions.

Following the methodological approach proposed in [1], we use data from the FSS on the presence and the contacts with siblings, children, grandchildren, other relatives, neighbors and friends, to define the potential support ego-centered (PSE)-network in which Italian elders were embedded. In particular, PSE-network is defined as "the set of not-cohabiting people (along with their role relations) who can be a possible source of support to the respondent" [1, p. 6]. The average number of alters is quite small (2.65). Some differences in the network size emerge by age classes: 48% among the oldest-old (80+) have a number of alters between 1 and 2, while 47% of the group of 65-69ys old have 2-3 alters.

We grouped the 6 identified potential alters in the ego-centered network in 3 main networks' typologies: "Immediate family" (siblings and children), "Extended family" (grandchildren and relatives) and "No family" (neighbours and friends). The most widespread network typology among the elderly is the *Comprehensive* one composed by siblings, children, grandchildren and other relatives plus friends and neighbors (30.7% of individuals aged 65+), followed by more oriented *family* network typologies with alters only from Immediate and Extended family (28%) or only children and siblings (9.9%).

FSS supplies also data on several types of provided and received support by respondents, with detailed information on the nature and the characteristics of the recipient. Looking at the support received by elderly, only 16.6% declared to have received support from a non-cohabiting people; on the other hand, about 26% of the elders declared to provide support to non-cohabiting people (55% of which are females and 45% are males) inside or outside their family circle. The provided support to the non-familiar circle represents about the 30%, with some relevant differences with respect to the place of residence (51.3% for elders living in the North of Italy, 30.6% for those in the South or Islands, while only 18.1% for those living in the Center). We highlight some differences according to the most important type of support provided to a family or non-family member: for the first category the most provided types of support are the care of children (51.6%) and monetary help (12.7%), while for the latter are keep company (23.3%) and economic help (17.4%).

3 Multilevel analysis

We propose a multilevel approach in order to analyse the network characteristics of the group of the 2386 elders who declare to provide support [10, 3]. In particular, we adopt a Bayesian multilevel analysis [6] to provide a new insight into the determinants of observing a provided support tie (our dependent variable) by elders to family or non-family members. We use a Bayesian approach mainly for two reasons: first, given the particular structure of our data, it allows a great flexibility in the estimation of multilevel models; second, it offers some advantages in terms of computational ease, as models can be easily estimated using the package “rstanarm” of the language Stan available in R.

We specify a 3-level logistic regression model for the presence of a support tie to a family member as opposed to a non-family member, where level 3 is represented by the Italian regions to account for geographical variation in providing support to family or non-family alters (denoted by k subscript), level 2 is represented by ego (denoted by j subscript) and level 1 (denoted by i subscript) by the alter. The model can be summarised as follow:

$$logit(\pi_{ijk}) = \beta_{jk} + \mathbf{x}'_{ijk}\beta \tag{1}$$

where π_{ijk} is the probability that the observed support tie between alter i and ego j within region k is to family members; β_{jk} is the intercept varying by level-two unit j and level-three unit k and $\mathbf{x}'_{ijk}\beta$ are models fixed effects, which may be characteristics of the ego, alters and the dyad ego-alter. In particular, gender, age, family typology, education, health conditions and PSE-network typology (comprehensive, family and other) are considered as egos attributes.

It is well known that homophily is an important explanatory factor for the configuration of personal networks [12, 11, 13]. To gain insight into the determinants of giving support, we also test two hypotheses: first the homophily by gender (the elders are easier willing to provide support to individuals of the same gender). Second, the type of personal network in which the elder is embedded can determine the homophily by generation: an intergenerational PSE-network facilitates the so-called intergenerational transfers; on the other hand, an intragenerational PSE-network eases intragenerational transfers. Thus, to take into account homophily, from information on alters we construct the two variables “same generation” and “same gender” (comparing the birth generation and gender of both ego and alter, where available).

To compare models, we use the leave-one-out information criterion (looic), that uses the log-likelihood evaluated at the posterior simulations of the parameter values [7, 18]. Note that the lower the value of looic, the higher the fit of the model.

First of all, we compare the single alter-level null model and the 3-level null model. The improvement in terms of looic (from looic=3831.3 to looic=3679.3) indicates that the multilevel approach we propose is suitable to investigate our data structure.

We consider 3 models: model 1 with only characteristics of ego; model 2 with characteristics of ego and homophily terms for generation and gender and model 3 including in model 2 the type of support provided. As usual in Bayesian analysis, we monitored the Markov Chain convergence through the Gelman-Rubin statistic $\hat{R}$ [6]: chains convergence has been reached for all the estimated models, since the value of such statistic is below the recommended value of 1.1. Table 1 summarises the results.

Table 1 Results of Bayesian multilevel models: posterior quantiles at 50%; 2.5% and 97.5% in brackets

Homophily of ego-alter						
Same generation			6.4	(4.6;9.0)	6.8	(5.1;9.2)
Same gender			7.0	(5.4;9.6)	7.1	(5.4;9.5)
Type of support (cat ref: kid care)						
Companionship					-3.7	(-4.4;-3.1)
Material/Other					-3.1	(-3.7;-2.6)
Economic					-2.5	(-3.1;-2.0)

Model 1 provides a good improvement in the fit with respect to the null model (looic= 3473.3). Elders who live in couple without cohabiting children are more likely to provide support to a family member if compared with other living arrangements, while this probability decreases as the age of ego increases. With respect to egos which can count on a *comprehensive* PSE-network, egos embedded in a *family* network typology tend to have a greater probability of a support tie to a family member, while this is less likely for ego embedded in other kinds of network. The perceived health conditions as well as the gender of the ego do not have an impact on the probability of a support tie to a family member.

According to the looic measure, adding homophily (model 2) terms to model 1 results in a remarkable improvement in the model fit (looic=2858.7, compared with the previous value of 3473.3). Parameter estimates for both generation and gender homophily have an impact on the probability of a family support tie; in particular, it is more likely to observe a support tie to a family member when ego and alter belong to the same generation as well as when they are of the same gender.

Considering also the type of support provided by ego (model 3), the model fit is still improved, with a looic=2344.8. According to the model estimates, with respect to provide support for kid care, it is less likely that other types of support (such as companionship, economic and other material support) are provided to a family member.

4 Conclusions

We proposed a Bayesian multilevel analysis of support ties provided by elders to family or non-family members. Some differences in the probabilities of ties to family alters compared with non-family alters can be noted: older elderly are less likely to provide support tie to their family circle as well as among the types of support the kid care is the more likely to be provided to a family member. Homophily between ego and alters appears to be an important explanatory factor in providing support, in particular with respect to gender and generation as revealed by our results. This can be interpreted as an evidence of a positive disposal elders have (or, more in general, people have) to provide aid to their family members also on the basis of same life experiences and attitudes.

Data mining and analysis of comorbidity networks from practitioner prescriptions

Il trattamento e l'analisi delle reti di comorbilitá delle prescrizioni dei medici generici

Giancarlo Ragozini, Giuseppe Giordano, Sergio Pagano, Mario De Santis, Pierpaolo Cavallo

Abstract For the present paper, the administrative databases of general practitioners were mined for healthcare systems analysis. A sample of 14,958 patients along with their 1,728,736 prescriptions were considered over a time span of eleven years. From this database, we derived a set of comorbidity networks by considering pathologies as nodes and the co-occurrences of two pathologies to the same prescription as links. The aim is to mine the complexity of this information by using network analysis techniques. Specifically, Islands algorithm method is well-suited to extract the most relevant and connected parts of large and dense networks, as in the present case. Main comorbidity patterns are discussed, along with future lines of research.

Abstract *In questo lavoro si mostra come un database amministrativo di un insieme di medici di base può essere considerato per un'analisi del sistema sanitario. Il database contiene un campione di 14,958 pazienti con le loro 1,728,736 prescrizioni mediche registrate in un arco temporale di 11 anni. Utilizzando i codici delle patologie contenute nelle prescrizioni, è possibile costruire la rete di comorbidità. Tale rete, densa di legami e con un numero elevato di nod, richiede metodologie di analisi appropriate. L'uso dell'algoritmo delle Islands è proposto per estrarre le principali strutture di associazione fra coppie di patologie.*

1 Introduction

Nowadays, the presence of patients affected by many different diseases at the same time is becoming a major health and societal issue. In the United States, for instance, 80% of the health budget is spent on patients with four or more diseases (8). In clinical literature, this phenomenon is known as comorbidity.

The idea of comorbidity has been around since 1921 (9) used in a positive or negative sense, with the terms ”syntropy” and ”dystropy” (10). The former is the mutual disposition, or the appearance of two or more diseases in the same individual, while the latter indicates those pathologies that are rarely found in the same patient at the same time. In addition, the literature differentiates two core concepts, comorbidity and multimorbidity: the latter is defined as the coexistence of two or more long-term conditions in an individual not biologically or functionally linked (8), while the former concept refers to a coexistence of conditions that are linked, either biologically or functionally (12).

Simply considering this taxonomy, the intrinsically complex nature of comorbidity can be easily understood. On this basis, the burden of morbidity and comorbidity is considered to be influenced by a number of factors –namely, health-related, socioeconomic, cultural, environmental, and behavioral characteristics– but there is a lack of agreement (4) on how to understand the complex interdependent relationships between diseases due to: 1) a large number of variables (many of which are latent), 2) a lack of accuracy in measurements, and 3) technological limitations in generating data.

In this paper, we propose an indirect approach for a large-scale study of comorbidity patterns based on the administrative databases of prescription data from general practitioners (GPs), without the necessity of a complex clinical study. This methodology could be easily replicated. Access to prescription data from GPs is relatively simple, as these data are used for administrative purposes by the national health system. Given this kind of data, a morbidity state is associated with a patient and such a state is considered both over time for the same subject and within different categorized subjects. A recent literature review (13) has shown that comorbidities can be studied from GP databases based on both diagnoses, using the International Classification of Diseases –ICD– codes, and medications, using pharmacy data.

The paper is organized as follows. Section 2 presents the data and how they are used to define the comorbidity networks, along with an overview of the methodology we used. In Section 3 we report the first results, while the final section is devoted to a brief discussion with the future lines of research.

2 Data and methodology

2.1 Data

The Electronic Health Recordings (EHR) of the prescriptions made by a group of ten GPs belonging to the Cooperative Medi Service and operating in a town in Southern Italy were analyzed. A total number of 14,958 patients, covering a time interval of eleven years from 2002 to 2013, was considered. The total number of analyzed prescriptions was 1,728,736. The data were provided in anonymous form, for both patients and GPs, in accordance with Italian law on privacy and the guidelines of the Declaration of Helsinki. This retrospective observational study involved data mining and analysis of comorbidity networks from practitioner prescriptions, with data analyzed in aggregate form, and the relevant Ethics Committee granted approval (Comitato Etico Campania Sud, document number 59, released on 2016-06-08).

After a patients visit to a GP, there is generally a prescription containing a series of items of various types: drugs, laboratory tests, imaging tests, etc. For each patient visit, the GP administrative prescription data provided the following information:

- patient ID: a unique random number assigned to the patient;
- demographic data: age and sex;
- prescription date;
- prescription type: drug, laboratory test, imaging, specialist referral, hospitalization;
- prescription code: a specific code for each prescription type;
- associated ICD diagnostic code: the pathology connected to the specific prescription.

In accordance with the Italian National Health System rules, each item present in a GP prescription has an associated possible disease, encoded using the International Classification of Diseases, Ninth Revision, Clinical Modification –ICD-9-CM.[1] The ICD is the standard diagnostic tool for epidemiology, health management, and clinical purposes and is maintained by the World Health Organization. This includes the analysis of the general health situation of population groups. It is used to monitor the incidence and prevalence of diseases and other health problems, proving a picture of the general health situation of countries and populations. Each code has the general form xxx.yy, where xxx is the general disease and yy is a specific occurrence. For example, 250 is the code for ”Diabetes”, and 250.91 is the code for ”Diabetes Type 1 (juvenile) with unspecified complications, not stated as uncontrolled”.

[1] For details see http://www.salute.gov.it/portale/home.html.

2.2 Network data definition

To analyze the comorbidity patterns, we defined a set of networks. In the first step, a two-mode network was derived by considering the ICD9CM diagnostic codes and the prescriptions as the two disjoint sets of nodes. They are linked if corresponding codes appear in prescriptions made to the same patient on the same day. The sex and age of patients, and type and time of prescriptions can be considered as attributes of a given prescription.

Formally, the two-mode network can be represented as a bipartite graph $\mathscr{B}$ consisting of the two sets of relationally connected nodes and can be represented by a triple $\mathscr{B}(\mathscr{V}_1, \mathscr{V}_2, \mathscr{L})$, with $\mathscr{V}_1$ denoting the set of ICD-9-CM codes, $\mathscr{V}_2$ the set of prescriptions, and $\mathscr{L} \subseteq \mathscr{V}_1 \times \mathscr{V}_2$ the set of ties.

Being interested in the association of pathologies, we derived the one-mode network of the ICD-9-CM codes by projecting the two-mode network. The corresponding graph will be represented by $\mathscr{G}(\mathscr{V}_1, \mathscr{E}, \mathscr{W})$, with $\mathscr{V}_1$ the set of ICD-9-CM codes, $\mathscr{E} \subseteq \mathscr{V}_1 \times \mathscr{V}_1$ the set of edges, and $\mathscr{W}$ the set of weights, $w : \mathscr{E} \to \mathscr{N}$, $w(v_{1i}, v_{1j}) =$ the number of times that two ICD-9-CM codes appear in the same prescription.

In addition, different networks were generated by selecting a subset of the original dataset according to the patients sex, age intervals (0-15, 15-30, 30-45, 45-60, 60-75, 75-105), and type of prescription.

2.3 The methodology

The one-mode comorbidity network $\mathscr{G}$ is a large and dense network, and it is sometimes difficult to extract the main relevant comorbidity patterns. In order to identify the most relevant and connected parts of the network, we used the Islands approach (3), which is an algorithm useful for finding important parts in large networks with respect to a given property of nodes or lines (edges). By representing a given or computed value of nodes/lines as a height of nodes/lines and by immersing the network into water up to selected level, the islands are derived (2). Given a threshold value t, it is possible to obtain a cut of the network $\mathscr{G}(t)$. By varying this level t, different islands are identified. For our purposes, we decided to use the line island approach, which looks for a connected subnetwork with several nodes in a specified interval, such that the edges inside the island have a higher weight than the edges connecting nodes in the island with their neighbors. Formally, a set of nodes $\mathscr{I} \subseteq \mathscr{V}_1$ is a regular line island in the network $\mathscr{G}$ if:

$$\max_{(v_{1i}, v_{1j}) \in \mathscr{E}, v_{1i} \notin \mathscr{I}, v_{1j} \in \mathscr{I}} w(v_{1i}, v_{1j}) \leq \min_{(v_{1i}, v_{1j}) \in \mathscr{T}} w(v_{1i}, v_{1j}),$$

where $\mathscr{T}$ is the spanning tree over $\mathscr{I}$.

In the following, we first have deleted all nodes with a degree lower than two (representing rare diseases) and then we have computed the islands with a minimum size of 2 and maximum size of 20.

3 First results

By using the island algorithm implemented in Pajek software (6) on the full one-mode network including all epidemiological codes and all patients, 28 islands are obtained (Figure 1): one large group consisting of 20 ICD-9-CM codes and 27 islands of size 2-4 nodes. All the islands are included in one large component. As for comorbidity, the largest island includes cardiovascular disease, hypertension, osteoarthritis and osteoporosis, diabetes, prostatic hypertrophy, atherosclerosis, carotid artery stenosis, kidney disease, cystitis, and thyroiditis. In the smaller islands, we found the check up and treatment for pregnancy and infertility, as well as links among different kinds of cancer. It seems that there is a strong comorbidity structure that includes a set of diseases already linked in the clinical studies (e.g. cardiovascular disease and hypertension, diabetes, and so on). Others are probably related to the patient's age (diseases of the elderly such as arthritis, osteoporosis, prostatic hypertrophy) or to the patient's gender (e.g., pregnancy and infertility).

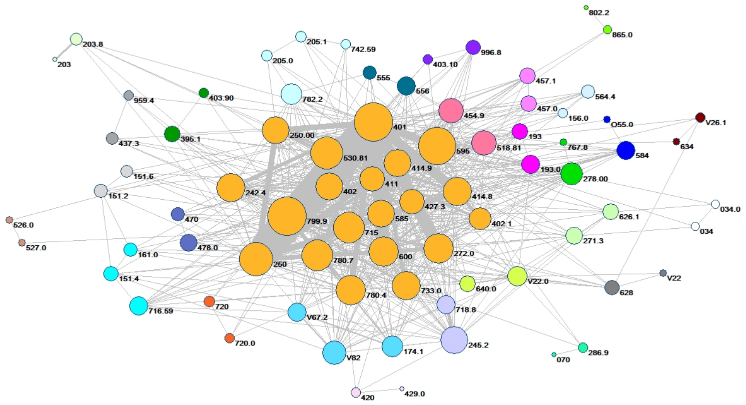

Fig. 1 Islands of size 2-20 in the comorbidity network. Node color= islands' partition; node size= nodes' degree.

Based on the data available, it is also possible to explore the effect of sex and age on the comorbidity network structure. To do that, the two-mode network can be divided into subnetworks according to these attributes associated with the prescriptions, and then specific one-mode networks can be derived and analyzed. By comparing the results of the islands algorithm for males and females divided by different age groups, different comorbidity patterns appear. For example, in the core of the main island of young females (Figure 2a), we found thyroiditis, gynecological problems, pregnancy, menstrual cramps, and cystitis; while on the periphery of the island, obesity, lipidosis, breast and thyroid cancer, arthritis and osteoarthritis were found. For older men (Figure 2d), in the core of the largest island we found arterial hypertension, prostatic hypertrophy, diabetes, heart disease, renal colic, and bronchitis; while, on the periphery, we found periodic check up after cancer, psychosis and depression, glaucoma, prostate cancer, and diverticula.

4 Further developments

As the first results have shown, the prescription database is a very rich source of information about people, diagnosis prevalence, and temporal emergence of diagnosis as a proxy of incidence index. The possibility of handling this kind of data in terms of networks seems very promising (5). The graph representation allows many algorithmic tools from the network domain. Graphs can be built on patients, prescriptions, or diagnosis, according to different aims and kinds of investigation. For instance, a graph whose nodes are patients and has links established as common diagnosis or prescriptions could be used to predict diagnosis as new links between nodes. Alternatively, building the graph on prescriptions tied by common diagnoses allows us to highlight specific occurrences of comorbidity. In both cases, network techniques can be exploited to extract relevant information. Looking for cohesive sets of patients and diagnoses calls for community detection methods. Such communities are dense parts of a graph that could reveal important features like frequent patterns of comorbidity.

Beyond the Islands algorithm method here proposed for the treatment of large and dense comorbidity networks, another promising technique we are investigating for this case study is the extraction of the association rules for bipartite network data (1). This technique is strictly related to the aim of finding frequent item sets in a large dataset and commonly applied in transactional data for marketing strategy. Applying association rules in medical diagnosis can be used to assist physicians in making a diagnosis. Even if reliable diagnostic rules are difficult and may result in hypotheses with unsatisfactory predictions, which are too unreliable for critical medical applications (7). Serban et al. (11) has proposed a technique based on relational association rules and supervised learning methods. It helps to identify the probability of illness in a certain disease.

In the case of medical prescriptions, the collection of prescriptions per diagnosis can be arranged, as defined above, in the bipartite graph $\mathscr{B}$ and arranged in a transaction matrix where each prescription is a transaction defined on the set $\mathscr{V}_2$, so that $\mathscr{V}_1$ is the universal set of items and each prescription in $\mathscr{V}_2$ is a subset of $\mathscr{V}_1$. In this context, the aim stated in the association rules setting is to find set of diagnosis that are strongly correlated in the prescription database and is coherent with the notion of close neighbors in bipartite graphs. In this context, the aim stated in the association rules setting is to find a set of diagnoses that is strongly correlated in the prescription database and is coherent with the notion of close neighbors in bipartite graphs.

The usual metrics derived from the association rules context –*Support*, *Confidence*, and *Lift*– will be used to characterize the graph representation of the diagnosis item set, defined as the projection of the bipartite graph induced by the prescription database. For the sake of computational efficiency, the analysis could concentrate on the subset of diagnosis having a minimum Support *S*. On the other hand, if the graph is partitioned in *k* disjoint communities (islands or blocks), it makes sense to apply the association rules search on the separate subgraph induced by the partition. The more meaningful rules are usually sorted by decreasing the value of *Lift*. The first important rules among diagnosis will help to uncover association between frequent patterns of diagnosis co-occurrence in the whole set of prescriptions.

Overlapping mixture models for network data (`manet`) with covariates adjustment

Modelli di mistura a gruppi sovrapposti per dati network (`manet`) con covariate

Saverio Ranciati and Giuliano Galimberti and Ernst C. Wit and Veronica Vinciotti

Abstract Network data often come in the form of *actor-event* information, where two types of nodes comprise the very fabric of the network. Examples of such networks are: people voting in an election, users liking/disliking media content, or, more generally, individuals - *actors* - attending events. Interest lies in discovering communities among these actors, based on their patterns of attendance to the considered events. To achieve this goal, we propose an extension of the model introduced in [5]: our contribution injects covariates into the model, leveraging on parsimony for the parameters and giving insights about the influence of such characteristics on the attendances. We assess the performance of our approach in a simulated environment.

Abstract *I dati network vengono spesso strutturati sotto forma di informazioni* attore-evento*, ovvero network dove esistono due tipologie di nodi. Alcuni esempi sono: persone che votano durante le elezioni, utenti che esprimono preferenza o meno su contenuti multimediali, o, più in generale, individui -* attori *- che partecipano a eventi. L'interesse risiede nel rilevare la presenza di gruppi fra questi attori, cluster che si differenzino per la propensione nel partecipare agli eventi in esame. A tale scopo, proponiamo un'estensione del modello introdotto in [5]: il nostro contributo contempla la presenza di covariate nel modello, sfruttando quindi un*

Key words: Bayesian inference, bimodal network, MCMC, probit regression

1 Introduction

Network data are becoming increasingly available and a propelling force in the pursuit of new methodological approaches devoted to analyze the complexity behind interactions among units in a system. A review about the methods and models adopted in this research area can be found in [3]. Some of these data come in the form of individuals attending events, or, more generally, a network structure where two different types of nodes exist: these are also called two-mode networks, bimodal networks, or affiliation networks [6, Chapter 8]. We focus on those data describing people's behavior with respect to attending or not a set of events, and we aim to discover if communities exist within the network itself, communities that differ in patterns of preferences to attend each event. A recent approach to do model-based clustering in this context was proposed by [5]: motivated by a dataset about terrorists participating to meetings and bombings, the authors introduced a mixture model for network data called `manet`, where each unit is allowed to potentially belong to more than one community. We build on their contribution and propose an extension of their model, in order to accomodate for external information about the network, in the form of covariates describing characteristics of the units or the events.

The main contributions of the paper are:

- extending `manet` [5] by introducing covariates into the model formulation;
- eliciting how some existing regression techniques can be used in the covariates-adjusted `manet` approach;
- providing results on a simulation study about the performances of our proposed model.

The remainder of the manuscript is organized as follows: in Section 2, first we outline `manet` original formulation, to familiarize the reader with the model's structure, and then we introduce the proposed extension; in Section 3, performance of `manet` with covariates adjustment is explored in a simulated environment; finally, in Section 4, we discuss the contribution and hint at future research trajectories.

2 Covariates adjustment for `manet`

Network data are organized in an $n \times d$ matrix Y of observations y_{ij}, collecting the attendances of $i = 1,\dots,n$ units - also called *actors* - to $j = 1,\dots,d$ events. Each realization y_{ij} comes from a binary random variable, with $y_{ij} = 1$ meaning individual i attends event j, and zero otherwise. We want to cluster these n actors based on their attendances via a model-based framework, and mixture models prove to be a suitable approach to achieve the task [1]. In the traditional setting, clusters are mutually exclusive and have (prior) sizes given by $\boldsymbol{\alpha} = (\alpha_1,\dots,\alpha_K)$. Usually, two conditions hold: (i) $\alpha_k \geq 0$, for each k; (ii) $\sum_{k=1}^{K} \alpha_k = 1$. Mixture models also have a hierarchical representation, attainable after introducing a unit-specific latent variable $\mathbf{z}_i = (z_{i1}, \dots, z_{iK})$: if actor i belongs to cluster k, the vector is full of zeros except for the k-th element $z_{ik} = 1$. Given the binary nature of response variables y_{ij}, for each actor $i = 1, \dots, n$ we have

$$\begin{aligned} \boldsymbol{\alpha} &\sim \text{Dirichlet}(\boldsymbol{\alpha}; a_1, \dots, a_K) \\ \mathbf{z}_i &\sim \text{Multinomial}(\mathbf{z}_i; \alpha_1, \dots, \alpha_K) \\ \mathbf{y}_i | (\mathbf{z}_i, \boldsymbol{\pi}) &\sim \prod_{k=1}^{K} \left(\prod_{j=1}^{d} \pi_{kij}^{y_{ij}} (1 - \pi_{kij})^{1-y_{ij}} \right)^{z_{ik}} \end{aligned} \tag{1}$$

for some hyper-parameters $(a_1, \dots, a_K)$; $\mathbf{y}_i = (y_{i1}, y_{i2}, \dots, y_{ij}, \dots, y_{id})$ is the attendance profile of the i-th actor to the d events, which we assume - given $\mathbf{z}_i$ - to be independent for all $j, j' = 1, \dots, d$ and $j \neq j'$. Vector $\boldsymbol{\pi}$ collects probabilities of attendance π_{kij} of a saturated model specification.

In many cases, one is interested in groups that are not mutually exclusive, allowing an *actor* to be allocated simultaneously to potentially more than a single cluster. We build on the approach suggested by [5], where a Bayesian **m**ultiple **a**llocation model for **net**work data (manet) is proposed. In manet, the hierarchical model in Equation 1 is modified by relaxing conditions on the cluster sizes $\boldsymbol{\alpha}$ and allocation vectors $\{\mathbf{z}_i\}$, allowing each actor to potentially belong to any number of the K clusters. The number of all possible group-allocating configurations is equal to $K^\star = 2^K$. Instead of working with the latent variables $\mathbf{z}_i$, a new $K^\star$-dimensional allocation vector $\mathbf{z}_i^\star$ is defined for each i. This vector satisfies $\sum_{h=1}^{K^\star} z_{ih}^\star = 1$, and a 1-to-1 correspondence exists between $\mathbf{z}_i$, which allocate actors into overlapping *parent* clusters, and $\mathbf{z}_i^\star$, which allocates actors into non-overlapping *heir* clusters. To this re-parametrization corresponds, in manet, the following hierarchical model

$$\begin{aligned} \boldsymbol{\alpha}^\star &\sim \text{Dir}(\boldsymbol{\alpha}^\star; a_1, \dots, a_{K^\star}), \\ \mathbf{z}_i^\star | \boldsymbol{\alpha}^\star &\sim \text{Multinom}(\mathbf{z}_i^\star; \alpha_1^\star, \dots, \alpha_{K^\star}^\star), \\ \mathbf{y}_i | \mathbf{z}_i^\star, \boldsymbol{\pi} &\sim \prod_{h=1}^{K^\star} \prod_{j=1}^{d} \Big[\text{Ber}\big(y_{ij}; \pi_{hij}^\star\big) \Big]^{z_{ih}^\star}. \end{aligned} \tag{2}$$

with prior $\pi_{kij} \sim \text{Beta}(\pi_{kij}; b_1, b_2)$, and (b_1, b_2) suitable hyper-parameters. For example, when $K = 2$, actor i may be assigned:

- to none of the two clusters, $\mathbf{z}_i = (0,0)$, corresponding to $\mathbf{z}_i^\star = (1,0,0,0)$;
- only to the first *parent* cluster, $\mathbf{z}_i = (1,0)$, corresponding to $\mathbf{z}_i^\star = (0,1,0,0)$;
- only to the second *parent* cluster, $\mathbf{z}_i = (0,1)$, corresponding to $\mathbf{z}_i^\star = (0,0,1,0)$;
- both of them $\mathbf{z}_i = (1,1)$, corresponding to $\mathbf{z}_i^\star = (0,0,0,1)$.

The advantage of working with re-parametrization in Equation 2 is that $\{\pi_{hij}\}$ are not additional parameters to be sampled, but probabilities of attendances produced by $\boldsymbol{\pi}$. For each actor i and event j, $\pi_{hij}^\star$ are computed via a function $\psi\big(\boldsymbol{\pi}_{\cdot ij}, \mathbf{z}_i\big)$, so that we obtain $\pi_{hij}^\star$ by looking at which parent clusters originated h, through the vector $\mathbf{z}_i$, and combining their corresponding probabilities $(\pi_{1ij}, \dots, \pi_{Kij})$. We consider $\psi(\cdot) \equiv \min(\cdot)$. For the simple case where $K = 2$, an actor i belonging to both clusters, $\mathbf{z}_i = (1,1)$, deciding whether to attend an event j or not, will do so with probability $\pi^{\star}_{hij} = \psi(\pi_{1ij}, \pi_{2ij}) = \min(\pi_{1ij}, \pi_{2ij})$. When $\mathbf{z}_i = (0,0)$, $\pi^{\star}_{hij} = 0$. The saturated manet demands inference on $(K \times n \times d)$ probabilities of attendance, where each π_{kij} has only one observation to update the prior information with. In [5] authors prescribe a more feasible formulation for manet by setting π_{kij} to be only event- and cluster-specific, defining thus a quasi-saturated model with $\pi_{kij} \equiv \pi_{kj}$.

In this manuscript, we propose an extension of manet which introduces parsimony by exploiting covariates information. These covariates could be characteristic related to an actor, such as, gender, age, etc, or features of an event, i.e. type of event, date, duration, and so forth. We define $\mathbf{x}_{i\cdot} = (x_{i1}, \ldots, x_{il}, \ldots, x_{iL})$ to be the L-dimensional vector of covariates for actor i, and $\mathbf{w}_{j\cdot} = (w_{j1}, \ldots, w_{jq}, \ldots, w_{jQ})$ the Q-dimensional vector of covariates for event j. For simplicity, we assume the non-categorical covariates to be standardized, i.e. zero mean and unit variance. Covariates enter the model through a *link* function as in the generalized linear models context [4]. We add the following layers to the Bayesian hierarchical formulation

$$\begin{aligned}
&\boldsymbol{\mu}_k \sim \mathrm{N}(\mu_k; 0, \sigma^2_{\mu}), \quad \boldsymbol{\beta}_k \sim \mathrm{N}_L(\boldsymbol{\beta}_k; \mathbf{0}_L, \sigma^2_{\beta} I_L), \quad \boldsymbol{\gamma}_k \sim \mathrm{N}_Q(\boldsymbol{\gamma}_k; \mathbf{0}_Q, \sigma^2_{\gamma} I_Q),\\
&\eta_{kij} = \mu_k + \sum_{l=1}^{L} \beta_{kl} x_{il} + \sum_{q=1}^{Q} \gamma_{kq} w_{jq},\\
&\pi_{kij}(\mathbf{x}_{i\cdot}, \mathbf{w}_{j\cdot}) = g^{-1}(\eta_{kij}),
\end{aligned}$$

where: η_{kij} is the linear predictor; g^{-1} is the normal distribution's cumulative function $\Phi(\cdot)$, leading to a probit formulation; $\mathrm{N}(\cdot)$ is the normal distribution's density function, with subscripts denoting the dimension of vector or matrix; $(\sigma^2_{\mu}, \sigma^2_{\beta}, \sigma^2_{\gamma})$ are hyper-parameters. Notice that, for g^{-1} set equal to the identity function and only $\{\mu_{kj}\}$ as parameters in the linear predictor, we revert back to the quasi-saturated manet. Once the probabilities π_{kij} are obtained from linear predictors η_{kij}, the corresponding heir parameters $\pi^{\star}_{hij}$ can be computed by means of the combining function $\psi(\cdot)$, exactly as in the formulation without covariates in [5]. Computing linear predictors requires regression coefficients and intercepts to be sampled, and this can be done separately for each cluster as they are independent. However, when an actor i belongs to multiple clusters, it is not univocally defined to which posterior distribution among the K sets of $(\mu_k, \beta_{k1}, \ldots, \gamma_{kQ})$ its likelihood term will contribute to. We follow the prescription of [5] to disentangle this issue. We introduce auxiliary variables $s(\boldsymbol{z}_i, \boldsymbol{\pi}) = s_{kij}$, such that, for a fixed (i, j) we have: $s_{kij} = z_{ik}$ if $\sum_{k=1}^{K} z_{ik} = 1$, whereas, if $\sum_{k=1}^{K} z_{ik} > 1$ then $\boldsymbol{s}_{ij\cdot}$ is a K-dimensional vector of zeros, except for $s_{ik_{\min},j} = 1$. Here $k_{\min}$ denotes the index corresponding to the *parent* cluster having the lowest value of η_{kij}, for a fixed event j and actor i. After introducing the auxiliary variables $\{s_{kij}\}$ into the model, the complete-data likelihood becomes

$$\mathscr{L}_{Y,Z}(\boldsymbol{\mu}, \boldsymbol{\beta}, \boldsymbol{\gamma}; S) = \prod_{k=1}^{K} \prod_{j=1}^{d} \prod_{i=1}^{n} \left\{ \left[\Phi(\eta_{kij}) \right]^{y_{ij}} \left[1 - \Phi(\eta_{kij}) \right]^{1-y_{ij}} \right\}^{s_{kij}}. \tag{3}$$

Equation 3 is similar to the likelihood of a binary regression model with probit link function. Also, Equation 3 highlights that, in general, the model can be cast in a regression framework and thus, potentially, other regression techniques and/or extensions can be further exploited to refine `manet`. An outline of the general idea behind the MCMC implementation is: (i) first, all the observations Y are stacked into a vector $\tilde{\mathbf{y}}$ of length $(n \cdot d) \times 1$; (ii) for each k, a vector $\tilde{\mathbf{y}}_k$ is obtained by filtering $\tilde{\mathbf{y}}$ with rule $s_{kij} = 1$, and then a Bayesian probit regression is performed. For this last part, we refer to the work of [2], where the authors discuss a hierarchical Bayesian formulation of the probit model and provide technical details in the manuscript's Appendix. The MCMC algorithm for `manet` with covariates adjustment is implemented in an `R` script, and code is available upon request.

3 Simulation study

We generate 50 independent datasets from a probit model, with $K = 2$ overlapping groups; sample size and number of events are fixed to $n = 100$ and $d = 15$. Covariates are: (i) actor-specific categorical covariate with two levels, same proportions for both levels (50/100), coded with a single binary variable x_{i1}; (ii) event-specific categorical covariate with three levels, same proportions for the three levels (5/15), coded with two binary variables w_{j1} and w_{j2}. For each replicated dataset, we run: (i) our algorithm, labelled `manet+cov`; (ii) `manet`, with the homonymous `R` package. Number of MCMC iterations is set to 10000 with burn-in window equal to 4000. Results are numerically reported in terms of Adjusted Rand Index and misclassification error rate, averaged across the replicated datasets for both models, showed in percentage. Adjusted Rand Index (ARI) is a measure in the range $[0, 1]$, with higher values indicating better performance. The misclassification error rate (MER) quantifies the proportion of wrongly allocated units, with smaller values indicating better performance. In terms of classification accuracy, `manet` and its covariates-adjusted extension attain comparable ARI and MER, with results slightly in favor of `manet+cov`: more specifically, average ARI is 79.06% for `manet` and 81.26% for `manet+cov`, while average MER is 8.92% for `manet` and 8.10% for `manet+cov`. This corroborates the idea of employing covariate information if available, as the performance of the parsimonious `manet+cov` is on par with the more flexible quasi-saturated `manet`. Results for `manet+cov` are also visualized (see Figure 1) through posterior distributions of the regression coefficients, plotted after aggregating chains from all the independent datasets. Despite the additional uncertainty introduced by combining MCMC samples from different datasets, the posterior distributions show good behavior in terms of location and scale: all the densities in Figure 1 are centered around the true values used to generate data, and exhibit limited dispersion.

4 Conclusions

We have proposed an extension of the model formulated in [5], in order to accomodate for additional information in the form of actor and/or event covariates. By cast-

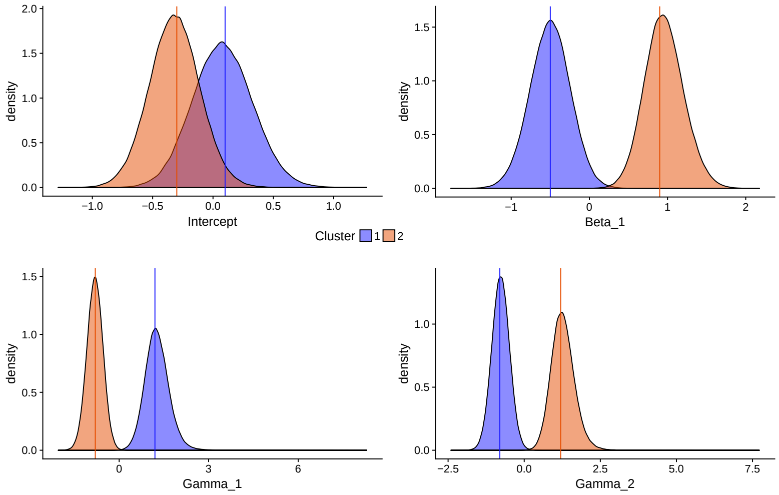

Fig. 1 Posterior distributions for the regression coefficients of `manet+cov`, computed after aggregating all the independent datasets' chains. True values are depicted as vertical lines in the plots, corresponding to parameters for: intercept, $\boldsymbol{\mu} = (0.1, -0.3)$; covariate x_{i1}, $\boldsymbol{\beta}_{\cdot 1} = (-0.5, 0.9)$; covariate w_{j1}, $\boldsymbol{\gamma}_{\cdot 1} = (1.2, -0.8)$; covariate w_{j2}, $\boldsymbol{\gamma}_{\cdot 2} = (-0.8, 1.2)$.

ing part of the inference problem into a binary regression framework, we highlighted the link between regression techniques and covariates-adjusted `manet`, paving the way for more interesting future refinements of the model - such as mixed effects, regularized regression, and so forth. We explored the performance of our proposed algorithm in a simulated environment, which shows appreciable preliminary outputs and encouraging results.

New Challenges in the Measurement of Economic Insecurity, Inequality and Poverty

Social protection in mitigating economic insecurity

La protezione sociale per l'attenuazione dell'insicurezza economica

Alessandra Coli

Abstract Economic insecurity is generally conceived as a feeling of concern about the material conditions that may prevail in the future in case of adverse events, like job loss or sickness. The welfare state turns a set of individual risks (including sickness, job loss and other risks undermining economic security) into social risks by way of social protection. As a consequence, lower economic insecurity is expected where the welfare state is stronger. This paper explores this connection empirically, using official statistics. The analysis is run on a selection of European countries, whose social protection systems differ in terms of social spending levels, kinds of risks covered and rules for accessing social protection.

Abstract *L'espressione insicurezza economica indica generalmente un sentimento di preoccupazione per le condizioni economiche che potrebbero manifestarsi in futuro, come conseguenza di eventi avversi quali la perdita del lavoro o problemi di salute. Il welfare state trasforma una serie di rischi individuali (tra i quali la disoccupazione, la malattia e altri rischi che possono minacciare la stabilità economica) in rischi sociali, attraverso l'attivazione di misure di protezione sociale. Di conseguenza è ipotizzabile un livello minore di insicurezza economica laddove il sistema di welfare risulti più forte. Questo lavoro si propone di esplorare empiricamente la relazione tra insicurezza economica e sistema di welfare, utilizzano dati della statistica ufficiale. L'analisi è condotta su una selezione di paesi Europei che differiscono per livello di spesa sociale, per tipologia di rischi coperti e per regole di accesso al sistema di protezione sociale.*

Key words: Official statistics, welfare state, subjective well-being

1 Introduction

Economic insecurity is generally conceived as a feeling of concern about the material conditions that may prevail in the future. Indeed, in case of adverse events, individuals may face difficulties in maintaining stable and satisfying living standards. Income instability is propelled by a variety of negative events, originating most commonly in the labour market and in the family. Particularly, thematic literature considers job loss, family dissolution, and poor health among the main triggers of economic insecurity.

The welfare state turns individual risks into social risks by way of social protection, whereby households and individuals are relieved from the financial burden of a number of risks and needs, including those mentioned above as causes of economic insecurity. As a consequence, lower economic insecurity is expected where the welfare state is stronger. This paper explores this connection empirically, using official statistics on social protection benefits and economic insecurity. To this end, an individual binary outcomes which separates "insecure" from "secure" households is modeled as a function of both family-level and country-level characteristics. The analysis is run on a selection of European countries, whose social protection systems differ considerably in terms of social spending levels, kinds of risks covered and rules for accessing social protection.

The paper is organized as follows. Section 2 discusses the connection between economic insecurity and welfare state. Section 3 describes variables and indicators used in the empirical analysis. Section 4 presents main results. Section 5 concludes.

2 Economic insecurity and the welfare state

Literature has proposed several definitions of the term "Economic insecurity". The common premise of all definitions is the idea that some economic misfortune might happen in the future and threaten people's quality of life. However, proposed definitions differ significantly from several points of view. According to some scholars, economic insecurity corresponds to the individual perception of the risk and the anxiety thereof ([11], [13],[2]), others identify economic insecurity with the probability of experiencing adverse events ([15], others with the outcome from the exposure to hardship causing economic losses ([14],[3]). Measures of economic insecurity proposed by literature are strikingly different as well, ranging from subjective to objective measures, based on different units of analysis, namely individual workers, households or countries. Osberg (2015) [11] makes a review of main alternative methodologies proposed.

In this work, the definition proposed by Osberg (1998) [11] is adopted, according to which economic insecurity is a state of anxiety produced by a lack of economic safety. Being anxiety an emotion, self-assessment of economic insecurity seems to be the most appropriate way to measure it. As suggested by Osberg (2015) [12], subjective anxiety should be assessed asking people if they are anxious with respect to different types of hazards. Unfortunately, current available surveys contain only broad few questions on “anxiety”, “worry” or “insecurity”, so that only proxy measures can be derived from existing data.

Economic insecurity has undoubtedly a relational dimension, since the sharing of individual risks within the household and the society allows one to smooth the risks themselves and their consequences. This aspect makes the choice of the unit of analysis an important preliminary issue. In line with one strand of the literature, this study considers economic insecurity as a household-level phenomenon since the individual feeling of uncertainty depends significantly on household composition [15].

However, the stability of economic life depends also on the social and institutional context where individuals live. Institutions regulate risk in different ways: making hazardous events less likely, moving the costs of a hazard from one actor to another or sharing the costs of a hazard across many actors. Welfare state deals with the last two kinds of interventions in particular. The amount of social spending represents a fundamental indicator of the institutional response to social risks, however other characteristics of the welfare state might affect the confidence of citizens in social protection. Literature on welfare regime typologies has proposed to focus on several dimensions([16], [5], [10]), like the composition of risks and needs covered, the quota of people covered and the rules for accessing benefits (whether means-tested or not). The kind of economic transactions through which benefits are delivered (whether benefits in cash or benefits in kind) and the origin of social spending, (whether public from general government taxes or private from employeer or employed social contributions) represent other characterizing aspects.

The following empirical analysis aims to explore the relationship between subjective economic insecurity and the level and kind of social protection delivered by the welfare state. In particular the aim is to assess which characteristics of welfare regimes help mitigate the feeling of economic insecurity of citizens.

3 Empirical analysis: data, variables and indicators

The data set derives from the combination of individual (micro) and country (macro) variables from different data sources. Micro data come from European Statistics on income and living conditions (Eusilc[1], [9]) and provide information on the social and demographic characteristics of the households and their members, on the level and kind of social benefits received and on the level of economic insecurity of the household. Macro data are used to detect the characteristics of European economic systems and their welfare system. Data are taken from Esspros [8] and Socx [1], which the main databases on social protection benefits of international official statistics.

[1] The responsibility for all conclusions drawn from the data lies entirely with the author.

Three main groups of variables are included: the outcome variable which allows us to separate “insecure” from “secure” households, a set of predictors relating to the country welfare system and a set of supplementary variables to control for household and country characteristics that may affect the outcome variable.

The outcome variable is called “INSECURITY” and derives from the combination of two measures of economic safety proposed by official statistics ([6]). The first is drawn from Eusilc module on wellbeing and concerns the respondent’s feeling about the financial situation of his/her family. The second variable is drawn from Eusilc standard module on household material deprivation and concerns the household’s capacity to afford an unexpected required financial expense, paying through its own resources. The amount of the expense is explicitly indicated in the questionnaire and depends on the national at-risk-at-poverty threshold. Based on these two variables, a proxy of household’s insecurity is defined. Particularly, a household is defined as insecure if the head of the household both expresses a score of 5 or lower (on a 0-10 scale) for the financial situation of the family and affirms that her/his household is not able to afford unexpected required expenses.

To characterize different social protection systems across countries, the following set of indicators is proposed: share of social benefits in kind over total benefits, share of means-tested benefits over total benefits, share of private social benefits over total social benefits, social expenditure per inhabitant in power purchased parities (henceforth PPP) and shares of social protection expenditure assigned respectively to health, sicks and disability, to old age and survivors, and to unemployment.

Finally, the following control variables/indicators are selected: number of members with tertiary education, number of members with up to lower secondary education, number of members with a job, number of unemployed members, number of retired members, number of old-age members, number of kids; furthermore, for each household, the amount of benefits received, the level of disposable income and equivalent disposable income (in PPP standard) and the tenure status of accomodation are considered. On the macro level, gross domestic product per inhabitant and household consumption expenditure per inhabitant, both expressed in standard PPP, are used to control for the country economy size.

Variables/indicators have been selected from a larger data set. Particularly, only those significantly associated with the measure of economic insecurity have been considered. Furthermore, some have been excluded to avoid multicollinearity problems when estimating the logistic model. Table 1 shows a synthetic description of variables.

The analysis concerns those European countries for which the complete data set is available, namely: Austria (AT), Belgium (BE), Czech Republic (CZ),Denmark (DK), Estonia (EE), Finland (FI), France (FR),Germany (DE), Greece (EL), Hungaria (HR),Ireland (IR), Italy (IT), Latvia (LV), Luxembourg (LU), Netherlands (NL), Norway (NO),Poland (PL), Portugal (PT), Slovakia (SK), Slovenia (SI), Spain (ES), Sweden (SE), Switzerland (CH), United Kingdom (UK). The choice of the year 2013 is motivated by the presence of an ad hoc module on subjective wellbeing in the 2013 Eusilc wave, which was essential to recover information on self-assessment of own household financial situation. Table 2 shows descriptive statistics

Table 1 Description of variables and indicators.

Name	*Description*	*Categories*
INSECURITY	Low level of satisfaction about the household financial situation AND inability to afford unexpected required expenses	0= not economically insecure, 1= economically insecure
FIN	Financial situation of the household	Score on a 0-10 sale
KIND	Share of in kind benefits over total benefits	Percentage values
MEANS	Share of means-tested benefits over total benefits	percentage values
PRIVATE	Share of private social benefits over total social benefits, 2011	Percentage values
SOCIAL	Social expenditure per inhabitant	Standards PPP
HEALTH	Share of social protection expenditure assigned to health, sicks and disability	Percentage values
OLDAGE	Share of social protection expenditure assigned to old age and survivors	Percentage values
FAMILY	Share of social protection expenditure assigned to family and children	Percentage values
UNEMP.	Share of social protection expenditure assigned to unemployment	Percentage values
NDEGREE	Number of members with tertiary education	Number
NLOW	Number of members with up to lower secondary education	Number
NWORK	Numbers of members with a job	Number
NUNEMP	Numbers of unemployed members	Number
NOLD	Number of members aged 75 or more	Number
NKIDS	Number of members aged less than 16	Number
BENEFITS	Benefits received as a quota of the country average disposable income of households, year 2012	Number
YF	Household disposable income	Standard PPP
HOUSE	The outright owner of the accomodation is a member of the household	0= no,1=yes
GDP	Gross domestic product per inhabitant	Standard PPP
CONS	Household consumption expenditure per inhabitant	Standard PPP

for the quantitative individual variables of the data set, whereas Table 3 points out differences among countries both for country-level variables and for the outcome variable.

4 Empirical analysis: methodology and results

The data set has a multilevel structure: individual families, on which economic insecurity is measured, are nested into countries, on which welfare state characteristics are observed. Given this data structure, multilevel models appear to be the natural

choice. Particularly, this analysis applies multilevel logistic regression with random intercept, in order to estimate the probability of experiencing economic insecurity, given some specific characteristics of the welfare state and other country-level and individual-level predictors.

Table 4 shows results of the multilevel logistic model. The model was fit to 200989 households within 24 countries, using standardized input data. A significant positive coefficient indicates that the predictor increases the probability of being classified as insecure, whereas a significant negative sign means that the predictor reduces the risk of economic insecurity. In case of categorical variables, the coefficient sign indicates whether the observed category increases (positive sign) or decreases (negative sign) the risk, compared to the reference category (see table 1 to check categories).

Our results show that some features of welfare systems significantly affects economic security, even when controlling for several characteristics of the household and of the country. Holding all other variables constant, the higher the level of per inhabitant social spending and the percentage of in kind services, the lower the probability of economic insecurity. Conversely, the risk of economic insecurity increases as the share of social benefits in favour of family overcome that assigned to the elderly. The controls generally perform in line with intuition. For instance, the presence of low-educated or unemployed members increases economic insecurity whereas the presence of high-educated or members with a job or retired decreases it. Furthermore, the risk of economic insecurity decreases with higher levels of household disposable income and when the outright owner of accommodation is a member of the household.

5 Conclusions

Improving the delivery of economic security is a socially important issue, as economic insecurity represents a major determinant of individual well-being.

This paper argues that social protection (namely the level and the kind of social benefits delivered), may play a relevant role in mitigating the extent of economic insecurity. An empirical analysis is run to investigate the relationship between economic insecurity (defined as the anxiety produced by a lack of economic safety) and main characteristics of the welfare state. In particular, a multilevel logistic regression (with random intercept) is fitted to 200989 households within 24 European countries. Welfare state characteristics are observed at the group (country) level, whereas the outcome is measured on individual families.

Results point out some interesting evidence. Holding all other variables constant, the higher the level of per inhabitant social spending and the percentage of in kind services, the lower the probability of economic insecurity. Conversely, the risk of economic insecurity increases as the share of social benefits in favour of family overcome that assigned to the elderly. Furthermore, household composition affects significantly household economic insecurity. Obviously, results depend on how economic insecurity is measured. Unfortunately, currently available statistics allow one to obtain only a proxy indicator of subjective economic insecurity in Europe.

Changes in poverty concentration in U.S. urban areas

Cambiamenti nella concentrazione della povertà nelle città americane

Francesco Andreoli and Mauro Mussini

Abstract This paper explores the changes in urban poverty concentration in U.S. cities in the 1980-2016 period. Since poverty is unevenly distributed between neighborhoods in a city, poverty concentration is measured by calculating the Gini index of neighborhood poverty headcount ratios. The change in the index is broken down into components along different dimensions, notably time and space.

Abstract *L'articolo esamina i cambiamenti nella concentrazione della povertà nelle aree urbane americane dal 1980 al 2016. La concentrazione della povertà è misurata con l'indice di Gini, calcolato per l'incidenza della povertà a livello di quartiere. La variazione dell'indice è scomposta secondo la dimensione spaziale e quella temporale.*

Key words: poverty, spatial concentration, decomposition

1 Introduction

Inequalities in American cities can be observed since income and opportunities are unevenly distributed within the cities [4, 2]. In the same American metro area there may be neighborhoods where most of the residents are at the bottom of the income distribution in the city, and other neighborhoods whose residents are mostly at the top. When poor individuals are more likely to live in some neighborhoods, poverty tends to be concentrated in such neighborhoods that offer fewer economic opportunities for their residents, causing a reduction in economic mobility [3]. The most

Mauro Mussini
Department of Economics, University of Verona, Via Cantarane 24 - 37129 Verona, e-mail: mauro.mussini@univr.it

used measures of the degree of concentrated poverty across the neighborhoods in a city are based on the fraction of poor individuals who live in neighborhoods with high poverty levels. For example, according to the American Census definition, concentrated poverty can be measured as the fraction of poor individuals in the city who live in neighborhoods where at least 40% of residents are poor. We use a conventional inequality index to measure urban poverty concentration. This takes the form of the Gini index of neighborhood poverty headcount ratios. The more unequally distributed are poverty proportions across the city neighborhoods with respect to the citywide distribution, the larger is urban poverty concentration. This concentration measure captures a form of segregation of poor individuals across the city neighborhoods: when urban poverty concentration is high, there are neighborhoods with very high shares of local residents who are poor, and neighborhoods that are nearly poverty-free.

The Gini index of urban poverty is broken down into spatial components by using the Rey and Smith spatial decomposition of the Gini index [6]. In this way, we assess whether urban poverty is spatially concentrated within the city. We analyze the dynamics of concentrated poverty in American metro areas by considering the change in the Gini index of urban poverty from 1980 to 2016. First, building on Andreoli and Mussini [1], we break down the change over time in the Gini index of urban poverty into components that are attributable to different sources of the change in urban poverty concentration. Second, the change over time in each spatial component of the concentration index is decomposed.

2 Decomposing changes in concentrated poverty

We introduce some preliminary definitions and notation that are used to express the Gini index of urban poverty in a matrix form. This matrix formulation of the index is suitable for the decomposition along different dimensions we use in our analysis. Consider a city with n neighborhoods. Let $\mathbf{p} = (p_1, \dots, p_n)^T$ be the $n \times 1$ vector of neighborhood poverty headcount ratios sorted in decreasing order and $\mathbf{s} = (s_1, \dots, s_n)^T$ be the $n \times 1$ vector of the corresponding population shares. $\mathbf{1}_n$ being the $n \times 1$ vector with each element equal to 1, $\mathbf{P}$ is the $n \times n$ skew-symmetric matrix:

$$\mathbf{P} = \frac{1}{\bar{p}} \left(\mathbf{1}_n \mathbf{p}^T - \mathbf{p} \mathbf{1}_n^T \right) = \begin{bmatrix} \frac{p_1 - p_1}{\bar{p}} & \dots & \frac{p_n - p_1}{\bar{p}} \\ \vdots & \ddots & \vdots \\ \frac{p_1 - p_n}{\bar{p}} & \dots & \frac{p_n - p_n}{\bar{p}} \end{bmatrix}, \tag{1}$$

where $\bar{p}$ is the poverty headcount ratio for the whole city. Let $\mathbf{S} = diag\{\mathbf{s}\}$ be the $n \times n$ diagonal matrix with diagonal elements equal to the population shares in $\mathbf{s}$, and $\mathbf{G}$ be a $n \times n$ G-matrix (a skew-symmetric matrix whose diagonal elements are equal to 0, with upper diagonal elements equal to -1 and lower diagonal elements equal to 1) [7]. The matrix formulation of the Gini index of urban poverty is

$$G(\mathbf{s},\mathbf{p}) = \frac{1}{2} tr\left(\tilde{\mathbf{G}}\mathbf{P}^{T}\right), \tag{2}$$

where the matrix $\tilde{\mathbf{G}} = \mathbf{SGS}$ is the weighting G-matrix, a generalization of the G-matrix [1, 5].

2.1 The components of the change in concentrated poverty

Assume that the distributions of poor and non-poor individuals between the neighborhoods in a city are observed at different times, notably t and $t+1$. Let $\mathbf{p}_t$ be the $n \times 1$ vector of the t neighborhood poverty headcount ratios sorted in decreasing order and $\mathbf{s}_t$ be the $n \times 1$ vector of the corresponding neighborhood population shares. Let $\mathbf{p}_{t+1}$ be the $n \times 1$ vector of the $t+1$ neighborhood poverty headcount ratios sorted in decreasing order and $\mathbf{s}_{t+1}$ be the $n \times 1$ vector of the corresponding population shares. The change in the degree of concentrated poverty between t and $t+1$ can be measured by the difference between the Gini index in $t+1$ and the Gini index in t [1]:

$$\Delta G = G(\mathbf{s}_{t+1},\mathbf{p}_{t+1}) - G(\mathbf{s}_t,\mathbf{p}_t) = \frac{1}{2} tr\left(\tilde{\mathbf{G}}_{t+1}\mathbf{P}_{t+1}^{T}\right) - \frac{1}{2} tr\left(\tilde{\mathbf{G}}_t\mathbf{P}_t^{T}\right). \tag{3}$$

As shown by Andreoli and Mussini [1], equation 3 can be decomposed to separate the components attributable to changes in neighborhood population shares, ranking of neighborhoods by poverty level and disparities between neighborhood poverty headcount ratios. To decompose ΔG some additional definitions and notation are needed. Let $\mathbf{p}_{t+1|t}$ be the $n \times 1$ vector of $t+1$ neighborhood poverty headcount ratios sorted in decreasing order of the respective t neighborhood poverty headcount ratios, and $\mathbf{B}$ be the $n \times n$ permutation matrix rearranging the elements of $\mathbf{p}_{t+1}$ to obtain $\mathbf{p}_{t+1|t}$. Let $\lambda = \bar{p}_{t+1}/\bar{p}_{t+1|t}$ be the ratio of the actual $t+1$ poverty headcount ratio in the whole city to the fictitious $t+1$ poverty headcount ratio which is the weighted average of $t+1$ neighborhood poverty headcount ratios where the weights are the corresponding population shares in t. The elements of $\mathbf{P}_{t+1|t} = \left(1/\bar{p}_{t+1|t}\right)\left(\mathbf{1}_n\mathbf{p}_{t+1|t}^{T} - \mathbf{p}_{t+1|t}\mathbf{1}_n^{T}\right)$ are the relative pairwise differences between the neighborhood poverty headcount ratios in $\mathbf{p}_{t+1|t}$. The decomposition of ΔG is

$$\Delta G = \frac{1}{2} tr\left(\mathbf{W}\mathbf{P}_{t+1}^{T}\right) + \frac{1}{2} tr\left(\mathbf{R}\lambda\mathbf{P}_{t+1}^{T}\right) + \frac{1}{2} tr\left(\tilde{\mathbf{G}}_t\mathbf{D}^{T}\right) = W + R + D, \tag{4}$$

where $\mathbf{W} = \tilde{\mathbf{G}}_{t+1} - \lambda\tilde{\mathbf{G}}_{t|t+1}$, $\mathbf{R} = \tilde{\mathbf{G}}_{t|t+1} - \mathbf{B}^{T}\tilde{\mathbf{G}}_t\mathbf{B}$ and $\mathbf{D} = \mathbf{P}_{t+1|t} - \mathbf{P}_t$. In equation 4, W is the component measuring the change in concentrated poverty due to changes in the distribution of population between neighborhoods. R is the re-ranking component that is greater than zero when at least two neighborhoods exchanged their ranks in the distribution of neighborhood poverty headcount ratios between t and $t+1$. D is the component measuring the change in relative disparities between neighborhood poverty headcount ratios. D is positive (negative) when relative disparities between neighborhood poverty headcount ratios increased (decreased) over time [1].

2.1.1 The role of the change in poverty incidence

Since component D would not reveal changes in neighborhood poverty headcount ratios if they all changed in the same proportion, this component is split into two further terms: one measuring the change in the poverty headcount ratio in the whole city, the second measuring the changes in relative disparities between neighborhood poverty headcount ratios by assuming that the poverty headcount ratio in the city is unchanged between t and $t+1$. Let c be the change in the poverty headcount ratio in the city by assuming that neighborhood population shares are unchanged over time:

$$c = \frac{\bar{p}_{t+1|t} - \bar{p}_t}{\bar{p}_t}. \tag{5}$$

Let $\mathbf{p}^c_{t+1|t} = \mathbf{p}_t + c\mathbf{p}_t$ be the vector of neighborhood poverty headcount ratios we would observe in $t+1$ if the change in every neighborhood poverty headcount ratio was equal to c in relative terms. Vector $\mathbf{p}_{t+1|t}$ can be expressed as

$$\mathbf{p}_{t+1|t} = \mathbf{p}^c_{t+1|t} + \mathbf{p}^\delta_{t+1|t}, \tag{6}$$

where the elements of vector $\mathbf{p}^\delta_{t+1|t}$ are the element-by-element differences between vectors $\mathbf{p}_{t+1|t}$ and $\mathbf{p}^c_{t+1|t}$. Since $\mathbf{p}^c_{t+1|t} = \mathbf{p}_t + c\mathbf{p}_t$, $\mathbf{p}_{t+1|t}$ can be rewritten as

$$\begin{aligned} \mathbf{p}_{t+1|t} &= \underbrace{\mathbf{p}_t + \mathbf{p}^\delta_{t+1|t}}_{\mathbf{p}^e_{t+1|t}} + c\mathbf{p}_t \\ &= \mathbf{p}^e_{t+1|t} + c\mathbf{p}_t, \end{aligned} \tag{7}$$

where the elements of $\mathbf{p}^e_{t+1|t}$ account for disproportionate changes in neighborhood poverty headcount ratios from t to $t+1$, as $\mathbf{p}^e_{t+1|t}$ would equal $\mathbf{p}_t$ if there were no disproportionate changes in neighborhood poverty headcount ratios. Given equations 5 and 7, matrix $\mathbf{P}_{t+1|t}$ can be written as

$$\begin{aligned} \mathbf{P}_{t+1|t} &= \left(1/\bar{p}_{t+1|t}\right)\left(\mathbf{1}_n \mathbf{p}^T_{t+1|t} - \mathbf{p}_{t+1|t}\mathbf{1}^T_n\right) \\ &= \frac{1}{1+c}\mathbf{P}^e_{t+1|t} + \frac{c}{1+c}\mathbf{P}_t. \end{aligned} \tag{8}$$

Since matrix $\mathbf{D}$ in equation 4 is obtained by subtracting $\mathbf{P}_t$ from $\mathbf{P}_{t+1|t}$, $\mathbf{D}$ can be rewritten as

$$\mathbf{D} = \mathbf{P}_{t+1|t} - \mathbf{P}_t \tag{9}$$

$$
\begin{aligned}
&= \frac{1}{1+c}\mathbf{P}^{e}_{t+1|t} + \frac{c}{1+c}\mathbf{P}_t - \mathbf{P}_t \\
&= \underbrace{\left(\frac{1}{1+c}\right)}_{C}\underbrace{\left(\mathbf{P}^{e}_{t+1|t} - \mathbf{P}_t\right)}_{\mathbf{E}} \\
&= C\mathbf{E}.
\end{aligned}
$$

By replacing **D** in equation 4 with its expression in equation 9, the decomposition of the change in concentrated poverty becomes

$$\Delta G = \frac{1}{2}tr\left(\mathbf{W}\mathbf{P}^{T}_{t+1}\right) + \frac{1}{2}tr\left(\mathbf{R}\lambda\mathbf{P}^{T}_{t+1}\right) + C\frac{1}{2}tr\left(\tilde{\mathbf{G}}_t\mathbf{E}^{T}\right) = W + R + CE. \tag{10}$$

C in equation 10 measures the change in the poverty headcount ratio for the whole city, and E captures the change in relative disparities between neighborhood poverty headcount ratios once the effect of the change in the proportion of poor people in the city has been removed. In other words, E is a “pure” component of disproportionate change between neighborhood poverty headcount ratios.

2.2 Spatial decomposition of the change in concentrated poverty

The components of the change in concentrated poverty described in Sect. 2.1 can be broken down into spatial components by using the Rey and Smith approach to the spatial decomposition of the Gini index [6]. Building on Andreoli and Mussini [1], the spatial components of ΔG, W, R and E are obtained. Let $\mathbf{N}_t$ be the $n \times n$ spatial weights matrix having its (i, j)-th entry equal to 1 if and only if the (i, j)-th element of $\mathbf{P}_t$ is the relative difference between the poverty headcount ratios of two neighboring neighborhoods, otherwise the (i, j)-th element of $\mathbf{N}_t$ is 0. Using the Hadamard product,[1] the relative pairwise differences between the poverty headcount ratios of neighboring neighborhoods can be selected from $\mathbf{P}_t$:

$$\mathbf{P}_{N,t} = \mathbf{N}_t \odot \mathbf{P}_t. \tag{11}$$

Since $\mathbf{P}^{e}_{t+1|t}$ and $\mathbf{P}_t$ are defined by the ordering of neighborhoods in t, $\mathbf{N}_t$ also selects the relative pairwise differences between neighboring neighborhoods from $\mathbf{P}^{e}_{t+1|t}$:

$$\mathbf{P}^{e}_{N,t+1|t} = \mathbf{N}_t \odot \mathbf{P}^{e}_{t+1|t}. \tag{12}$$

Given that $\mathbf{E} = \mathbf{P}^{e}_{t+1|t} - \mathbf{P}_t$, the Hadamard product between $\mathbf{N}_t$ and $\mathbf{E}$ is a matrix with nonzero elements equal to the elements of $\mathbf{E}$ pertaining to neighboring neighborhoods:

[1] Let **X** and **Y** be $k \times k$ matrices. The Hadamard product $\mathbf{X} \odot \mathbf{Y}$ is defined as the $k \times k$ matrix with the (i, j)-th element equal to $x_{ij}y_{ij}$.

$$\mathbf{E}_N = \mathbf{P}^e_{N,t+1|t} - \mathbf{P}_{N,t} = \mathbf{N}_t \odot \left(\mathbf{P}^e_{t+1|t} - \mathbf{P}_t\right) = \mathbf{N}_t \odot \mathbf{E}. \tag{13}$$

Let $\mathbf{P}_{N,t+1}$ be the matrix whose nonzero elements are the relative pairwise differences between the poverty headcount ratios of neighboring neighborhoods in $t+1$:

$$\mathbf{P}_{N,t+1} = \mathbf{N}_{t+1} \odot \mathbf{P}_{t+1}. \tag{14}$$

The decomposition of the change in the neighbor component of concentrated poverty is obtained by replacing $\mathbf{P}_{t+1}$ and $\mathbf{E}$ in equation 10 with $\mathbf{P}_{N,t+1}$ and $\mathbf{E}_N$, respectively:

$$\begin{aligned}\Delta G_N &= \frac{1}{2}tr\left(\mathbf{W}\mathbf{P}^T_{N,t+1}\right) + \frac{1}{2}tr\left(\mathbf{R}\lambda\mathbf{P}^T_{N,t+1}\right) + C\frac{1}{2}tr\left(\tilde{\mathbf{G}}_t\mathbf{E}^T_N\right) \\ &= W_N + R_N + CE_N.\end{aligned} \tag{15}$$

$\mathbf{J}_n$ being the matrix with diagonal elements equal to 0 and extra-diagonal elements equal to 1, the matrix with nonzero elements equal to the relative pairwise differences between the $t+1$ poverty headcount ratios of non-neighboring neighborhoods is

$$\mathbf{P}_{nN,t+1} = (\mathbf{J}_n - \mathbf{N}_{t+1}) \odot \mathbf{P}_{t+1}. \tag{16}$$

The matrix selecting the elements of $\mathbf{E}$ related to the pairs of non-neighboring neighborhoods is

$$\mathbf{E}_{nN} = (\mathbf{J}_n - \mathbf{N}_t) \odot \mathbf{E}. \tag{17}$$

The decomposition of the change in the non-neighbor component of concentrated poverty is obtained by replacing $\mathbf{P}_{t+1}$ and $\mathbf{E}$ in equation 10 with $\mathbf{P}_{nN,t+1}$ and $\mathbf{E}_{nN}$, respectively:

$$\begin{aligned}\Delta G_{nN} &= \frac{1}{2}tr\left(\mathbf{W}\mathbf{P}^T_{nN,t+1}\right) + \frac{1}{2}tr\left(\mathbf{R}\lambda\mathbf{P}^T_{nN,t+1}\right) + C\frac{1}{2}tr\left(\tilde{\mathbf{G}}_t\mathbf{E}^T_{nN}\right) \\ &= W_{nN} + R_{nN} + CE_{nN}.\end{aligned} \tag{18}$$

Given equations 15 and 18, the spatial decomposition of the change in concentrated poverty is

$$\Delta G = W_N + W_{nN} + R_N + R_{nN} + C\left(E_N + E_{nN}\right). \tag{19}$$

3 The dynamics of concentrated poverty in American cities

We use information on income and population distributions within U.S. metro areas over the 1980-2016 period from the U.S. Census Bureau database. Information about population counts, income levels and family composition at a very fine spatial grid is taken from the decennial census Summary Tape File 3A. Census tracts are the spatial units of observation, and poverty headcount ratios at the federal poverty line provided by the U.S. Census Bureau are calculated. The 1980-2016 period is divided into five sub-periods to observe the dynamics of each component of the change in concentrated poverty. Since the changes in the population distribution within cities played a minor role in the change in concentrated poverty, we focus our attention on the components measuring the re-ranking effect (R) and the effect of the disproportionate change between census tract poverty headcount ratios (E) for the largest three American metro areas: New York, Los Angeles and Chicago. Concentrated poverty decreased in each of the three metro areas during the period considered, with the largest reduction in Chicago ($\Delta G = -0.11088$) where concentrated poverty ($G = 0.54921$) was greater than in the other two cities in 1980. The degree of concentrated poverty was 0.49669 in New York and 0.41069 in Los Angeles in 1980. Figure 1 shows the spatial decomposition of E. The poverty headcount ratios of non-neighboring census tracts in Chicago have become less unequal, especially during the decade from 2000 to 2010. The decrease in disparities between the poverty headcount ratios of non-neighboring census tracts has been less pronounced in New York and Los Angeles. The decrease in disparities between the poverty headcount ratios of neighboring census tracts in New York has been greater than in the other two cities.

Figure 2 shows the spatial components of the re-ranking effect. The largest re-ranking effect occurred between non-neighboring census tracts in Chicago during the 2000-2010 sub-period. This re-ranking effect partly offset the effect of the reduction in inequality between the poverty headcount ratios of non-neighboring cen-

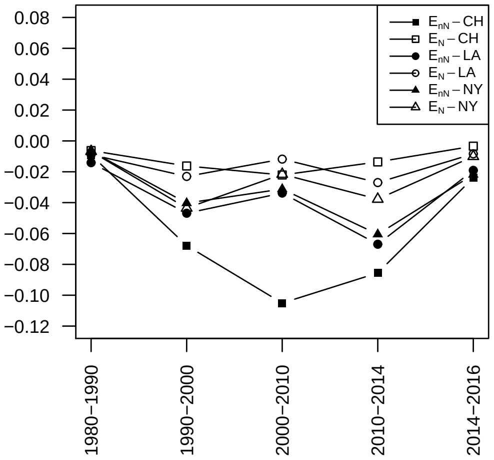

Fig. 1 Spatial components of E in Chicago (CH), Los Angeles (LA) and New York (NY) in the 1980-2016 period.

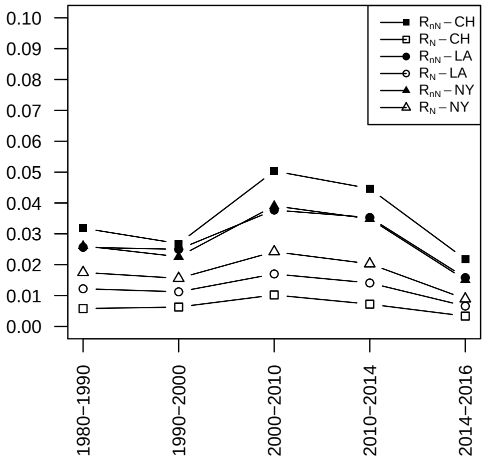

Fig. 2 Spatial components of R in Chicago (CH), Los Angeles (LA) and New York (NY) in the 1980-2016 period.

sus tracts in the city in that decade, especially in view of the increase in poverty incidence in the city ($C = 0.79812$) that weakened the effect of the reduction in inequality between census tract poverty headcount ratios.

Evaluating sustainability through an input-state-output framework: the case of the Italian provinces

Valutazione delle sostenibilità attraverso un sistema input-state-output: analisi sulle province Italiane

Achille Lemmi[1], Laura Neri[2], Federico M. Pulselli[3]

Abstract In line with the recommendation of monitoring local context, in this paper we propose to investigate regional (NUTS2) and provincial (NUTS3) economic systems in a schematic and usable way: three different indicators are used to take into account resource use (input), societal organization (state) and to quantify the outputs of the system (output). A fuzzy cluster analysis is applied to the input-state-output indicator framework, that, as a whole, represents the interconnection of the three aspects of sustainability, namely environmental, social and economic. This framework is a useful and comprehensive tool for investigating and monitoring local context economic systems.

Abstract *In linea con le direttive di monitorare sistemi come le economie nazionali in un contesto locale, questo lavoro, propone l'analisi dei sistemi economici regionali (NUTS2) e provinciali (NUTS3) in modo semplice schematico e fruibile: tre diversi indicatori sono utilizzati per tenere conto dell'uso delle risorse (input), organizzazione della società (stato) e per quantificare l'output del sistema (output). Un'analisi cluster sfocata viene applicata agli indicatori del framework input-state-output, che, nel suo complesso, rappresentano l'interconnessione dei tre aspetti della sostenibilità, in particolare ambientale, sociale* ed economica.

Key words: Sustainability, input-state-output, fuzzy cluster analysis

1 Introduction

In recent years there has been an increasing interest in the measurement of collective phenomena at the local level. The EU Committee of the Regions (2014) strongly recommend local authorities to define their own “2020 vision”, based on a territorial dimension, overcoming the present top-down approach of country targets fitting all regions irrespectively. Italy is subdivided into 20 regions (NUTS2) representing the first-level of administrative divisions; the country is further subdivided into 107 provinces (NUTS3). Though progressive measures are trying to eliminate this intermediate administrative level, provinces still play an important role in planning, coordination and cooperation at local level in connection with municipalities and other local bodies. According to OECD Regional Well-being (2016, http://www.oecd.org/cfe/regional-policy/hows-life-country-facts-italy.pdf) “Italy has the largest regional disparities among the OECD countries in safety, with the Aosta Valley ranking in the top 1% and Sicily in the bottom 10% of the OECD regions. Important regional differences are found also in jobs, environment, community, civic engagement, income and access to services”. In line with the recommendation of monitoring local context, in this paper we propose to investigate regional (NUTS2) and provincial (NUTS3) economic systems in a schematic and usable way: three indicators are used to take into account resource use, societal organization and to quantify the outputs of the system. This framework is consistent with an input-state-output scheme (I-S-O, Pulselli et al., 2015), representing the ordered triad environment–society–economy. A three-storey pyramid represents the mutual relationships among the three dimensions of sustainability, rotating the pyramid clockwise, the succession of the stages is oriented from left to right, consistently with the I-S-O framework

2 Data and Methods

In this framework different combinations of indicators can be used to account for the input-state-output. The study here presented is referred to provincial areas, so the preliminary challenge to face is the data availability. Then, the aim of the research is to produce an “objective” classification of the Italian provinces in terms of the three aspects of sustainability. Such classification should be useful for designing and delivering policy responses to economic, environmental and social needs at the local level.

2.1 The indicators

The input indicator should be representative of what a system extracts/obtains, directly or indirectly, from the environment. Referring to provincial areas, which are sub-regional systems, poor datasets are systematically produced, especially in the environmental field. Therefore, no encompassing methods, like emergy evaluation (as in Pulselli et al., 2015) or ecological footprint, or other environmental accounting methods can apply. In this case we used an aggregation of energy consumption measures, collected from two institutional databases (Terna: National electric network; DGERM: Ministry of Economic Development). In particular, we selected electricity consumption and sale of a set of fuel types, for all the provinces of Italy. In order to aggregate these measures, we calculated the equivalent in terms of CO_2 emission to show both the use of resources (electricity and fuels) and the environmental pressure (emissions) on the other. The result is an estimation of gross CO_2 emission due to almost all the items composing the energy sector. In order to monitor the environmental pressure of human activities on each provincial territory and compare provinces, the amount of CO_2 per unit area is computed. This choice helps determine the contribution of human actions (that imply energy consumption) to climate change independently of the number of inhabitants in each area. To encompass the characteristics of the state, a synthetic indicator describing a form of societal organization should be used. Considering the critical importance of reducing unemployment, in order to drive toward inclusive society, an indicator related to the labour market seems to be appropriate. Again, availability and reliability of data at NUTS3 level is the critical issue to face: it has been retained that the most reliable official statistics should be the Labour Force Survey, so the unemployment rate has been chosen as key state indicator.Gross Domestic Product (GDP) is the principal aggregate for measuring economic development/growth of a country/region. In this analysis we maintain this logic, considering the GDP per inhabitants in purchasing parity power as output indicator of the I-S-O system.

2.2 Methods

Our goal is to produce an “objective” classification of the Italian provinces in terms of the three aspects of sustainability, namely environmental, social and economic, according to the chosen triad: CO_2 per unit area, unemployment rate and GDP per inhabitants in purchasing parity power.

Data clustering is recognized as a statistical technique for classifying data elements into different groups (known as clusters) in such a way that the elements within a group possess high similarity while they differ from the elements in a different group. By using the triad of indicators, the clustering algorithm starts from an initial partition of the provinces into a fixed number of groups, where each group is initially randomly chosen. The grouping is then updated: based on the distance between every single observation and the reference objects of each group, every observation is reallocated to the closest group aiming to produce a classification that is reasonably “objective” and “stable”. The classification obtained by using the crisp cluster analysis suffers for both a poor homogeneity within group and a lacking separation between the groups. For this reason, we explored the clustering procedure by using a soft clustering known as Fuzzy Cluster Analysis, a very important clustering technique based on fuzzy logic. In case of soft clustering techniques, fuzzy sets are used to cluster data, so that each point may belong to two or more clusters with different degrees of membership. In many situations, fuzzy clustering is more natural than hard clustering.

Objects on the boundaries between several clusters are not forced to fully belong to one of the cluster, but rather are assigned membership degrees between 0 and 1 indicating their partial membership. The most popular algorithm, the fuzzy c-means (developed by Dunn in 1973 and improved by Bezdek in 1981), aims at minimizing an objective function –the weighted within-groups sum of square- whose (main) parameters are the membership degrees and the parameters determining the localisation as well as the shape of the clusters. Objects are assigned to clusters according to membership degrees in [0,1]: 0 is where the data point is at the farthest possible point from a cluster's center and 1 is where the data point is the closest to the center. Each of the c clusters is represented by a cluster center. These centers are chosen randomly in the beginning, then each data vector is assigned to the nearest prototype according to a suitable similarity measure and each center is replaced by the centre of gravity of those data assigned to it. The alternating assignment of data to the nearest center and the update of the cluster centres is repeated until the algorithm converges, i.e., no more changes happen.

Although the extension from crisp to fuzzy clustering seems to be an obvious concept, it turns out that to actually obtain membership degrees between zero and one, it is necessary to introduce a so-called fuzzifier in fuzzy clustering. Usually, the fuzzifier is simply used to control how much clusters are allowed to overlap. This fuzzifier function creates an area of crisp membership values around a prototype while outside of these areas of crisp membership values, fuzzy values are assigned. The analysis has been performed by using the fuzzy clustering with polynomial fuzzifier (Frank Klawonn and Frank Hoppner, 2003).

A problem that frequently occurs in real data analysis is the presence of one or more observation presenting anomalous values, i.e. outliers. Such a subset, that may be referred to as noise, tends to disrupt clustering algorithms making difficult to detect the cluster structure of the remaining domain points. According to the adopted approach the first k standard clusters are homogeneous, whereas the noise cluster, serving as a "garbage collector", contains the outliers and is usually not formed by objects with homogeneous.

All data have been standardized before performing the cluster analysis. The analysis has been conducted by using R and specifically the R package *fclust* (Giordani, Ferraro, 2018). The package provides the cluster solution, cluster validity index and plots and also the visualization of fuzzy clustering results.

The analysis has been performed by using the fuzzy clustering with polynomial fuzzifier with noise cluster. For assessing cluster validity, some have been evaluated: here, just the so called partition coefficient (PC) is presented. Given that the closer to unity the PC index the "crisper" the clustering is and that value close to $1/n_c$ (where n_c is the number of clusters) indicates that there is no clustering tendency, a PC=0.92, indicates a significant cluster structure.

As regard to the visual inspection of fuzzy clustering results -VIFCR- (Klawonn et al., 2003) is a scatter plot where, for each object, the coordinates u_1 and u_2 denote, respectively, the highest and the second highest membership degrees. All points lie within the triangle with vertices (0,0), (0.5,0.5) and (1,0). In the ideal case of (almost) crisp membership degrees all points are near the vertex (1,0). This graph has been evaluated for different partition and the partition with three cluster, plus the noise one, containing just one province (Milan), seems to be the best one (Fig.1).

The algorithm applied to reach the fuzzy clustering solution, assigns an objects to clusters only if the corresponding member function degree is greater than 0.5. In this way the closest hardest partition can be identified by assigning an object to the cluster according to the maximal membership function (>0.5) and the characteristics of each cluster can be identified. The cardinalities and the average membership function of the closest hardest cluster are reported in Table 1, as well as the average of each indicator considered in the clustering procedure. Specifically, in Table 2, the list of provinces belonging to each cluster, according to the maximal membership function, are reported; it is worth to point out that cluster 4, the noise one, includes just Milan.

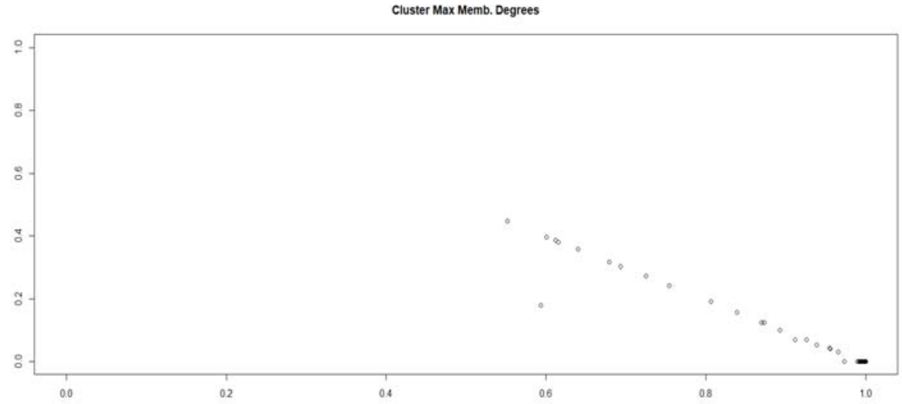

Figure 1: Scatter plot: for each observation, the coordinates u_1 and u_2 denote, respectively, the highest and the second highest membership degrees.

Table 1: Size, average membership function and average values for the indicators by cluster

Cluster	*size*	*m.f.*	*CO₂_area*	*Unempl_rate*	*pps_ab*
1	27	0.96	2272.88	7.75	30866.67
2	44	0.94	912.13	10.31	24854.34
3	35	0.97	804.13	19.78	17046.71
4	1	1	12755.85	7.68	44493.13

In order to have a vision of the distribution of each indicator within each cluster, the boxplots can be observed (Figure 2).

PCA plot (Figure 3) is a very useful tools to visualize the data: this has nothing to do with the type of clustering algorithm or the accuracy of the algorithm used, however it is a useful representation to recognize the utility of the fuzzy clustering, given that the clusters, are clearly separated but the borderline units provinces in this study, are very close.

Table 2: The list of provinces belonging to the four clusters according to the maximal membership function

3. An attempt of taxonomy according to the triad

Cluster composition (Table 2) and average values of indicators (Tab. 1) suggest a hig h heterogeneity among clusters emphasizing the existence of economic disparities.
In Cluster 1 there are 27 provinces: Rome, plus 26 provinces located in the North or Central Italy. Comparing Cluster 1 with Cluster 2 and 3, we can observe the highest a verage level of CO_2 per area, the highest GDP per capita and the lowest unemployme nt rate. Observing Fig. 2, we can also realize that the unemployment rate is quite ho mogeneous within the cluster while the GDP per capita and the level of CO_2 per area present the largest variability if compared with the variability of Cluster 2 and 3. Thi s result is justified considering the presence of very peculiar provinces in this cluster, like Bolzano (belonging to an autonomous region) with the highest GDP per capita (40000 Euro) (out of Milan), and the lowest unemployment rate among all the Italian provinces, and the lowest level of CO_2 per area within Cluster 1. and Livorno, the pr ovince presenting the lower membership function for this cluster (0.64), maybe due t o its GDP which is closer to the average GDP per capita computed for Cluster 2.
Cluster 2 is the most heterogeneous cluster as regard to the geography of provinces. I t is composed mainly by provinces located in the North and Central Italy plus provin ces of Lazio (out of Rome and Viterbo) and Abruzzo plus Nuoro and Potenza. All th e provinces in Cluster2, out of Torino, have small medium dimension. This cluster is characterized by high variability in GDP, ranging from 17900 for Nuoro to 29900 fo r Siena and low variability in CO_2. Torino presents the lowest membership function (0.55) among all the provinces, being a borderline unit between Cluster 2 and 1. Clus ter 3 is composed by whole Calabria, Campania, Molise, Puglia, Sicilia and Sardegn a (out of Nuoro), plus Viterbo (Lazio). This cluster is very similar to the one, labelle d as “Minimal system with high social risks” by Bertin (2012) in his classification co ncerning the welfare state systems of the Italian regions. Cluster 3 is characterized by the lowest average level of CO_2 emission per area, although such level is biased

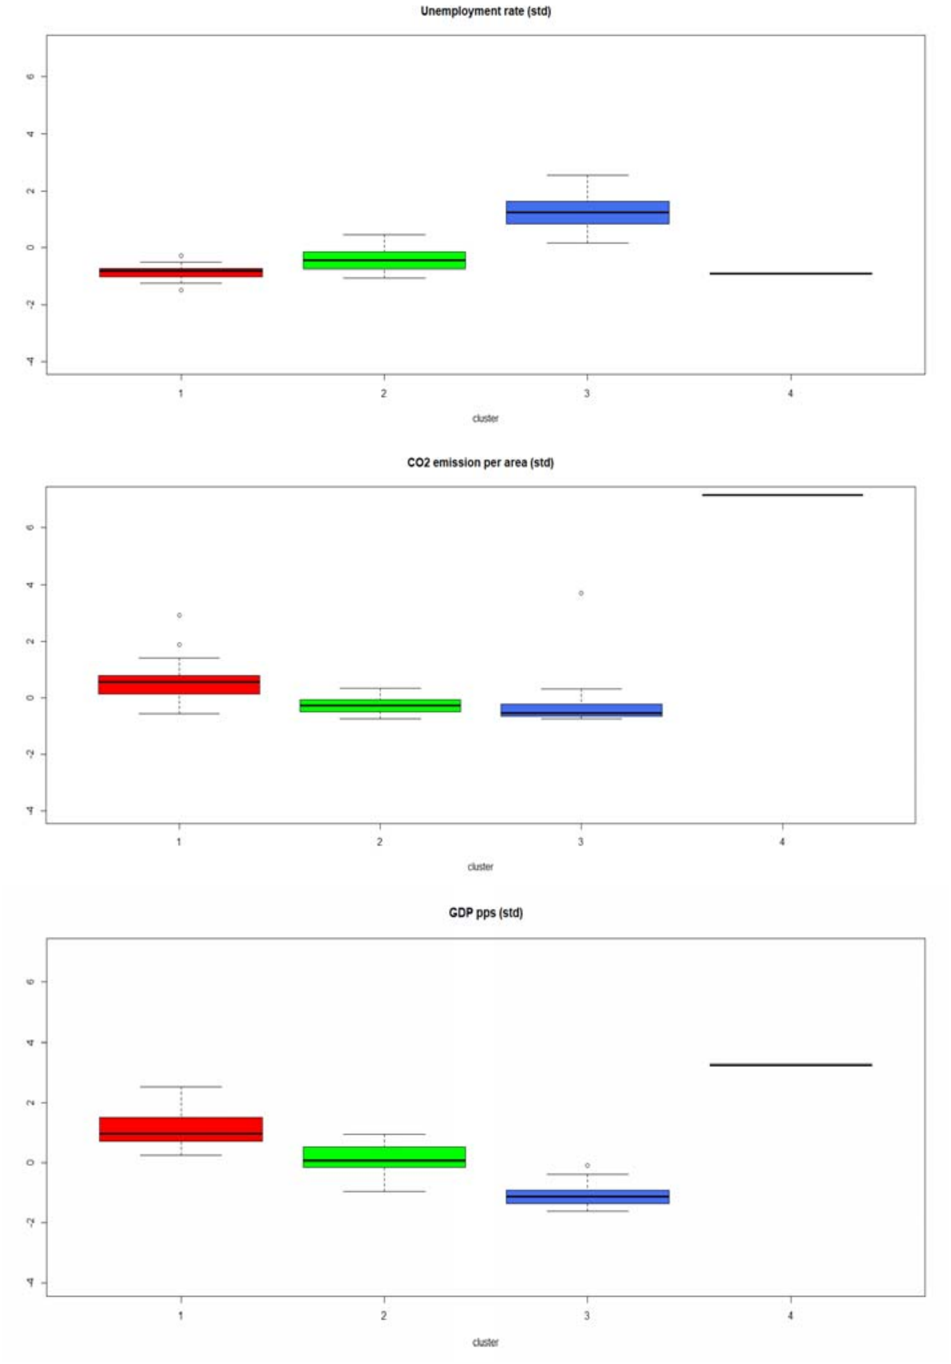

Figure 2: Boxplot-cluster structure

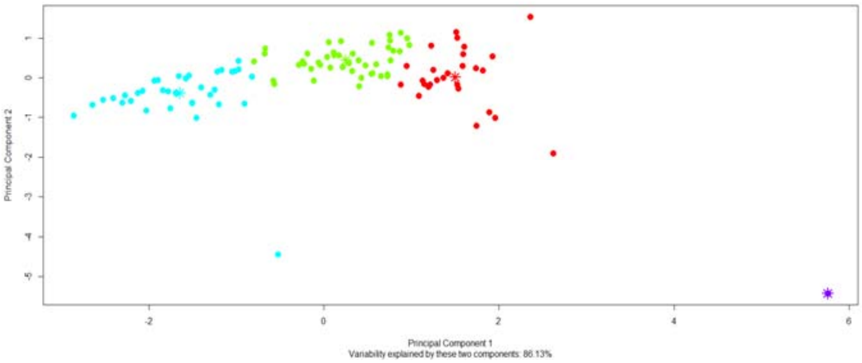

Figure 3: Principal component plot of the cluster structure

due to the membership of Napoli, presenting the highest level of CO_2 among all Italian provinces (out of Milan). As regard to the unemployment rate and GDP, the cluster presents an evident disparity with respect to the others. As regard to GDP per capita, the level of Cagliari (23400), the highest value within cluster 3, is lower than the minimum value in Cluster 1 (25500) registered for Livorno. It is interesting to observe that Napoli is a borderline unit between cluster 3 and 2.

Finally, Cluster 4, the one containing just Milan, is for sure a true outlier with respect to the level of CO2 emission per area (more than ten times the average values of all the other provinces i.e.12755.85 vs 1218.29) and GDP per capita which in Milan is nearly double than the average values of all the other provinces (44493 vs 23812).

The analysis conducted confirm the well-known dualism, resulted in a North-South divide in GDP per capita and in labour-market performance, adding a new element: the Southern Italian provinces are homogeneous with respect to the considered characteristics whilst the Northern and Central provinces are not homogeneous even if they belong to the same region. This result suggests that local policies can be better aligned and tailored to specific local opportunities and challenges. Moreover, the clustering structure obtained can be an useful tool to adopt, considering that provinces belonging to the same cluster could share ways to generate better outcomes for environment, jobs and the economy, trying to reach provinces of their cluster.

New Methods and Models for Ordinal Data

Weighted and unweighted distances based decision tree for ranking data.

Alberi decisionali per ranking data basati su distanze pesate e non pesate

Antonella Plaia, Simona Buscemi, Mariangela Sciandra

Abstract Preference data represent a particular type of ranking data (widely used in sports, web search, social sciences), where a group of people gives their preferences over a set of alternatives. Within this framework, distance-based decision trees represent a non-parametric tool for identifying the profiles of subjects giving a similar ranking. This paper aims at detecting, in the framework of (complete and incomplete) ranking data, the impact of the differently structured weighted distances for building decision trees. The traditional metrics between rankings don't take into account the importance of swapping elements similar among them (element weights) or elements belonging to the top (or to the bottom) of an ordering (position weights). By means of simulations, using weighted distances to build decision trees, we will compute the impact of different weighting structures both on splitting and on consensus ranking. The distances that will be used satisfy Kemenys axioms and, accordingly, a modified version of the rank correlation coefficient τ_x, proposed by Edmond and Mason, will be proposed and used for assessing the trees' goodness.

Abstract *I dati di preferenza rappresentano un particolare tipo di ranking data (ampiamente usati nello sport, nella ricerca sul web, nelle scienze sociali), dove un gruppo di persone dá le sue preferenze su un set di alternative. In questo contesto, gli alberi decisionali basati sulle distanze rappresentano uno strumento non parametrico per identificare i profili di soggetti che forniscono un ranking simile. Questo "articolo" mira ad indagare, nel contesto di ordinamenti completi e incompleti, quale sia l'impatto delle differenti distanze pesate sulla costruzione di alberi decisionali. Le tradizionali metriche tra ordinamenti non prendono in considerazione l'importanza di scambiare elementi simili tra di loro (pesi di item) o elementi che stanno in cima o in coda a una classifica (pesi di posizione). Usando le distanze pesate per la costruzione degli alberi, condurremo uno studio di sim-*

ulazione per misurare l'impatto di differenti sistemi di peso sia sugli splitting sia sull'individuazione del consensus ranking. Le distanze che saranno usate rispettano gli assiomi di Kemeny.

Key words: weighted distances, ranking, Kemeny, consensus, trees

1 Introduction

Distances between rankings and the rank aggregation problem have received a growing consideration in the past few years. Ranking and classifying are two simplified cognitive processes usefull for people to handle many aspects in their life. When some subjects are asked to indicate their preferences over a set of alternatives (items), ranking data are called preference data. One great issue of interest in literature is: what can be done to identify, through subject-specific characteristics, the profiles of subjects having similar preferences? In order to answer to this question, different solutions have been proposed: distance-based tree models [15], distance-based multivariate trees for ranking [4], log-linearized Bradley-Terry models [9] and a semi-parametric approach for recursive partitioning of Bradley-Terry models for incorporating subject covariates [18]. Lee and Yu (2010) [15] investigated the development of distance-based models using decision tree with weighted distances, where weights are related to items. The traditional metrics between rankings don't take into account the importance of swapping elements similar among them (element weights) or elements belonging to the top (or to the bottom) of an ordering (position weights). Kumar and Vassilvitskii (2010) [14] provided an extended measure for Spearman's Footrule and Kendall's τ, embedding weights relevant to the elements or to their position in the ordering. The purpose of this paper is to investigate the effect of different weighting vectors on the tree. A particular attention is given to the weighted Kemeny distance and to the consensus ranking process for assigning a suitable label to the leaves of the tree. The stopping criterion for detecting the optimum tree is a properly modified Tau_x [10].

The rest of the paper is organized as follows: Section 2 introduces different metrics between rankings, their properties and their weighted extension; Section 3 introduces the weighted correlation coefficient; after a brief view on decision trees, in Section 4 we perform our analysis through a simulation study and, in the end, a short conclusion is presented (Section 5).

2 Distances between rankings

Ranking data arise when a group of n individuals (experts, voters, raters etc) shows their preferences on a finite set of items (k different alternatives of objects, like movies, activities and so on). If the k items are ranked in k distinguishable ranks, a complete ranking or linear ordering is achieved [8]. A ranking π is, in this case, one of the $k!$ possible permutations of k elements, containing the preferences given by the judge to the k items. When some items receive the same preference, then a tied ranking or a weak ordering is obtained. In real situations, many times it happens that not all items are ranked: partial rankings, when judges are asked to rank only a subset of the whole set of items, and incomplete rankings, when judges can freely choose to rank only some items. In order to get homogeneous groups of subjects having similar preferences, it's natural to measure the spread between rankings through dissimilarity or distance measures among them. Within the metrics proposed in literature to compute distances between rankings, the Kemeny distance will be here considered [13]. The Kemeny distance (K) between two rankings π and σ is a city-block distance defined as:

$$K(\pi,\sigma) = \frac{1}{2}\sum_{r=1}^{k}\sum_{s=1}^{k}|a_{rs} - b_{rs}| \tag{1}$$

where a_{rs} and b_{rs} are the generic elements of the $k \times k$ score matrices associated to π and σ respectively, assuming value equal to 1 if the item r is preferred to or tied with the item s, -1 if the item s is preferred to the item r and 0 if $r = s$.
K is in a one-to-one correspondence, $\tau = 1 - 2d/D_{max}$, to the rank correlation coefficient τ_x proposed by [10] defined as:

$$\tau_x(\pi,\sigma) = \frac{\sum_{r=1}^{k}\sum_{s=1}^{k} a_{rs}b_{rs}}{k(k-1)}. \tag{2}$$

2.1 Weighted distances

Kumar and Vassilvitskii (2010) [14] introduced two aspects essential for many applications involving distances between rankings: positional weights and element weights. In short, i) the importance given to swapping elements near the head of a ranking could be higher than the same attributed to elements belonging to the tail of the list or ii) swapping elements similar between themselves should be less penalized than swapping elements which aren't similar. In this paper, we deal with case i) and consider the weighted version of the Kemeny metric. For measuring the weighted distances, the non-increasing weights vector $w = (w_1, w_2, ..., w_{k-1})$ constrained to $\sum_{p=1}^{k-1} w_p = 1$ is used, where w_p is the weight given to position p in he ranking.

Given two generic rankings of k elements, π and σ, the Weighted Kemeny distance was provided by [11] as follows:

$$K^w(\sigma,\pi) = \frac{1}{2}\left[\sum_{\substack{r,s=1\\ r<s}}^{k} w_r|a_{rs}^{(\sigma)} - b_{rs}^{(\sigma)}| + \sum_{\substack{r,s=1\\ r<s}}^{k} w_r|b_{rs}^{(\pi)} - a_{rs}^{(\pi)}|\right], \tag{3}$$

where (σ) states to follow the σ ranking and (π), similarly, orders according to π (see [16] for more details).

3 A new suitable rank correlation coefficient

In this paper we propose a new consensus measure, suitable for position weighted rankings. It represents an extension of τ_x proposed by [10] that handles linear and weak rankings when the position occupied by the items is relevant. It is defined as:

$$\tau_x^w(\pi,\sigma) = \frac{\sum_{r<s}^{k} a_{rs}^{\sigma} b_{rs}^{\pi} w_r + \sum_{r<s}^{k} a_{rs}^{\pi} b_{rs}^{\sigma} w_r}{Max[K^w(\sigma,\pi)]}, \tag{4}$$

where the denominator represents the maximum value for the Kemeny weighted distances, equal to:

$$Max[K^w(\pi,\sigma)] = \sum_{r=1}^{m-1} (m-1) w_r \cdot n. \tag{5}$$

A consensus measure has to satisfy conditions like unanimity, anonymity and neutrality, i.e. the consensus in every subset of individuals is maximum if and only if all opinions are the same and the degree of consensus is not affected by permutations of the voters or permutations of the alternatives, respectively. Furthermore, it could fulfill some other properties such as maximum dissension, reciprocity and homogeneity, i.e.: in each subset of two subjects, the minimum consensus is achieved if the preferences are linear orderings and each one is the reverse of the other one; if all individual orderings are reversed then level of consensus doesn't change and, in the end, if a subset of agents is replicated, then the consensus in that group doesn't change [11]. By simulations, we verified the fulfillment of these properties.

4 Decision Trees and Simulation Study

Decision trees are non parametric recursive statistical tools used for classification and prediction issues. The most known decision tree methodology is applied when the response variable is categorical or quantitative. Recently the procedure has been extended to rankings as response variable. For more details see [16]. In this paper we will use the weighted Kemeny distance (3) as impurity function and τ_x^w (4) as a measure of goodness of the tree. In particular, we are interested in evaluating the effect both on the splits and on the leaf labels of different weighting vectors w. For this reason, following [7], we consider a theoretical population partition of the predictor space (X_1 and X_2): Fig. 1 shows one of the nine datasets considered in the simulation plan, with $X_1 \sim U(0,10)$ and $X_2 \sim U(0,6)$. The number of rankings falling in each group was defined by a random number drawn from a normal distribution $N(10,2)$ and each number was divided by the summation of all of them, obtaining a relative frequency distribution for each sub-partition.

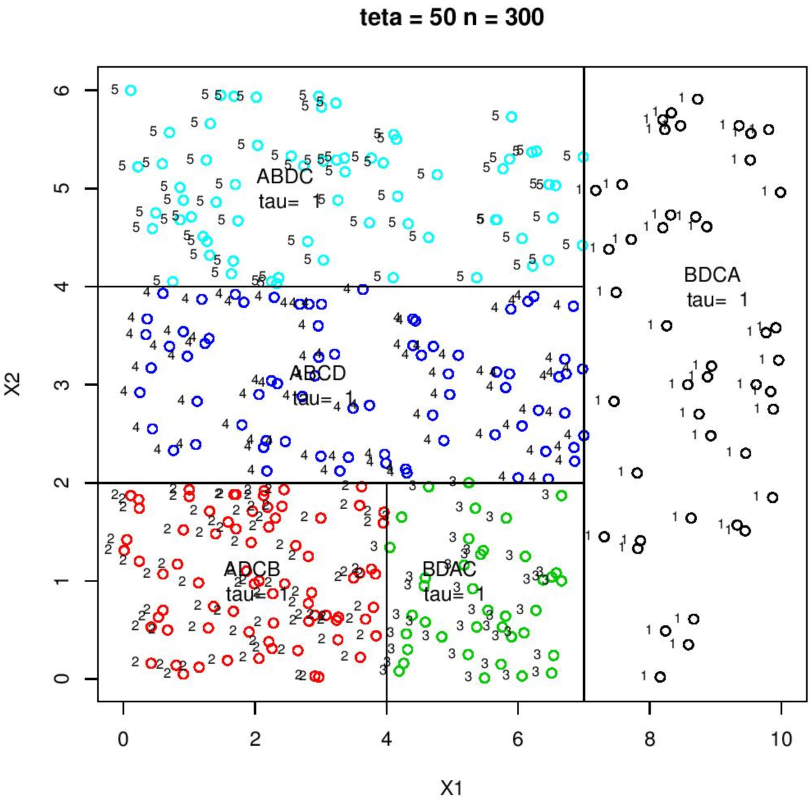

Fig. 1: Generation of homogeneous groups of ranking

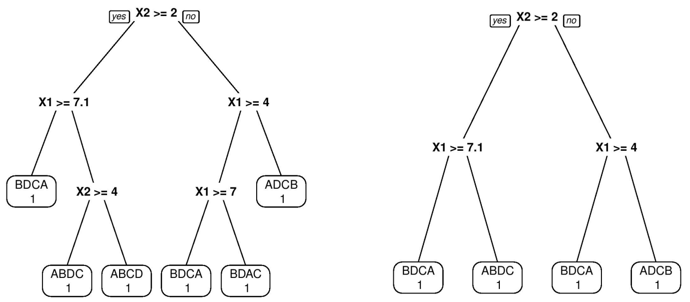
The rankings of $k = 4$ items of each sub-partition were generated from a Mallows Model [12], varying the dispersion parameter θ, according to three different level of noise (low with $\theta = 50$, medium with $\theta = 2$ and high with $\theta = 1$). Considering three levels for the sample size (50, 100 and 300), the experimental design counts 3x3=9 different experiments. For each dataset, five different weighting vectors are considered : $w_1 = (1/3, 1/3, 1/3)$, $w_2 = (3/6, 2/6, 1/6)$, $w_3 = (1/2, 1/2, 0)$, $w_4 = (2/3, 1/3, 0)$ and $w_5 = (1, 0, 0)$.

With reference to the data in Fig. 1 (corresponding to $\theta = 50$ and $n = 300$), Fig. 2 reports two of the five trees obtained: in particular, Fig. 2a shows the tree corresponding to w_1, which perfectly recreates the original partition of the predictor space; Fig. 2b corresponds to w_3 and, as expected, does not perform the two splits $X \gtreqless 4$ and $X \gtreqless 7$ (the couples of rankings below each of the split in fig. 2a do not differ for the first two positions).



(a) Decision tree with w_1 weights (b) Decision tree with w_3 weights

Fig. 2: Decision tree models for weighted rankings

5 Conclusion

In this paper, we have focused on distance-based decision trees for ranking data, when the position occupied by items is relevant. We have proposed the weighted Kemeny distance as impurity function and a relative proper weighted consensus measure to be computed in each leaf and for the whole tree. Our methodology found to be capable of identifying correctly homogeneous groups of rankings for the relevant positions (according to the weighting structure). Future developments could be an analytical study of the properties of the new consensus measure and a replication of the same analyses both with an increasing number of items and in the case of weak orderings.

A dissimilarity-based splitting criterion for CUBREMOT

Carmela Cappelli, Rosaria Simone and Francesca Di Iorio

Abstract CUBREMOT (CUB REgression MOdel Trees) is a model-based approach to grow trees for ordinal responses that relies on a class of mixture models for evaluations and preferences (CUB). The original proposal considers deviances in log-likelihood to partition observations. In the present paper a new splitting criterion is introduced that, among the significant splitting variables, chooses the one that maximizes a dissimilarity measure. This choice is tailored to generating child nodes as far apart as possible with respect to the estimated probability distributions. An application to real data on Italians' trust towards the European Parliament taken from the official survey on daily life conducted by the Italian National Institute of Statistics (ISTAT) in 2015 is presented and discussed in comparison with alternative methods.
Abstract *Nel presente lavoro viene proposto un nuovo criterio di split per la procedura* CUBREMOT *(CUB REgression MOdel Trees).* CUBREMOT *è uno strumento per crescere alberi per risposte ordinali ai cui nodi sono associati modelli mistura per le valutazioni e preferenze (modelli* CUB*) e che utilizza un criterio di split basato sulla differenza in log-verosimiglianza. Il criterio di split alternativo che viene qui introdotto utilizza invece un indice di dissimilarità per generare, attraverso lo split di un nodo padre, nodi figli che siano il più distanti possibile in termini della distribuzione di probabilità stimata. La validità dell'approccio e il confronto con altri metodi sono mostrati mediante l'applicazione a dati reali sulla fiducia verso il Parlamento Europeo sulla base dell'indagine multiscopo condotta nel 2015 dall'ISTAT.*

Department of Political Sciences, University of Naples Federico II, Via Leopoldo Rodinò, 22, 80138 Napoli, e-mail: carcappe@unina.it, e-mail: rosaria.simone@unina.it, e-mail: fdiiorio@unina.it

1 Introduction

In the spirit of the model-based partitioning approach [9], CUBREMOT [2, 3] is a tool for growing trees for ordinal responses in which every node is associated with a CUB model [4]. This approach to model preferences, judgements and perceptions is based on the idea that discrete choices arise from a psychological process that involves a personal *feeling* and an inherent *uncertainty* both possibly related to explanatory covariates.
The splitting criterion employed in CUBREMOT computes the log-likelihood increment from the father node to the child nodes for each possible split, and at the given step chooses the one that maximizes such deviance. Thus, this criterion selects the covariate that entails the most plausible values for CUB parameters in the child nodes among the variables that are significant for at least one of the model components at the father node.
We propose a further splitting criterion that focuses on the dissimilarity between child nodes, aiming at generating child nodes as far apart as possible with respect to the probability distributions estimated by CUB models. Both splitting criteria generate a model-based tree whose terminal nodes provide different profiles of respondents, which are classified into nodes according to levels of feeling and uncertainty conditional to the splitting covariates. In what follows, we briefly recall the main features of CUBREMOT, then we present the new splitting criterion and we illustrate the results of an application to data from the official survey on daily life conducted by the Italian National Institute of Statistics (ISTAT) in 2015 focusing on Italians' trust towards the European Parliament.

2 Background and Methodology

CUB models paradigm [4] designs the data generating process yielding to a discrete choice on a rating scale as the combination of a *feeling* and an *uncertainty* component. The resulting mixture prescribes a shifted Binomial distribution for feeling to account for substantial likes and agreement and assigns a discrete Uniform distribution for uncertainty to shape heterogeneity. Then, if R_i denotes the response of the i-th subject to a given item of a questionnaire,

$$Pr(R_i = r|\pi_i, \xi_i) = \pi_i \binom{m-1}{r-1} \xi_i^{m-r}(1-\xi_i)^{r-1} + (1-\pi_i)\frac{1}{m}, \quad r = 1, \dots, m,$$

where the model parameters π_i and ξ_i are called uncertainty and feeling parameter, respectively. Covariates may be included in the model in order to relate feeling and/or uncertainty to respondents' profiles. Customarily, a logit link is considered:

$$logit\,(\pi_i) = \boldsymbol{x}_i\boldsymbol{\beta}; \qquad logit\,(\xi_i) = \boldsymbol{w}_i\boldsymbol{\gamma}\,, \tag{1}$$

where $\boldsymbol{x}_i, \boldsymbol{w}_i$ are the values of selected explanatory variables for the i-th subject. If no covariate is considered neither for feeling nor for uncertainty, then $\pi_i = \pi$ and $\xi_i = \xi$ are constant among subjects. Estimation of CUB models relies on likelihood methods and on the implementation of the Expectation-Maximization (EM) algorithm.
In CUBREMOT, CUB models are employed in the top-down partitioning algorithm that grows the tree as follows. According to binary recursive partitioning, each of the available covariates is sequentially transformed into suitably splitting variables or binary questions which are Boolean condition on the value (or categories) of the covariate where the condition is either satisfied ("yes") or not satisfied ("no") by the observed value of that covariate (for details see [1]). In this respect any split s can be seen as a dummy variable.
Then, for a given node $k \geq 1$ with size n_k, a CUB without covariates is fitted, whose log-likelihood at the final ML estimates $(\hat{\pi}_k, \hat{\xi}_k)$ is denoted by $\mathscr{L}_{n_k}(\hat{\pi}_k, \hat{\xi}_k)$. Then, a CUB with splitting variable s is tested: if it is significant for at least one component, it implies a split into a left and right child nodes that will be associated with the conditional distributions $R|s = 0$ with parameter values $(\hat{\pi}_{2k}, \hat{\xi}_{2k})$ and $R|s = 1$ with parameter values $(\hat{\pi}_{2k+1}, \hat{\xi}_{2k+1})$, respectively, Thus, the splitting criterion proposed in [2, 3] at the given step chooses the split that maximizes the deviance:

$$\Delta \mathscr{L}_k = \left[\mathscr{L}_{n_{2k}}(\hat{\pi}_{2k}, \hat{\xi}_{2k}) + \mathscr{L}_{n_{2k+1}}(\hat{\pi}_{2k+1}, \hat{\xi}_{2k+1})\right] - \mathscr{L}_{n_k}(\hat{\pi}_k, \hat{\xi}_k). \tag{2}$$

Indeed, such difference measures the improvement in log-likelihood yielded by the inclusion of the significant splitting variable and the best split, being associated with the maximum log-likelihood increment, provides the child nodes characterized by the most plausible values for CUB parameters.

Here we propose an alternative splitting criterion based on the concept of dissimilarity between child nodes: the proposal considers a proper version of the normalized index proposed by [8] that compares the estimated probability distribution with the observed relative frequencies and it is generally considered in the framework of CUB models as a goodness of fit measure. Specifically, aiming at the generation of child nodes that are the farthest apart from each other in terms of distribution of the responses, in the set $\mathscr{S}_k = \{s_{k,1}, \dots, s_{k,l}\}$ of the l significant splitting variables for node k, a CUBREMOT is grown by choosing, at each step, the split maximizing the distance between the estimated CUB probability distributions $\hat{p}_{2k}$ and $\hat{p}_{2k+1}$ for the child nodes in terms of the dissimilarity measure:

$$Diss(2k, 2k+1) = \frac{1}{2}\sum_{r=1}^{m} |\hat{p}_{2k} - \hat{p}_{2k+1}|. \tag{3}$$

The choice of this normalized index entails that, as long as CUB models estimated at the child nodes provide an adequate fitting, the splitting variable generates an optimal partition of the father node in terms of the chosen distance. In particular, the resulting terminal nodes determine well-separated profiles of respondents, in terms of both feeling (agreement, preferences, and so on) and uncertainty (indecision, het-

erogeneity).
Note that, up to now, no retrospective pruning is implemented for CUBREMOT , as two natural stopping rules are available: node partitioning stops (i.e. a node is declared terminal) if either none of the available covariates is significant or the sample size is too small to support a CUB model fit.

3 Application

In order to grow a CUBREMOT using the defining splitting criterion in [2, 3], data from the yearly multiscope survey on daily life run by ISTAT in 2015 have been considered. The data set and its detailed description are available at:
www.istat.it/it/archivio/129916.
Here, the chosen response variable is *Trust in EU Parliament* (TEP for short) and it has been collected on a Likert type scale with 11 categories, ranging from 0 = 'I totally distrust it', to 10 = "I have absolute trust in it": as customarily, it has been forward shifted to the range 1-11 for CUB models fitting. For illustrative purposes, only a subset of the available covariates has been given in input to the procedure. Moreover, for the sake of saving space, the CUBREMOT growth has been stopped to three levels and only node 7 and 10 have been declared terminal according to the stopping rules defined in section 2. The tree is displayed in Figure 1, highlighting that the following covariates affect evaluations and discriminate response patterns:

1. *Political Talk* (PT), an ordinal factor with levels from 1= "On daily basis" to 6 = "Never" to assess the frequency of involvement in political talks and discussion;
2. *Economic Satisfaction* (*ES*): an ordinal factor asking interviewees to assess their satisfaction towards their wealth status within the previous 12 months, on a balanced scale with levels 1 ="Very satisfied", 2 = "Fairly Satisfied", 3 = "Little Satisfied" up to 4 = "Not at all satisfied";
3. *General Satisfaction* (*GS*): an ordinal factor asking interviewees to assess their overall life satisfaction on a rating scale ranging from levels 0 ="Not all satisfied" up to 10 = "Extremely Satisfied";
4. *Trust in Italian Parliament* (TIP): an ordinal variable asking respondents to rate their perceived trust in the Italian Parliament, collected on the same scale as the chosen response variable TEP.

For each node, the number of observations n_k, the estimated CUB parameters π and ξ, as well as the dissimilarity between the estimated CUB probabilities for the descending split (*DissB*) are reported while Figure 2 shows fitted (vertical bars) and estimated distributions at selected nodes by reporting also their dissimilarity. We might conclude that *Trust towards the Italian Parliament* plays a prominent role in the understanding and modelling of *Trust towards the European Parliament* but it interacts with the perception of economic well-being and general satisfaction as well as with the direct involvement of the respondents in political talks. In addition, having chosen the CUB paradigm as the root of the model-based approach, nodes

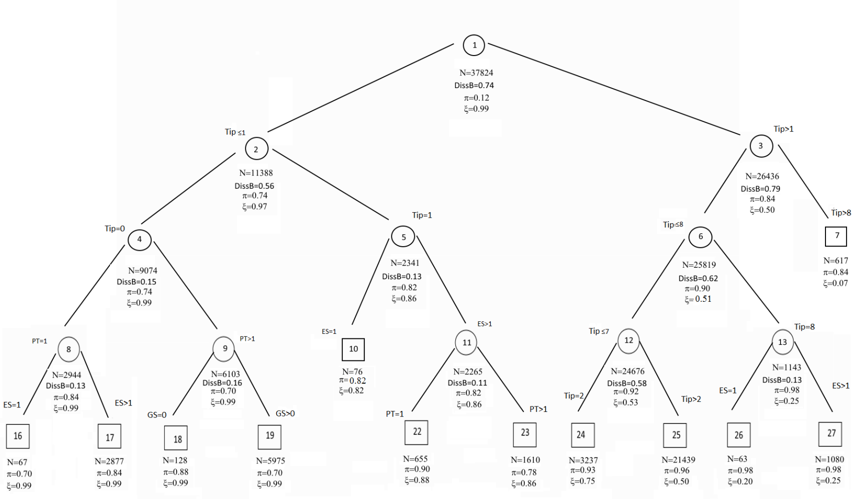

Fig. 1 CUBREMOT for *Trust for European Parliament* assuming a dissimilarity splitting rule

can be discriminated both in terms of trust (feeling) and in terms of indecision and heterogeneity of the respondents. For instance, at the first split the procedure recognizes a major difference between those with an extremely low trust towards the Italian Parliament ($TIP \leq 1$) and those giving higher evaluations: as shown by Figure 2, these two groups correspond to people with extremely low trust towards the EU Parliament and people with intermediate evaluations, respectively. From Nodes 10, 13, one derives that satisfaction for the economic status is associated, in general, with a higher trust (as measured by $1-\xi$) but also with a higher indecision (Node 16). People claiming to be always involved in political talks ($PT = 1$) are in general more resolute and homogeneous in the responses (Node 8 against Node 9) and also less trustful of the European Parliament (Node 22 against Node 23).

4 Final remarks

In a comparative perspective, a tree for the chosen response variable has been grown using the `RpartScore` package [5], which implements the work of [7] to deal with ordinal responses as an extension of the `Rpart` package. In this respect, since it is a common belief that, when the number of categories is high as in the selected case study, the response can be treated as numeric, a tree using standard `Rpart` has also been grown. In both cases, the only splitting variable able to grow the tree is TIP, no other covariate is selected even when relaxing the parameters that control the growth of the tree. On the contrary, the proposed approach allows to disclose several drivers of the responses at different levels and with different strength. Also notice that the

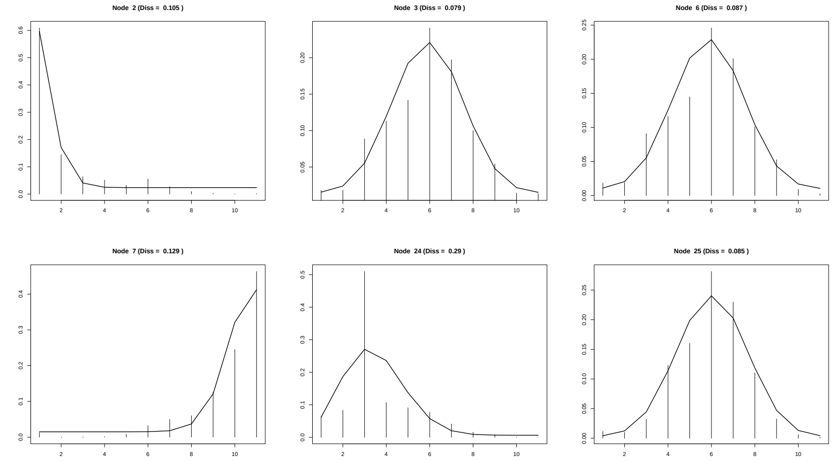

Fig. 2 Observed and fitted probability distributions at selected nodes

dissimilarity-based splitting criterion grows a different tree with respect to the log-likelihood splitting criterion but they both allow to disentangle various determinants of the response assuming specific decision rules on variable importance. Ongoing research involves a deep comparison with other tree-based methods based on simulation studies as well as the implementation of retrospective pruning while future research will be devoted to a more flexible modelling of the node distributions by considering extensions of CUB models.

Constrained Extended Plackett-Luce model for the analysis of preference rankings

Cristina Mollica and Luca Tardella

Abstract Choice behavior and preferences typically involve numerous and subjective aspects that are difficult to be identified and quantified. For this reason, their exploration is frequently conducted through the collection of ordinal evidence in the form of ranking data. Multistage ranking models, including the popular Plackett-Luce distribution (PL), rely on the assumption that the ranking process is performed sequentially, by assigning the positions from the top to the bottom one (*forward order*). A recent contribution to the ranking literature relaxed this assumption with the addition of the discrete *reference order* parameter, yielding the novel *Extended Plackett-Luce model* (EPL). In this work, we introduce the EPL with order constraints on the reference order parameter and a novel diagnostic tool to assess the adequacy of the EPL parametric specification. The usefulness of the proposal is illustrated with an application to a real dataset.

Key words: Ranking data, Plackett-Luce model, Bayesian inference, Data augmentation, Gibbs sampling, Metropolis-Hastings, model diagnostics

1 Introduction

A *ranking* $\pi = (\pi(1), \dots, \pi(K))$ of K items is a sequence where the entry $\pi(i)$ indicates the rank attributed to the i-th alternative. Data can be equivalently collected in the ordering format $\pi^{-1} = (\pi^{-1}(1), \dots, \pi^{-1}(K))$, such that the generic component $\pi^{-1}(j)$ denotes the item ranked in the j-th position. Regardless of the adopted

format, ranked observations are multivariate and, specifically, correspond to permutations of the first K integers.

The statistical literature concerning ranked data modeling and analysis is reviewed in [3] and, more recently, in [1]. Several parametric distributions on the set of permutations $\mathscr{S}_K$ have been developed and applied to real experiments. A popular parametric family is the *Plackett-Luce* model (PL), belonging to the class of the so-called *stagewise ranking models*. The basic idea is the decomposition of the ranking process into $K-1$ stages, concerning the attribution of each position according to the *forward order*, that is, the ordering of the alternatives proceeds sequentially from the most-liked to the least-liked item. The implicit forward order assumption has been relaxed by [4] in the *Extended Plackett-Luce model* (EPL). The PL extension relies on the introduction of the *reference order* parameter indicating the rank assignment order. In this work, we investigate a restricted version of the EPL with order constraints for the reference order parameter representing a meaningful rank attribution process and we also introduce a novel diagnostic to assess the adequacy of the EPL assumption as the actual sampling distribution of the observed rankings.

2 The Extended Plackett-Luce model with order constraints

2.1 Model specification

The implicit assumption in the PL scheme is the forward ranking order, meaning that at the first stage the ranker reveals the item in the first position (most-liked alternative), at the second stage she assigns the second position and so on up to the last rank (least-liked alternative). [4] suggested the extension of the PL by relaxing the canonical forward order assumption, in order to explore alternative meaningful ranking orders for the choice process and to increase the flexibility of the PL parametric family. Their proposal was realized by representing the ranking order with an additional model parameter $\rho=(\rho(1),\dots,\rho(K))$, called reference order, where the entry $\rho(t)$ indicates the rank attributed at the t-th stage of the ranking process. Thus, ρ is a discrete parameter given by a permutation of the first K integers and the composition $\eta^{-1}=\pi^{-1}\rho$ of an ordering with a reference order yields the sequence $\eta^{-1}=(\eta^{-1}(1),\dots,\eta^{-1}(K))$ which lists the items in order of selection, such that the component $\eta^{-1}(t)=\pi^{-1}(\rho(t))$ corresponds to the item chosen at stage t and receiving rank $\rho(t)$. The probability of a generic ordering under EPL can be written as

$$\mathbf{P}_{\text{EPL}}(\pi^{-1}|\rho,\underline{p})=\mathbf{P}_{\text{PL}}(\pi^{-1}\rho|\underline{p})=\prod_{t=1}^{K}\frac{p_{\pi^{-1}(\rho(t))}}{\sum_{v=t}^{K}p_{\pi^{-1}(\rho(v))}}\qquad \pi^{-1}\in\mathscr{S}_K, \tag{1}$$

Hereinafter, we will shortly refer to (1) as EPL$(\rho,\underline{p})$. The quantities p_i's are the support parameters and are proportional to the probabilities for each item to be ranked in the position indicated by the first entry of ρ.

Differently from [4], we focus on a restriction $\tilde{\mathscr{S}}_K$ of the whole permutation space S_K for the reference order parameter. Our choice can be explained by the fact that, in a preference elicitation process, not all the possible $K!$ orders seem to be equally natural, hence plausible. Often the ranker has a clearer perception about her extreme preferences (most-liked and least-liked items), rather than middle positions. In this perspective, the rank attribution process can be regarded as the result of a sequential "top-or-bottom" selection of the positions. At each stage, the ranker specifies either her best or worst choice among the available positions at that given step. With this scheme, the reference order can be equivalently represented as a binary sequence $\underline{W} = (W_1,\ldots,W_K)$ where the generic W_t component indicates whether the ranker makes a top or bottom decision at the t-th stage, with the convention that $W_K = 1$. One can then formalize the mapping from the restricted permutation ρ to $\underline{W}$ with the help of a vector of non negative integers $\underline{F} = (F_1,\ldots,F_K)$, where F_t represents the number of top positions assigned before stage t. In fact, by starting from positing by construction $F_1 = 0$, one can derive sequentially

$$W_t = I_{[\rho(t)=\rho_{\mathrm{F}}(F_t+1)]} = \begin{cases} 1 & \text{at stage } t \text{ the top preference is specified,} \\ 0 & \text{at stage } t \text{ the bottom preference is specified,} \end{cases}$$

where $I_{[E]}$ is the indicator function of the event E and $F_t = \sum_{v=1}^{t-1} W_v$ for $t = 2,...,K$. Note that, since the forward and backward orders $(\rho_{\mathrm{F}},\rho_{\mathrm{B}})$ can be regarded as the two extreme benchmarks in the sequential construction of ρ, this allows us to understand that $\rho_F(F_t+1)$ corresponds to the top position available at stage t. Conversely, $B_t = (t-1)-F_t$ is the number of bottom positions assigned before stage t and thus, symmetrically, one can understand that $\rho_B(B_t+1)$ indicates the bottom position available at stage t.

The binary representation of the reference order suggests that, under the constraints of the "top-or-bottom" scheme, the size of $\tilde{\mathscr{S}}_K$ is equal to 2^{K-1}. The reduction of the reference order space into a finite set with an exponential size, rather than with a factorial cardinality, is convenient for at least two reasons: i) it leads to a more intuitive interpretation of the support parameters, since they become proportional to the probability for each item to be ranked either in the first or in the last position and ii) it facilitates the construction of a Metropolis-Hastings (MH) step to sample the reference order parameter.

2.2 Bayesian estimation of the EPL via MCMC

Inference on the EPL and its generalization into a finite mixture framework was originally addressed from the frequentist perspective in [4]. Here we consider the original MCMC methods recently developed by [6] to solve Bayesian inference for the constrained EPL.

In the Bayesian domain, the data augmentation with the latent quantitative variables $\underline{y} = (y_{st})$ for $s = 1,\ldots,N$ and $t = 1,\ldots,K$ crucially contributes to make it tractable analytically the inference for the EPL . The auxiliary variables y_{st}'s are assumed to be conditionally independent on each other and exponentially distributed with rate parameter equal to the normalization term of the EPL, see also [5]. For the prior specification, independence of $\underline{p}$ and ρ is assumed together with independent Gamma densities for the support parameters, motivated by the conjugacy with the model, and a discrete uniform distribution on $\tilde{\mathscr{S}}_K$ for the reference order. [6] presented a tuned joint Metropolis-within-Gibbs sampling (TJM-within-GS) to perform approximate posterior inference, where the simulation of the reference order is accomplished with a MH algorithm relying on a joint proposal distribution on ρ and $\underline{p}$, whereas the posterior drawings of the latent variables y's and the support parameters are performed from the related full-conditional distributions. At the generic iteration $l+1$, the TJM-within-GS iteratively alternates the following simulation steps

$$\begin{aligned}
\rho^{(l+1)}, \underline{p}' &\sim \text{TJM}, \\
y_{st}^{(l+1)} | \pi_s^{-1}, \rho^{(l+1)}, \underline{p}' &\sim \text{Exp}\left(\sum_{i=1}^{K} \delta_{sti}^{(l+1)} p_i'\right), \\
p_i^{(l+1)} | \underline{\pi}^{-1}, \underline{y}^{(l+1)}, \rho^{(l+1)} &\sim \text{Ga}\left(c+N, d+\sum_{s=1}^{N}\sum_{t=1}^{K} \delta_{sti}^{(l+1)} y_{st}^{(l+1)}\right).
\end{aligned}$$

3 EPL diagnostic

Simulation studies confirmed the efficacy of the TJM-within-GS to recover the actual generating EPL, together with the benefits of the SM strategy to speed up the MCMC algorithm in the exploration of the posterior distribution. However, we were surprised to verify a less satisfactory performance of the TJM-within-GS in terms of posterior exploration in the application to some real-world examples, such as the famous `song` dataset analyzed by [2]. Since the joint proposal distribution relies on summary statistics, the posterior sampling procedure is expected to work well as long as the data are actually taken from an EPL distribution. So, the unexpectedly bad behavior of the MCMC suggested to conjecture that, for such real data, the EPL does not represent the true (or in any case an appropriate) data generating mechanism. This has motivated us to the develop some new tools to appropriately check the model mis-specification issue.

Suppose we have some data simulated from an EPL model. We expect the marginal frequencies of the items at the first stage to be ranked according to the order of the corresponding support parameter component. On the other hand, although computationally demanding to be evaluated in terms of their closed form formula we expect the marginal frequencies of the items at the last stage to be ranked according to the reverse order of the corresponding support parameter component. After proving such a statement one can then derive that the ranking of the marginal frequencies of the items corresponding to the first and last stage should sum up to

$(K+1)$, no matter what their support is. Of course, this is less likely to happen when the sample size is small or when the support parameters are not so different of each other. In any case, one can define a test statistic by considering, for each couple of integers (j,j') candidate to represent the first and the last stage ranks, namely $\rho(1)$ and $\rho(K)$, a discrepancy measure $T_{jj'}(\pi)$ between $K+1$ and the sum of the rankings of the frequencies corresponding to the same item extracted in the first and in the last stage. Formally, let $\underline{r}_j^{[1]} = (r_{j1}^{[1]},\dots,r_{jK}^{[1]})$ and $\underline{r}_{j'}^{[K]} = (r_{j'1}^{[K]},\dots,r_{j'K}^{[K]})$ be the marginal item frequency distributions for the j-th and j'-th positions, to be assigned respectively at the first [1] and last [K] stage. In other words, the generic entry $r_{ji}^{[s]}$ is the number of times that item i is ranked j-th at the s-th stage. The proposed EPL diagnostic relies on the following discrepancy

$$T_{jj'}(\pi) = \sum_{i=1}^{K} |(\text{rank}(\underline{r}_j^{[1]})_i + \text{rank}(\underline{r}_{j'}^{[K]})_i - (K+1))|,$$

implying that the smaller the test statistics, the larger the plausibility that the two integers (j,j') represent the first and the last components of the reference order. To globally assess the conformity of the sample with the EPL, we consider the minimum value of $T_{jj'}(\pi)$ over all the possible rank pairs satisfying the order constraints

$$T(\pi) = \min_{(j,j')\in\mathscr{P}} T_{jj'}(\pi), \tag{2}$$

where $\mathscr{P} = \{(j,j') : j \in \{1,K\} \text{ and } j \neq j'\}$.

3.1 Applications to real data

We fit the EPL with reference order constraints to the `sport` dataset of the `Rankcluster` package, where N=130 students at the University of Illinois were asked to rank K=7 sports in order of preference: 1=Baseball, 2=Football, 3=Basketball, 4=Tennis, 5=Cycling, 6=Swimming and 7=Jogging. We estimated the Bayesian EPL with hyperparameter setting $c = d = 1$, by running the TJM-within-GS for 20000 iterations and discarding the first 2000 samplings as burn-in phase. We show the approximation of the posterior distribution on the reference order in Figure 1, where it is apparent that the MCMC is mixing sufficiently fast and there is some uncertainty on the underlying reference order. The modal reference order is (7,1,2,3,4,6,5), with slightly more than 0.4 posterior probability. However, when we compared the plausibility of the observed diagnostic statistic with the reference distribution under the fitted EPL, we got a warning with a bootstrap classical p-value approximately equal to 0.011. This should indeed cast some doubt on the use of PL or EPL as a suitable model for the entire dataset. In fact, we have verified that, after suitably splitting the dataset into two groups according to the EPL mixture methodology suggested by [4] (best fitting 2-component EPL mixture

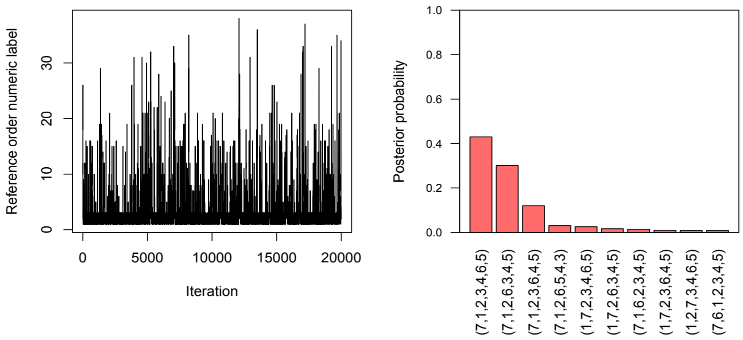

Fig. 1: Traceplot (left) and top-10 posterior probabilities (right) for the reference order parameter.

with BIC=2131.20), we have a different more comfortable perspective for using the EPL distribution to separately model the two clusters. The modal reference orders are (1,2,3,4,5,6,7) and (1,2,3,7,4,5,6) and the estimated Borda orderings are (7,6,4,5,3,1,2) and (1,2,3,4,6,7,5), indicating opposite preferences in the two subsamples towards team and individual sports. In this case, no warning by the diagnostic tests applied separately to the two subsamples is obtained, since the resulting p-values are 0.991 and 0.677.

4 Conclusions

We have addressed some relevant issues in modelling choice behavior and preferences. In particular, we have further explored the idea in [4] related to the use of the reference order specifying the order of the ranks sequentially assigned by introducing monotonicity restrictions on the discrete parameter to describe a "top-or-bottom" attribution of the positions. Our contribution allows to gain more insights on the sequential mechanism of formation of preferences, whether or not it is appropriate at all and whether it privileges a more or less natural ordered assignment of the most extreme ranks. Additionally, some issues experienced when implementing a well-mixing MCMC approximation motivated us to derive a diagnostic tool to test the appropriateness of the EPL distribution, whose effectiveness has been checked with an application to a real example.

A prototype for the analysis of time use in Italy
Un prototipo di analisi sull'uso del tempo in Italia

Stefania Capecchi and Manuela Michelini

Abstract Our study focuses on a sub-sample of the Italian time use survey, where respondents are asked to evaluate to what extent each moment of the day is enjoyable. A mixture model framework is implemented to highlight the main components of the data generating process by which interviewees express their point subjective well-being (BESP) towards daily activities. A prototypical proposal is presented to understand interactions between individual evaluation of each activity and subjects' covariates.

Abstract *Lo studio approfondisce i risultati dell'Indagine sull'uso del tempo per un sottoinsieme di rispondenti individuando un modello mistura per la valutaizone espressa dagli intervistati in merito al "Benessere Soggettivivo Puntuale" (BESP). Il prototipo di analisi qui proposto consente di stimare l'effetto congiunto sulle risposte della natura dell'attività svolta e delle caratteristiche dei soggetti anche in termini di eterogeneità.*

Keywords: Time use survey, Point subjective well-being, Mixture models

1 Introduction

Our study aims to investigate people's moods and feelings towards daily activities, stemming from a sub-sample of the Italian time use survey, where respondents are asked to evaluate to what extent each moment of the day is enjoyable, the so-called *Point subjective well-being* (BESP). The following question is considered: "Is this

Stefania Capecchi

a pleasant moment?", taking into account the specific activity and the context. Preliminary results are provided exploiting a model to explicitly take into account both feeling and heterogeneity in response patterns and their relationships with activities and subjects' characteristics.

The paper is organized as follows: in the next Section the survey design is briefly sketched; rationale for the prototype model-based approach are presented in Section 3; main results are interpreted in Section 4. Final considerations conclude the work.

2 Main survey features

Time use studies are an important section of current surveys in several contexts [4, 11, 10]. In Italy, time use survey is carried out five-yearly by Istat (the Italian National Institute of Statistics) as a part of an integrated system of social surveys, the Multipurpose Surveys on Households. Referred to the resident population in private households, it is a large sample survey (about $19,000$ families and $45,000$ individuals aged more than 11 years) whose core aim is to learn about the way each respondent allocates her/his time. Interviewees are asked to fill in a daily journal (24 hours, divided into 144 intervals, 10 minutes each), specifying their activities in detail [7]. The survey covers all daily life aspects which, in this study, have been clustered in 10 main activities: *personal care; job, education; houseworking; caregiving; social life; sport and leisure; games and hobbies; TV, radio and reading; travel*. In the following, reference is made to 2014 survey.

Exploratory results provide measures on the amount of time people use to spend in various daily activities on an average day of the year. In 2014 the average day of the population in Italy was as follows: 48.7% of 24 hours was dedicated to personal care (sleeping, eating, and so on), 8.8% to paid work, 3.6 % to study, 12.6% to houseworking, 21% to free time and 5.2% to travel (see [7] for more details).

For the first time, the 2014 survey measures the level of enjoyment associated with daily activities, rating the feeling on a scale from -3 to $+3$, with -3 meaning "not enjoyable at all" and $+3$ "very enjoyable". Work and study turn out to be the least pleasant activities where leisure time is the most enjoyable one, although the rate is decreasing with age. Cultural activities, sports and outdoor leisure, social life, considered as a whole, made the day much more enjoyable.

In fact, individual, activity-related, and temporal dimensions should be jointly considered in a comprehensive model and this study explores such detailed information in order to propose a first probabilistic approach to examine survey results. Given the experimental nature of the proposal, a random sub-sample of 894 adult subjects is considered (aged over 20) and the activities are classified according to the above mentioned 10 groups. Then, individual characteristics as gender, age, education level, marital status, presence of children, number of household members and self-assessed economic condition, are registered. Finally, the day is considered as a working one or a public holiday.

3 Modelling framework for the affective component

A possible approach considers observed data on BESP as the realization of a process by which respondents choose ordinal ratings to denote perceived well-being when involved in each activity. These sequences of affective assessments are the results of a complex interaction of subjective, environmental and time-dependent circumstances. Then, as a first instance, it seems interesting to compute the probability of each rating as a function of the activity itself as well as of the individual characteristics by taking the ordinal structure of responses into account. As a matter of fact, for each i-th subject, a sub-sample of 12 responses –one per hour, out of 144 responses, picked in the time interval from $08:00$ a.m. to $08:00$ p.m. – has been selected. Thus, time effect and serial correlation are partially removed and (almost) conditional independence may be assumed.

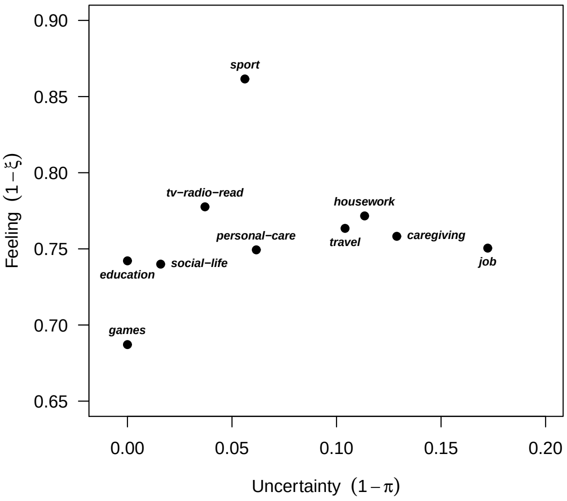

Fig. 1 Estimated models of the expressed enjoyment for different activities

A class of mixture models is applied to parameterize both *feeling* and *indecision/heterogeneity* components in the response pattern [8, 3, 9]; more extensive discussions of the approach –also in different contexts– are in [2, 1]. In particular, the parameters may be easily related to subjects' covariates and to the performed activity. By assuming conditional independence, all the observations may be considered as a whole. These models are estimated and checked by an R package available on the CRAN repository [6] and the visualization of the estimated distributions is an effective added value of the approach.

From a formal point of view, original response R_i^* are transformed into $R_i = R_i^* + 4$ in order to get the first $m = 7$ integers as support. Then, responses are linked to W_i subjects' covariates and A_k activities, for $i = 1,\dots,n$ and $k = 1,\dots,K$ by means of a logistic function.

Thanks to this structure, it is possible to visualize and compare the enjoyment declared by the sampled subjects in performing different activities in terms of both feeling and heterogeneity as in Figure 1. Sports and leisure are the most appreciated activities whereas games and hobbies get the lowest level of feeling. Other mandatory activities, such as those of caregiving and housework, travel and job (the latter with a comparatively higher level of heterogeneity) receive appreciation. In fact, heterogeneity in response patterns is very limited and feeling may be considered as the prominent component in this case study.

4 A more complex modelling structure

A more complex model implies that responses are considered as jointly conditional to the type of activity performed and subjects' characteristics. Thus, the basic model is:

$$Pr\left(R_i = r \mid W_i, A_{i,k}\right) = \pi\, b_r(\xi_{i,k}) + (1-\pi)\,\frac{1}{m}\,, \quad r = 1,2,\dots,m\,, \tag{1}$$

where $b_r(\xi_{i,k})$ is a shifted Binomial distribution, for $i = 1,2,\dots,n$ and

$$logit(1-\xi_{i,k}) = \gamma_0 + \sum_{j=1}^{J} \gamma_j\, w_{i,j} + \sum_{h=1}^{H} \delta_h A_{i,h}\,,$$

Here, the dummy $A_{i,k} = 1$ if the i-th subject is performing the k-th activity in the selected sequences of responses. Then, the comparison between log-likelihoods of nested models (computed at maxima) solves in a likelihood ratio test (LRT) to infer on the significance of the covariates and/or the activities.

Table 1 Log-likelihoods and *LRT* of different models

Models	*Log-likelihood*	*LRT*	*g*
Benchmark	−17196.91		
Activity dummies	−17120.62	152.58	5
Subjects' covariates	−17018.59	356.64	7
Omnibus	−16959.35	475.12	11

Summarizing several intermediate steps, Table 1 reports such investigations and compares a benchmark model (a crude model of all the responses without covariates) with respect to: i) a model including only activities coded as dummies; ii) a model with only subjects' covariates and their possible interactions, if significant; iii) a comprehensive (*omnibus*) model where both subjective variables and activities dummies are considered. LRTs are shown with their degrees of freedom (*g*) and all of them are highly significant.

From the model including only activities (here non reported for brevity), it turns out that :

- Activities gathered in the constant (that is: *personal care –mainly, meals–; job; education; caregiving; social life*) exert the prevailing effect on the responses;
- watching tv, listening to the radio and reading have positive effects on well-being;
- houseworking and sport activities positively affect response pattern;
- quite moderate is the role of mobility;
- playing games and hobbies have an adverse effect.

Although the consideration of activities significantly improves log-likelihood, the role of subjects' covariates is comparatively by far more relevant if considering LRT. Then, the joint specification of these explanatory components implies an *omnibus model* implemented with all the significant covariates, that is:

$$\begin{cases} 1-\hat{\pi} &= \underset{(0.006)}{0.107} \\ logit(1-\hat{\xi}_i) &= \underset{(0.045)}{0.838} + \underset{(0.027)}{0.080} Act1_i + \underset{(0.076)}{0.713} Act2_i - \underset{(0.144)}{0.350} Act3_i + \underset{(0.060)}{0.119} Act4_i \\ & \quad + \underset{(0.029)}{0.109} Act5_i + \underset{(0.035)}{0.191} Gender_i + \underset{(0.035)}{0.146} Married_i \\ & \quad + \underset{(0.044)}{0.272} Holiday_i - \underset{(0.002)}{0.013} Education_i + \underset{(0.009)}{0.070} Components_i \\ & \quad - \underset{(0.045)}{0.213} Gender_i \times Married_i, \ + \underset{(0.057)}{0.134} Married_i \times Holiday_i \end{cases}$$

Here, significant activities are denoted as: `Act1` (*houseworking*), `Act2` (*sport and leisure*), `Act3` (*games and hobbies*), `Act4` (*Tv, radio and reading*), `Act5` (*mobility*); as a consequence, the impact on the constant derives from all the other activities, `Act0` (*personal care; job; education; caregiving; social life*). Thus, *ceteris paribus* with subjects' covariates, the impact on the enjoyment of the activities may be estimated as follows: `Act0`= 0.838; `Act1`= 0.919; `Act2`= 1.552; `Act3`= 0.489; `Act4`= 0.957; `Act5`= 0.947. It is confirmed that the largest and smallest contributions to enjoyment are given by *sport and leisure* and *games and hobbies*, respectively. Notice that holiday significantly impacts on the response with an additional $+0.272$ and a significant positive interaction with married people, estimated as 0.134.

The subjects' characterization influences the positive responses with respect to women, married people and household's components. Gender and marital status interact on the responses so that the final impact, *ceteris paribus*, is zero and 0.191 for unmarried men and women, respectively, and 0.146 and 0.124 for married men and women, respectively. Then, generally speaking, married women express lower enjoyment in their activities.

5 Concluding remarks

Time use survey is considered strategic for the knowledge of the population's lifetime as it allows to detect everyday life organization in society and in families. Moreover, distributions of affective states, expressed through specific tasks and duties evaluation, provide valuable information on people's moods, in general and across different activities. When clustering population groups and specific activities, such an investigation may offer important complements to other measures of well-being.

According to these perspectives, to address and evaluate policy interventions, even in the fields of work-life balance and sustainability, the proposed modelling prototype is suitable to give useful insights to establish priority hierarchies at both individual and aggregated level. Thus, further research should be pursued to exploit the dynamic content of the expressed enjoyment during day as related to different activities. This objective might be achieved by generalizing the proposed models and including both longitudinal aspects and switching expressed modalities.

New Perspectives in Supervised and Unsupervised Classification

Robust Updating Classification Rule with applications in Food Authenticity Studies

Robust Updating Classification Rule con applicazioni a studi di autenticità degli alimenti

Andrea Cappozzo, Francesca Greselin and Thomas Brendan Murphy

Abstract In food authenticity studies the central concern is the detection of products that are not what they claim to be. Here, we introduce robustness in a semi-supervised classification rule, to identify non-authentic sub-samples. The approach is based on discriminating observations with the lowest contributions to the overall likelihood, following the *impartial trimming* established technique. Experiments on real data, artificially adulterated, are provided to underline the benefits of the proposed method.

Abstract *Negli studi di autenticità degli alimenti risulta cruciale saper riconoscere prodotti contraffatti. In questo paper si adotta un approccio robusto per modificare una regola di classificazione semi-supervised e poter quindi identificare potenziali adulterazioni. L'approccio basato sulla selezione delle osservazioni che danno minore contributo alla verosimiglianza globale, seguendo tecniche ben note di impartial trimming. Esperimenti su dati reali, artificialmente adulterati, evidenziano l'efficacia del metodo proposto.*

worthy learning data are employed to build a decision rule. However, in a context in which the final aim is to detect potentially adulterated samples, also the learning data may be unreliable and thus it can strongly damage the classifier performance [9]. Especially if the training size is small, mislabelled data in the learning phase can be detrimental for the decision phase. The aforementioned problem is known as “label noise” and it is not new in the statistical learning literature: a discussion was already reported in [11]. We refer the reader to [3] for a review of related work on this topic.

Considering the aforementioned issues in dealing with food data, the present work introduces a robust semi-supervised model-based classification method. The methodology arises as a modification of the framework first developed in [4], here endowed with robust techniques. The rest of the manuscript is organized as follows: in Section 2 the proposed Robust Updating Classification Rule is introduced and an EM algorithm for parameter estimation is detailed in Section 3. Section 4 describes the data reduction procedure for the spectra of raw homogenized meat samples; the proposed method is then applied to a scenario with adulterated labels and benchmark results are considered. The paper concludes with some considerations for future research.

2 Robust Updating Classification Rule

The aim of the proposed method is to construct a model where possibly adulterated observations are correctly classified as such, whilst preventing them to bias parameter estimation. To account for useful information about group heterogeneity that may be contained also in the unlabelled samples, we adopt a semi-supervised approach. This methodology was originally developed in [4], the present work employs functional PCA [14] for data reduction and incorporates robust estimation for outlier detection, with the specific role of identifying the adulterated samples. Our conjecture is that the illegal subsample is revealed by selecting observations with the lowest contributions to the overall likelihood, and that impartial trimming [7] prevents their bad influence on parameter estimation for authentic samples. The updating classification rule is modified for providing reliable estimates even when there are mislabelled samples in the training data. Additionally, given the semi-supervised nature of the methodology, outlying observations in the test data can also be discarded in the estimation procedure.

Denote the labelled data by x_n; $n = 1,\dots,N$, and their associated label variables l_{ng}, $g = 1\dots G$ and $n = 1,\dots N$ where $l_{ng} = 1$ if observation n comes from group g and $l_{ng} = 0$ otherwise. Likewise, denote the unlabelled data by y_m, $m = 1,\dots,M$ and their associated unknown labels z_{mg}, $g = 1\dots G$ and $m = 1,\dots M$. Both labelled and unlabelled data are p-dimensional. We construct a procedure for maximizing the *trimmed observed-data likelihood*:

$$L_{trim}(\pi,\theta|\boldsymbol{x}_N,\boldsymbol{l}_N,\boldsymbol{y}_M)=\prod_{n=1}^{N}\left[\prod_{g=1}^{G}(\pi_g f(x_n|\theta_g))^{l_{ng}}\right]^{\zeta(x_n)}\prod_{m=1}^{M}\left[\sum_{g=1}^{G}\pi_g f(y_m|\theta_g)\right]^{\eta(y_m)} \tag{1}$$

where π_g denotes the vector of mixing proportions, θ_g represent the parameters of the gth mixture component and $\zeta(\cdot)$, $\eta(\cdot)$ are 0-1 trimming indicator functions, that tell us whether observation x_n and y_m are trimmed off or not. A fixed fraction α_l and α_u of observations, respectively belonging to the labelled and unlabelled data, is unassigned by setting $\sum_{n=1}^{N}\zeta(x_n)=\lceil N(1-\alpha_l)\rceil$ and $\sum_{m=1}^{M}\eta(y_m)=\lceil M(1-\alpha_u)\rceil$. The less plausible observations, under the currently estimated model, are therefore tentatively trimmed out at each iteration that leads to the final estimate. α_l and α_u represent the *trimming level* for the *training* and *test* set, respectively, accounting for possible adulteration in both datasets. In our approach a final value of $\zeta(x_n)=0$, as well as $\eta(y_m)=0$, corresponds to identify x_n and y_m, respectively, as illegal observations. We consider the case in which $f(\cdot|\theta_g)$ indicates the multivariate normal density distribution, where $\theta_g=(\mu_g,\Sigma_g)$ respectively denotes the mean vector and the covariance matrix in the G mixture components. For performing the maximization of (1), an EM algorithm [5] is employed and different constraints on the eigenvalue decomposition of the covariance matrices are considered for parsimony [1]. In addition, the singularity issues that may be introduced in the case of heteroscedastic covariance matrices (i.e., with volume and/or shape free to vary across components) are avoided considering a restriction on the eigenvalues on the matrices Σ_g. Particularly, we fix a constant $c\geq 1$ such that

$$M_n/m_n\leq c \tag{2}$$

where $M_n=\max_{g=1\ldots G}\max_{j=1\ldots p}\lambda_j(\Sigma_g)$ and $m_n=\min_{g=1\ldots G}\min_{j=1\ldots p}\lambda_j(\Sigma_g)$, $\lambda_j(\Sigma_g)$ being the eigenvalues of the matrix Σ_g. Such restriction leads to a well-defined maximization problem [8].

3 The EM algorithm

The EM algorithm for implementing the robust updating classification rule involves the following steps:

- *Initialization:* set $k=0$. Find starting values by using model-based discriminant analysis. That is, find $\hat{\pi}^{(0)}$ and $\hat{\theta}^{(0)}$ using only the labelled data through standard approaches, such as *mclust* routines [6]. If the selected model allows for heteroscedastic Σ_g and (2) is not satisfied, the constrained maximization is also applied, see [8] for details.
- *EM Iterations:* Denote by $\hat{\theta}^{(k)}$ the parameters at the current iteration of the algorithm.
  - *Step 1 - Concentration*: after computing the quantities $D_g(y_m,\hat{\theta}^{(k)})=\hat{\pi}_g^{(k)}f(y_m|\hat{\theta}_g^{(k)})$, the trimming procedure is implemented by discarding the $\lceil N\alpha_l\rceil$ observations x_n with smaller values of

$$D(x_n|\hat{\theta}^{(k)}) = \sum_{g=1}^{G} f(x_n|\hat{\theta}_g^{(k)})^{l_{ng}} \quad n = 1,\dots,N$$

and discarding the $\lceil M\alpha_u \rceil$ observations y_m with smaller values of

$$D(y_m|\hat{\theta}^{(k)}) = \max\{D_1(y_m|\hat{\theta}^{(k)}),\dots,D_G(y_m|\hat{\theta}^{(k)})\} \quad m = 1,\dots,M$$

- *Step 2 - Expectation*: for each non-trimmed observation y_m the posterior probabilities

  $$\hat{z}_{mg}^{(k+1)} = \frac{D_g(y_m|\hat{\theta}^{(k)})}{\sum_{t=1}^{G} D_t(y_m|\hat{\theta}^{(k)})} \text{ for } g = 1\dots G \text{ and } m = 1,\dots M$$

  are computed.
- *Step 3 - Constrained Maximization*: the parameters are updated, based on the non-discarded observations and their cluster assignments:

  $$\hat{\pi}_g^{(k+1)} = \frac{\sum_{n=1}^{N}\zeta(x_n)l_{ng} + \sum_{m=1}^{M}\eta(y_m)\hat{z}_{mg}^{(k+1)}}{\lceil N(1-\alpha_l)\rceil + \lceil M(1-\alpha_u)\rceil} \quad \text{for } g = 1\dots G$$

  $$\hat{\mu}_g^{(k+1)} = \frac{\sum_{n=1}^{N}\zeta(x_n)l_{ng}x_n + \sum_{m=1}^{M}\eta(y_m)\hat{z}_{mg}^{(k+1)}y_m}{\sum_{n=1}^{N}\zeta(x_n)l_{ng} + \sum_{m=1}^{M}\eta(y_m)\hat{z}_{mg}^{(k+1)}} \quad \text{for } g = 1\dots G$$

  The estimation of the variance covariance matrices depends on the considered constraints on the eigenvalue decomposition [1].
  If $\lambda_j\left(\hat{\Sigma}_g^{(k+1)}\right)$, $g = 1\dots G$, $j = 1\dots p$ do not satisfy (2) the constrained maximization described in [8] must be applied.
- *Step 4 - Convergence of the EM algorithm*: the Aitken acceleration estimate of the final converged maximized log-likelihood is used to determine convergence of the EM algorithm [2]. If convergence has not been reached, set $k = k+1$ and repeat steps 1-4.

The final estimated values $\hat{z}_{mg}$ provide a classification for the unlabelled observations y_m, assigning observation m into group g if $\hat{z}_{mg} > \hat{z}_{mg'}$ for all $g' \neq g$. Final values of $\zeta(x_n) = 0$, and $\eta(y_m) = 0$, classify x_n and y_m respectively, as illegal observations.

4 Meat samples: classification results in presence of adulteration

The algorithm described in Section 3 is employed in performing classification for the meat dataset [10]. This dataset reports the electromagnetic spectrum from a total of 231 homogenized meat samples, recorded from 400-2498 *nm* at intervals of 2 *nm*. Figure 1 reports the spectra for each meat type, measured as the amount of light reflected by the sample at a given wavelength.

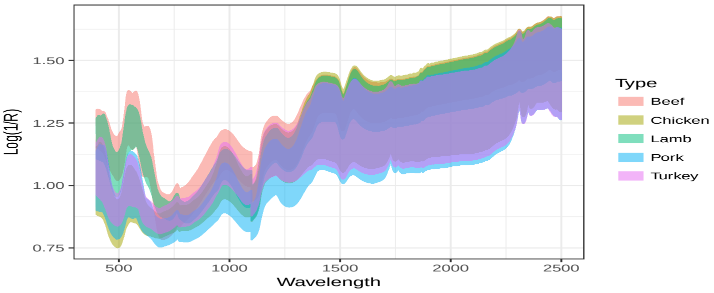

Fig. 1 Functional representation of the NIR spectra of five homogenized meat types, meat dataset

To reduce the dimension of the data using a functional data analysis approach, we perform functional Principal Component Analysis (fPCA) and retain the first 15 scores vectors. Details on the employed procedure can be found in [14].

The robust updating classification rule is employed for classifying the meat samples. To do so, we divided the data into a training sample and a test sample. We investigated the effect of different proportions for the data in terms of classification accuracy. Particularly, 3 split proportions have been considered: 50% - 50% , 25% - 75% and 10% - 90% for training and test set, respectively, within each meat group. Additionally, for each split a 8% of pork observations in the training set were wrongly labelled as beef, for artificially creating an adulteration scenario. Results confronting the misclassification rate for the original [4] and robust updating classification rule are reported in Table 1.

Table 1 Average correct classification rates for the unlabelled five meat groups (after data reduction by using fPCA) for 50 random splits in training and test data, employing robust and non-robust updating classification rule. Standard deviations are reported in parentheses. Results on the original dataset (without adulteration) are reported in the rightmost columns, for a comparison.

	Adulterated Dataset		Original Dataset	
	Upclassify	Robust Upclassify	Upclassify	Robust Upclassify
50% Tr - 50% Te	84.42 (4.49)	91.51 (3.89)	91.20 (3.11)	95.39 (1.74)
25% Tr - 75% Te	79.55 (4.29)	93.55 (1.30)	85.75 (3.80)	93.63 (4.74)
10% Tr - 90% Te	66.37 (8.64)	86.97 (11.87)	78.59 (5.04)	87.24 (6.99)

The average misclassification rates reported in Table 1 highlight the improvement in employing the robust version of the method, whenever noise labels are present in the training set. To compare results between robust and non-robust method, the trimmed observations were classified a-posteriori according to the Bayes rule, and assigned to the component g having greater value of $D_g(y_m, \hat{\theta}) = \hat{\pi}_g f(y_m|\hat{\theta}_g)$. As expected, the negative effect due to mislabelling increases when the training sample size is small. Labelled and unlabelled trimming levels were set equal to 0.1 and 0.05 respectively for the Robust Upclassify method. Interestingly, on average, higher classification rates are obtained for the 25% - 75% training test split: the robust methodology perfectly identified the mislabelled units in each of the 50 splits. For the 50% - 50% and 10% - 90% case the robust method detected on average respectively 85% and 88% of the mislabelled units. According to Mclust nomenclature, the EEE and the VVE models were almost always chosen in each scenario: model selection was performed through *trimmed BIC* [13]. As a last worthy note, in Table 1 we underline the positive impact in terms of classification rate of a small proportion of impartial trimming ($\alpha_l = \alpha_u = 0.05$) also in the case of an unadulterated training sample, fostering the employment of the robust version of the algorithm.

Further research directions will consider the integration of a wrapper approach for variable selection, along the lines of [12], and the adoption of robust mixtures of factor analyzers for jointly performing classification and dimensionality reduction.

A robust clustering procedure with unknown number of clusters

Una procedura di cluster analysis robusta con un numero di cluster incognito

Francesco Dotto and Alessio Farcomeni

Abstract A new methodology for robust clustering without specifying in advance the underlying number of Gaussian clusters is proposed. The procedure is based on iteratively trimming, assessing the goodness of fit, and reweighting. The forward version of our procedure is initialized with a high trimming level and $K = 1$ populations. The procedure is then iterated throughout a fixed sequence of decreasing trimming levels. New observations are added at each step and, whenever a goodness of fit rule is not satisfied, the number of components K is increased. A stopping rule prevents our procedure from using outlying observations. Additional use of a backward criterion is discussed.

Abstract *In questo lavoro viene introdotta una metodologia per la cluster analysis robusta che non richiede la specificazione a priori del numero di cluster gaussiani. La procedura si basa, iterativamente, sul trimming, la valutazione della bontà di adattamento ed il reweighting. La sua versione forward viene inizializzata fissando un livello di trimming alto e $K = 1$ popolazioni sottostanti. In seguito la procedura viene iterata all'interno di una griglia fissata di livelli trimming decrescenti. Ad ogni passo vengono reinserite osservazioni e, laddove l'adattamento peggiori sostanzialmente, il numero di componenti K viene aumentato. Una regola di arresto garantisce che valori anomali non vengano usati per stimare i parametri. Si discute infine un criterio aggiuntivo di tipo backward.*

1 Introduction

Model based clustering procedures for multivariate data can be inconsistent in presence of contamination. A trimming step is often used to guarantee robustness. Impartial trimming is based on discarding a fixed proportion α of observations lying far from their closest centroid. A detailed review of robust clustering may be found in part II of [7]. The procedure of [10] is based on pre-specifying α and the number of clusters K. Simultaneously fixing the tuning parameters is still an open problem. First, it shall be noticed that the two parameters are clearly intertwined. Indeed the optimal α depends on the chosen K and also the *vice versa* holds. We propose here to use iterative reweighting to obtain robust cluster analysis without having to specify in advance these two tuning parameters. Our approach is related to the forward search philosophy (e.g., [1]), but with substantial differences. The rest of the paper is as follows. In Section 2.1 we briefly review the `tclust` methodology and its reweighted version. Our new proposal for robust clustering is presented in Section 3 while its application to real data example is provided in Subsection 3.2. Finally Section 4 contains the concluding remarks and the further directions of research.

2 Trimming approach to cluster analysis and its reweighted version

2.1 The `tclust` methodology

Within this subsection we briefly present the `tclust` methodology, [10], whose `R` implementation is presented in [9] and its reweighted version introduced in [4]. Let $x_i \in \mathbb{R}^p$ be a sample point, $f(\cdot)$ the multivariate normal density, μ_j and Σ_j be location and scatter parameters, respectively, of the j-th group. Additionally let $g_{\psi_i}(\cdot)$ be the contaminating density and K the number of groups. Then the likelihood function associated to the spurious outliers model is given by:

$$\left[\prod_{j=1}^{K}\prod_{i\in R_j} f(x_i;\mu_j;\Sigma_j)\right]\left[\prod_{i\notin R_j} g_{\psi_i}(x_i)\right] \tag{1}$$

Additionally it must be pointed out that, in equation (1), $R = \bigcup_{j=1}^{K} R_j$ represents the set of the clean observations and is such that $\#R = \lceil n(1-\alpha)\rceil$ and only the clean data give a contribution to the likelihood function, while, noise component, whose likelihood is given by the right hand side of equation (1) give no contribution to the likelihood function. The maximum likelihood estimator of (1) exists if and only if the following condition on the contaminating density holds:

$$\arg\max_{\mathscr{R}} \max_{\mu_j,\Sigma_j} \prod_{j=1}^{k} \prod_{i \in R_j} f(x_i;\mu_j,\Sigma_j) \subseteq \arg\max_{\mathscr{R}} \prod_{i \notin \cup_{j=1}^{k} R_j} g_{\psi}(x_i) \tag{2}$$

As pointed out in [5], condition (2) states that identification of clean observations by maximization of the right hand term of (2) identifies the same observations as would identification of contaminated observations by maximizing the part of the likelihood corresponding to the noise. Thus, once clean observations are identified by maximizing the right hand term of (2), then the contaminated entries are optimally identified.
Additionally, if the condition (2) holds, the MLE of the likelihood function (1) has a simple representation and its maximization reduces to the maximization of:

$$\sum_{j=1}^{K} \sum_{i \in R_j} \log f(x_i;\mu_j,\Sigma_j) \tag{3}$$

2.2 The `tclust` without specifying α in advance

We now focus our attention to two tuning parameters, that are required to be fixed by the user in order to appy the `tclust` methodology: the trimming level α and the number of clusters K. In [4] is introduced a contribution, known as reweighted `tclust` or `rtclust` for the sake of brevity, designed to avoid the specification of the trimming level α. The idea behind such contribution is starting with a high trimming level α_0 the `tclust`, for which efficient computing is possible ([9]). Once the procedure is initialized, L decreasing trimming levels $\alpha_1 > \alpha_2 > \ldots > \alpha_L$ are fixed; then the `rtclust` algorithm proceeds, for each $l = 1, 2 \ldots, L$, as follows:

1. *Initialization:* Set the initial parameters' set $\pi_1^0,...,\pi_k^0,\pi_{k+1}^0$, $\mu_1^0,...,\mu_k^0$ and $\Sigma_1^0,...,\Sigma_k^0$ obtained by applying the `tclust` with a high trimming level α_0.
2. *Reweighting process:* Consider $\alpha_l = \alpha_0 - l \cdot \varepsilon$ with $\varepsilon = (\alpha_L - \alpha_0)/L$ for $l = 1,...,L$

2.1 *Fill the clusters:* Given $\pi_1^{l-1},...,\pi_k^{l-1},\pi_{k+1}^{l-1}$, $\mu_1^{l-1},...,\mu_k^{l-1}$ and $\Sigma_1^{l-1},...,\Sigma_k^{l-1}$ from the previous step, let us consider

$$D_i = \min_{1 \le j \le k} d^2_{\Sigma_j^{l-1}}(x_i, \mu_j^{l-1}) \tag{4}$$

and sort these values as $D_{(1)} \le ... \le D_{(n)}$. Take the sets

$$A = \{x_i : D_i \le D_{([n(1-\alpha_l)])}\} \text{ and } B = \{x_i : D_i \le \chi^2_{p,\alpha_L}\}$$

Now, use the distances in (4) to obtain a partition $A \cap B = \{H_1,...,H_k\}$ with

$$H_j = \left\{ x_i \in A \cap B \;:\; d_{\Sigma_j^{l-1}}(x_i, \mu_j^{l-1}) = \min_{q=1,\dots,k} d_{\Sigma_q^{l-1}}(x_i, \mu_q^{l-1}) \right\}.$$

2.2 *Update cluster weights* The proportion of contamination is estimated by computing

$$\pi_{k+1}^l = 1 - \frac{\#B}{n}.$$

Given $n_j = \#H_j$ and $n_0 = n_1 + ... + n_k$ the cluster weights are estimated by computing:

$$\pi_j^l = \frac{n_j}{n_0}\left(1 - \pi_{k+1}^l\right). \tag{5}$$

2.3 *Update locations and scatters:* Update the cluster centers by taking μ_j^l equal the sample mean of the observations in H_j and the scatter by computing the sample covariance matrix of the observations in H_j multiplied by its consistency factor.

3. *Output of the algorithm:* $\mu_1^L,...,\mu_k^L$ and $\Sigma_1^L,...,\Sigma_k^L$ are the final parameters estimates for the normal components. From them, final assignments are done by computing

$$D_i = \min_{1 \le j \le k} d^2_{\Sigma_j^L}(x_i, \mu_j^L),$$

for $i = 1,...,n$. Observations assigned to cluster j are those in H_j with

$$H_j = \left\{ x_i : d_{\Sigma_j^L}(x_i, \mu_j^L) = \min_{q=1,\dots,k} d_{\Sigma_q^L}(x_i, \mu_q^L) \text{ and } D_i \le \chi^2_{p,\alpha_L} \right\}$$

and the trimmed observations are observations not assigned to any of these H_j sets (i.e., those observations with $D_i > \chi^2_{p,\alpha_L}$).

There are, in our opinion, two great advantages in using `rtclust`. First, as shown in th simulation study and the theoretical properties reported in [4], high robustness with high efficiency can be reached at the same time. Secondly no much tuning is required. Indeed the final estimated contamination level is independent to the initial trimming α_0 and the assumptions on constraint on the eigenvalues can be relaxed after the initialization. It shall be noticed that, besides the required number of groups K - to which are dedicated the further sections of the paper - the parameter α_L my need tuning too. Such parameter establishes how far the outliers are supposed to be placed with respect to the bulk of the data. Such choice is pretty subjective and strongly depends on the context of application only heuristics. We only recall the guidelines provided in [2] for generally tuning in robust statistics and the contribution provided in [6] where an example of the tuning of the parameter α_L is provided.

3 The `tclust` without specifying α and K in advance

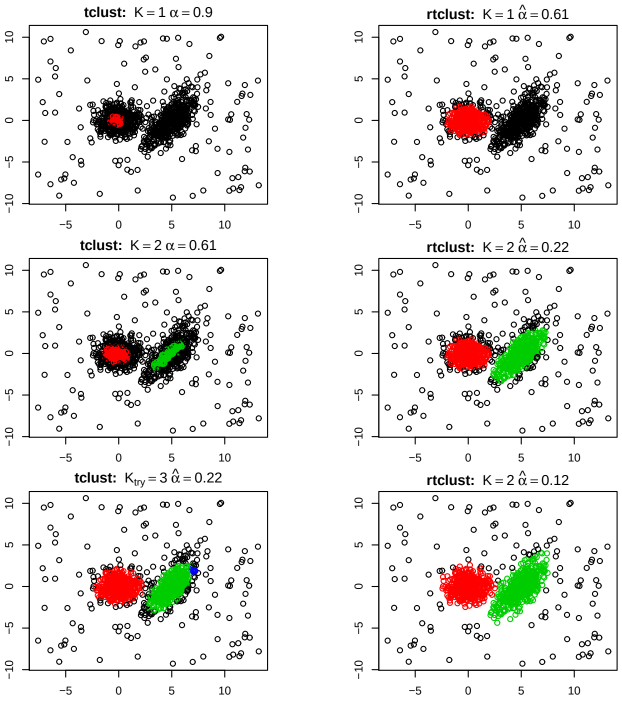
3.1 Introduction

We now outline an automatic methodology based on reweighting that does not need the imposition of the desired number of groups by the user. We do so by applying the reweighting logic to both reinsert the wrongly discarded observations and increase the number of groups, if required. To do so, we resort the forward search philosophy outlined in [1]. In practice, we start by applying the `tclust` method with $K = 1$ and $\alpha = .9$ imposed. Then, we apply the reweighting approach outlined in [4] to estimate the true contamination level $\hat{\varepsilon}$ given $K = 1$ population. Once we can rely on a "precise" estimate of the contamination level we try to increase number of groups imposing $K_{try} = K + 1$ and a trimming level equal to $\hat{\varepsilon}$. The goodness of fit of this new proposed model is evaluated by computing the proportion of observations that are flagged as outlying in the new proposed model that were not flagged as outlying at the previous step. The underlying idea is the following. If a considerably high proportion of observations initially considered clean at the previous step, are recognized as outlying in the current step as a higher number of underlying groups is imposed, the this means that a high dense region of points (a potential cluster) has been trimmed off in the previous step. Algorithmically speaking we alternate the `tclust` and the `rtclust` up to convergence within the steps described in Algorithm 1. A graphical counterpart is provided in Figure 1.

Algorithm 1

```
   Initialization:
1. Fix: $K_0 = 1, \alpha_0 = .9$ and $\rho \in [0.01, 0.05]$
2. Let $mod_{rew}$ be the output of rtclust with $K_0$ and $\alpha_0$ imposed
   Update:
3. Take $\hat{\varepsilon}$ estimated by the model $mod_{rew}$ and set $K_{try} = K + 1$.
4. Launch the tclust with $\alpha = \hat{\varepsilon}$ and $K = K_{try}$ imposed.
5. Take $\pi_{new}$: the proportion of observations flagged as outlying by $mod_{try}$.
   Stopping rule:
6. If $\pi_{new} \leq \rho$ then stop. Else, if $\pi_{new} > \rho$:
   • $K = K + 1$
   • Calculate $mod_{rew}$ by launching rtclust with K imposed.
   • Repeat steps 3-6.
   Final output:
7. Return the output of $mod_{rew}$ as the final output of the algorithm.
```

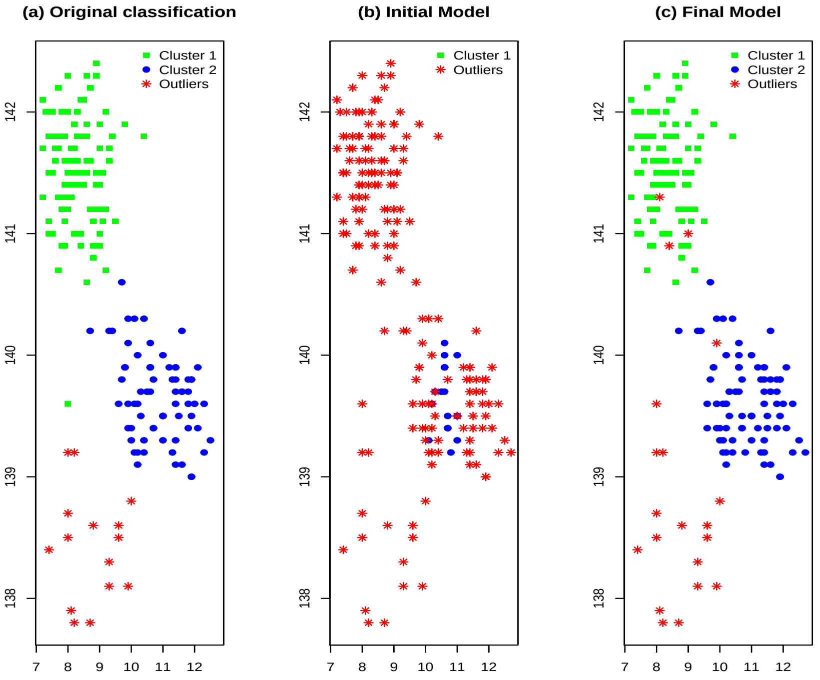
Fig. 1 The application of Algorithm 1 to a 2- dimensional simulated composed by $K = 2$ clusters and a proportion of contaminating points equal to 0.10.



3.2 A real data application

In this Section we apply the proposed iterative reweighting approach to the 6-dimensional "Swiss Bank Notes" data set presented in [8] which describes certain features of 200 Swiss 1000-franc bank notes divided in two groups: 100 genuine and 100 counterfeit notes. This is a well known benchmark data set. In [8], it is pointed out that the group of forged bills is not homogeneous since 15 observations arise from a different pattern and are, for that reason, outliers. As stated in Algorithm 1 we start by imposing a trimming level $\alpha_0 = .9$ and $K = 1$ clusters. The obtained results, that are briefly summarized in Figure 2, are in substantial agreement with characteristics described in [8]. Indeed $K = 2$ are automatically estimated by the algorithm while the estimated proportion of outliers is slightly overestimated: 10% of outliers are recognized by the algorithm while in [8] the declared percentage of outliers is equal to 7.5%.

Fig. 2 Fourth against the sixth variable of the Swiss Bank Notes data set. (a) The original classification. (b) The initial classification obtained by imposing $K = 1$ and $\alpha_0 = .9$. (c) The final output of Algorithm 1



4 Concluding Remarks

We outlined a robust procedure for clustering data that does not need the specification in advance of the required number of groups and of the proportion of outlying observations. We are aware of the fact that, as pointed out in [11], *There are no unique objective "true" or "best" clusters in a dataset. Clustering requires that the researchers define what kind of clusters they are looking for.* In conclusion, as pointed out in [3], we do not think that a fully automatized way to fix simultaneously all the parameters is to be expected. Indeed, the outlined methodology can be viewed as an additional tool to be combined with researchers' specification and a priori informations to provide a better understanding of the phenomenon of interest.

Issues in joint dimension reduction and clustering methods

Metodi congiunti di riduzione della dimensionalità e classificazione automatica: alcuni aspetti applicativi

Michel van de Velden, Alfonso Iodice D'Enza and Angelos Markos

Abstract Joint data reduction (JDR) methods consist of a combination of well established unsupervised techniques such as dimension reduction and clustering. Distance-based clustering of high dimensional data sets can be problematic because of the well-known curse of dimensionality. To tackle this issue, practitioners use a principal component method first, in order to reduce dimensionality of the data, and then apply a clustering procedure on the obtained factor scores. JDR methods have proven to outperform such sequential (tandem) approaches, both in case of continuous and categorical data sets. Over time, several JDR methods followed by extensions, generalizations and modifications have been proposed, appraised both theoretically and empirically by researchers. Some aspects, however, are still worth further investigation, such as *i*) the presence of mixed continuous and categorical variables; *ii*) outliers undermining the identification of the clustering structure. In this paper, we propose a JDR method for mixed data: the method in question is built upon existing continuous-only and categorical-only JDR methods. Also, we appraise the sensitivity of theproposed method to the presence of outliers.

Abstract *Abstract in Italian* I metodi congiunti di sintesi dei dati (Joint data reduction, JDR) rappresentano una combinazione di approcci di analisi non supervisionata quali tecniche fattoriali e classificazione automatica. La classificazione automatica, quando basata sulla distanza tra le osservazioni, diventa di difficile applicazione quando queste siano descritte da un elevato numero di variabili, a causa della *maledizione della dimensionalità*. Per aggirare tale problema, è pratica comune ridurre la dimensionalità dei dati utilizzando tecniche fattoriali, e applicare successi-

vamente la classificazione automatica sui fattori ottenuti in precedenza. In letteratura è stato dimostrato empiricamente che a tale approccio sequenziale è preferibile utilizzare dei metodi JDR. Il filone di ricerca sui metodi JDR comprende varianti, generalizzazioni e confronti teorici ed empirici tra i diversi metodi proposti. Tuttavia, alcuni aspetti applicativi non sono ancora stati oggetto di studio: in particolare, si fa riferimento ai casi di dataset che contengano sia variabili quantitative che qualitative, e alla presenza di valori anomali. L'obiettivo del presente contributo è quello di presentare un metodo di JDR che sia applicabile ad insiemi di dati di tipo misto. Inoltre, si vuole valutare la robustezza delle soluzioni ottenute in presenza di valori anomali.

Key words: Dimension reduction, cluster analysis, mixed data sets

1 Joint dimension reduction and clustering methods

Distance-based clustering methods aim at defining groups such that observations that belong to the same group are similar to each other. The distance or dissimilarity measure being used depends on the nature of the considered variables. When the set of observations is described by a large number of variables, it becomes difficult to calculate meaningful pair-wise dissimilarities and, hence, to define clusters. To overcome this problem, methods that combine dimension reduction with cluster analysis have been proposed.

The most straightforward approach is to apply dimension reduction prior to clustering, the latter being therefore applied to the scores obtained in the first step. In this two-step approach, however, two different criteria are optimized: in particular, while dimension reduction aims at defining a reduced set of combinations of the original variables that maximize the original variability, cluster analysis aims at maximize the between-groups variability. This may lead to the cluster masking problem (e.g., van Buuren and Heiser, 1989; De Soete and Carroll, 1994; Vichi and Kiers, 2001) and several solutions have been proposed that proposed a combined optimization of the two steps. We refer to this class of methods as joint data reduction (JDR).

Methods for JDR have been proposed that deal with continuous and categorical data. In particular, for continuous (or, interval) data we consider reduced K-means (De Soete and Carroll, 1994), factorial K-means (Vichi and Kiers, 2001) as well as a compromise version of these two methods. For categorical data, cluster correspondence analysis (van de Velden et al, 2017), which, for the analysis of categorical data, is equivalent to GROUPALS (van Buuren and Heiser, 1989), multiple correspondence analysis and K-means (MCA K-means; Hwang et al, 2006), and iterative factorial clustering of binary variables (i-FCB; Iodice D'Enza and Palumbo, 2013) are considered.

2 Clustering mixed data

Data sets with observations being described by both continuous and categorical variables are common in real applications. Since most clustering procedures are designed to deal with variables on a same scale, a simple strategy is to homogenize the variables in a pre-processing phase. That is, either re-coding the continuous variables or the categorical ones. Recoding of continuous variables is achieved via discretization, the range of each continuous variable is split into a set of intervals, and all the values falling in a same interval are labeled with a same category. Of course, such kind of discretization leads to a loss of the original information. To overcome this issue, an alternative transformation through discretization is to code the original values of a continuous variable into a pre-specified number of fuzzy categories, i.e. to a set of k nonnegative values that sum to 1, quantifying the *possibility* of the variable to be in each category. These *pseudo-categorical* values represent each value of a continuous variable uniquely and exactly, i.e. the numerical information of the original variable is preserved (Aşan and Greenacre, 2011). Recoding of categorical data variables aims to put them on the same scale as the continuous. A rather general pre-processing and standardization approach is described in Mirkin (2012). Another approach, described by Everitt et al (2011), consists of clustering the data by type of variable, and then merge the obtained clustering solutions; the obvious drawback of this approach is that any relation between the two sets of variables is ignored.

A more direct approach is to use a dissimilarity measure designed for mixed data. The most popular one is Gower's dissimilarity coefficient, which takes into account the different nature of the variables (e.g., see Everitt et al (2011)). Once pairwise distances are obtained, a clustering procedure such as partitioning around medoids (PAM) can be applied on the distance matrix. Further partitioning methods for mixed data consist of extensions of K-means: examples are the K-prototypes (Huang, 1998), and the K-means Modha-Spangler weighting (Modha and Spangler, 2003), among others. In all of these approaches, assigning weights to variables is a sensitive task.

Probabilistic or model-based clustering is also a very popular way of clustering mixed-type data. Such methods typically assume the observations to follow a normal-multinomial finite mixture model and proved to be effective when the parametric assumptions are met. In this paper, however, we focus on distance-based clustering approaches.

3 JDR for mixed data

Let $\mathbf{X}$ denote a centered and standardized $n \times Q$ data matrix,, $\mathbf{B}$ is a $Q \times d$ columnwise orthonormal loadings matrix, i.e. $\mathbf{B}'\mathbf{B} = \mathbf{I}_d$, where d is the user supplied dimensionality of the reduced space. Furthermore, $\mathbf{Z}_K$ is the $n \times K$ binary matrix indicating cluster memberships of the n observations into the K clusters. Finally, we use $\mathbf{G}$ to

denote the $K \times d$ cluster centroid matrix.
A JDR method for continuous data is reduced K-means clustering (RKM) De Soete and Carroll (1994): both the dimension reduction and cluster analysis aim at maximizing the *between* variance of the clusters in the reduced space. The RKM objective function is

$$\min \phi_{\text{RKM}}\left(\mathbf{B}, \mathbf{Z}_K, \mathbf{G}\right) = \left\|\mathbf{X} - \mathbf{Z}_K \mathbf{G}\mathbf{B}'\right\|^2, \tag{1}$$

where $\|\cdot\|$ denotes the Frobenius norm. It can be shown, that the above minimization problem is equivalent to

$$\max \phi'_{\text{RKM}}(\mathbf{Z}_K, \mathbf{B}) = trace \mathbf{B}'\mathbf{X}'\mathbf{P}\mathbf{X}\mathbf{B} \tag{2}$$

Similar to RKM is cluster CA, a JDR method for categorical data: CCA aim is also to maximize the between cluster variation in reduced space. Let $\mathbf{Z} = [\mathbf{Z}_1, \ldots, \mathbf{Z}_p]$ be the superindicator matrix of dummy coded categorical data and $\mathbf{M}$ the corresponding centering operator. The objective of cluster CA can be expressed as

$$\max \phi_{\text{clusca}}(\mathbf{Z}_K, \mathbf{B}) = trace \mathbf{B}'\mathbf{Z}'\mathbf{M}\mathbf{P}\mathbf{M}\mathbf{Z}\mathbf{B} \quad \text{s.t.} \quad \frac{1}{np}\mathbf{B}^{'}\mathbf{D}_z\mathbf{B} = \mathbf{I}_k. \tag{3}$$

subject to

Comparing this equation to (2), we see that the methods are closely related. Furthermore, letting $\mathbf{B}^* = \frac{1}{\sqrt{np}}\mathbf{D}_z^{1/2}\mathbf{B}$ it is possible to re-write the clusterCA optimization problem as

$$\min \phi_{\text{CCA}}\left(\mathbf{B}^*, \mathbf{Z}_K, \mathbf{G}\right) = \left\|\mathbf{D}_z^{-1/2}\mathbf{M}\mathbf{Z} - \mathbf{Z}_K\mathbf{G}\mathbf{B}^{*\prime}\right\|^2, \tag{4}$$

subject to

$$\mathbf{B}^{*\prime}\mathbf{B}^* = \mathbf{I}_k$$

which is closely related to the RKM problem in Equation 1, and therefore the two equations can be combined to define the problem for mixed data. In particular from Equations (1) and (4) we can formulate as objective for a joint analysis of mixed data:

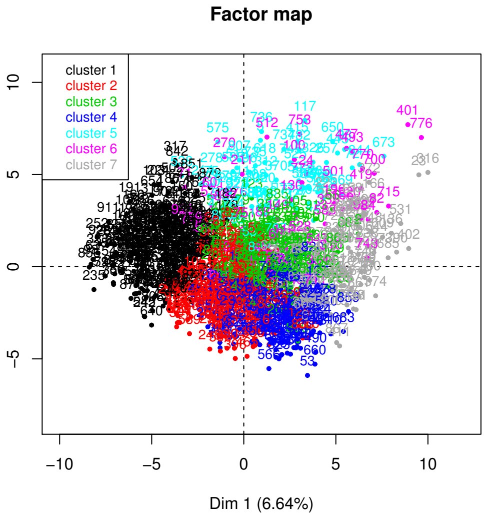
$$\min \phi_{\text{mixed RKM}}\left(\tilde{\mathbf{B}}, \mathbf{Z}_K, \mathbf{G}\right) = \left\|\left(\mathbf{X} \quad \mathbf{D}_z^{-1/2}\mathbf{M}\mathbf{Z}\right) - \mathbf{Z}_K\mathbf{G}\tilde{\mathbf{B}}'\right\|^2, \tag{5}$$

where $\tilde{\mathbf{B}}' = [\mathbf{B}_1' \quad \mathbf{B}_2']$ and $\tilde{\mathbf{B}}'\tilde{\mathbf{B}} = \mathbf{I}_d$.
In a similar way, it is possible to combine FKM with clusterCA and define a further JDR method for mixed data.

4 Clustering patients with low back pain

In this section, we illustrate Mixed RKM on a real dataset. The dataset was part of a clustering challenge connected with the International Federation of Classification

Fig. 1 Mixed RKM factorial map of the patients on the first and second dimension. Clusters are indicated with different colours.



Societies (IFCS) 2017 conference. It contains baseline and outcome assessment of low back pain in 928 adult patients who were consulting chiropractors in Denmark. The clustering aim is to find a (semi-) automatic classification of the patients based on 112 pain history and work-related variables, in order to find clinically applicable and useful groups. 38 of the variables were treated as continuous and 84 as categorical. The data set along with associated meta-data and variable descriptions, can be downloaded at http://ifcs.boku.ac.at/repository/challenge2/.

Missing data were imputed using the regularised iterative FAMD algorithm (Audigier et al, 2016). Mixed RKM was then applied on the imputed dataset. The number of dimensions, 5, was determined on the basis of both empirical and statistical criteria. Solutions between 3 and 12 clusters were investigated. Average Silhouette Width and the Calinski-Harabasz index were used to assess cluster separation. A solution with 7 clusters was selected. Figure 1 depicts the object (patient) scores on the first and second dimension. The seven clusters are indicated with different colours. The description of each cluster in terms of the variables involved in clustering as well as a set of external (outcome) variables was perfomed using the function `catdes()` (package `FactoMineR` Lê et al (2008)). All clusters were significantly associated with external (outcome) variables, which provides evidence for external validity.

Cluster 1 (8.7%): acute suffering LBP, psychological effects of pain, mild improvement after 12m.

Cluster 2 (13.5%): acute suffering LBP, reduced activity, little time in pain, major improvement after 12m.

Cluster 3 (5.2%): leg pain only, showed mild improvement after 12m.
Cluster 4 (9.2%): acute suffering LBP, pain attributed to work, higher bmi, mild improvement after 12m.
Cluster 5 (16.4%): acute suffering LBP, age higher than average, reduced physical activity, little improvement after 12m.
Cluster 6 (12.2%): mild LBP intensity, age less than average, no psychological effects, major improvement after 12m.
Cluster 7 (34.6%): low LBP intensity, major improvement.
Finally, the application of mixed RKM to simulated mixed data, with and without presence of outliers, showed promising results both in terms of effectiveness in cluster structure identification and robustness to outliers.

New Sources, Data Integration and Measurement Challenges for Estimates on Labour Market Dynamics

The development of the Italian Labour register: principles, issues and perspectives

Il registro del Lavoro in Italia: caratteristiche principali e prospettive

C. Baldi, C. Ceccarelli, S. Gigante, S. Pacini

Abstract The ongoing construction of a Labour Register is greatly enhancing the labour statistics either due to the production of output directly or by constituting a coordination framework able to provide a much greater coherence to the entire system for labour statistics. The setting up of such a register in Italy is extremely challenging since it is based on a plurality of administrative sources.
Some pillars of the register: the construction of a set of classifications and coding rules to convert administrative standards into statistical classifications; the definition of the main statistical unit of the register, the job position; the set of measures on labour input to fulfil either directly or indirectly a variety of statistical needs.
Abstract *Il registro tematico del Lavoro, nell'ambito del nuovo sistema integrato dei Registri Istat, sarà il perno delle statistiche sul mercato del lavoro. Una delle sfide principali è legata alla molteplicità di fonti che devono essere integrate per garantire la copertura desiderata in termini di unità e variabili. I pilastri fondamentali del registro di seguito descritti sono: la costruzione di un sistema di metadati per passare da informazioni amministrative a statistiche; la definizione dell'unità base del registro, la posizione lavorativa; un set di misure dell'input di lavoro per soddisfare, direttamente o indirettamente, una serie di output statistici.*

Key words: register, job position, labour statistics, labour input measures, metadata

1 The centrality of labour statistics in the system

Labour indicators occupy a very central place in the statistical system. At the intersection between social and business statistics, employment figures on one side represent the level of participation of individuals in the productive system of a society and the basis for the wellbeing of individuals, households and society as a whole; on the other side they represent the labour input for the production processes of the system of economic units and a factor that drives economic growth. In the same way, given their dual nature (ILO, (1973)), wages represent at the same time the main component of labour cost for the employers and the earning for the employee, the main, or sole, component of personal income for a large share of the population.

Given their importance, in the European statistical system a number of regulations and agreements deals with labour indicators[1]. Employment related figures are also fundamental for the Population Census and some social surveys (LFS, Eu-Silc).

Up to very recently, most national statistical systems organized the production of the above indicators according the classical stove-pipe model, with independent processes, mostly based on traditional surveys with an increasing role of administrative registers. This model has shown several limitations in term of production costs, a large and growing burden on respondents, and various levels and types of inconsistencies among similar indicators. The very attempts of reconciliation have been a post-production exercise usually directed to explain the coarsest discrepancies, still leaving a fragmentation of information in which the users can get easily lost.

The need of releasing integrated instead of disjoint indicators and improving the efficiency of the production processes, in a context of rapid growth of demand of statistical information, is as key points of the strategy of the European Statistical System for the next decade (ESS, (2014)).

Italy is facing this challenge placing at the basis of the production process a system of registers, micro level databases, originated mainly from administrative sources that cover the whole population of statistical units (UNECE, (2017)). In the context of labour statistics, the foundation of the measurement process will be the Labour Register (hereinafter LR). With a complex and rich structure of information, it aims to be the basis for most

[1] Among the labour statistics, beside the household based quarterly Labour Force Survey (LFS), on the business side there are the four yearly Labour Cost and Structure of Earning Surveys, the quarterly Labour Cost Index and Job Vacancy statistics. Moreover, regulations on the business register, structural and short-term business statistics, contain indicators of employment, hours worked, wages, social contributions and labour costs. In the same vein, these variables are central in the National Accounts.

labour market indicators and analysis, requested by international regulations and national needs, either directly using its information for the output, or indirectly, coupled with surveys, to estimate variables not present in it or that do not perfectly fit the statistical definitions.

To be able to accomplish the task of coordinating the entire system of labour statistics and, at the same time, fulfilling the standards required by different regulations and needs, the register, whose main characteristics are describes in § 2, requires at least three main foundations explored in what follows. First a system of metadata, regularly maintained, able to map the administrative information into a variety of statistical classifications (§ 3). Second a multiplicity of statistical units in order to fulfil either the Business or the Social statistics together with precise rules to pass from one to another maintaining the coherence of information (§ 4). Finally a system of measures for the main variables to accommodate different needs (§ 5).

2 The Italian Labour Register: main characteristics

The LR, in the new Integrated System of Registers, is a thematic framework on jobs and their measures in term of labour input, labour cost and income due to work.

The architecture of the LR is based on the main following principles.

Comprehensiveness and completeness. The scope of the register is to cover all regular jobs active in the national territory in all sectors of economic activity, either private or public. Both dependent and independent paid jobs are included. It aims to cover also unpaid work position such as volunteer positions, and positions of persons in training. As for the variables, considering the available sources of information, it contains a number of measures of labour input, working and paid time, wages, social contributions, gross and net income received by each person.

Granularity. Since the register aims to be as flexible as possible to satisfy a variety of needs, it contains information at the maximum level of detail available in the input sources in terms of units, variables and time references. Units and variables will be explored more in detail in § 4 and 3. Here it is important to note that, depending on the variables, there are measures available referred to each day, week, month or year.

Longitudinality. The different statistical units have to be followed over time with rules that defines the continuity. The unit defined in §4 permits to track the relationship between an employer and an employee since its inception and, over time, to construct the working career of each worker within and across employers and status of employment. The longitudinal structure will allow to disentangle, in econometric studies, specific employee from specific employer effects.

Integrability. The register is strictly linked on one hand to the Population Register, through the person ID, and on the other to the Economic Units Registers through the unit ID, with the obvious advantage of matching a lot more information. Moreover, also the Income Register is strictly related. More precisely, they have to be jointly built in order to have measures of labour income, and its components, usable in different conceptual frameworks (from the Camberra group document on statistics on income to the LCS and SNA regulations). The system will also permit to integrate information on samples from households and business surveys.

Extended usability. This infrastructure will be used for a number of scopes: from the construction of standard macro statistical indicators, as mentioned in § 5, to the evaluation of labour policies and the releases of longitudinal microdata standard files for the researchers.

In order to fulfil the previous principles, and in particular to guarantee the coverage of the units and the availability of target variables, a number of different administrative sources have to be integrated. The backbone of the system are the Social Security Institute (INPS) sources, among them the UniEmens declaration[1] is one of the most important. Moreover, the tax declarations, especially those submitted by the economic units for their workers (the new CU declaration) are necessary to guarantee the coverage of both units and variables. In particular the CU, besides checks, is needed to ensure the coverage of not dependent jobs under a threshold of income, and to ensure for variables related to taxation and net income.

One of the main task is to check all this sources and establish the rules to integrate them.

3 A metadata system to bridge administrative and statistical reality

Different regulations requires different classifications and different variables. For instance, although related concepts, wages and salaries as required by LCS and ESA regulations and earnings from the SES regulation have different definitions. One of these differences is related to the payments from the employer to the employee in the face of sickness, maternity,

[1] The UniEmens declaration is referred to the private and public dependent jobs and different information for different subpopulations of workers may be available. Moreover, other sources have to be integrated to cover in particular self-employed workers or worker assimilated to employees such as collaborators.

accidents etc.., which are excluded from the wages and salaries because they are defined imputed social contributions while are included in earnings. Another example regards the classification of work relationships and persons employed in status of employment types of classification. The most representative case is that of project workers that are classified as self-employed in the context of NA, outworkers with respect to the economic units they work for in the BR and dependent contractors, within the more general category of employees, in the incoming ICSE 2018.

This implies that in order the Register may satisfy the different statistical needs a complex system of metadata that maps the administrative information to the different statistical standards has to be built and maintained. This operations requires three main steps: a) a recognition of all the statistical requirements to produce an output metadata system; b) the collection of the metadata of various input sources and their integration in a input metadata system that represent the fiscal-social security reality in a unified way; c) the mapping of the input metadata into the output one. The ideal solution should be to pinpoint the atomic statistical items that can be combined in different ways to get to different definitions. After that an evaluation of which of these tiles are available in the administrative data or may be calculated or estimated, also through other administrative and statistical sources, is needed to map the two information. With reference to the imputed social contribution represented by the payments for sickness, maternity and so at the expense of the employer the Italian social security data have no sufficient details to easily estimate them: right now they are imputed according to the information collected by register-based surveys (in particular the Labour Cost Survey).

4 The statistical units

In order to satisfy the variety of needs stemming from the social and economic studies, the LR will allow analysis based on three main statistical units: the individual, the economic unit, and the job position. This last one, very specific of this register, is the position involving one or two subjects to perform a labour activity.

The job position is defined as the work relationship established between an economic unit and an individual and defined by a starting date. An important attribute of the job position is the ending date, which will be lacking up to the moment of the cessation of the relationship.

In the context of dependent (or assimilated) employment, this statistical unit corresponds to the employment contract between an employer and an employee where the starting date is the date of activation of the contract and the ending date its cessation. Moreover, each job position is characterized by a wealth of other attributes such as the type of contract, the working time, the occupational qualification, the workplace, etc..[1]

The rationale for defining this statistical unit in this way is multiple.

First, it is the basis for analysis of all labour market policies that have an impact on the definition of contracts or formation of new ones. Second, being the natural link with the Compulsory communication (Cc) unit, it is the basis of the extension of the register to the information contained in this source especially useful for short-term estimates of employment dynamic (Rapiti et al,(2018))). Third, the duration of the job position is an essential policy parameter as it makes possible to better evaluate the fragmentation of the employment careers with all its implications. All in all, this statistical unit permits a very rich stock-flow accounting connecting on one side levels of employment, gross and net changes and on the other workers and jobs. Fourth, the business based labour statistics measure parameters referred to job position.

The passage from a statistical unit to another is governed by a set of rules. For instance to characterize, in a given period - say a year, an employee in terms of the type of contract or type of working time it is needed to decide which statistical rules to apply when an employee has had more than one position in the year.

The multiplicity of statistical units and these rules allows to provide alternative representations of the same or related phenomena projected on populations of different units. For instance, in conjunction with the metadata, it permits to analyse the relationships between the inequality of price of labour, defined at the level of job position, to the inequality of earnings among individuals. Moreover, it allows to switch from measures that make sense only for some units (the wages can be defined both at enterprises and at job level) to other that makes sense only for another unit (the income which is related to the individual level).

In the following, some figures are provided to assess the cardinality of the LR in terms of different statistical units. In the year 2015 (Table 1), the segment of the LR referred to the dependent employment in the private sector, is composed of 1.6 millions of enterprises, 14 millions of employees that generate 17.5 millions of job positions.

Table 1: Universe of the dependent jobs in the private sector. Year 2015

[1] Since some of these attributes can change within the duration of a job, the labour register will also allow analysis on another statistical unit, the sub-positions, that is the temporal portion of the job homogeneous for a number of these attributes, type of working time, type of contract, and occupational qualification. This might be very important to evaluate the contract transformations e.g. from fixed term to permanent, that do not constitute an interruption of the same position.

UNITS	*MEASURES*
Employers	1,573,529
Employees	14,004,534
Couples employers / employees	16,075,725
Job positions	17,495,470
Sub-positions	18,752,967

5 The measures of labour input

Different metrics of labour input are necessary to serve different statistical scopes (Table 2). As for dependent jobs, a set of measures are related to the formal activity of each job. The number of jobs formally active in specific dates, along with those activated and closed in an interval, provides the necessary data for the stock-flow accounting that is the number of days each contract has been formally active during a period (e.g. a year). A natural extension of these measures is the average number of formally active job positions in an interval where the average is calculated using as weights the number of days of formal duration in the interval. Those measures are important also because they are the the same used within the Cc system, with the important value added that the LR provides not only the magnitude of the gross and net job flows but also the level of the job stocks.

However, the formal duration of the job may provide wrong signals if one is interested in the effective work input especially for some types of contracts (e.g. job on call). In fact in traditional business statistics and the NA the measure used to calculate the average number of jobs is one where each job is weighted with a quantity that expresses the effective activity (such as the number of days for which the job has been covered by social contributions). Compared with the former measure it reduces dramatically the weights of the contracts such as the jobs on call and, at the same time, corrects the importance of those cases, that might be affected by errors in the dates of activations and cessations.

Besides the measures of jobs stocks and flows, either pointwise or over intervals, the register provides variables to evaluate the time paid by the employer and time worked. The number of hours paid, used primarily as denominator of wages to capture the effective price of labour (e.g. the wage rates), reduces the weight of part-time workers and excludes from the computation the time paid by the social security for events of sicknesses, maternity, accidents, short time allowances etc… Moreover, the time for paid overtime is accounted for. Finally, the number of hours worked, excluding the time spent on holidays and time in the above events paid by the employer, provides the foremost metric to measure the labour input, and as such, is used as denominator in important indicators (e.g. hourly labour cost, labour productivity).

Table 2: Different concepts and measures in the universe of the dependent jobs in the private sector. Year 2015

Concepts	*Measures*
Number of distinct job position active for at least one day in the period	17,495,470
Average number of effectively active Job positions (based on days covered by contributions)	11,381,696
Average number of formally active Job positions (based on days covered by contract)	12,018,315
Number of job position formally active in a determined date e.g. January 1st	11,231,636
Number of jobs activated (activations) in an interval e.g. the first 6 months of the year	3,281,377
Number of jobs terminated (cessations) in an interval e.g. the first 6 months of the year	1,107,739

DIGGING INTO LABOUR MARKET DYNAMICS: TOWARD A RECONCILIATION OF STOCK AND FLOWS SHORT TERM INDICATORS[*]

F. Rapiti, C. Baldi, D. Ichim, F. Pintaldi, M. E. Pontecorvo, R. Rizzi

Abstract

The recent availability of short-term job flows from Compulsory Communication (Cc) administrative database has increased the publicly disseminated information. While creating opportunities for a deeper labour market understanding, job flows measures might also generate misleading interpretations, especially when compared with stocks statistics. To address this issue and to fill data gaps, the Italian National Institute of Statistics (Istat) promoted an Agreement among Istat, Inps, Ministry of Labour and social policy, Inail and Anpal to produce harmonised, complementary and coherent statistics with three specific outputs: a quarterly joint press release, an annual report and a labour market statistical information system. The main challenge is to reconcile flows and stock data deriving from administrative and statistical sources. This paper illustrates the statistical treatment applied to the Cc database to achieve a better comparability with official statistics used in the quarterly joint press release disseminated since December 2016.

Sintesi

APPROFONDENDO LA DINAMICA DEL MERCATO DEL LAVORO: VERSO UNA RICONCILIAZIONE DEGLI INDICATORI CONGIUNTURALI DI STOCK E FLUSSI

La recente disponibilità di dati congiunturali sui flussi di posizioni lavorative da fonte amministrativa (Comunicazioni Obbligatorie-Co) ha aumentato le informazioni diffuse al pubblico. Pur creando opportunità per una più approfondita comprensione del mercato del lavoro, le misure relative ai flussi potrebbero anche generare interpretazioni fuorvianti, soprattutto se confrontate con le statistiche sugli stock. Per affrontare questo problema e colmare dei data gap nelle statistiche sul mercato del lavoro, l'Istituto Nazionale di Statistica (Istat) ha promosso un accordo con Ministero del lavoro e politica sociale, Inps, Inail e Anpal per produrre statistiche armonizzate, complementari e coerenti. La sfida principale è riconciliare i dati sui flussi e sugli stock derivanti da fonti amministrative e statistiche. Questo paper illustra il trattamento statistico applicato ai dati delle Co, nel contesto del comunicato trimestrale congiunto pubblicato a partire da dicembre 2016, per ottenere una migliore comparabilità con le statistiche ufficiali.

Key words: employment, labour market, stock and flows indicators

1 Introduction

In recent years in Italy there has been an increase in availability of short-term indicators from administrative sources aiming at monitoring the employment trends. Aspiring to favour a better understanding of the labour market, the Ministry of labour and social policy (Mlps) and the National social security institute (Inps) have been disseminating new short-term statistics based on jobs flows. The brand new and interesting job flows indicators have surely enriched the public debate on employment

[*] The authors are very grateful to the members of the Inter-Institutional Technical Working Group of the Mlps, Istat, Inps, Inail and Anpal Agreement who contributed to the development and implementation of the joint quarterly press release and to the building and sharing of the background knowledge behind this paper.

. Sometimes they have also contributed to generate misleading interpretations, especially when compared with Istat traditional Labour force stock statistics (Anastasia, 2017). Different figures provided for (almost) the same phenomenon by various institutions turned out in an overload of information. The natural multidimensionality of the labour market and the consequent use of different indicators only partly explains the users' impression of experiencing an information “excess”. The diffusion of data which are not completely coherent with the concepts, definitions and classifications of official statistics (Istat, 2015) has given rise to misinterpretation, exaggeration and inappropriate interpretation of technically correct numbers. Some media talked about a “war of numbers on employment” focused on the numerical assessment of the recent labour market reform (Giovannini, 2015).

Data, information and knowledge are three different concepts and moving from the first to the latter is a complex process in which official statistic have a responsibility. National statistical authorities have to promote whatever action is necessary to empower public by improving their capacity of extraction of useful knowledge from data. In turn, such actions will increase official statistics credibility. Istat, aware of the key importance of the labour market issue, decided to act for the sake of an informed, transparent and impartial public debate, and promoted a Coordination Agreement among five Institutions Istat, Inps, Mlps, the National Institute for Insurance against Accidents at Work (Inail) and subsequently National Agency for Active Labour Policies (Anpal). The scope is to cooperate to exploit the full potential of the available information assets, to fill information gaps and to disseminate integrated, harmonized, non-redundant and high quality data and analyses. The Agreement, started to be implemented in December 2016, relies on sharing different data sources, metadata and methodology to make, together, a step forward to understand the labour market functioning. The five institutions should jointly release information to empower public to comprehend the real state of employment. There are three specific outputs: a quarterly joint press release with short-term indicators, an annual joint structural report and an underlying statistical information system to be jointly used by the five institutions. By now, the first two outputs are released on a regular basis, while the third is under construction.

The paper focuses on the data integration process applied for the publication of the quarterly joint press release. In particular, the statistical treatment applied to the Compulsory Communication-Cc database (flows data) to achieve comparability with stock based official statistics (Istat) is illustrated. The main challenge is to reconcile flows and stock data derived from administrative and statistical sources.

The structure of the paper is the following. Section 2 synthetizes the recent debate on labour market trends and the relevance of stock and flows data. In Section 3, after a brief description of the Cc database, the statistical treatment of flows data is detailed. Several comparisons with other data sources are presented in Section 4. Some concluding remarks and future work are sketched in Section 5.

2 The recent debate on labour market trends and the importance of stock and flows information

In 2015-16 the public debate on labour market focused on the effects of the policy reform called “Jobs Act” and in particularly on the social security hiring incentive (so called “decontribuzione”) and the new open-ended contract ‘‘Contratto a tutele crescenti’’. In the discussions, stock have been opposed to flow indicators, statistical surveys to administrative data and jobs against persons employed. Some national newspapers even misinterpreted quarter-over-quarter activations changes with quarter-over-quarter employment changes (Anastasia, 2017).

It is useful to remind here that a stock quantity is measured at a specific point in time (or averaged over a period), whereas a flow quantity is measured over an interval. As reported in the next section, the level of employment in a given moment in time is a stock measure, while its change between two moments is a flow measure. More precisely, it is a net flow which can be obtained also from the balance between the gross flows in and out of employment. The analysis of the change starting from the gross flows provides further insights into the labour dynamics revealing the massive gross flows behind the much smaller net flows (highlighting the underlying heterogeneity).

Stock and flows labour indicators are currently produced from two different sources (and points of view): mainly household surveys and data collected from the side of employer. In the first case, they refer to persons (headcount), in the latter to jobs. The most important and used short-term indicators to monitor labour market are Istat Lfs's quarterly average stocks (employment, unemployment, etc.). Based on Oros survey, Istat also releases quarterly indicators of average stocks of jobs. It should be stressed that the Mlps and Inps releases both refer to flows (activations, cessations, transformations). However, the most extensive and long term experience in regularly releasing short- term gross and net flows of jobs is that of Veneto Lavoro-Labour market observatory[1]. As for other international experiences, only Statistics New Zealand and Bureau of labor statistics in USA release short-term quarterly indicators. The first institute releases results with a delay of 12 months and employs administrative data while the latter uses a traditional business survey[2].

The main objective of the quarterly joint press release (hereafter Note) is to present information from different sources in order to provide an integrated overview of employment trends. To reach this aim, a particular attention has been given to metadata information with a systematic review of the concepts, definitions, classifications, differences between data sources and implications of different survey techniques. The analyzed data are those from the Istat's Lfs and Oros processes, the Inps's Observatory on precariousness, the Inail's work injuries and the Mlps's Cc. The latter has been processed in a way to make these indicators as much comparable as possible with stocks statistics (see section 3).

The Note was welcomed by the media and succeeded in clarifying many issues related to the interpretation and comparison of different indicators. It has apparently achieved the result to calm the stormy waters of the public debate about employment trends. Notwithstanding, the complexity of the phenomena still leaded some analysts to require further simplification and invoke a single indicator, possibly "carved in stone". However, in a data driven society in which any private and public decision is based on information, more data and indicators, produced by different providers, means also more freedom to choose and to evaluate, which, in turn, strengthen a pluralistic and democratic society (Alleva, 2017).

3 Jobs, Activations and Cessations. A bit of stock-flow accounting

In this section, after a brief description of the Cc database, the definitions and computations needed to relate Cc flow statistics to stock statistics are illustrated. Since March 2008, the Compulsory Communications System (Cc) encloses all the

[1] http://www.venetolavoro.it.

[2] See https://stats.govt.nz/ and https://www.bls.gov/bdm/.

communications sent by public and private employers to notify activation, extension, transformation and cessation of jobs, as well as business transfers and change of company name. The Cc encloses different forms. The main one is Unilav, through which all private and public employers (excluding the temporary work agencies for agency workers) fulfil the obligation to communicate any job-related event, i.e. activations, extensions, transformations and cessations of jobs. The events must be communicated within the day before their entry into force.

Every form has a Linked Employer Employee Database information structure with individual data regarding both the employer (fiscal code, name, economic activity sector, flag public administration, registered office, place of work) and the worker (fiscal code, surname, name, sex, date and place of birth, citizenship, permit to stay and motivation, place of residence, education level). Jobs are characterized by a common set of information, i.e. contract type, working time, professional qualification, seasonal work, etc. Moreover, specific dates, depending on the kind of event (activation, cessation, training period cessation, extension, transformation), are useful to determine the duration of job. The coverage of the Cc source is really wide and for this reason very useful for statistical purposes. In terms of employers, it includes all public and private employers belonging to all economic sectors with the exception of armed forces. Referring to the contract type it includes: all regular employees; part of self-employed workers (project workers, occasional contractors, self-employed in entertainment sector, business agents, association in participation; stages and socially useful work. Cc excludes also some managerial contracts of public and private corporations. For further details on the Cc see Baldi *et al.* 2011.

In order to derive Cc-based statistical indicators comparable with the more traditional ones, the link between stocks and flows (Davis *et al.*, 2006) is exploited. The Cc's implicit statistical unit is the employer-employee work relationship, here called job and denoted by $\mathbb{J}_j$. A job is characterized by an activation date, $t_a(j)$, and, possibly, a cessation date, $t_c(j)$. Let us consider a fixed period of time *q*, for example a given quarter, identified by beginning, *b(q)*, and ending dates, *e(q)*. Considering a pair q - $\mathbb{J}_j$, in a given date *t*, a job may be active or not; in the period *q*, $\mathbb{J}_j$ may be active at least for one day or not active at all. In notation, the period-indicator function

$$I_j(q) = 0, if\ t_c(j) < b(q)\ or\ e(q) < t_a(j);\ 1, otherwise \qquad [1]$$

signals whether a given job is active during *q*. Similarly, the date-indicator function

$$I_j(t) = 1, if\ t_a(j) \le t \le t_c(j);\ 0, otherwise \qquad [2]$$

signals whether a given job is active at date *t*. It is straightforward to observe that the following identity holds:

$$I_j(t) = I_j(q) * I_j(t)\ \forall j, q \text{ and } \forall\ b(q) \le t \le e(q)\ .$$

It follows that J_t, i.e. the number of active jobs at any date *t*, is given by $J_t = \sum_j I_j(t)$. Consequently, the average number of jobs over the period *q* may be expressed as

$$\begin{aligned} \bar{J}_q &= \frac{\sum_{t=b(q)}^{e(q)} J_t}{e(q) - b(q)} = \frac{\sum_{t=b(q)}^{e(q)} \sum_j I_j(t)}{e(q) - b(q)} = \frac{\sum_j \sum_{t=b(q)}^{e(q)} I_j(t)}{e(q) - b(q)} \qquad [3] \\ &= \frac{\sum_j \sum_{t=b(q)}^{e(q)} I_j(t) * I_j(q)}{e(q) - b(q)} = \Sigma_j \frac{\sum_{t=b(q)}^{e(q)} I_j(t)}{e(q) - b(q)} * I_j(q) = \Sigma_j D_{qj}^s * I_j(q) \end{aligned}$$

where D_{qj}^s denotes the standard duration of a job $\mathbb{J}_j$ in a period *q*, i.e. $D_{qj}^s = \frac{\sum_{t=b(q)}^{e(q)} I_j(t)}{e(q)-b(q)}$ (the standard duration is defined as the number of days the job has been active during

q standardized by the length of (q). Equation [3] states that $\bar{J}_q$ equals the weighted sum of the active jobs where the weights equal the standard durations.

The stock-flow relationship relates the number of jobs, activations and cessations: the difference between the number of jobs at times *t* and *t-1* equals the difference between the number of activations at time *t* and the number of cessations at time *t-1*:

$$J_t = J_{t-1} + A_t - C_{t-1} \qquad [4]$$

where A_t and C_t represent the number of job activations and cessations occurring at a given date *t*, respectively (Figure 1). The asymmetry between A_t and C_t is due to equation [2]. Indeed, a job $\mathbb{J}_j$ has to be considered "active" even in its end date $t_c(j)$. Consequently, a job will be excluded from the jobs stock only the day after $t_c(j)$.

It is easy to see that both J_t and $\bar{J}_q$ may be expressed in terms of a stock of jobs at a time 0 and a difference between activations and cessations. In fact, putting *t* = 0 in equation [4] and then iterating over time *t*, the number of jobs J_t may be expressed as:

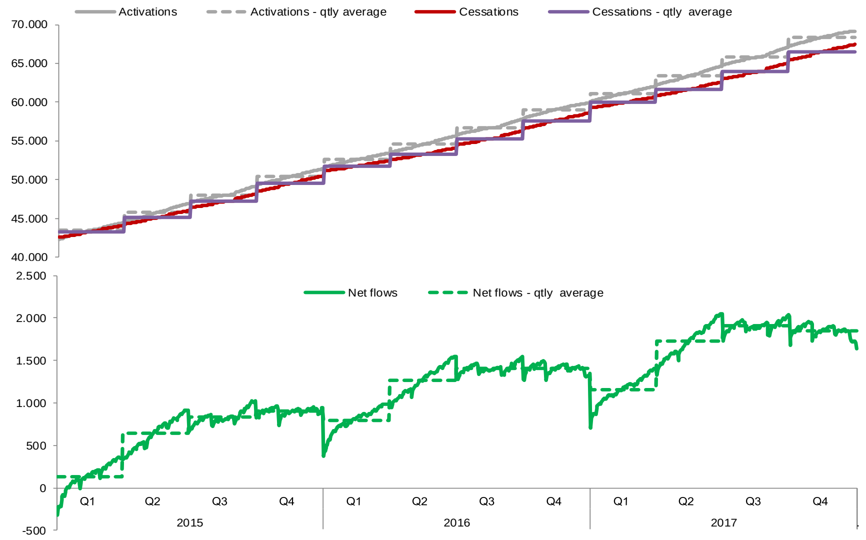
$$J_t = J_0 + \sum_{s=1}^{t} A_s - \sum_{s=0}^{t-1} C_s = J_0 + A_t^u - C_t^u \qquad [5]$$

Averaging over the period *q*, the average number of jobs over *q* may be obtained:

$$\bar{J}_q = \frac{\sum_{t=b(q)}^{e(q)} J_t}{e(q)-b(q)} = J_0 + \frac{\sum_{t=b(q)}^{e(q)} \sum_{s=1}^{t} A_s}{e(q)-b(q)} - \frac{\sum_{t=b(q)}^{e(q)} \sum_{s=0}^{t-1} C_s}{e(q)-b(q)} = J_0 + \overline{A_q^u} - \overline{C_q^u} \qquad [6]$$

where $\overline{A_q^u}$ and $\overline{C_q^u}$ represent, respectively for the activations and cessations, the average over the period *q* of the flows cumulated from the starting point.

Figure 1: Cumulated daily activations, cessations, net flows and quarterly averages Q1.2015 –Q4.2017



The Cc system registers only job activations and cessations. Thus, only the terms A_t^u and C_t^u in [5] and $\overline{A_q^u}$ and $\overline{C_q^u}$ in [6] may be derived using the Cc data. It follows that the number of jobs cannot be calculated within the Cc system. However, the changes of this level may be calculated. Indeed, using [5], the *change between pointwise number of jobs* (CPJ) at the end dates of two consecutive quarters becomes:

$$J_{e(q)} - J_{e(q-1)} = (J_0 + \Sigma_{s=1}^{e(q)} A_s - \Sigma_{s=0}^{e(q)-1} C_s) - (J_0 + \Sigma_{s=1}^{e(q-1)} A_s - \Sigma_{s=0}^{e(q-1)-1} C_s) \qquad [7]$$
$$= \Sigma_{s=b(q)}^{e(q)} A_s - \Sigma_{s=b(q)-1}^{e(q)-1} C_s$$

Furthermore, using [6], the *change of the average number of jobs* (CAJ), becomes:

$$\bar{J}_q - \bar{J}_{q-1} = \left(J_0 + \overline{A_q^u} - \overline{C_q^u}\right) - \left(J_0 + \overline{A_{q-1}^u} - \overline{C_{q-1}^u}\right) = \left(\overline{A_q^u} - \overline{C_q^u}\right) - \left(\overline{A_{q-1}^u} - \overline{C_{q-1}^u}\right) \qquad [8]$$

Notice that CAJ in equation [8] takes into consideration the standard duration of each job in the two quarters, while CPJ in equation [7] does not. Indeed, in equation [7], only pointwise periods, i.e. the end dates of different quarters, are considered. On the contrary, in equation [8], the average number of jobs over a period is involved and $\bar{J}_q$ implicitly takes into account the standard durations, see [3]. It means that CAJ better measures the change of total amount of work between periods.

The two indicators CAJ and CPJ have both weaknesses and strengths. Being based on the average number of active jobs over a period, the CAJ allows for a better comparability to many labour market indicators, for instance, the Labour Force Survey and Oros. From the timeliness point of view, CPJ clearly outperforms CAJ. An unexpected surge of activations at the end of a quarter should be signaled much more evidently by CPJ than by CAJ. However, the meaningfulness of the CPJ signal depends on the duration of the created jobs. If the duration of the activated jobs is considerable, the CPJ could signal such labour input increase soon while CAJ would signal it only the following quarter. If, instead, the created jobs are very short lived, CPJ could give "too strong" and erratic signals that might be misinterpreted as a sign of durable increase in employment. This feature is crucial in a system with a very high share of short-term contracts (Istat et al. 2017). In other terms, average-based indicators, like CAJ, would provide a more accurate measure of the "long-term" impact of such events, but at the cost of a possible delay. The two ways of calculating changes thus prove complementary to each other and their joint use improves the interpretation of the labour market short-term evolution.

4 Comparison of different indicators

This section compares three of the sources analyzed in the quarterly joint Note, Cc (calculated as CAJ), Oros and Lfs, which are more comparable thanks to the length of their time series. These sources differ in several aspects: administrative vs. survey data; stock vs. flows measures, demand side and jobs (Cc and Oros) vs. supply side and persons (Lfs). Thus, different definitions of employment arise: Cc and Oros are based on the relationship between employer and worker established through a formal work contract; Lfs is based on individuals who claim to have done at least one hour of paid work in the reference week. Therefore, the difference between the coverage of the sources must be considered: Lfs includes dependent and independent, regular and irregular employment and all the economic activity sectors (A-U sections of Nace 2007); Cc includes regular employees and some dependent self-employment in the A-U sectors, while Oros includes regular employees in the industry and services sectors (from B to S, excluding O). Thus, in order to correctly compare the sources, the analysis was limited only to the employees in industry and private services (B to N) sectors, excluding temporary agency worker contracts (which are absent from Cc) and job-on-call work because this type of the contract do not imply an actual labor input. The Cc, Lfs and Oros labour market trends are very close. They unequivocally depict the decline in employment during the economic crisis and the troughs of the business cycle at the end of 2013. The subsequent employment recovery appears stronger in the administrative source (Cc). In the year-on-year quarterly changes comparison, the dynamics of jobs in Oros and Cc exhibit a more similar trend. The Lfs trend is more irregular, showing opposite patterns with respect to Cc trend in few quarters and a forward shift in the 2016 employment growth peak (Figure 2). In the absolute cumulative changes, the Cc series shows a divergence with respect to the other two; the drift increases over time especially from the end of 2015 (Fig. 3).

Figure 2: Lfs, Cc (CAJ) and Oros absolute year-on-year absolute quarterly changes in industry and private service (B-N). Q1.2011-Q4.2017. Raw data

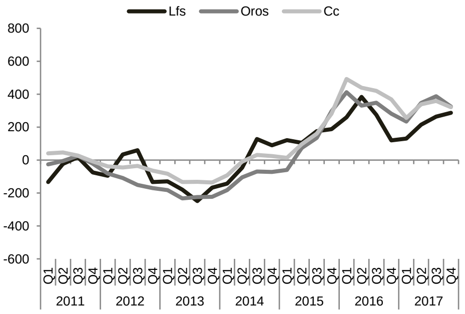


Figure 3: Lfs, Cc (CAJ) and Oros absolute cumulative changes in industry and private service (B-N). Q1.2011-Q4.2017 (Q4.2010=0). Raw data and moving averages

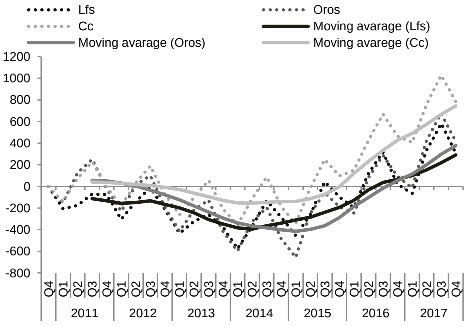

On the other hand, the series of cumulative changes of Lfs and Oros are closer in the last period and slightly compensate the diverging trends in previous years. The differences may be due to the previous definition and measurement issues, as well as to over-coverage and under-coverage errors (De Gregorio *et al.*, 2014). Indeed, administrative data generally tend to have over-coverage errors, e.g. false activations, while survey data more often have under-coverage errors, e.g. sampling and non-sampling errors, (Statistics Canada 2009).

To further investigate the determinants of such differences between trends, a microdata level record-linkage was performed. The Cc and Lfs 2011-2015 microdata were integrated by linking the records corresponding to the individuals having at least one activation in the Lfs reference week. The very preliminary results show that there are cases of employed persons without an employment relationship (persons absent in the Cc data; probably irregular workers) and cases of contracts without work (i.e. unemployed or inactive persons in Lfs with formal contract in Cc[3]). Differences were also found with respect to job duration. There are fixed-term contracts from the Lfs side which are open-ended in the Cc data. On the contrary, a continuous and uninterrupted succession of fixed-term contracts with the same employer can be considered "de-facto open-ended contracts" (Istat-Cnel, 2017). In general, individuals tend to declare their own employment status rather than the formal one. These first results suggest that the differences between the de-facto (from Lfs) and the formal (Cc) conditions should be considered. In some cases, such differences may indicate different and more complex phenomena rather than simple inconsistencies.

5 Conclusions and future development

The Agreement signed in December 2015 represents a real step forward in the collaboration among the five Italian main producer of labour market statistical

[3] This may be caused by temporal misalignment between work and contract, especially for short-term jobs and different irregular practices (fictitious work i.e. false assumptions only to get social security benefits).

information. In the quarterly joint Note the combination of comparable variables on clear and unambiguous domains and use of precise definitions and transparent methodology enhance the release of more coherent statistics. The statistical treatment of the Cc data source allows the estimation of the change of average number of active jobs over a period (CAJ), an indicator more comparable and consistent with traditional statistics on stocks. However, comparing the sources, non-negligible deviations in trends remain. Such deviations are due to definitional and conceptual differences and to many other factors that must be further investigated. A more systematic micro integration of the sources is going to be carried on. This is one of the tasks of the inter-institutional technical working group created to implement the Agreement.

The integration of sources at micro level involves a new phase of literacy to statistical data, oriented to the complexity of the modern labour market phenomena. Sometimes, it is not much a question of distinguishing between “right” and “wrong” data but rather the correct interpretation of its meaning. The differences between the sources must be carefully analyzed, being able to discern between: i) unwanted and (theoretically) avoidable errors (e.g. non-sample survey errors, wrong reporting in questionnaire or in administrative form); ii) irregular or false declarations for interest of the individual or firm; iii) diversity of meaning of the phenomenon. The non-complete comparability between data from different sources has always been one of the main obstacles to their integrated use. This issue becomes even more relevant when developing an integrated statistical system based on microdata. In this context, consistency at micro level becomes crucial. Furthermore, the ability to distinguish the reasons causing the differences and the importance of define hierarchies among sources are fundamental. The final objective is to derive an integrated and validated micro dataset which enables deeper labour market analyses founded on the full exploitation of the richness of integrated variables (profession, education level, etc.).

How effective are the regional policies in Europe? The role of European Funds

Efficacia delle politiche regionali in Europa. Il ruolo dei Fondi Europei

Gennaro Punzo, Mariateresa Ciommi, and Gaetano Musella

Abstract The European Structural and Investment Funds are the leading policy instrument through which the EU encourages growth-enhancing conditions for less well-off regions in order to make territorial cohesion within countries. In this work, we perform the Difference in Differences technique to assess the effectiveness of the 2007-2013 EU funding in achieving the convergence in employment levels across NUTS2 regions. Controlling for the socio-economic background at the regional level, a special focus is devoted to Italy. Some empirical results suggest that the EU funding was not effective enough to help the convergence for most countries.

Abstract *I Fondi Strutturali e di Investimento Europei rappresentano il principale strumento attraverso cui l'UE promuove la crescita delle regioni meno sviluppate e indirizza il processo di coesione territoriale nei singoli paesi. Con l'ausilio del metodo delle differenze nelle differenze, il lavoro valuta il contributo dei fondi europei, relativi al periodo di programmazione 2007-2013, alla convergenza dei livelli di occupazione tra le regioni NUTS2. Particolare attenzione è dedicata al caso Italia tenendo conto del background socio-economico delle regioni. Si rileva un ruolo non sempre decisivo dei fondi europei nella realizzazione del processo di convergenza territoriale interno ai diversi paesi dell'Unione.*

Key words: Employment, EU funding, Diff-in-Diff, Regional convergence

1 Introduction

Narrowing socio-economic disparities between richer and poorer regions is one of the key principles on which the European Union (EU) has been based ever since its inception (Art. 158 of the founding Treaty, art. 130a of the Maastricht Treaty). From this perspective, the EU policies promote growth-enhancing conditions for the least-developed regions and the European Structural and Investment Funds (ESI Funds) are the most intensively instruments used by the EU institutions for encouraging the territorial convergence. During the last programming cycles (2000-2006, 2007-2013, 2014-2020), most of the ESI Funds is channelled through the European Fund for Regional Development (EFRD), the European Social Fund (ESF) and the Cohesion Fund (CF) with the aim of leading the less well-off regions to a real convergence within countries [10] and making the EU's system of market integration viable [5].

As regards employment, territorial convergence consists in lowering disparities in employment rates between regions through a spiral of economic growth. In the current programming period (2014-2020), a new legislative framework for these funds has been brought forward and a new set of rules clearly links the ESI Funds with the EU 2020 Strategy for smart, sustainable and inclusive growth [10]. Indeed, at least three of the five headline goals of the EU 2020 Strategy relate directly to employment and productivity, with a focus on the target of "new skills for new jobs". In particular, within the Strategy's objective of sustainable growth, EU 2020 fosters a high-employment economy that delivers social and territorial cohesion. In this respect, the European Commission sets the first target that 75% of the population aged 20-64 should be employed by 2020, and within the seven flagship initiatives, the Commission puts forward "an agenda for new skills and jobs" [9] to empower people by developing skills throughout the lifecycle with a view to better match labour supply and demand.

In this paper, having regard to the close links between the different programming periods of the ESI Funds (the progress reached in a period lays the basis for the time after), we investigate the impact of the EU funding on employment at regional level within each EU country over the period 2007-2013. Some researchers have analysed the relationship between the structural funds of the previous programming cycles and the economic convergence at national and regional levels with conflicting results (see, among others, [4], [13], [5]), which often also depend on the empirical strategy used [2]. By performing the Difference-in-Differences (DiD) strategy, we assess the extent to which the EU funding has supported the convergence for employment between 2007 and 2013, paving the way for the first headline goal of the EU 2020 Strategy. Later, controlling for the socio-economic background at the regional level, a special concern is devoted to Italy with the aim of exploring the main reasons behind the controversial impact of EU funds on regional employment.

With specific reference to the 2007-2013 funding period, NUTS2 regions with a per capita GDP lower than 75% of the EU average were eligible under the convergence objective[2]. Because of the enlargement to EU-25, a phasing-out support was assured to regions[3] that were below the threshold of 75% of GDP for the EU-15 while they were above the same threshold for the EU-25. Based on the Council Regulations (No 1080/2006 and 1083/2006), the convergence objective concerned 84 regions within 18 Member States of EU-27 with a total of 154 million inhabitants, and on the "phasing-out" basis, other 16 regions within 8 countries with a population of 16.4 million. The amount allocated for ESI Funds was assigned to the convergence regions (70.47%) and "phasing-out" regions (4.95%), while the remaining part concerned the Cohesion Fund (24.58%).

2 Methods and data

The effect of the regional funds on local employment and their contribution to convergence across EU NUTS2 regions is exploited by the DiD strategy [3]. This method evaluates the differential effect of a treatment by comparing the change over time in the outcome for the treated group with the change that has occurred in the same timespan for the control group.

The DiD strategy allows us to compare the NUTS2 regions that received the EU funding (treated group) between 2007 and 2013 with those regions that did not (control group). Both groups of regions are analysed before (2000-2006) and after (2014-2016) the 2007-2013 funding period. The DiD model is drawn as follows:

$$y = \alpha_0 + \alpha_1 S + \delta_0 T + \delta_1 T \cdot S + X\beta + u \qquad (1)$$

where y is the *Nx1* vector of the outcome variable. S is a dummy variable that takes on value 1 for the recipient regions and 0 otherwise; α_1 accounts for the difference between the two groups prior to treatment; α_0 is the intercept. T is a dummy whose value is 1 for the period of treatment and 0 otherwise; δ_0 captures the time effects, and thus the changes in the outcome variable in the absence of the treatment. The interaction term $(T \cdot S)$ is the same as a dummy equal to 1 for those treated units in the treatment period; δ_1 represents the treatment effect. X is the *NxK* matrix of

[2] The entire national territories of Bulgaria, Estonia, Latvia, Lithuania, Malta, Poland, Romania and Slovenia were eligible for funding. Instead, a selection of NUTS2 regions was eligible for the following EU countries: Czech Republic (Střední Čechy, Jihozápad, Severozápad, Severovýchod, Jihovýchod, Střední Morava, Moravskoslezsko); Germany (Brandenburg-Nordost, Mecklenburg-Vorpommern, Chemnitz, Dresden, Dessau, Magdeburg, Thüringen); Greece (Anatoliki Makedonia, Thraki, Thessalia, Ipeiros, Ionia Nisia, Dytiki Ellada, Peloponnisos, Voreio Aigaio, Kriti); Spain (Andalucía, Castilla-La Mancha, Extremadura, Galicia); France (Guadeloupe, Guyane, Martinique, Réunion); Hungary: Közép-Dunántúl, Nyugat-Dunántúl, Dél-Dunántúl, Észak-Magyarország, Észak-Alföld, Dél-Alföld); Italy (Calabria, Campania, Puglia, Sicilia); Portugal (Norte, Centro, Alentejo, Região Autónoma dos Açores); Slovakia (Západné Slovensko, Stredné Slovensko, Východné Slovensko); the United Kingdom (Cornwall and Isles of Scilly, West Wales and the Valleys).

[3] Belgium (Province du Hainaut); Germany (Brandenburg-Südwest, Lüneburg, Leipzig, Halle); Greece (Kentriki Makedonia, Dytiki Makedonia, Attiki); Spain (Ciudad Autónoma de Ceuta, Ciudad Autónoma de Melilla, Principado de Asturias, Región de Murcia); Austria (Burgenland); Portugal (Algarve). Italy Basilicata; the United Kingdom (Highlands and Islands).

covariates and β the vector of coefficients. Finally, $u \sim N(0, \sigma_u^2)$ is the *Nx1* vector of uncorrelated errors.

Formally, δ_1 is given by the following difference in differences:

$$\delta_1 = [E(y|x, S = 1, T = 0) - E(y|x, S = 0, T = 0)] - [E(y|x, S = 1, T = 1) - E(y|x, S = 0, T = 1)] \tag{2}$$

Let $\bar{y}_{S,T}$ be the average of the outcome variable in the group of regions S at time T, the estimation of the treatment effect (diff-in-diff) is:

$$\hat{\delta}_1 = (\bar{y}_{1,0} - \bar{y}_{0,0}) - (\bar{y}_{1,1} - \bar{y}_{0,1}) = \hat{\Delta}_0^{\bar{y}} + \hat{\Delta}_1^{\bar{y}} \tag{3}$$

Thus, $\hat{\Delta}_0^{\bar{y}}$ is the difference of the averages of the outcome variable *before* the EU funding between recipient and control regions, and $\hat{\Delta}_1^{\bar{y}}$ is the difference of the averages *after* the EU funding between recipient and control regions.

The DiD model requires that the assumption of parallel paths is satisfied. It postulates that the average change in the control group represents the counterfactual change in the treated group if there was no treatment. In other words, without treatment, the average change for the treated would have been equal to the observed average change for the controls (for details, see [14]).

Our analysis draws upon official data from Eurostat, Istat, and SIEPI[4]. The data, which are related to NUTS2 regions, cover a seventeen-year period, spanning from 2000 to 2016. The outcome variable, the Total Employment Rate (EMRT), is the percentage of employed persons aged 20-64 in relation to the working-age population. The covariates are: *i*) Total Population by Educational Attainment Level (PEALT), which represents the share of the total population with tertiary education (ISCED 5-8); *ii*) Active Labour Market Policies (ALMP), expressed as the average annual number of beneficiaries of active policies; *iii*) per capita Gross Domestic Product (per capita GDP); *iv*) Total Early Leavers from Education and Training (ELETT), which is the share of 18 to 24 year olds having attained ISCED 0-2 level and not receiving any formal or non-formal education or training; *v*) People at-Risk-of-Poverty or Social Exclusion (PRPSE), which is the percentage of the total population below either the poverty threshold (60% of the national median equivalised disposable income after social transfers) or severely materially deprived or living in a household with a very low work intensity; *vi*) five dimensions of the Institutional Quality Index (IQI), which are Corruption, Government effectiveness, Regulatory quality, Rule of law, Voice and accountability. More specifically, Corruption measures the degree of corruption of those performing public functions and crimes against the public administration; Government effectiveness evaluates the quality of public service and the policies of local governments; Regulatory Quality measures the ability of government to promote and formulate effective regulatory interventions; Rule of law quantifies the crime levels, shadow economy, police force, and magistrate productivity; Voice and accountability assesses the degree of freedom of the press and association [15].

3 Empirical findings

We analyse the role of the EU funding in fostering homogeneity in employment across NUTS2 regions within countries. Once the treated group (regions exposed to convergence objective) and the control group (regions not included in the objective) are defined, we perform the DiD estimations. In doing so, we compare the average employment rates across the two groups of regions before and after the provision of EU funds. First, we test the effectiveness of the EU funding in 10 EU countries[5] for a total of 256 NUTS2 regions (84 treated and 172 untreated) through DiD null models (Section 4.1). Second, we estimate the DiD model for Italian regions (5 treated and 16 untreated) by controlling for a set of covariates (Section 4.2).

3.1 The European context

Before assessing the effect of EU funds on the convergence objective, we verify the parallel-path assumption by using the Mora&Reggio's approach [14]. It tests whether, in the absence of the EU policy, the averaged EMRTs of the two groups of regions follow the same trend. Based on our results, the parallel-trend assumption is met for each country covered (Tables 1-2), which means that the group of control regions may be considered as a suitable counterfactual for the group of treated regions[6].

Tables 1-2 show the estimations of DiD models by country without controlling for covariates. They allow us to evaluate exclusively the differential effects of EU funds on EMRTs between the treated and untreated regions. Our evidence suggests that the EU funding did not influence significantly the convergence process for employment in most countries. In fact, except for Germany and Italy, the insignificance of $\hat{\delta}_1$ coefficients shows that, on average, the differences between the employment rates of the control and treated groups look much the same before and after the provision of EU funds. It could be assumed that in some countries (Austria, Czech and Slovak Republics, and the United Kingdom) convergence processes were already underway, though at different timing and extent, before the entry into force of the EU policy. However, between 2007 and 2013, the average employment levels have even raised faster in the untreated regions of Belgium and Hungary while they have decreased for both groups of regions in Spain and Portugal, widening in either case the territorial divergence within country.

[5] We exclude France and Greece from the analysis for reasons of data availability.

[6] This is a quite remarkable when one considers that the economic recession reached its highest intensity before the end of 2009 in most EU countries in the middle of the 2007-2013 programming cycle and that these EU funds were not designed to offset the adverse effects of the crisis. Therefore, although some Member States have been more vulnerable than others (i.e., the countries of southern Europe), the parallel-trend test claims that the averages of employment rates of the treated regions would follow the same trend of those of the control regions even during the years of the crisis. Probably, the crisis has had a quite pervasive impact on employment levels within each country without significant differences in the averages of employment rates between the less- and more-developed regions.

Italy and Germany show opposite effects of the 2007-2013 funding. In Germany, the employment divide between the treated and untreated regions is practically disappeared after the treatment, and more importantly, the EU target of 75% of the population employed has been reached, on average, in both groups of regions long before the date appointed by the EU 2020 Strategy. Instead, in Italy, the two groups of regions show an increased gap in average rates of employment such that the diff-in-diff estimate is even negative. Italian regions exposed to convergence retain, on average, significant lower levels of employment than those of the control group: they still have a long way to go before converging in employment.

3.2 The Italian context

With the aim of exploring the main reasons behind the potential failure of the EU funding policies in Italy and how much of the lack of regional convergence can be attributed to the incapacity of the Country and its recipient regions to generate economic growth, we perform a DiD model by including a set of control variables (see Section 2). In fact, the impact of EU funds on economic development cannot avoid some institutional, political, and socio-economic factors.

The analysis is carried out by using a log-log model in which each coefficient (except for those of the IQI dimensions) represents the percentage change in the employment rate for a percentage change in the given covariate (i.e., elasticity of the dependent variable with respect to covariates). In the preliminary step, we resort to the instrumental variables (IV) method to overcome the endogenous relationships between the employment rates and per capita GDP and some specific dimensions of IQI. In detail, we use exogenous covariates and their lagged versions as instruments. The Sargan-Hansen's *J* test leads to conclude with the exogeneity, and thus, the validity of these instruments.

Table 3: Diff-in-Diff estimates, Italy. Model with covariates, 2004-2012

	Coeff	*S.E.*
per capita GDP	0.280***	.023

Corruption	0.135***	.021
Government Effectiveness	0.162***	.026
Regulatory Quality	0.115***	.032
Rule of law	-0.012	.016
Voice and Accountability	-0.066*	.037

**Significant at 10%; **Significant at 5%; ***Significant at 1%;*

The employment growth is positively related to the GDP level (Table 3) in accordance with the literature that investigated this topic for the most developed countries (see, among others, [6; 16; 18]). It is definitely clear the negative effect on regional performance of low human capital and poor/deprived/excluded people. However, the active labour market policies, which could be regarded as a proxy of the degree of unionisation of a country [12], seem not to help the unemployed in finding jobs. A significant share of the observed gap in employment between regions is also attributable to differences in the quality of institutions [1; 17; 8]. In particular, three out of the five dimensions of institutional quality (i.e. corruption, government effectiveness and regulatory quality) suggest that a more efficient legal system and a lower propensity to corruption improve the employment performance of regions.

4 Conclusions

Except for Germany, the convergence process seems not to be closely linked to the EU funding. Countries whose labour markets are characterised by hybrid patterns (either polarised or upgraded) with a joint contraction of low-, middle- and high-skill jobs [7; 11] even show wider divergences at the end of 2007-2013 period. Italy experienced a reduction in employment rates throughout the entire territory and an increasing territorial divergence that states the failure of EU funding. Inefficiencies of national policies and the poor quality of institutions reflected in bureaucracy and mismanagement of funds, which enable synergies between different funding sources with restriction in national funds when a larger availability of EU funds existed [5].

Labour market condition in Italy during and after the financial crises: a segmented regression analysis approach of interrupted time series

Le condizioni del mercato del lavoro in Italia nel periodo durante e successivo alle crisi finanziarie: un'analisi basata sulle serie temporali interrotte

Lucio Masserini and Matilde Bini

Abstract
One of the most widely recognized indicators of the labour market condition is a rising unemployment rate. In Italy, after the 2008 global financial crisis and the 2012 European sovereign debt crisis, this indicator continuously increased over time until late 2014, after which it seems to happen a trend reversal. The aim of this paper is to assess the existence a significant trend reversal in the unemployment rate after 2014, by analysing quarterly data collected from the Italian National Institute of Statistics using a segmented regression analysis approach of interrupted time series. In particular, the analysis is carried out considering some subpopulations of interest, by stratifying unemployment rate for age groups, in order to examine youth unemployment, gender and macro-regions. Moreover, a focus is given to the analysis of the percentage of people Not Engaged in Education, Employment or Training, to provide a more in-depth analysis of the labour market.

Abstract *Uno degli indicatori più ampiamente riconosciuti come misura della recessione è il tasso di disoccupazione. A partire dalle due recenti crisi mondiali, quella finanziaria globale del 2008 e quella del debito sovrano europeo del 2012, questo indicatore in Italia è costantemente aumentato fino a quando al termine del*

2014 subisce un'inversione di tendenza, ciò forse dovuto ai recenti interventi locali introdotti nel mercato del lavoro. Lo scopo di questo lavoro è di valutare l'esistenza di un'inversione di tendenza significativa dell'indicatore dopo il 2014, analizzando i dati trimestrali raccolti dall'Istituto Nazionale di Statistica Italiano, utilizzando un approccio di analisi di regressione segmentato delle serie temporali interrotte. In particolare, l'analisi è stata realizzata considerando alcune sottopopolazioni di interesse, stratificando il tasso di disoccupazione per fasce di età, al fine di esaminare la disoccupazione giovanile, sul genere e sulle macro-regioni. Inoltre, un'attenzione particolare è stata data all'analisi della percentuale di persone non impegnate nell'istruzione, nell'occupazione o nella formazione per fornire un'analisi più approfondita del mercato del lavoro.

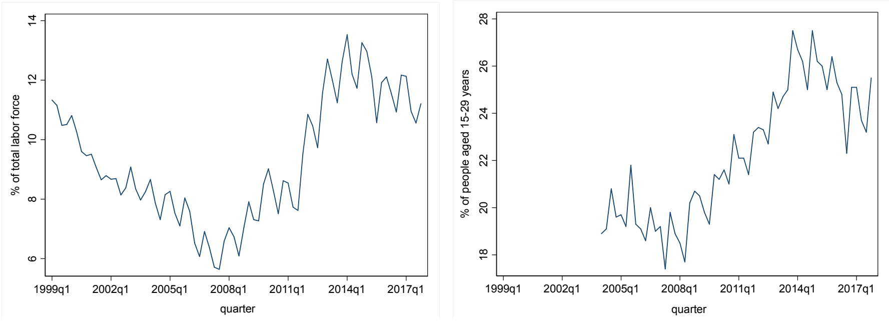
Key words: unemployment rate, interrupted time series analysis, segmented regression, NEET

1 Introduction

The recent two economic crises occurred around the world during the period from late 2000s to late 2011, produced negative effects on countries' economies, particularly on GDP growth, on labour productivity and on labour market. As revealed by the International Labour Organization (ILO, 2001), already since the 2009 about 22 million people were unemployed worldwide in particular in developed economies and in the European Union. The unemployment rate continued towards a dramatically increase with high and persistent levels of unemployment until 2014 after which, it seems to happen a trend reversal, maybe due to the recent domestic interventions introduced in the labour market. The aim of this paper is to assess the existence of a significant trend reversal in the unemployment rate after 2014, using a segmented regression analysis approach of interrupted time series. Quarterly data were collected from the website of the Italian National Institute of Statistics. the analysis is carried out considering some subpopulations of interest, by stratifying unemployment rate for age groups, in order to examine youth unemployment, gender and macro-regions. Changes in the trend are also evident in the percentage of a particular sub group of young people, defined as neither employed nor in education or training (NEET). This could mean that local interventions produced effects in some extent also to this category.

2 Data and empirical strategy

Data were collected from I.Stat, the warehouse of statistics currently produced by the Italian National Institute of Statistics (ISTAT) which provides an archive of about 1,500 time series (http://dati.istat.it/). Quarterly data on two different kind of indicators were downloaded from the theme ‘Labour and wages’: UR for the period 1993–four quarter of 2017, overall and stratified by gender, age groups and macro-regions; and the percentage of NEET for the period 2004– four quarter of 2017, overall and stratified by gender. Such data are derived from the official estimates obtained in the Labour force survey, carried out on a quarterly basis interviewing a sample of nearly 77,000 households representing 175,000 individuals. According to the Eurostat definition (Eurostat, 2017), UR is given by the number of people unemployed as a percentage of the labour force. The youth unemployment rate (YUR) is the number of unemployed 15–24 years-old expressed as a percentage of the youth labour force, and the NEET refers to the percentage of people aged between 15 and 29 years who currently do not have a job, are not enrolled in training or are not classified as a student. Figure 1a illustrates the trend in the overall UR in Italy from 1999 to the end of 2017. The choice of such a long period allows for a more accurate estimate of the secular trend, and this will be useful for the subsequent analysis. Looking at the graph, UR steadily declines until the third quarter of 2007 (2007q3). Then, starting from the fourth quarter of 2007 (2007q4), period in which the effects of the financial crisis following the bankruptcy of Lehman Brothers begin to appear, UR undergoes a first shock and shows a trend reversal. Afterwards, UR increases even more dramatically up to 13.26% at the end of 2014 (2014q4), after the European sovereign-debt crisis occurred in the late 2011 (2011q4). After this peak, UR seems to show a new trend reversal, showing a possible structural change.



(a) (b)

Figure 1: Total UR (a) and percentage of NEET (b) in Italy over the observed period

Figure 1b illustrates the trend of the overall percentage of NEET in Italy from the first quarter of 2004 (2004q1) to the four quarter of 2017 (2017q4). Here the series is shorter because data from previous years are not available. This trend seems, at least partly, to be similar to that of UR. Indeed, after a slight decrease in the period before the onset of the global financial crisis (2007q3), the percentage of NEET starts a steeply and steady growth that continues unchanged also after the occurrence of the sovereign debt crisis (2011q3). And as in UR, a trend reversal occurred starting from the end of 2014 (2014q4).

In the light of the previous considerations, the analysis period was divided into the following four sub-periods: the period before the so-called 2008 global financial crisis (until 2007q3); the subsequent three-year period known as the Great Recession aftermath of the financial crisis, characterised by a general economic decline observed in world markets (2007q4–2011q3); the period following the European sovereign debt crisis, which resulted in a second economic recession (2011q4–2014q4); and finally, the last three years (2015q1–2017q4), during which it seems to glimpse a slight decrease in both the UR and the percentage of NEET. Consequently, the three breaks in the series were set in 2007q4, 2011q4 and 2015q1. Therefore, the analysis period is limited to the years 1999q1–2017q4 for the UR and to 2004q1–2017q4 for the percentage of NEET. The identified interruptions allow to highlight: the severity of the two financial crises, respectively, the continuation of their effects in the subsequent years of recession, and the more recent trend reversal occurred after the end of 2014.

3 Interrupted time series analysis

In this study, a segmented regression approach of interrupted time series (ITS) analysis was carried out in order to assess and measure, in statistical terms, whether and how much the two financial crises have changed the level and trend in the outcome variables, immediately and over time, and to see if these changes are short- or long-term (Wegner, Soumerai and Zhang, 2002).

ITS analysis (Shadish, Cook and Campbell, 2002) is a simple but powerful tool used in quasi-experimental designs for estimating the impact of population-level or large scale interventions on an outcome variable observed at regular intervals before and after the intervention. In such circumstances, ITS allows to examine any change on the outcome variable in the post-intervention period given the trend in the pre-intervention period (Bernal, Cummins and Gasparrini, 2016). In this respect, the underlying secular trend in the outcome before the intervention is determined and used to estimate the counterfactual scenario, which represents what would have happened if the intervention had not taken place and serves as the basis for comparison. For the purposes of our study the interventions are given by two unplanned and real-world events, the aforementioned and well recognized financial crises, and by the subsequent already mentioned trend reversal. In segmented regression of ITS, each sub-period of the series is allowed to exhibit its own level and trend, which can be represented by the intercept and slope of a regression model, respectively. The intercept indicates the value of the series at the beginning of an observation sub-period; and the slope is the rate of change during a segment (or sub-period). Therefore, by following this approach it is possible to compare the pre-crisis level and trend with their post-crisis counterpart, in order to estimate the magnitude and statistical significance of any differences.

The ITS regression model with a single group under study (here, the Italian population), two interventions, which in this study are given by the two economic recessions in 2007q4 and 2011q4, and a possible UR trend reversal in 2015q1, can be represented as it follows (Linden and Adams, 2011; Bernal, Cummins and Gasparrini, 2016):

$$y_t = \beta_0 + \beta_1 T_t + \beta_2 x_{t2007q4} + \beta_3 T_{t2007q4} x_{t2007q4} + \beta_4 x_{t2011q4} + \beta_5 T_{t2011q4} x_{t2011q4} + \\ + \beta_6 x_{t2015q1} + \beta_7 T_{t2015q1} x_{t2015q1} + \varepsilon_t .$$

In particular, y_t is the aggregated outcome variable at each equally-spaced time-points t, here represented by quarters; T_t is the time elapsed since the start of the study, where t varies between 1999q1 to 2017q4 for UR and between 2004q1 to 2017q4 for NEET, respectively; $x_{t2007q4}$ is a dummy variable indicating the onset of the global financial crisis in fourth quarter of 2007, coded as 0 (pre-crisis period) and 1 (post-crisis period); $T_{t2007q4}x_{t2007q4}$ is the interaction term between time and the 2007q4 global financial crisis; $x_{t2011q4}$ is a dummy variable indicating the onset of the 2011q4 European sovereign debt crisis, coded as 0 (pre-crisis period) and 1 (post-crisis period); and $T_{t2011q4}x_{t2011q4}$ is the interaction term between time and 2011q4 European sovereign debt crisis. Finally, $x_{t2015q1}$ is a dummy variable indicating the time in which a new trend reversal occurred, coded as 0 (before the trend reversal) and 1 (after the trend reversal); and $T_{t2015q1}x_{t2015q1}$ is the usual interaction term. Accordingly, β_0 is the intercept and represents the starting level of the outcome variable at T = 1999q1 for UR and T = 2004q1 for NEET, respectively; β_1 is the slope and represents the trajectory (or secular trend) of the outcome variable until the 2007q4 global financial crisis; β_2 is the level change that occurs immediately following the 2007q4 global financial crisis (compared to the counterfactual); β_3 is the difference between the slope pre and post the global financial crisis; β_4 is the level change that occurs immediately following the 2011q4 European sovereign debt crisis; β_5 is the difference between the slope pre and post the European sovereign debt crisis; β_6 is the level change that occurs immediately following the 2014q4 (compared to the counterfactual); β_6 is the difference between the slope pre and post the trend reversal; and ε_t represents the random error term which is assumed to follow a first auto-regressive (AR1) process. The regression coefficients are estimated by using Ordinary least-squares (OLS) method with the Newey-West (1987) standard errors.

4 Results

Four periods of linear trend were considered to analyse UR and NEET, with interruptions at 2007q4, 2011q4 and 2015q1, respectively. Separate segmented regression models were then estimated for age groups, gender and macro-regions via ordinary least-squares by using Newy-West standard errors in order to handle one lag autocorrelation. To account for the correct autocorrelation structure, Cumby-Huizinga test (Cumby and Huizinga, 1992) was performed and results confirm that autocorrelation was present at lag 1, but not at higher orders (up to the 9 lags were tested). Results are shown in Table 1 for the UR and in Table 2 for the NEET. As regards the UR, the 1999 base rate showed some variability in the considered subgroups. In fact, starting from 10.754 at national level, its value was particularly higher for the age group 15–24 (26.726) and for the South macro-regions (20.211) but lower for the North East (4.538) and North West (5.831) macro-regions, as well as for the males (8.177) and for the 45–54 age group. Moreover, the trend prior to the 2008 global financial crisis (1999q1–2007q3) showed a significant and general decrease, both at national level (-0.137; $p < 0.001$) and for the different age groups, macro regions and gender. Such reduction was more pronounced for the sub-groups traditionally considered as the most vulnerable ones, namely South macro-regions (-0.266; $p < 0.001$), females (-0.202; $p < 0.001$) and YUR (-0.182; $p < 0.001$). The onset of the global financial crisis (2007q4) caused an immediate and substantial UR increase at national level (+0.788; $p < 0.05$) and in almost all the considered subgroups but no significant change was detected for younger people (age groups 15–24 and 25–34) and the North-East macro region. In particular, the more severe direct consequences were observed among females (+1.061; $p < 0.001$), for people in the central (+1.047; $p < 0.001$) and southern regions (+0.978; $p < 0.05$) and for the intermediate age group 35–44 (+0.997; $p < 0.001$). The aftermath of the financial crisis was quite strong and resulted in the Great recession in the subsequent years during which a substantial and significant trend change was observed compared to the previous period (+0.253 $p < 0.001$). However, in this case, the most serious consequences occurred particularly for YUR (+0.717; $p < 0.001$) and, to a much lesser extent, for the South macro-regions (+0.365; $p < 0.001$). On the other hand, the immediate consequences of the second financial crisis, following the European sovereign debt crisis (2011q4) were even stronger when compared to the previous financial crisis and resulted in a second economic recession, with an UR increase almost double at the national level (+1.540; $p < 0.001$). Such increase was higher for YUR (+3.676; $p < 0.05$) and for the South macro region (+2.611; $p < 0.001$) while there was no significant increase again for North East macro region.

After this second financial shock, the UR seems to further accelerate its increase only in some sub-groups while at national level no significant trend difference was observed. In particular, such acceleration was particularly higher for the South macro-regions (+0.355; $p < 0.001$), age group 25–34 (+0.246; $p < 0.05$) and females (+0.187; $p < 0.001$) while no significant further rate increase was detected for YUR. However, it should be emphasized here that this further increase, although lower than the one highlighted during the Great Recession, where present has to be added to that already existing, thus making particularly critical the situation.

* $p < 0.10$; ** $p < 0.05$; *** $p < 0.01$

The consequences of this second financial crisis seem to run out by the end of 2014. Indeed, a trend reversal occurs staring from 2015q1. In particular, the rate change decreases significantly only overall (-1.234; p < 0.05), for females (-1.515; p < 0.001), age group 35–44 (-1.225; p < 0.001) and the South macro-region (-2.290; p < 0.001). On the other hand, the trend change is more evident and is significant for all categories except for age class 55–64 and shows a stronger reduction for young generation 25–34 (-1.607; p < 0.001) and, to a lesser extent, for the South macro-region (-0.501; p < 0.001).

As regards the percentage of NEET, a considerable heterogeneity was found in the 2004 base rate, which was 19.866 at national level. Its value was higher for the South macro-regions (29.798) but lower for the North East (10.522) and North West (12.575) macro-regions; moreover, it was higher for females (24.584) than males (15.152). On the other hand, its trend prior to the 2008 global financial crisis (2004q1–2007q3) was basically constant at national level. The onset of the of the global financial crisis (2007q4) did not cause an immediate impact on the percentage of NEET, overall and in any of the considered sub-groups. However, a significant trend change was found both at national level (+0.316; p < 0.001) and for all the other sub-groups; such change was particularly higher only for the macro-regions of Center (+0.404; p < 0.001). The European sovereign debt crisis (2011q4) does not seem to alter this situation, neither for the rate change nor for the trend change. This means that after this second financial crisis the rise of the percentage of NEET remains steady and equal to the previous period without showing any jump. But for the last trend change (2015q1), results reveal to be significant for all sub groups, particularly for females (-0.680; p < 0.001). This confirms that after the end of the two crises and local interventions, a new period of recovery has finally started again. Also for the percentage of NEET, a trend reversal occurs staring from 2015q1. In particular, analogously to the UR, this reduction is significant for all the considered sub-groups, but it is more pronounced for males (-0.680; p < 0.001) and lower for females (-0.369; p < 0.001) and South marco-region (-0.482; p < 0.001).

Quantile and Generalized Quantile Methods

Multiple quantile regression for risk assessment

Regressione quantile multipla per la valutazione del rischio

Lea Petrella and Valentina Raponi

Abstract This paper proposes a maximum-likelihood approach to jointly estimate conditional marginal quantiles of multivariate response variables using a linear regression framework.We consider a slight reparameterization of the Multivariate Asymmetric Laplace distribution proposed by Kotz et al (2001) and exploit its location-scale mixture representation to implement a new EM algorithm to estimate model parameters. The idea is to extend the link between the Asymmetric Laplace distribution and the well-known univariate quantile regression model to a multivariate context. The approach accounts for association among multiple response variables and study how such association structure and the relationship between responses and explanatory variables can vary across different quantile levels of the conditional distribution of the responses. A penalized version of the EM algorithm is also presented to tackle the problem of variable selection. The validity of our approach is analyzed in a simulation study, where we also provide evidence on the efficiency gain of the proposed method compared to estimation obtained by separate univariate quantile regressions. A real data application is finally proposed to study the main determinants of financial distress in a sample of Italian firms.

Abstract *Questo lavoro propone un approccio di massima verosimiglianza per stimare congiuntamente i quantili marginali condizionati associati a variabili risposta multivariate, in un contesto di modelli di regressione lineare multivariata. Viene considerata una leggera riparametrizzazione della distribuzione Asimmetrica di Laplace Multivariata proposta da Kotz et al. (2001) e viene proposto un nuovo algoritmo EM per la stima dei parametri del modello, sfruttando la particolare rappresentazione a mistura tipica della distribuzione Asimmetrica di Laplace. L'idea é quella di estendere il link esistente tra la distribuzione di Laplace e il modello*

di regressione quantile univariato ad un contesto multivariato. L'approccio proposto consente di tenere conto dell'eventuale associazione esistente tra le variabili risposta e intende studiare come tale struttura di associazione vari quando si considerano diversi quantili della distribuzione condizionata della variabile risposta. Viene inoltre proposto un algoritmo EM penalizzato (PEM) per affrontare il problema di selezione delle variabili. La validita' del nostro approccio viene analizzata attraverso uno studio di simulazione, attraverso il quale viene anche mostrato il guadagno in termini di efficienza del modello proposto rispetto alla stima ottenuta da (separate) regressioni quantili univariate. Infine, viene proposta un'applicazione empirica con l'obiettivo di studiare le determinnti principali del distress finanziario in un campione di aziende italiane.

Parametric Modeling of Quantile Regression Coefficient Functions

Modelli Parametrici per i Coefficienti di una Regressione Quantilica

Paolo Frumento and Matteo Bottai

Abstract In standard quantile regression (QR), quantiles are estimated one at the time. An alternative approach, which is referred to as *quantile regression coefficients modeling* (QRCM), is to describe the functional form of the regression coefficients parametrically. This approach facilitates estimation and inference, simplifies the interpretation of the results, and generates more efficient estimators. Moreover, thanks to the imposed parametric structure, it makes it easier to estimate quantiles in situations involving latent variables, missing or partially observed data, and other complications arising in survival analysis, longitudinal data analysis, and causal inference, where applying standard QR proves difficult and computationally inefficient. We describe the method, discuss applications, and illustrate the R package `qrcm`.

Abstract *I metodi standard di regressione quantilica (*QR*) permettono di stimare un quantile alla volta. Un approccio alternativo, noto come* ***quantile regression coefficients modeling*** *(*QRCM*) è quello di descrivere i coefficienti di regressione con un modello parametrico. Questo metodo semplifica la stima e l'inferenza, migliora l'interpretazione dei risultati, e aumenta l'efficienza degli stimatori. La struttura parametrica permette di stimare i quantili in presenza di variabili latenti, dati mancanti o incompleti, e altre complicazioni tipiche in analisi di sopravvivenza, in presenza di dati longitudinali, e in inferenza causale, dove le tecniche standard sono difficilmente applicabili e computazionalmente inefficienti. In questo lavoro, descriviamo il metodo e le sue applicazioni, e illustriamo il pacchetto R* `qrcm`*.*

Modelling the effect of Traffic and Meteorology on Air Pollution with Finite Mixtures of M-quantile Regression Models

Uno studio dell'effetto del traffico e delle variabili meteo sulla concentrazione di particolato atmosferico attraverso l'uso di modelli M-quantile a mistura finita

Simone Del Sarto, Maria Francesca Marino, Maria Giovanna Ranalli and Nicola Salvati

Abstract Between 2012 and 2015, the PMetro project collected meteorological, aerosol, and gas measurements by using dedicated instruments integrated on one of the cabins of the Minimetro, a public conveyance of the town of Perugia. In this work, the effect of vehicular traffic and meteorological variables on the distribution of particulate matter (PM) is analyzed using a Finite Mixture of M-Quantile regression models. Results show that radon concentration and vehicular traffic have the largest effect on the distribution of PM. In particular, the parameter estimate for radon concentration is always positive and increases along the M-quantiles, while the effect of vehicular traffic is similar both for lower and higher PM concentrations.
Abstract *Fra il 2012 ed il 2015, il progetto PMetro ha raccolto dati meteo e sulla concentrazione di particolato atmosferico e gas usando strumentazione appositamente installata su una delle cabine del Minimetro, una linea di trasporto urbana su rotaia della città di Perugia. In questo lavoro usiamo modelli M-quantile a mistura finita per studiare l'effetto del traffico e delle variabili meteo sulla distribuzione del particolato atmosferico. I risultati principali mostrano che la concentrazione di radon ed il traffico sono le variabili che incidono maggiormente, con andamenti, tuttavia, diversi per diversi valori degli M-quantili.*

Key words: Particulate Matter, PMetro, Spatio-temporal data, Random Parameters

1 Introduction

Air quality is determined by the level of the so called "atmospheric aerosol", including concentration of natural and anthropogenic pollutants, such as gases and particulate matter (PM). Atmospheric aerosol represents a critical component of the atmosphere that impacts not only on regional air pollution and human health, but also on global climate [10]. Aerosol formation in the atmosphere involves several and complex processes and particle abundance at a given time depends also on atmospheric dispersion, chemical transformation and particle loss processes. As a consequence, the concentration of PM in the atmosphere is highly variable in time and space, then the choice of the location and the time resolution of the air monitoring stations is crucial and regulated by law (e.g., Directive 2008/50/EC).

PMetro (`www.pmetro.it`) is a project that ran between 2012 and 2015 and whose main purpose was to create an innovative system to monitor urban air-quality in real-time in Perugia (Central Italy). PMetro used highly resolved space-time meteorological, aerosol and gas measurements from instruments integrated on one of the cabins of the Minimetro, a public conveyance of the town. In this paper, we aim at assessing the effect of vehicular traffic on the distribution of PM in the town of Perugia using PMetro data, while controlling for other climatic and environmental factors which may have an impact on the PM concentration. To this end, we consider the Finite Mixture of M-Quantile regression models recently introduced in the literature [3].

The proposed approach allows us to pursue a two-fold aim. First, it allows us to "move beyond mean regression" [8] which can provide a rather incomplete picture of the phenomenon under investigation. Second, it allows us to account for heterogeneity in the data, by means of random parameters having unspecified distribution. This is directly estimated from the observed data and, as a result, allows us to avoid unverifiable assumptions on the random parameter distribution.

The paper is organized as follows. Section 2 provides a close insight into the data and the modeling issues. Section 3 illustrates the finite mixture of M-quantile regression models, while Section 4 shows the results of the application to the PMetro data. Finally, Section 5 summarizes our findings.

2 Data

Aerosol data, in particular size-fraction particle number counts, were collected by an Optical Particle Counter (OPC) placed on one of the cabins of the Minimetro. The OPC provided a measure of particle number concentration in the air (i.e., the count of particles) sampled every six seconds through an aspiration line sited on the roof of the cabin. Furthermore, the cabin provided a signal which allowed its exact positioning along the path [5].

The concentration measure collected by the OPC was divided into 22 dimensional bins according to the particle diameter, expressed in micrometers (μm, 10^{-6} meters), from 0.28 μm to 10 μm. In this paper, we focus on particles with a diameter lower than 1.10 μm, obtained summing the first nine dimensional bins. This kind of particles are often called "fine" particles, even if the classification in fine and coarse is not universal and can be different according to the location (urban/rural) and/or the spatial position of the monitoring stations [11].

OPC data are integrated with two other datasets providing information on traffic volume and meteorological conditions. These three types of data have different temporal resolutions, as they were collected with different time frequencies (six seconds for OPC, five minutes for traffic, and one hour for meteorological conditions). Moreover, the OPC was a mobile station, since it collected data in the transect of the town covered by the Minimetro path, while traffic and meteorological data were obtained from fixed stations, located along the metro path. To exploit the information included in all these datasets, only OPC data collected at a particular crossroad, where traffic and meteorological conditions are available as well, are considered.

In particular, we focus on data collected from March, 2014 to February, 2015: in this period, considering the days in which all the data sources are simultaneously available, we have data for 201 days. Since Minimetro operated between 6.30 and 21.30, only the data collected within this time period are considered. Furthermore, with the aim of tackling different time resolutions, we summarize OPC, traffic, and meteorological data every half-hour. Considering that these latter are collected every hour, we computed the average between two consecutive measurements to obtain half-hour information. Last, as it is typically done when dealing with particle concentration [11], we log-transformed and normalized such a variable as follows

$$y = \log\left[\frac{count+1}{\log 1.10 - \log 0.28}\right].$$

As far as potential explanatory variables are concerned, we consider the following meteorological covariates: radon concentration, temperature, wind speed, total solar radiation and rainfall. Vehicular traffic is also considered; this is measured in terms of number of vehicles passed through the crossroad at each half-hour. Furthermore, the cumulative count of vehicles passed in the previous hours (with respect to the current time point) is also taken into account, with the aim of investigating the best proxy of vehicular traffic. More details on this issue are provided in Section 4. Here, we focus on complete data only, for a total of 5,437 observations referred to 201 days. In the following section we describe the model used.

3 Finite Mixture of M-quantile regression models

Let Y_{ij} be a continuous response variable for unit $j = 1, \dots, n_i$, belonging to cluster $i = 1, \dots, m$, and let $\mathbf{x}_{ij}$ denote a p-dimensional vector of observed covariates. We aim at analyzing the effect of these covariates on the joint distribution of the observed responses y_{ij}. To ensure robustness with respect to possible outliers in the data and to obtain a deeper description of the response variable distribution, we focus on a M-quantile specification of the regression model. Also, as we are dealing with clustered observations, dependence between measures recorded from units in same cluster represents a crucial aspect to be taken into account for deriving unbiased estimates. Typically, such a dependence is modelled by including in the response data model sources of unobserved heterogeneity in the form of cluster-specific random parameters. In this respect, for a given M-quantile $q \in (0,1)$, let $\mathbf{b}_{i,q}$ denote an r-dimensional vector of random parameters associated to the i-th cluster, distributed according to the density $f_{b,q}(\cdot)$; frequently, a Gaussian distribution is considered for such random parameters.

Here, we follow a different path and consider the semi-parametric approach suggested by [3], according to which the mixing distribution $f_{b,q}(\cdot)$ is left unspecified and is directly estimated from the data. In particular, a nonparametric maximum likelihood approach is considered to estimate $f_{b,q}(\cdot)$; this is known to lead to a discrete mixing distribution putting masses $\pi_{k,q} > 0$ on locations $\zeta_{k,q}, k = 1, \dots, K$, with $\sum_{k=1}^{K} \pi_{k,q} = 1$, see also [1, 2].

As it is commonly done when dealing with mixed effect models, we assume that, conditional on the (discrete) random parameters $\mathbf{b}_{i,q}$, responses Y_{ij} are independent each other and, for a given M-quantile $q \in (0,1)$, follow a Generalised Asymmetric Least Informative (GALI) distribution [4, 3] :

$$Y_{ij} \mid \mathbf{b}_{i,q} \sim \frac{1}{B_q(\sigma_q)} \exp\{-\rho_q[y_{ij} - MQ_q(y_{ij} \mid \mathbf{x}_{ij}, \mathbf{b}_{i,q}; \psi)]\}. \tag{1}$$

In the equation above, $\rho_q(\cdot)$ denotes the Huber loss function, $B_q(\cdot)$ is a normalising constant that ensures the density integrates to one, and σ_q is a M-quantile-specific scale parameter. Last, $MQ_q(y_{ij} \mid \mathbf{x}_{ij}, \mathbf{b}_{i,q}; \psi)$ indicates the q-th M-quantile of the conditional response distribution. For $\mathbf{b}_{i,q} = \zeta_{k,q}$, this is modeled according to the following expression:

$$MQ_q(y_{ij} \mid \mathbf{x}_{ij}, \mathbf{b}_{i,q}; \psi) = MQ_q(y_{ij} \mid \mathbf{x}_{ij}, \zeta_{k,q}; \psi) = \mathbf{x}'_{ij}\beta_q + \mathbf{w}'_{ij}\zeta_{k,q},$$

where ψ is the influence function corresponding to $\rho_q(\cdot)$, β_q is a p-dimensional vector of fixed effects, and $\mathbf{w}_{ij}$ is a subset of $\mathbf{x}_{ij}$ containing the covariates whose effect is assumed to vary with clusters.

Based on the modeling assumptions introduced so far, the joint *conditional* density of all responses coming from the i-th cluster, $\mathbf{y}_i$, is given by:

$$f_q\left(\mathbf{y}_i \mid \zeta_{k,q}; \beta_q, \sigma_q, \mathbf{X}_i\right) = \prod_{j=1}^{n_i} f_q\left(y_{ij} \mid \zeta_{k,q}; \beta_q, \sigma_q, \mathbf{x}_{ij}\right),$$

with $f_q(y_{ij} \mid \zeta_{k,q}; \beta_q, \sigma_q, \mathbf{x}_{ij})$ being the GALI distribution in equation (1) with $\mathbf{b}_{i,q} = \zeta_{k,q}$, and $\mathbf{X}_i$ being the matrix of all observed covariates for cluster i .

Denoting by Φ_q the vector of all model parameters associated to the q-th M-quantile, this can be efficiently estimated from the following observed data log-likelihood function:

$$\ell_q(\Phi_q) = \sum_{i=1}^{m} \log\left\{\sum_{k=1}^{K} f_q\left(\mathbf{y}_i \mid \zeta_{k,q}; \beta_q, \sigma_q, \mathbf{X}_i\right) \pi_{k,q}\right\}. \tag{2}$$

As it may be noticed, the expression in equation (2) resembles the likelihood of a finite mixture model defined on K distinct components; the maximization of such a function can be directly pursued by exploiting an extended version of the standard EM algorithm [6]. To conclude this section, it is worth to highlight that the assumption of GALI distributed responses is merely ancillary and it is simply introduced to cast standard estimation of M-quantile regression models into a maximum likelihood context.

4 Results

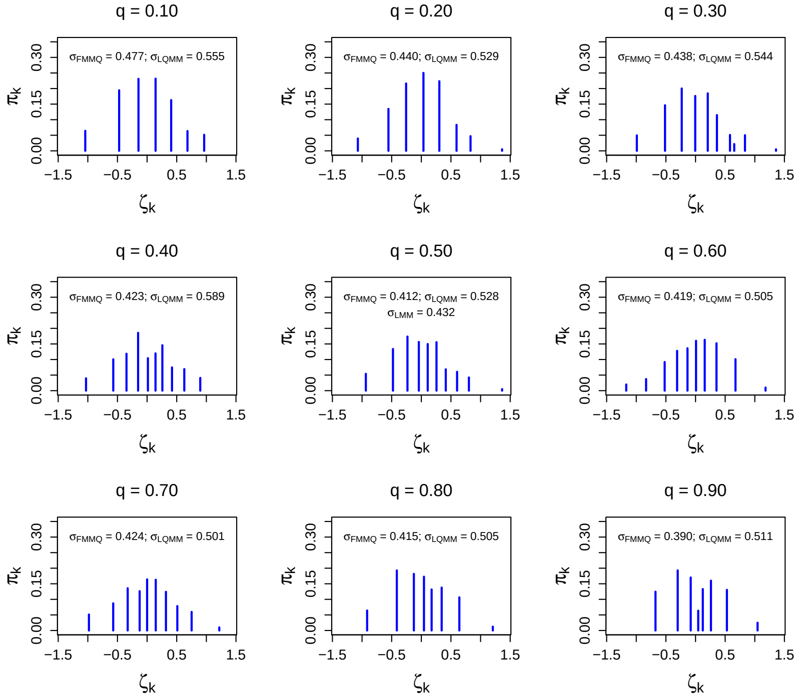
In this section, we exploit the model described so far to analyze PMetro data introduced in Section 2. Our aim is that of characterizing the evolution over time of air quality in Perugia in terms of a number of covariates summarizing traffic level and meteorology conditions.

A preliminary analysis was conducted with the aim of selecting the covariate that best represents the vehicular traffic in town. Such an analysis led us to retain as optimal proxy of vehicular traffic the cumulative sum of vehicles passed in the previous 4 hours. Other covariates included into the model are: the logarithmic transform of radon concentration (log-*Radon*), the temperature (*Temp*) and its quadratic transform (*Temp*^{2}), the wind speed (*WSP*), the total solar radiation on the logarithmic scale (log-*TSR*), and the rainfall (*Rain*). To account for sources of unobserved heterogeneity among days which are non captured by the available covariates, we also included in the model a discrete random intercept having unspecified distribution.

To analyse the possible differential effect of observed covariates on different parts of the (conditional) response variable distribution, we considered a grid of M-quantile levels ranging from $q = 0.1$ to $q = 0.9$. For each q, we run the estimation algorithm for a varying number of mixture components and retained the optimal solution according to the BIC index. In this respect, we selected $K = 10$ for $q = 0.3, 0.4, 0.5, 0.6, 0.7$, $K = 8$ for $q = 0.2, 0.8, 0.9$, and $K = 7$ for $q = 0.1$. That is, the optimal K is higher when focusing on the center of the conditional response distribution and reduces at the tails. Here, a reduced amount of information is available and, therefore, a reduced amount of (unexplained) variability is present.

We represent in Figure 1 the estimated distribution of the random parameters for varying q; at the top of this figure, we also report the standard deviation of such a distribution – σ_{FMMQ}. For comparison, we also report the standard deviation of the random parameters obtained under a standard linear quantile mixed model (LQMM) specification [7] and, for for $q = 0.5$, the estimated standard deviation obtained from a linear mixed model (LMM) [9]. By looking at these values, we observe that σ_{LQMM} is always lower than σ_{FMMQ}. This may be due to the slight (positive) asymmetry and/or bi-modality of the random parameter distribution, especially for some q values. While this feature is easily captured by the FMMQ approach, the same is not true when considering the a parametric specification for $b_{i,q}$.

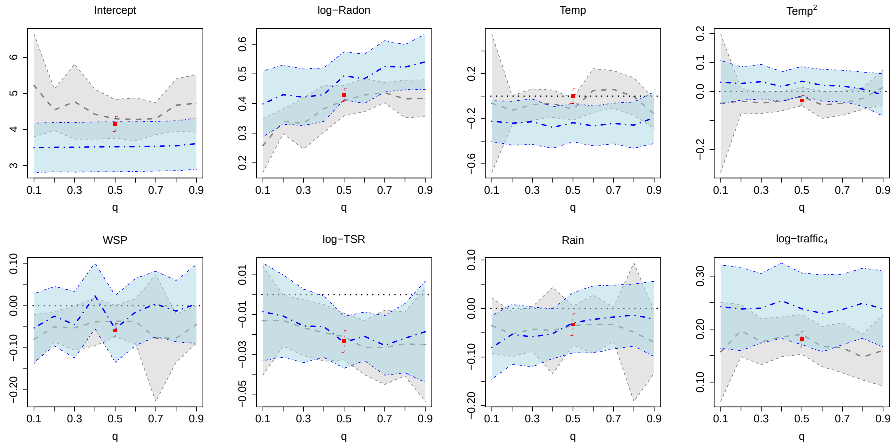
Fig. 1 Estimated random coefficient distribution for varying q. In each plot, the estimated standard deviation of the random parameter distribution is reported.



Finally, to understand whether the effect of the covariates differs across M-quantiles, we report in Figure 2 the evolution of fixed parameter estimates for different q, together with the corresponding 95% confidence intervals. For comparison, we also report for each M-quantile q the estimates obtained under the LQMM and LMM specifications. For all the covariates, confidence intervals obtained under LQMM and FMMQ always overlap suggesting that the two methodologies lead to similar results. In particular, the radon concentration estimate is always positive and significant, and, in particular, increases with q. This implies that the effect of radon on fine particle count is stronger when concentrations are higher. Total solar radiation has a similar behavior in the opposite direction: it has a negative effect on fine particle concentration, and this effect is stronger when concentrations are higher.

We would have expected an increasing pattern for vehicular traffic. However, results reported in Figure 2 highlight that this estimate remains quite constant with q. This implies that the relative impact of an increase in vehicular traffic remains the same for lower and for higher concentrations of fine particle concentrations. This pattern is similar to that from LQMM.

Fig. 2 Fixed parameter estimates and 95% confidence intervals under FMMQ (grey), LQMM (blue) and LMM (red), for varying q.



5 Conclusions

In this paper, we analyzed data on air quality to assess the effect of vehicular traffic. Fine particle concentration depends on a complex process and we included meteorological variables in our model to try to isolate the effect of traffic. We used a finite mixture of M-quantile regression models to investigate the effect of the covariates at different locations of the response distribution, to account for the clustered structure of the data without resorting to a parametric (usually Gaussian) distribution for the random parameters, and to deal with outlying observations. We used data for a whole year in order to account for seasonal trends.

Since vehicular traffic is the only variable that policy makers can control to reduce fine particle concentration, we can use the findings in this paper to provide guidelines. A common act enforced to reduce pollution in Italy is to restrict circulation in designated areas and days, alternating vehicles with an odd/even plate number. This implies roughly halving the number of vehicles. From the findings in our paper, we can state that reducing by 50% the number of vehicles implies a reduction of 10% of fine particle concentration, other things being equal. This relative reduction is essentially the same in spite of the fact that we are in day with a relatively low or high fine particle concentration. Of course, this also implies that the effect will be higher in absolute terms.

Recent Advances on Extreme Value Theory

Extremes of high-order IGARCH processes

Valori estremi per processi IGARCH di ordine elevato

Fabrizio Laurini

Abstract The extremal properties of GARCH processes are of wide interest for market risk management. Only for simple GARCH(1,1) extremes have been widely discussed. Much remains to be found about the dependence structure of extreme values for higher order GARCH. Although recent research has identified the multivariate regular variation property of stationary GARCH(p,q) processes, currently there are no methods for numerically evaluating extreme components, like the average length of an extreme period. Only very simple special cases are well understood, but these are of little practical relevance, as bounded distribution of the error term is assumed. We present a unified toolkit that tackles the above critics and it is usable for Integrated GARCH(p,q) processes, assuming innovations with unbounded support or asymmetry. With our method we are able to generate the forward tail chain of the process to derive all extremal features. The convergence of our numerical algorithm is very fast due to an efficient implementation of a particle filtering simulation technique.

Abstract *Le proprietà estreme dei processi GARCH sono di interesse centrale per la gestione del rischio di mercato. Soltanto per semplici GARCH(1,1) i valori estremi sono stati caratterizzati. Molto resta da studiare riguardo la dipendenza dei valori estremi per processi GARCH di ordine più elevato. Sebbene recentemente si siano usate connessioni con le proprietà di variazione regolare multivariata dei processi GARCH(p,q), al momento non ci sono metodi in grado di quantificare tali caratteristiche estreme. Pertanto, soltanto casi speciali sono stati compresi a fondo, ma questi sono spesso irrilevanti da un punto di vista pratico, visto che viene assunta una forma sul termine d'errore con distribuzione limitata. Si presenta un insieme di tecniche unificato volto a superare tutti questi inconvenienti ed è usabile anche per processi GARCH(p,q) Integrati con innovazioni a supporto illimitato e asimmetriche. Il metodo si basa sulla cosiddetta forward tail chain per derivare tutti gli*

1 Introduction

The risk management in the stock markets, commonly called *market risk management*, suggests the use of statistical tools and models which aim at reducing the potential size of losses, occurring by sudden drops or growth in the stock market. Such losses are even amplified when the volatility of the stock market is substantial. Hence, modeling and forecasting the temporal evolution of the market volatility is of great concerns for financial institutions.

Consider the daily log-returns $X_t = \log P_t - \log P_{t-1}$, $(X_t \in \mathbb{R})$ where P_t, $t = 1, 2, \ldots$, is the price of a generic asset. Then a broad class of models, mostly adopted to describe the market volatility, is the generalized autoregressive conditionally heteroscedastic (GARCH) introduced by [3]. For market risk management one of the most important issue is the presence of extreme values of daily log-returns. Therefore, understanding the extreme properties for such processes is fundamental, and this can be achieved by considering the marginal and the clustering properties of GARCH processes.

GARCH(p,q) models, for integers p and q, have the form

$$X_t = \sigma_t Z_t \quad \text{with} \quad \sigma_t^2 = \alpha_0 + \sum_{i=1}^{q} \alpha_i X_{t-i}^2 + \sum_{j=1}^{p} \beta_j \sigma_{t-j}^2, \quad t = 1, 2, \ldots, \quad \text{and} \quad \alpha_0 > 0. \tag{1}$$

For fixed t Z_t and σ_t are independent. The independent and identically distributed (IID) sequence $\{Z_t\}_{t \geq 1}$ is assumed to be symmetric with $E(Z_t^2) = 1$. Conditions on the parameters $\alpha_i, i = 1, \ldots, q$ and $\beta_j, j = 1, \ldots, p$ are discussed in Section 2.

GARCH(p,q) processes $\{X_t\}_{t \geq 1}$ satisfies mixing conditions, so that the key parameter for quantifying the impact of extreme values is the extremal index $\theta_X \in (0, 1]$. The extremal index θ_X measures the level of clustering of extreme values, with the clustering of extreme increasing for θ_X decreasing.

An important interpretation of the extremal index is provided using the cluster size distribution $\pi_X(i), i = 1, 2, \ldots$, since $\sum_{i=1}^{\infty} i \pi_X(i) = (\theta_X)^{-1}$, so θ_X is the reciprocal of the limiting mean cluster size of extreme values. The special case $\theta_X = 1$ means no clustering of extremes. Extremes of GARCH(p,q) models have been studied by [1], but formulae for θ_X do not exist.

[2] were the first to propose computational algorithms for the evaluation of θ_X. Their algorithms make a very strict assumption that the innovation Z_t has bounded support, ruling out many important distributions used by practitioners, e.g., Z_t being Gaussian or t-distributed. We propose an entirely new algorithm that does not re-

quire these assumptions, and critically allows unbounded support for Z_t, as we take $Z_t \sim \mathrm{ST}(0,1,\lambda,\nu)$ scaled to have unit variance.

The relevant feature of the proposed algorithm is to simulate directly the tail chain of a GARCH(p,q) model. The tail chain of a process, introduced by [2], will be discussed later. The approach used here extends the algorithm of [4] for GARCH$(1,1)$ processes.

We derive the theory for obtaining the extremal index of a GARCH(p,q) process, and we provide a Monte Carlo algorithm for the numerical evaluation θ_X and associated cluster size distribution. Precisely, with our algorithm we first obtain the cluster size distribution $\pi_{X^2}(\cdot)$ and the extremal index θ_{X^2} for the square of the process, and then derive $\pi_X(\cdot)$ and θ_X. All results do not require the symmetry of Z.

2 Technical background, notation and assumptions

2.1 SRE representation for GARCH

Let us start by defining stationarity for GARCH(p,q) processes. We focus on the squared GARCH process, $X_t^2{}_{t\geq 1}$, and rewrite the process as a stochastic recurrence equation (SRE) as this enables the exploitation of a range of established results for such processes, e.g., the existence of results for the marginal distribution.

Let the $(p+q)$ vector $\mathbf{Y}_t$, the $(p+q)\times(p+q)$ matrix $\mathbf{A}_t$ and the $(p+q)$ vector $\mathbf{B}_t$ be

$$\mathbf{Y}_t = \begin{pmatrix} X_t^2 \\ \vdots \\ X_{t-q+1}^2 \\ \sigma_t^2 \\ \vdots \\ \sigma_{t-p+1}^2 \end{pmatrix} \qquad \mathbf{A}_t = \begin{pmatrix} \alpha^{(q-1)} Z_t^2 & \alpha_q Z_t^2 & \beta^{(p-1)} Z_t^2 & \beta_p Z_t^2 \\ I_{q-1} & 0_{q-1} & I_{q-1} & 0_{q-1} \\ \alpha^{(q-1)} & \alpha_q & \beta^{(p-1)} & \beta_p \\ 0_{q-1} & 0_{p-1} & I_{p-1} & 0_{p-1} \end{pmatrix} \qquad \mathbf{B}_t = \begin{pmatrix} \alpha_0 Z_t^2 \\ 0_{q-1} \\ \alpha_0 \\ 0_{q-1} \end{pmatrix} \tag{2}$$

where $\alpha^{(s)} = (\alpha_1,\ldots,\alpha_s) \in \mathbb{R}^{(s)}$, $\beta^s = (\beta_1,\ldots,\beta_s) \in \mathbb{R}^s$, I_s is the identity matrix of size s, 0_s is a square matrix of zeros of size s and 0_s is a column vector of zeros having length s. In each case here if $s<0$ then these terms are to be interpreted as being dimensionless. Then it follows that the squared GARCH(p,q) processes satisfies the SRE

$$\mathbf{Y}_t = \mathbf{A}_t \mathbf{Y}_{t-1} + \mathbf{B}_t, \qquad t \geq 1, \tag{3}$$

where $\{\mathbf{A}_t\}_{t\geq 1}$ and $\{\mathbf{B}_t\}_{t\geq 1}$ are each sequences of IID stochastic matrices and vectors. The formulation of the SRE via (2) is less parsimonious than that of [1], but has the benefit of covering all GARCH(p,q) processes, even when $p=q=1$.

It is necessary and sufficient that there is a negative top Lyapunov exponent of $\mathbf{A}_t$ for the existence of a unique, strictly stationary solution of SRE (3). Under the condition $E \ln^+ \|\mathbf{A}_t\| < \infty$ (here $\ln^+ x = \ln x$, if $x \geq 1$ and 0 otherwise), the top Lyapunov exponent is

$$\gamma = \lim_{t \to \infty} \frac{1}{t} \ln \|\mathbf{A}_t \mathbf{A}_{t-1} \cdots \mathbf{A}_1\| \tag{4}$$

almost surely, so that, via expression (4) a relatively simple simulation can be performed to obtain γ.

If $\sum_{j=1}^{p} \beta_j < 1$ then $\gamma < 0$. This stationary condition covers various forms of GARCH process including the IGARCH(p,q) process which has the property that

$$\sum_{i=1}^{q} \alpha_j + \sum_{j=1}^{p} \beta_j = 1. \tag{5}$$

For second-order stationarity a stronger condition is required, namely the left hand side of equation (5) is required to be strictly less than 1. This condition implies that $\gamma < 0$, and the second moment of X_t^2 are finite, and so is the fourth moment of X_t. So an IGARCH(p,q) is strictly stationary but has infinite variance and so is not second-order stationary.

2.2 Tail chain process and regular variation for squared GARCH

Taking a heavy tailed process $\{\mathbf{Y}_t\}_{t \geq 1}$ as strictly stationary, the tail chain is defined in the following way. When $u \to \infty$, if for any $t \geq 1$

$$(\mathbf{Y}_0/u, \mathbf{Y}_1/X_0, \ldots, \mathbf{Y}_t/\mathbf{Y}_0) \mid \|\mathbf{Y}_0\| > u,$$

converges weakly to $(\hat{\mathbf{Y}}_0, \hat{\mathbf{Y}}_1, \ldots \hat{\mathbf{Y}}_t)$. The tail process $\{\hat{\mathbf{Y}}_t\}_{t \geq 1}$ exists if and only if $\{\mathbf{Y}_t\}_{t \geq 1}$ is jointly regularly varying.

[1] show that there exists a unique stationary solution to the SRE (3) and this solution exhibits a multivariate regular variation property, i.e., for any $t \geq 1$, any norm $\|\cdot\|$ and all $r > 0$,

$$\frac{\Pr(\|\mathbf{Y}_t\| > rx, \mathbf{Y}_t/\|\mathbf{Y}_t\| \in \cdot)}{\Pr(\|\mathbf{Y}_t\| > x)} \xrightarrow{v} r^{-\kappa} \Pr(\mathbf{D}_t \in \cdot), \qquad \text{as } x \to \infty, \tag{6}$$

where $\xrightarrow{v}$ denotes vague convergence, $\kappa \geq 0$, and $\mathbf{D}$ is $p+q$ dimensional random vector in the unit sphere (with respect to a norm $\|\cdot\|$) defined by $\mathbb{S}^{p+q} \subset \mathbb{R}^{p+q}$. If condition (6) holds $\mathbf{Y}_t$ exhibits multivariate regularly variation with index κ and $\mathbf{D}$ is termed the spectral tail process of the vector $\mathbf{Y}_t$.

The subsequent results link γ to κ. There is structure imposed on both κ and $\mathbf{D}$ by the GARCH(p,q) process. In particular, κ is the unique positive solution of the equation

$$\lim_{t \to \infty} \frac{1}{t} \ln E \left(\|\mathbf{A}_t \mathbf{A}_{t-1} \cdots \mathbf{A}_1\|^{\kappa} \right) = 0. \tag{7}$$

For all the numerical evaluations, we will use the norm $\|\mathbf{A}\| = \sum |a_{ij}|$. In general κ can be found only by numerical solution of equation (7) via Monte Carlo. However for any IGARCH$(1,1)$ process $\kappa = 1$; see [1].

A consequence of the multivariate regular variation property (6) is that all the marginal variables of $\mathbf{Y}_t$ have regularly varying tails with index κ, so in particular for $r \geq 1$

$$\Pr(X_t^2 > rx \mid X_t^2 > x) \to r^{-\kappa}, \qquad \text{as } x \to \infty. \tag{8}$$

3 Tail chain for IGARCH process with asymmetric Z

3.1 Particle filter algorithm

In this Section an algorithm to sample from $\mathbf{D}$ is presented. The property $E(\|\mathbf{AD}_0\|^\kappa) = 1$, proved by [2], is extensively used to this aim. After obtaining κ via Monte Carlo (7), that require as inputs the coefficients and a sample from Z^2, the steps are the following

- Initialize with the estimate of the empirical distribution of $\widetilde{\mathbf{D}}_0$. The empirical distribution is estimated using m extreme values from a simulated squared GARCH(p,q), where the extremes are the m largest values of the squared sequence.
- From the empirical distribution $\widetilde{\mathbf{D}}_0$ we initialize the procedure by taking J particles with equal weight $w_0^{(j)} = 1/J$ and sample from $\widetilde{\mathbf{D}}_0$ with probabilities given by $w_0^{(j)}$. At this step of the sampling is made with replacement, i.e. it is possible to set $J > m$.
- The empirical distribution after the first run of the algorithm is computed by first using the transition
$$\mathbf{D}_1^\star = \mathbf{A}^{(j)}\widetilde{\mathbf{D}}_0, \qquad j = 1,\ldots,J, \tag{9}$$
where the $\mathbf{A}^{(j)}$ are independent copies of $\mathbf{A}$. Since we neglect the random vector $\mathbf{B}$ when computing the transition (9), then $\mathbf{D}_1^\star$ has to be normalized. A proper (yet empirical) distribution can be obtained by simply scaling the $\mathbf{D}_1^\star$, i.e.
$$\widetilde{\mathbf{D}}_1 = \frac{\mathbf{D}_1^\star}{\|\mathbf{D}_1^\star\|}.$$
- The new particles weights are subsequently updated exploiting $E(\|\mathbf{AD}_0\|^\kappa) = 1$. We take advantage of that property by first storing

$$w_j^\star = \|\mathbf{D}_1^\star\|^\kappa, \quad \text{normalized with} \quad w_j^{(1)} = \frac{w_j^\star}{\sum_{j=1}^J w_j^\star}, \qquad j = 1,\ldots,J. \tag{10}$$

- In general particle weights $w_j^{(1)}$ from iteration 1 are no longer identical, and that will be the case in all iterations.
- Iterate S times using recursions similar to (9) and (10), where at each fixed replicate s, $(s = 1,\dots,S)$ the J particles of $\widetilde{\mathbf{D}}_s$ are sampled, with replacement, with updated weights $w_j^{(s)}$, $j = 1,\dots,J$.
- In our algorithm we check that these conditions hold at convergence. We noticed that with small S the weights stabilize, and we have a good sample from $\mathbf{D}_t$, i.e. $\widetilde{\mathbf{D}}_S \to \mathbf{D}_t$.

3.2 Random thinning for the IGARCH

Mapping from the squared process to the "original" process require to rule out extremes in the X_t^2 which do not belong to the X_t process. First note that if X_t^2 is regularly varying with index $\kappa > 0$ then if

$$\Pr(Z_t > x \mid |Z_t| > x) \to \delta \qquad \text{as } x \to \infty, \tag{11}$$

where $0 < \delta < 1$ then it follows that X_t is a regularly varying random variable, with index $\kappa/2$, in both its upper and lower tails.

To translate results about the tail chain of the squared GARCH process we take the first component of $\hat{\mathbf{Y}}_t$ to be denoted as $\{\hat{Y}_t\}$. To study properties for the tail chains of the GARCH $\{\hat{X}_t\}_{t\geq 1}$ process we adopt a similar strategy to [4]. It is key to recognise that there are two tails chains for $\hat{X}_t$, a lower and an upper tail chain $\hat{X}_t^l$ and $\hat{X}_t^u$ respectively, with $\hat{X}_t^u = B_t(\hat{Y}_t)^{1/2}$ and $\hat{X}_t^l = -B_t(\hat{Y}_t)^{1/2}$ where B_t is a sequence of IID Bernoulli(δ) variables, with δ given by limit (11), where $B_t = \{-1, 1\}$ with respective probabilities $\{1-\delta, \delta\}$.

An extreme event for the tail chain $\{\hat{Y}_t\}_{t\geq 1}$ of the squared GARCH does not occur in the upper tail $\{\hat{X}_t^u\}_{t\geq 1}$ and lower tail $\{\hat{X}_t^l\}_{t\geq 1}$ with respective probabilities $P^u(\delta)$ and $P^l(1-\delta)$ where

$$P^u(\delta) = \sum_{i=1}^{\infty} \pi_{X^2}(i)\delta^i$$

and $\pi_{X^2}(i)$ is the probability that a cluster of length i is in the $\{X_t^2\}$ series.

For the upper and lower tail behaviour of $\{X_t\}$ it follows that the respective extremal indices are

$$\theta_X^u(\delta) = \delta^{-1}\theta_{X^2}\{1 - P^u(\delta)\} \tag{12}$$

and $\theta_X^l(1-\delta)$ respectively, where θ_{X^2} is the extremal index of the squared GARCH process. Similarly, the upper and lower tail limiting cluster size distributions of $\{X_t\}$ are given by

$$\pi_X^u(i,\delta) = \Big\{1 - P(\delta)\Big\}^{-1} \sum_{j=i}^{\infty} \pi_{X^2}(j) \binom{j}{i} \delta^i (1-\delta)^{j-i} \text{ for } i = 1, 2, \dots. \tag{13}$$

and $\pi^l_X(i, 1-\delta)$. Thus once we have derived $\pi_{X^2}(\cdot)$, obtaining $\pi_X(\cdot)$ is immediate for both tails of the GARCH process.

4 Some results for the GARCH(2,2)

In this example a GARCH$(2,2)$ process is considered with standard Gaussian innovation Z_t and parameters $\alpha_1 = \alpha_2 = 0.2$, $\beta_1 = 0.3$ and $\beta_2 = 0.25$.

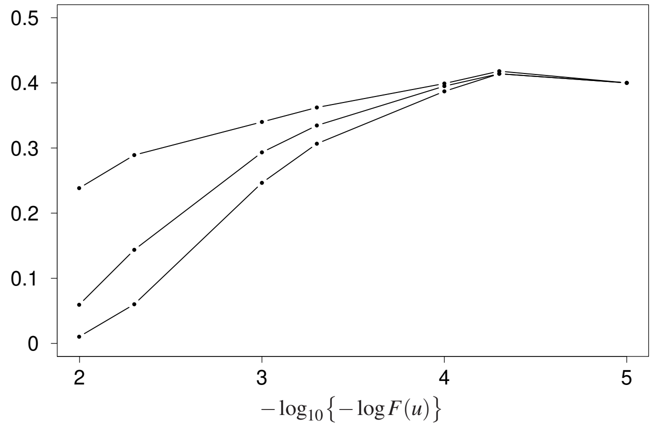

Fig. 1 Runs estimation of the extremal index for a stationary GARCH$(2,2)$ process.

To check our results, we simulate 10^7 values from such a configuration. An estimate of the extremal index with the runs method, which require run length (here $m = 100, 500, 1000$) and a sequence of high thresholds u_n, is considered. The length of the sample size reduces considerably the bias of runs method, even if only one simulation is considered. In Figure 1 we plot u_n on the $-\log_{10}\{-\log F(u_n)\}$ scale. Such choice standardises the upper tail of the distribution. From this plot we can conjecture that the extremal index might lie in the interval 0.25–0.45, but we cannot say more.

From the same GARCH$(2,2)$ structure we now turn to our algorithm, with Monte Carlo value of $\kappa = 1.83$. Figure 2 shows the numerical evaluation of θ and the (little) sensitivity of our algorithm to the number of initial seeds and threshold selection. For each fixed level of threshold, darker points in Figure 2 correspond to lower number of initial seeds. More precisely, white empty circles show results θ with a number of initial seeds higher than other circles and thus more reliable (in this example white filled circles correspond to nearly 250000 initial cluster of extremes, while black filled circles are about 10000 initial seeds).

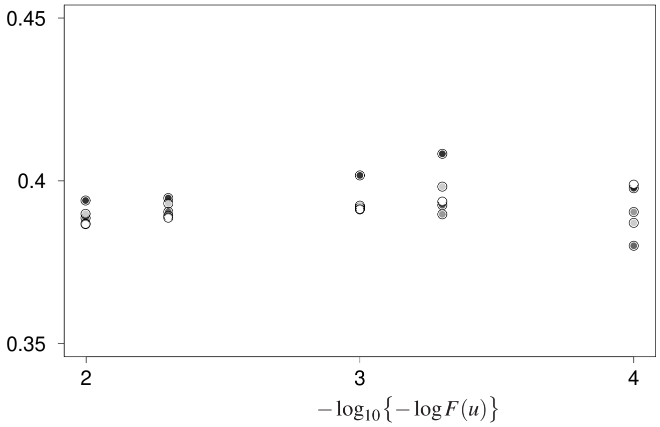

Fig. 2 Sensitivity to θ_X for the GARCH(2,2) process for a range of thresholds and a variety of initial seeds. For a fixed threshold darker circles correspond to a smaller number of initial seeds.

5 Summary and final remarks

We simulate a number of independent seeds conditioning on the event of being at extreme levels. For each initial seed we exploit the autoregressive property of GARCH processes and simulate only clusters of extreme values. The accuracy of our method relies on the number of such cluster of extremes. The usefulness of simulating from within a cluster is two-fold, as we avoid computation inefficiency derived by simulating long sequences of GARCH processes and reduce the influence on the subjective choice of a suitable high threshold.

Acknowledgements The work is part of a broader project involving Paul Fearnhead and Jonathan Tawn, Lancaster University - UK, which are kindly acknowledged. Simone Padoan read carefully an early draft and made a number of useful comments.

Spatial Economic Data Analysis

Spatial heterogeneity in principal component analysis: a study of deprivation index on Italian provinces
Eterogeneità spaziale nell'analisi delle componenti principali: uno studio sull'indice di deprivazione sulle province italiane

Paolo Postiglione[1], M. Simona Andreano[2], Roberto Benedetti[3], Alfredo Cartone

Abstract Principal Component Analysis (PCA) is a tool often used for the construction of composite indicators even at the local level ([18]). In general, when we are dealing with spatial data, the method of PCA, in its classical version, is not appropriate for the synthesis of simple indicators. The objective of this paper is to introduce a method to take into account the spatial heterogeneity in PCA, extending the contribution introduced by [19]. The proposed method will be implemented for the definition of a deprivation index on Italian provinces.

Abstract *L'analisi delle componenti principali (ACP) è uno strumento spesso utilizzato per la costruzione di indicatori compositi anche a livello locale ([18]). In generale, quando stiamo lavorando su dati spaziali, l'ACP, nella sua versione classica, non è appropriata per la sintesi di indicatori semplici. L'obiettivo di questo lavoro è di introdurre un metodo che considera l'eterogeneità spaziale nell'ACP, estendendo l'idea di [19]. Il metodo proposto sarà implementato per la definizione di un indice di deprivazione nelle province italiane.*

Key words: Simulated annealing, GWPCA, composite indicators, spatial effects.

1. Introduction

Principal Component Analysis (PCA, [12]) is a statistical method largely adopted in empirical applications. PCA returns a set of independent variables of correlated variables by decomposing the eigen-structure of the variance-covariance matrix ([13]). Typical output of PCA are vectors of loadings corresponding to eigenvectors and new sets of coordinates corresponding to components. PCA is a dimension-reduction tool that can be used to reduce a large set of variables to a small set that

[4] University of Chieti-Pescara, Department of Economic Studies, email: alfredo.cartone@unich.it

still contains most of the information in the large set. It is also used to the aim of exploring the data.

PCA is often applied on geographically distributed data ([3]). Spatial data present particular characteristics that should be considered when applying statistical technique: spatial dependence and spatial heterogeneity that are the two inherent characteristics of spatial data. Spatial dependence can be defined as "the propensity for nearby locations to influence each other and to possess similar attributes" ([8]). On the other hand, as evidenced by [1], there are two distinct forms of spatial heterogeneity: structural instability and heteroscedasticity. Structural instability concerns the presence of varying structural parameters over space. Heteroscedasticity leads to different error variances of the spatial units.

In this paper, our main aim is to consider the problem of spatial heterogeneity when using PCA for geographically distributed data. In particular, we will address the idea that coefficient estimates can vary across space, leading to spatial structural instability. As argued by [19], the analysis and the assessment of heterogeneity for geographically distributed data is one of the main challenges for the spatial analysts. Empirical models that do not take into account for structural heterogeneities may show serious misspecification problems ([20]).

PCA can also be employed to define composite indicators ([17]). The use of composite indicators is common in practical analyses because we often meet multidimensionality in the real world ([16]). The loadings of PCA may be used as weights in the building of the composite indicators. Some Authors (see, for example, [4]) criticize this use of PCA, because the weights from PCA are defined through a statistical technique and may not reflect the relevance of the single variable for the underlying phenomenon. However, weights from PCA may be less "subjective" because these are not assigned by the researcher and are data-driven, differently from the case of "normative" weights. See [2]) for a discussion about the methods for deriving composite indicators.

Spatial heterogeneity has been considered in PCA through the approach denoted as geographically weighted principal components analysis (GWPCA) ([5]). This method allows for differences in the loadings and scores structure due to spatial instability. The output of GWPCA is represented by estimates of the covariance matrix and sets of components for each locality ([10]). In this way, distinct composite indicators are defined differently for each locality. It is clear that the interpretation of such a list of different composite indicators at local level is not entirely straightforward.

In this paper, we propose to use a modified version of simulated annealing (SA) introduced by [19] to identify zones of local stationarity in the eigenvalues and in the corresponding eigenvectors defined by PCA. The presence of the heterogeneity is a criterion to divide the sample of observations (i.e. regions) into smaller homogeneous groups. Therefore, in our case, we are able to define a composite indicator for each partition identified by SA algorithm.

The use of PCA for deriving composite indicators of deprivation has been extensively explored ([18]). Deprivation may be defined "as a state of observable and demonstrable disadvantage relative to the local community or the wider society or nation to which an individual, family or group belongs" ([21]). Its measurement considers several dimensions from both the social and economic sphere to assess the presence of disparities. In this paper, our aim is to define a composite indicator of deprivation for group of Italian provinces.

The layout of the paper is the following. Section 2 is devoted to briefly summarize the methodological contribution of the paper. In particular, we review the main characteristics of PCA and how SA can be applied to identify zone of local stationarity for eigenvalues and eigenvectors. Section 3 contains the description of our data set and shows the results of the composite indicator for Italian provinces. Finally, section 4 concludes.

2. The methodology

PCA is based on the analysis of a matrix $\mathbf{X}_{nm}$ where $i = 1, \dots, n$ denotes the statistical units and $j = 1, \dots, m$ the variables, respectively. The central idea of PCA is the representation of units in q-dimensional subspaces (with $q < m$) retaining the maximum of statistical information. The reduction of data dimensionality allows us easier interpretative analysis. A primary result in PCA is ([13]):

$$\mathbf{A\Lambda A}^t = \mathbf{\Sigma} \tag{1}$$

where $\mathbf{\Lambda}$ is the diagonal matrix of eigenvalues, $\mathbf{A}$ is the corresponding matrix of loadings (i.e., the eigenvectors), and $\mathbf{\Sigma}$ is the variance/covariance matrix. The eigenvalues in $\mathbf{\Lambda}$ represent the variance of the principal component, $\mathbf{Y}_j$ defined as:

$$\mathbf{Y}_j = \mathbf{Xa}_j \tag{2}$$

where $\mathbf{a}_j$ is the j-th column of the loading matrix $\mathbf{A}$ of $\mathbf{\Sigma}$ and represents the contribution of each variable in $\mathbf{X}$ to the j-th principal component $\mathbf{Y}_j$.

In practice, the component scores related to components $q + 1$ to m represent the Euclidean distances alongside the axes of the corresponding orthogonal vectors to a q-dimensional linear subspace. The first q loadings are chosen so that this subspace contains the highest proportion of the total variance of the data points. In essence, PCA seeks a linear combination of variables such that the maximum variance is extracted from the variables. The first q components are described by:

$$\mathbf{Y} = \mathbf{XA}_q \tag{3}$$

where $\mathbf{Y}$ is the score matrix, $\mathbf{A}_q$ is the loading matrix with the only q columns of $\mathbf{A}$. [13] demonstrates that the best (least squares) rank q approximation to $\mathbf{X}$ is $\mathbf{XA}_q\mathbf{A}_q^t$ and the residual matrix $\mathbf{S}$ can be defined as:

$$\mathbf{S} = \mathbf{X} - \mathbf{XA}_q\mathbf{A}_q^t = \mathbf{XA}_{-q}\mathbf{A}_{-q}^t \tag{4}$$

where $\mathbf{A}_{-q}$ is the loading matrix with the first q columns removed. In the case of application of PCA to spatially distributed data, the underlying implicit hypothesis is that the variance and covariance structure of the process is constant throughout the geographical area under investigation. This assumption is obviously not realistic

([10]). Therefore, it is necessary to relax this hypothesis, to consider in some way the spatial effects in the definition of the principal components.

A first appropriate technique for PCA for spatial data is represented by Geographically Weighted Principal Component Analysis, (GWPCA, [5], [9]). The equation (1) can be generalized to the case of GWPCA as ([10]):

$$\mathbf{A}(u_i, v_i)\mathbf{\Lambda}(u_i, v_i)\mathbf{A}(u_i, v_i)^t = \mathbf{\Sigma}(u_i, v_i) \tag{5}$$

where $\mathbf{\Lambda}(u_i, v_i)$ is the diagonal matrix of local eigenvalues, $\mathbf{A}(u_i, v_i)$ is the corresponding matrix of local eigenvectors, $\mathbf{\Sigma}(u_i, v_i)$ is the local variance-covariance matrix, and (u_i, v_i) are the coordinates of spatial unit i.

The output of GWPCA consists in different loadings and component scores defined for each spatial unit. In practice, GWPCA defines completely different index for each spatial unit as function of distinct loadings. This produces remarkable difficulties in the interpretation of the results.

To simplify the reading of the phenomena, in this paper we propose to apply simulated annealing (SA) algorithm to PCA to identify groups of spatial units that are supposed to share the same eigenvectors (i.e., the same composite indicators). This approach was introduced by [19] and improved by [20] for the analysis of economic growth. The main idea of this framework is that the appropriate treatment of spatial heterogeneity is substantially equivalent to partition an area in groups of geographical zones not necessarily conterminous that have similar component scores. Following this methodology, the output is not represented by different loadings for each spatial unit as in the case of GWPCA, but distinct loadings for every groups of regions identified by SA.

SA is a stochastic relaxation algorithm that was originally introduced in statistical mechanics by [15] and [14]. [7] observes that a spatial combinatorial optimization problem might be described through a Markov Random Field (MRF). The probability measure of a MRF using Gibbs distribution is defined through the energy function $U(\mathbf{X}, \mathbf{k})$, that represent in our algorithm the objective function to be minimized, and a control parameter, T (see [6]; [19]). $U(\mathbf{X}, \mathbf{k})$ depends on observed data $\mathbf{X}$, and the label vector $\mathbf{k} = (k_1, k_2, \dots, k_i, \dots, k_n)$, which categorizes the heterogeneous zones, identifying clusters of regions. $U(\mathbf{X}, \mathbf{k})$ is defined by considering two different effects: a measure of the goodness of fit of the model, and a proximity constraint that describes the extent of aggregation of the spatial units. In particular, at the l-th iteration of the procedure, the energy function is defined as:

$$U(\mathbf{X}, \mathbf{k}) = \beta \sum_{i=1}^{n} I_i \; - (1-\beta) \sum_{r=1}^{n} \sum_{s=1}^{n} \mathbf{c}_{rs} \mathbf{1}_{(k(j)_r = k(j)_s)} \tag{6}$$

where the first part in the right-hand-side is the interaction term, with $I_i = \sum_{k=q+1}^{p} s_i^2$, with s_i the entry of the matrix of the residual matrix $\mathbf{S}$ defined by equation (4); while the second one is the penalty term defined through a Potts model (see [19]). Specifically, $\mathbf{c}_{rs}$ is the element (r, s) of a binary contiguity matrix, $\mathbf{1}_{(k(j)_r = k(j)_s)}$ is the indicator function of the event and $k(j)_r = k(j)_s$, and $(1-\beta)$ is a parameter that discourages configurations with not conterminous units. The parameter $(1-\beta)$ is chosen by the researcher and models the importance of the proximity of the spatial units. Note that the two parts of the energy function (6) are balanced with complementary weight. At the initial value of control parameter T_0, each unit i, is randomly classified as $k_{i,0}$, where $k_{i,0} \in \{1,2,\dots,K\}$ with K is the number of clusters. This step defines the initial configuration S_0. At the $(l+1)$-th iteration, given a current configuration S_l, a different configuration $S_l \neq S_{l+1}$ is randomly chosen, defining a new energy function $U(S_{l+1})$ the is compared with the previous one $U(S_l)$. The old configuration S_l is substituted by the new S_{l+1} in accordance to the probability:

$$Pr_{l,l+1} = max\left\{1, exp\left(-\frac{U(S_{l+1})-U(S_l)}{T_l}\right)\right\} \tag{7}$$

It is worth noting that probability (7) allows to avoid entrapments in local minimum, by defining positive probability for the change of configuration also when the objective function $U(S)$ increases. In essence, more likely patterns (i.e. configurations with lower states of energy) are always accepted, but it is also possible to accept also poorer configurations.

3. Empirical evidence

The proposed methodology is applied to define a deprivation index for Italian provinces. Data set derive from the 15th Population and Housing Census (2011) by Italian National Statistical Institute.

In this paper, a set of ten variables is adopted to build an area-based indicator of material deprivation. The choice of variables has been carried on according to the definition of deprivation index by [17] that suggest choosing a small set of variables able to capture socio-economic deprivation and assist policy makers in a wide set of decisions, for example, public health and tracking inequalities. The variables cover both economic and social domains. Income, educational attainment (proportion of people without high school diploma, School), and employment (Empl) are considered together with social conditions, as the proportion of people living alone (Unip), the percentage of separated, widowed, or divorced people (SVD), and the proportion of single parent families living in each area (Sin_Par). Furthermore, to have a better definition of the deprivation, we include other indicators, and use some of the variables proposed by [11] to assess the level of material deprivation: lack of car possession among resident families (Car), percentage of families living in house of property (Hou), and available surface in residence houses per person (Sqm) are added to assess the level of material deprivation. Moreover, the percentage of foreigners living in the Province (Frg) is considered as an additional variable, particularly to evaluate situation of social exclusion.

PCA is performed on Italian provinces and four components are selected which capture 80% of the variance in the data set. In Table 1, the loadings of the first four components are reported.

The eigenvector corresponding to the first component is characterized by a dominance of the economic variables: employment, income, and house dimension. These are negatively correlated to deprivation. Lack of car possession is positively linked to deprivation, displaying that owning a car decreases the level of material deprivation. On the other side, social variables tend to be lower in magnitude. In the second component, the picture is substantially different with social variables higher in magnitude, and negatively correlated to the deprivation level. Interestingly, the percentage of foreign people reverses its sign, being negative in the first component and positive in the second.

Table 1: Loadings for first 4 components of global PCA.

Proportion of variance	0.34	0.22	0.14	0.10
Cumulative variance	0.34	0.56	0.70	0.80

In standard PCA, homogeneity across space is assumed, and the same set of loadings may be used to derive an indicator of deprivation for the whole Country. Nevertheless, spatial heterogeneity could characterize the structure of the variance-covariance matrix. Therefore, the hypothesis of spatial homogeneity could be relaxed, allowing loadings to change according to different spatial configurations.

To avoid potential drawbacks of spatial heterogeneity in PCA, SA is adopted for identifying clusters of spatial units.

In this paper we identify three different clusters, and this spatial configuration is considered for further analysis. The selected combination produces an improvement in the proportion of explained variance when compared to the standard PCA. Finally, a level of $(1-\beta)$=0.3 is chosen, and 4 components are retained for all configurations.

In Figure 1, the groups are mapped, where white denotes the first cluster, light grey the second group, and dark grey the third regime.

The first group (i.e., white) is mainly composed by provinces in the North-East of the Peninsula and some part of Tuscany. Provinces closer to Alps and the Centre - especially in the Apennine mountains - compose the second groups (i.e., light gray), while the third regime (i.e., dark grey) characterizes mostly the Southern part of the Country and few Provinces of the North (e.g. Turin).

As expected, the three clusters show substantial differences in terms of their indicators structures. The eigenvectors of the first component of the three groups are shown in Table 2. Particularly interesting is the impact of the social variables. While in the first group social variables contribute positively to the level of deprivation, in the other spatial clusters the effects (i.e., Sin_Par, SVD, Unip) on the deprivation is negative. Other significant differences in the loadings structure can be found in the heterogeneous effect on deprivation of school attainment and the different magnitude of employment in the diverse regimes.

4. Conclusion

In this paper we propose a method for considering spatial heterogeneity in PCA. In fact, when dealing with geographically distributed data, the application of the classical framework of PCA could be misleading and lead to incorrect results. To overcome this drawback, the proposed method extends to PCA, the SA algorithm introduced by [19] for analyzing regional economic growth.

Applying SA to PCA let to highlight different structures of the multivariate phenomenon taking into account the presence of spatial heterogeneity. Results show the differences in the computing the composite indicator in each cluster. Especially the effect of social variables varies from first to second and third groups and a substantial difference of the North provinces with the rest of the Country is highly evident. However, results of SA help policy maker in the interpretation of the global phenomenon, improving interpretability of the indicator levels while considering different spatial regimes.

Spatial Functional Data Analysis

Object oriented spatial statistics for georeferenced tensor data

Statistica spaziale orientata agli oggetti per dati tensoriali georeferenziati

Alessandra Menafoglio and Davide Pigoli and Piercesare Secchi

Abstract We address the problem of analysing a spatial dataset of manifold-valued observations. We propose to model the data by using a local approximation of the Riemannian manifold through a Hilbert space, where linear geostatistical methods can be developed. We discuss estimation methods for the proposed model, and consistently develop a Kriging technique for tensor data. The methodological developments are illustrated through the analysis of a real dataset dealing with covariance between temperatures and precipitation in the Quebec region of Canada.

Abstract Si considera il problema dell'analisi di osservazioni georeferenziate a valori in una varietà Riemanniana. Si propone di modellare i dati usando approssimazioni locali della variet stessa attraverso opportuni spazi di Hilbert, dove metodi geostatistici lineari possono essere sviluppati. Sono discussi metodi di stima per il modello proposto, ed consistentemente sviluppato un metodo di Kriging per dati tensoriali. Gli sviluppi metodologici sono illustrati attraverso l'analisi di un dataset reale riguardante l'analisi di matrici di covarianza tra temperature e precipitazioni nella regione del Quebec, in Canada.

1 Introduction

The statistical analysis of spatial complex data has recently received much attention in the literature, motivated by the increasing availability of heterogenous datasets in environmental field studies. In this framework, Object Oriented Spatial Statistics (O2S2) (Menafoglio and Secchi, 2017) is a recent system of ideas and methods that allows the analysis of complex data when their spatial dependence is an important issue. The foundational idea of O2S2 is to interpret data as *objects*: the *atom* of the geostatistical analysis is the entire object, which is seen as an indivisible unit rather than a collection of features. In this view, the observations are interpreted as random points within a space of objects – called *feature space* – whose dimensionality and geometry should properly represent the data features and their possible constraints.

In this communication, we focus on the problem of analyzing a set of spatial tensor data. These are georeferenced data whose feature space is a Riemannian manifold. Informally, Riemannian manifolds are *mildly* non-Euclidean spaces, in the sense that they are non-Euclidean, but can be locally approximated through a Hilbert space. In this setting, the linear geostatistics paradigm (Cressie, 1993) cannot be directly applied, as the feature is not close with respect to the Euclidean geometry (e.g., a linear combination of elements in the manifold does not necessarily belong to the manifold). However, following Pigoli *et al.* (2016), we shall discuss the use of a tangent space approximation to locally describe the manifold through a linear space, where the linear methods of Menafoglio et al. (2013) can be applied.

Although the presented approach is completely general, for illustrative purposes we will give emphasis to the case of positive definite matrices. The latter find application in the analysis and prediction of measures of association, such as the covariance between temperature and precipitation measured in the Quebec region of Canada, which are displayed as green ellipses in Figure 1 (data source: Environment Canada on the website http://climate.weatheroffice.gc.ca).

2 A tangent space approximation to kriging for tensor data

To set the notation, call $\mathscr{M}$ a Riemannian manifold and, given a point P in $\mathscr{M}$, let $\mathscr{H}$ be the tangent space at the point P, $\mathscr{H} = T_P\mathscr{M}$. The latter is a Hilbert space when equipped with an inner product $\langle \cdot, \cdot \rangle_{\mathscr{H}}$ in $\mathscr{H}$. Given two points, the shortest paths between these points on the manifold is called geodesics. Under technical assumptions on $\mathscr{M}$, for every pair $(P;T) \in \mathscr{M} \times T_P\mathscr{M}$, there is a unique geodesic curve $g(t)$ such that $g(0) = P$ and $g(0) = T$. The exponential map is defined as the smooth map from $T_P\mathscr{M}$ to $\mathscr{M}$, which maps a tangent vector $T \in T_P\mathscr{M}$ to the point at $t = 1$ of the geodesic starting in P in direction T. We denote by $\exp_P$ the exponential map in P, and by $\log_P$ its inverse. More details on these definitions and on the properties of Riemannian manifolds can be found, e.g., in (Lee, 2012) and a detailed example for the case of the manifold of positive definite symmetric matrices is discussed in Section 3.

Given a spatial domain $D \subseteq \mathbb{R}^d$ and n locations $s_1,...,s_n$ in D, we indicate by $S_{s_1},...,S_{s_n}$ the manifold-valued observations at those locations (e.g., the covariance matrix between temperature and precipitation of Figure 1). As in classical geostatistics, we assume the data to a partial observation of a random field $\{S_s, s \in D\}$, valued in $\mathscr{M}$. For a location s in the spatial domain D, we model the random element S_s, taking value in $\mathscr{M}$, as

$$S_s(\mathbf{a},P) = \exp_P(A(\mathbf{f}(s);\mathbf{a}) + \delta_s), \tag{1}$$

where, $A(\mathbf{f}(s);\mathbf{a})$ is a drift term defined in the tangent space $\mathscr{H}$, and δ_s is a zero-mean stochastic residual. In this work, we focus on drift terms expressed in a linear form

$$A(\mathbf{f}(s);\mathbf{a}) = \sum_{l=0}^{L} f_l(s) \cdot a_l,$$

where $a_0,...,a_L$ are coefficients belonging to $\mathscr{H}$ and $f_l(s)$ are scalar regressors. We further assume that the random field $\{\delta_s, s \in D\}$, is a zero-mean globally second-order stationary and isotropic random field in the Hilbert space $\mathscr{H}$, with covariogram C (Menafoglio et al., 2013), i.e., for s_i, s_j in D,

$$C(\|s_i - s_j\|_d) = \mathbb{E}[\langle \delta(s_i), \delta(s_j) \rangle^2_{\mathscr{H}}],$$

$\|s_i - s_j\|_d$ denoting the distance between s_i, s_j in D. We denote by $\Sigma \in \mathbb{R}^{n\times n}$ the covariance matrix of the array $\delta = (\delta_{s_1},...,\delta_{s_n})^T$ in $\mathscr{H}^n$, that is $\Sigma_{ij} = C(\|s_i - s_j\|_d^2)$, and call $R \in \mathscr{H}^n$ the array of residuals $R_i = A(\mathbf{f}(s);\mathbf{a}) - \log_P(S_i)$. Given the array R and a matrix $A \in \mathbb{R}^{p\times n}$, we define the matrix operation AR as $(AR)_i = \sum_{j=1}^n A_{ij} R_j$, $i = 1,...,p$.

Given the observations $S_{s_1},...,S_{s_n}$, we now aim to estimate the model (1), and make prediction at unsampled locations. To estimate $(P,\mathbf{a})$ accounting for the spatial dependence, a generalized least square (GLS) criterion, based on minimizing the functional

$$(\widehat{P},\widehat{a}) = \underset{P\in\mathscr{M},\mathbf{a}\in\mathscr{H}^{L+1}}{\operatorname{argmin}} ||\Sigma^{-1/2}R||^2_{\mathscr{H}^n}, \tag{2}$$

can be used. In (2), $\mathscr{H}^n$ denotes the cartesian space $\mathscr{H} \times \cdots \times \mathscr{H}$, which is a Hilbert space when equipped with the inner product $\langle \mathbf{x},\mathbf{y} \rangle_{\mathscr{H}^n} = \sum_{i=1}^n \langle x_i, y_i \rangle_{\mathscr{H}}$. Given Σ, problem (2) can be solved iteratively, by alternatively minimizing the GLS functional in (2) with respect to P given $\mathbf{a}$ and viceversa. Since in practice both the parameters and the spatial dependence are unknown, one needs to resort to a nested iterative algorithm. The complexity of such minimization is problem dependent, and may require the development of specific optimization techniques.

Given the estimated $(\widehat{P},\widehat{a},\widehat{\Sigma})$, the spatial prediction can be performed by using the tangent space model as follows. In the Hilbert space $\mathscr{H}$, the simple kriging predictor for δ_{s_0} is well-defined and it is obtained as $\sum_{i=1}^n \lambda_i^0 \widehat{\delta}_{s_i}$, where $\widehat{\delta}_{s_i}$ indicates the estimated residual at s_i, $\widehat{\delta}_{s_i} = A(\mathbf{f}(s_i);\widehat{a}) - \log_{\widehat{P}}(S_i)$, and the vector of kriging weights $\lambda_0 = (\lambda_1^0,...,\lambda_n^0)$ is found as $\lambda_0 = \widehat{\Sigma}^{-1} c$, with $c = (\widehat{C}(||s_1 -$

$s_0||_d), \ldots, \widehat{C}(||s_n - s_0||_d))^T$. The spatial prediction of S at the target location s_0 is then

$$\widehat{S}_0 = \exp_{\widehat{P}}(\widehat{a}_0^{GLS}(\widehat{P}) + \sum_{l=1}^{L} \widehat{a}_l^{GLS}(\widehat{P}) f_l(s_0) + \sum_{i=1}^{n} \lambda_i^0 \widehat{\delta}_{s_i}),$$

where $\mathbf{f}(s_0)$ is the vector of covariates given at the location s_0. Uncertainty quantification of such estimate can be performed by resampling methods, e.g., via bootstrap (Pigoli *et al.*, 2016).

3 Analysis of covariance matrices in the Quebec region

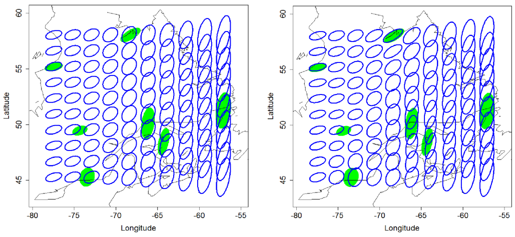
We here discuss the application of the method recalled in Section 2 to the covariance matrices displayed in Figure 1. Those data where estimated from temperature-precipitation data recorded in the month of January along the years 1983-1992.

Recall that the covariance matrix of a p-variate random variable belongs to the Riemannian manifold $PD(p)$ of positive definite matrices of dimension p, which is a convex subset of $\mathbb{R}^{p(p+1)/2}$ but it is not a linear space. The tangent space $T_P PD(p)$ to $PD(p)$ in the point $P \in PD(p)$ can be identified with the space of symmetric matrices of dimension p, $Sym(p)$. A Riemannian metric in $PD(p)$ is then induced by the inner product in $Sym(p)$. Following (Pigoli *et al.*, 2016), we consider the scaled Frobenius inner product in $Sym(p)$, which induces the exponential map $\exp_P(A) = P^{\frac{1}{2}} \exp(P^{-\frac{1}{2}} A P^{-\frac{1}{2}}) P^{\frac{1}{2}}$, and the logarithmic map $\log_P(D) = P^{\frac{1}{2}} \log(P^{-\frac{1}{2}} D P^{-\frac{1}{2}}) P^{\frac{1}{2}}$, where $\exp(A)$ stands for the exponential matrix of $A \in Sym(p)$, and $\log(C)$ for the logarithmic matrix of $C \in PD(p)$.

The linear model for the drift in the tangent space was set to $A(\phi_i, \lambda_i) = a_0 + a_1 \phi_i$, (ϕ, λ) denoting longitude and latitude. Such model was chosen by Pigoli *et al.* (2016) as to guarantee the stationarity of the residuals of (2). The drift coefficients and the structure of spatial dependence were estimated by numerically optimizing functional (2). The estimated drift and the predicted field are displayed in Figure 1a-b. A possible meteorological interpretation is associated with the exposition of the region toward the sea. Indeed, the drift model accounts for the distance between the location of interest and the Atlantic Ocean, which is likely to influence temperatures, precipitations and their covariability.

4 Conclusion and discussion

Object Oriented Spatial Statistics allows dealing with general types of data, by using key ideas of spatial statistics, revised according to a geometrical approach. In this communication we focused on the spatial analysis of tensor data, through the use of a tangent space approximation. Such approximation is appropriate to threat observations whose variability on the manifold is not too high. Simulation studies



(a) Estimated drift (b) Kriging prediction

Fig. 1 Kriging of the (temperature, precipitation) covariance matrix field during January, with a drift term depending on longitude. A covariance matrix S at location s is represented as an ellipse centered in s and with axis $\sqrt{\sigma_j}e_j$, where $S\mathbf{e}_j = \sigma_j e_j$ for $j = 1,2$. Horizontal and vertical axes of the ellipses represent temperature and precipitation respectively. In subfigure (a) and (b) green ellipses indicate the data, blue ellipses the estimated drift and the kriging interpolation, respectively. Modified from (Pigoli *et al.*, 2016).

(Pigoli *et al.*, 2016) showed that the method is robust to a moderate increase of the variability on the manifold. However, in cases characterized by a very high variability, more complex models should be used. A recent extension of the model, which is currently investigated by the authors, regards the use of local tangent space models to describe the field variability. This approach is based on the idea of embedding the model here illustrated in a novel computation framework developed in (Menafoglio *et al.*, 2018) and based on the idea to repeatedly partition the domain through Random Domain Decompositions. Such an extension will potentially allow to improve the characterization of the field variability, and the associated predictions.

A Spatio-Temporal Mixture Model for Urban Crimes

Un Modello Mistura per Dati Spazio-Temporali Relativi alla Criminalità

Ferretti Angela, Ippoliti Luigi and Valentini Pasquale

Abstract This paper considers the determinants of severe crimes at the census-tract level in Pittsburgh, Pennsylvania. We develop a mixture panel data model to describe the number of severe crimes that allows for temporal as well as spatial correlation, together with significant heterogeneity across census tracts. We use traditional Bayesian mixtures admitting uncertainty about the number of groups. We focus on pooling regression coefficients across clusters, implying that census-tracts belonging to the same cluster are similar. The clustering is done in a data-based fashion.

Abstract *In questo articolo ci proponiamo di studiare le determinanti dei reati gravi verificatisi nei distretti della città di Pittsburgh (Pennsylvania). A tal fine, si propone una mistura di modelli di regressione per dati panel che consente di cogliere la correlazione temporale e spaziale, nonchè l'eterogeneità tra i distretti. Assumendo come incognito il numero delle componenti della mistura, il modello consente di pervenire ad una classificazione in cui i gruppi si distinguono per diversi profili di covariate.*

1 Introduction

Any individual behaviour is a product of interaction between the person and the setting [1]. In recent years, the spatio-temporal urban distribution of crimes is receiving growing attention not only from researchers (criminologists, sociologists, economists, geographers, etc) but also from law enforcement agencies. In particular, in [11] it is highlighted a need to “integrate geographic and temporal representation and analyses” and in [10] it is stated that “the most under-researched area of spatial criminology is that of spatio-temporal crime patterns”. In this paper, we aim at addressing such needs by proposing a mixture panel data model for high-dimensional urban crime count data. The model allows to include temporal and spatial effects, socio-economic census tract characteristics and random effect components to take care of the heterogeneity existing across census tracts. Additionally, our model extends a “traditional” panel data model in many ways. For example, model coefficients are pooled across clusters, implying that census tracts belonging to the same cluster are similar. However the number of clusters is not known in the data but it is determined by the Dirichlet process.

The paper is organized as follows. In section 2 we present our model and the econometric methodology. In section 3 we describe our empirical dataset and discuss the empirical results.

2 Model Specification

Let y_{it} be the number of Part I offenses in census tract i $(i = 1,...,N)$ at time t $(t = 1,...,T)$. Let us assume that, conditionally on the mean, the y_{it}'s are mutually independent with Poisson distribution, $y_{it} \sim Po(\exp(\eta_{it}))$. The logarithm of the conditional mean is given as follows:

$$\eta_{it} = \nu + \phi \eta_{it-1} + \rho \sum_{l=1}^{N} W_{il} \eta_{lt} + x_{it}' \beta + \delta_{it} \qquad (1)$$

where x_{it} is a vector including strictly exogenous variables, ν is the intercept, β is a vector of regression parameters, η_{it-1} is the temporally lagged value of η_{it}, W_{il} is a generic element of a matrix W reflecting contiguity relations between the N census tracts, ρ is a scalar parameter reflecting the strength of spatial dependence, and δ_{it} can be related to a set of common determinants as $\delta_{it} = \xi_t' \gamma_i + \varepsilon_{it}$ where $\varepsilon_{it} \sim N(0, \sigma^2)$. The linear combination $\xi_t' \gamma_i$ transfers the contemporaneous correlation from the errors to the conditional expectation part of the model. Since in our empirical analysis we choose to include the first latent factor (principal component) as common regressor ξ_t, γ_i can be interpreted as a parameter vector of factor loadings specific for each census tract.

We consider a generalization of model (1) as used in [9], where the number of Part I offenses is modeled as a mixture of C^* unobserved clusters, whose coefficients

are pooled only across census tracts having similar characteristics. Particularly, the cluster-specific coefficients imply that census tracts belonging to the same cluster are defined by common effects, while census tracts belonging in different clusters have structural differences in their severe crimes' determinants.
Let $r_i = j$ index that census tract i belongs to cluster j, for $j = 1,...,C^*$ clusters in total, and with a respective probabilities $\pi_{i1} = P[r_i = 1], \pi_{i2} = P[r_i = 2], ..., \pi_{iC^*} = P[r_i = C^*]$, where $0 \leq \pi_{i1}, \pi_{i2}, ..., \pi_{iC^*} \leq 1$ and $\sum_{j=1}^{C^*} \pi_{ij} = 1$. The model we use can be written as

$$\eta_{it} = \nu_j + \phi_j \eta_{it-1} + \rho \sum_{l=1}^{N} W_{il} \eta_{lt} + x'_{it} \beta_j + \delta_{it} \tag{2}$$

$$if \quad r_i = j \qquad\qquad j = 1,...,C^*;$$

where ϕ_j and $\beta_j, j = 1,2,...,C^*$ are cluster specific coefficients.

2.1 Dirichlet Process Mixture Model

One of features of model (2) is the number of clusters C^*. In order to address to this question, in this paper we adopt a truncated Dirichlet process model to define the prior over the mixing probabilities based on some (large) upper bound C (see [4]).

Denote the respose variable $\eta_i = (\eta_{i1}, \eta_{i2}, \ldots, \eta_{iT})'$ and a set of covariates $z_{it} = \left(1, \eta_{it-1}, \sum_{l=1}^{N} W_{il} \eta_{lt}, x'_{it}\right)'$ observed at time t for the ith individual. With no loss of generality here, we rewrite model (2) as $\eta_{it} = z'_{it} \tau_j + \varepsilon_{it}$ where $\tau_j = (\nu_j, \rho, \phi_j, \beta'_j)'$ and $\delta_{it} = \varepsilon_{it}$. Then the density of the mixture is

$$f(\eta_i | z, \theta) = \sum_{j=1}^{C} \pi_j \left(\prod_{t=1}^{T} f_j\left(\eta_{it} | z_{it}, \psi_j\right) \right)$$

where $\theta = \{\alpha, \pi_{1:C}, \psi_{1:C}\}$, $\psi_j = \{\tau_j, \sigma_j^2\}$, $\sum_{j=1}^{C} \pi_j = 1$ with $0 \leq \pi_j \leq 1$, f_j are the C component densities and α is a precision parameter of the Dirichlet process. The mixture model can be realized through the configuration indicators r_i for each observation η_i with prior $P(r_i = j | \pi) = \pi_j$, so that we obtain the standard hierarchical model:

$$(\eta_i | r_i = j, z_i, \psi_j) \sim f_j(\eta_i | \psi_j). \qquad (\psi_j | G) \sim G \qquad (G | \alpha, G_0) \sim DP(\alpha, G_0). \tag{3}$$

where $G(\cdot)$ is an uncertain distribution function, $G_0(\cdot)$ is the prior mean of $G(\cdot)$ and $\alpha > 0$ the total mass, or precision of the DP. From the *Pólya Urn Scheme*,

$$\psi_j | \psi_1, \psi_2, ..., \psi_{j-1} \sim \frac{\alpha}{j-1+\alpha} G_0(\cdot) + \frac{1}{j-1+\alpha} \sum_{k=1}^{j-1} \delta_{\psi_k}(\cdot) \tag{4}$$

where $\delta_{\psi_k}(\cdot)$ is the point mass distribution at ψ_k. The truncated Dirichlet process prior is such that

$$\pi_1 = V_1, \qquad \pi_j = V_j \times \prod_{i=1}^{j-1}(1 - V_i), \tag{5}$$

$j > 1$, where V_i has a Beta distribution $Be(1,\alpha)$, $i < C$ indipendently over i and $V_C = 1$. Prior specification for each component j ($j = 1,...,C$) is completed with the following distribution,

$$G_0(\tau_j, h_j^{-1}) = N(\tau_j|\tau_0, h_j^{-1})Ga(h_j|a,b) \tag{6}$$

where $h_j^{-1} = \sigma_j^2$; and with a Gamma prior $\alpha \sim Ga(\varsigma_1, \varsigma_2)$. Placing a prior on α ([4]) allows us to draw inferences about the number of mixture components through the role of α of the *Pólya Urn Scheme* as the prior number of observations in each component.

3 Application

In this section we apply model (2) to study the determinants of census tract severe crimes in Pittsburgh, Pennsylvania. We first describe the full dataset and next we give details on empirical results.

3.1 Data

The crime dataset that we used includes monthly (January 2008 to December 2013) counts of Part I and Part II offenses for each of the 138 2000 census tracts in Pittsburgh, Pennsylvania. Part I offenses, also known as index crimes, regroup serious felonies in the following eight categories: criminal homicide, forcible rape, robbery, aggravated assault, burglary, larceny-theft (except motor vehicle theft), motor vehicle theft and arson. Part I offenses consist of the number of offenses in these categories that are known to law enforcement. Part II offenses include 21 categories of non-serious felonies and misdemeanors for which only arrest data were collected. A more detailed description of these variables are provided in [7].

The dependent variable in our study, y_{it}, is the number of Part I offenses in census tract i for $i = 1,...,138$ in month t for $t = 1,...,72$. Potential covariates include the log of number of Part I offenses in census tract at time $t-1$, the log of Part II offenses lagged by 1 month as leading indicator and the spatially lagged state variable. In addition, in order to account for heterogeneity across census tracts, we collected data on the following 15 time-invariant socio-economic variables from the Census 2000 (US Census Bureau and Social Explorer Tables): log of median income (*Lmi*), civilian unemployment rate (*Cur*), poverty rate (*Pvr*), percentage of population with less than a high school degree (*Hdl*), percentage of population with a bachelor degree or higher (*Bdh*), rental housing units as percentage of occupied housing units (*Rhu*), percentage of households having been in the same house for more than 1 year (*Sh1*), percentage of female-headed households (*Fhh*), housing units vacancy rate (*Hvr*), percentage of total population that is African-American (*Paa*), log of total population (*Ltp*), log of population density per square mile (Lpd), dropout rate age 16–19 (*Dra*), percentage of total population under 18 ($U18$) and group quarter proportion (*Gqp*). Finally, missing values for our socio-economic covariates in 14 census tracts that do not have a regular resident population were replaced by dummies.

3.1.1 Results

By means of a Markov chain Monte Carlo approach, posterior inference was based on the last $50,000$ draws (after a burn-in of $5,000$) using every 5th member of the chain to avoid autocorrelation within the sampled values. From the computational viewpoint, we first sample η_{it} from its marginal distribution using the adaptive rejection sampling [2] and then we draw all the other parameters. Conditional on η_{it}, the full conditional posterior distributions take convenient functional forms and can be easily sampled from. Convergence of the chains of the model was monitored visually through trace plots as well as using the R-statistic of [3] on two chains simultaneously started from different initial points.

Results indicate the existence of two clusters of census tracts in Pittsburgh, with 42 census tracts (30%) belonging to cluster 1 and 96 census tracts (70%) belonging to cluster 2. Also, we note that the temporal correlation parameters referring to the Part II crime data, only impact in cluster 1. This suggests that crime hot spots may arise first as a concentration of soft crimes that later hardens into more serious crimes. Consistently, if a large number of Part I offenses happen at time $t-1$, a huge number of the same crimes will occur at time t. The spatial dependence in Part I offenses is relevant in both clusters, so we do have a spatial diffusion of certain types of crime in Pittsburgh. This result could provide a useful tool for efficient allocation of law enforcement resources.

Of the 15 socio-economic determinants of severe crimes, only the *Cur* seems to be relevant in both clusters. The positive influence of civilian unemployment rate on the number of Part I offenses confirms the social organization theory according to which bad socio-economic conditions, such as job unavailability, give rise to criminal motivation. For the rest of potential determinants we find that they can have an impact in one cluster but not the other. While *Ldp* and *Fhh* do not provide any impact in group 1, they become important in group 2. Here, census tracts with a small population size or lack of residential instability should enjoy lower number of Part I offenses. Furthermore, the variables *Lmi*, *Pvr* and *U18* appear with a negative sign in cluster 2. In contrast, *Hvr* and *Hdl* represent important determinants for the Part I offenses with positive and negative signs, respectively, only in cluster 1.

Overall, this study shows that criminal dynamics have different features across the two clusters, with differences which cannot be captured by traditional regression analyses.

Statistical Methods for Service Quality

Cumulative chi-squared statistics for the service quality improvement: new properties and tools for the evaluation

Il chi quadrato cumulato per la qualità dei servizi: nuove proprietà e strumenti per la valutazione

Antonello D'Ambra, Antonio Lucadamo, Pietro Amenta, Luigi D'Ambra

Abstract In service quality evaluation, data are often categorical variables with ordered categories and collected in two way contingency table. The Taguchi's statistic is a measure of the association between these variables as a simple alternative to Pearson's test. An extension of this statistic for three way contingency tables handled in two way mode is introduced. We highlight its several properties, the approximated distribution, a decomposition according to orthogonal quantities reflecting the main effects and the interaction terms, and an extension of cumulative correspondence analysis based on it.

Abstract *Nella valutazione della qualità dei servizi erogati, i dati rappresentano spesso variabili qualitative ordinali raccolte in tabelle di contingenza a due vie. L'indice di Taguchi è una misura dell'associazione esistente tra queste variabili e nasce come un'alternativa al test di Pearson in presenza di variabili ordinali. In questo lavoro viene presentata una estensione di questo indice per tabelle di contingenza a tre vie. Se ne evidenziano diverse proprietà, la distribuzione approssimata, una decomposizione rispetto a quantità che riflettono gli effetti principali e l'interazione, nonchè un'estensione dell'analisi delle corrispondenze.*

Key words: Two and three way contingency tables, Chi-squared statistic, Taguchi's statistic, Interaction term, Main effects, Service quality evaluation.

1 Introduction

Service companies have given increasing importance to customer satisfaction (hereafter CS) over the years worldwide. Measuring the quality of a service is indeed a fundamental and strategic function for every firms because it allows checking the level of efficiency and effectiveness perceived by users. In service quality evaluation, data are often categorical variables with ordered categories and usually collected in two way contingency table. To determine the nature of the association, tests involving the Pearson chi-squared statistic are generally considered. However, the statistic does not take into account the structure of ordered categorical variables [1]. To overcome this problem, Taguchi [6, 7] developed a simple statistic that does take into consideration the structure of an ordered categorical variable. It does so by considering the cumulative frequency of the cells of the contingency table across the ordered variable. An extension of this statistic for three way contingency tables handled in two way mode is introduced in section 4, highlighting some properties and its approximated distribution. Moreover, an extension of correspondence analysis based on the suggested new statistic is proposed to study the association from a graphical point of view. It highlights the impacts of the main effects and the interaction terms on the association. This is obtained in section 5 by means of a decomposition of the new statistic according to orthogonal quantities reflecting several effects.

An application on real data about service quality evaluation using all the theoretical results will be shown in the extended version of this paper.

2 Notations

Let A, B, and Y be categorical variables with $i = 1, \dots, I$, $k = 1, \dots, K$ and $j = 1 \dots, J$ categories, respectively, and suppose $(A_1, B_1, Y_1), \dots, (A_n, B_n, Y_n)$ is a random sample of the random vector (A, B, Y). The basic data structures in this paper are two and three-way contingency tables $\mathbf{N}$ and $\check{\mathbf{N}}$ of orders (I, J) and (I, K, J) with frequencies $\{n_{ij}\}$ and $\{n_{ikj}\}$ counting the numbers of observations that fall into the cross-categories $i \times j$ and $i \times k \times j$, respectively. $\mathbf{N}$ cross classifies n statistical units according to two categorical variables A and Y while $\check{\mathbf{N}}$ according to three categorical variables A, B, and Y. Table $\check{\mathbf{N}}$ is handled in this paper in two way mode by row unfolding it according to variables A and B: the resulting two way contingency table $\tilde{\mathbf{N}}$ is then of size $[(I \times K) \times J]$ with general term n_{ikj}. We consider row variables A and B as predictors and the column variable Y as response, reflecting a unidirectional association between the categorical variables (rows versus column). Moreover, suppose that Y has an ordinal nature with increasing scores.

We denote by p_{ij} the probability of having an observation fall in the i-th row and j-th column of the table, with $\mathbf{P} = \{p_{ij} = n_{ij}/n\}$. $p_{i.} = \sum_{j=1}^{J} p_{ij}$ and $p_{.j} = \sum_{i=1}^{I} p_{ij}$ denote the probabilities that A and Y are in categories i and j, respectively.

Considering the two way table $\mathbf{N}$, let $z_{is} = \sum_{j=1}^{s} n_{ij}$ and $z_{.s} = \sum_{j=1}^{s} n_{.j}$ be the cumulative count and the cumulative column total up to the j-th column category, respectively, with $s = 1,\dots,J-1$. $d_s = z_{.s}/n$ denotes the cumulative column proportion. Let $\tilde{\mathbf{P}} = \{p_{ikj} = n_{ikj}/n\}$ be the joint relative frequency distribution. Moreover, let $\mathbf{D}_I = \{p_{i.} = \sum_{j=1}^{J} p_{ij}\}$ and $\mathbf{D}_J = \{p_{.j} = \sum_{i=1}^{I} p_{ij}\}$ be diagonal matrices containing the row and column sum of $\tilde{\mathbf{P}}$, respectively. Let $\mathbf{D}_{IK} = diag(p_{ik.})$ (marginal row) and $\mathbf{D}_J = diag(p_{..J})$ (marginal column) be also the diagonal matrices with generic elements $p_{ik.} = \sum_{j=1}^{J} p_{ikj}$ and $p_{..j} = \sum_{i=1}^{I}\sum_{k=1}^{K} p_{ikj}$, respectively.

Lastly, denote $C_{iks} = \sum_{j=1}^{s} n_{ikj}$ with $s = 1,\dots,J-1$ the cumulative frequencies of the $\{ik\}$-th row category up to the s-th column categories. Their consideration provides a way of ensuring that the ordinal structure of the column categories is preserved. Similarly, denote, $\tilde{d_s} = \sum_{j=1}^{s} p_{..j}$ the cumulative relative frequency up to the s-th column category.

3 The Taguchi's statistics in a nutshell

Taguchi [6, 7] proposed a measure of the association between categorical variables where one of them possesses ordered categories by considering the cumulative sum of cell frequencies across this variable. He introduced this measure as a simple alternative to Pearson's test in order to consider the impact of differences between adjacent ordered categories on the association between row and column categories. In order to assess the unidirectional association between the row and (ordered) column variables, Taguchi [6, 7] proposed the following statistic

$$T = \sum_{s=1}^{J-1} \frac{1}{d_s(1-d_s)} \sum_{i=1}^{I} n_{i.} \left(\frac{z_{is}}{n_{i.}} - d_s\right)^2 \qquad (1)$$

with $0 \leq T \leq [n(J-1)]$. This statistic performs better than Pearson's chi-squared statistic when there is an order in the categories on the columns of the contingency table and it is more suitable for studies (such as clinical trials) where the number of categories within a variable is equal to (or larger than) 5 [8].

Takeuchi and Hirotsu [8] and Nair [3] showed also that the T statistic is linked to the Pearson chi-squared statistic $T = \sum_{s=1}^{J-1} \chi_s^2$ where χ_s^2 is Pearson's chi-squared for the $I \times 2$ contingency tables obtained by aggregating the first s column categories and the remaining categories $(s+1)$ to J, respectively. For this reason, the Taguchi's statistic T is called the *cumulative chi-squared statistic* (hereafter CCS). Nair [3] considers then the class of CCS-type statistics

$$T_{CCS} = \sum_{s=1}^{J-1} w_s \left[\sum_{i=1}^{I} n_{i.} \left(\frac{z_{is}}{n_{i.}} - d_s\right)^2\right] \qquad (2)$$

corresponding to a given set of weights $w_s > 0$. The choice of different weighting schemes defines the members of this class. Examples of possible choices for w_j are to assign constant weights to each term (i.e. $w_s = 1/J$) or assume it proportional to the inverse of the conditional expectation of the s-th term under the null hypothesis of independence (i.e. $w_s = [d_s(1-d_s)]^{-1}$). It is evident that T_{CCS} subsumes T in the latter case. Moreover, Nair shows that T_{CCS} with $w_s = 1/J$ (that is $T_N = \sum_{s=1}^{J-1}(1/J)\sum_{i=1}^{I} N_{i.}(z_{is}/n_{i.} - d_s)^2$) has good power against ordered alternatives.

Nair [3, 4] highlighted the main properties of the CCS-type tests by means of a matrix decomposition of this statistic into orthogonal components. Lastly, Taguchi’s statistics can be also viewed as an approximate sum of likelihood ratios within the regression model for binary dependent variables following a scaled binomial distribution, providing in this way a different interpretation of this statistic [2]. Refer to [2] for a wider and deeper study with other new interpretations and characteristics of this statistic.

4 Cumulative Correspondence Analysis and Taguchi’s Statistics for three way contigency tables handled in two way mode

In this paper we introduce a new extension of the Taguchi’s statistic on a three-way contingency table, where one of the variables consists of ordered responses, handled in two way mode. We name ”Multiple Taguchi’s statistic” the following measure of the unidirectional association between the rows and (ordered) column variables

$$T^M = \sum_{s=1}^{J-1} \frac{1}{\tilde{d_s}(1-\tilde{d_s})} \left[\sum_{i=1}^{I} \sum_{k=1}^{K} n_{ik.} \left(\frac{C_{iks}}{n_{ik.}} - \tilde{d_s} \right)^2 \right] \qquad 0 \le T_M \le n(J-1) \tag{3}$$

Likewise formulas (1) and (2) it is also possible to consider a class of CCS-type statistics T^M_{CSS} corresponding to a given set of weights $w_s > 0$. The choice of different weighting schemes defines the members of this class.

It is possible to show that there is a link between Multiple Taguchi’s statistic, Pearson Chi-Squared statistic and C-Statistics $T^M = \sum_{s=1}^{J-1} \chi^2(s) = \frac{n}{n-1} \sum_{s=1}^{J-1} C(s)$. Here $\chi^2(s)$ and $C(s) = (n-1)[\sum_{i=1}^{I} \sum_{j=1}^{s} p_{ik.} \left(p_{ikj}/p_{ik.} - p_{..j}\right)^2]/(1-\sum_{j=1}^{J} p^2_{..j})$ are the Pearson chi-squared and the C-statistics, respectively, for a $[(I \times K) \times 2]$ contingency table obtained by aggregating the first j column categories and the remaining categories $(j+1)$ to J.

It is possible to highlight other properties by means of a matrix decomposition of the CCS-type statistic T^M_{CSS} into orthogonal components. For instance, this allows to introduce the Multiple Taguchi’s statistic at heart of a new cumulative extension of correspondence analysis (hereafter MTA). Main goal of MTA is to show how similar cumulative categories are with respect to joined nominal ones from a graphical point of view. We represent the variations of column categories rather than the categories on the space generated by cumulative frequencies. Let define the matrix

$$\mathbf{R} = \mathbf{D}_{IK}^{-1} \tilde{\mathbf{P}} \mathbf{A}^T \mathbf{W}^{\frac{1}{2}} \tag{4}$$

where $\mathbf{W}$ is a diagonal square matrix of dimension $[(J-1)\times(J-1)]$ with general term w_s and $\mathbf{A}$ the following $[(J-1)\times J]$ matrix

$$\mathbf{A} = \begin{bmatrix} 1-\tilde{d}_1 & -\tilde{d}_1 & \dots & -\tilde{d}_1 \\ 1-\tilde{d}_2 & 1-\tilde{d}_2 & \dots & -\tilde{d}_2 \\ \vdots & \vdots & \ddots & \vdots \\ 1-\tilde{d}_{J-1} & 1-\tilde{d}_{J-1} & \dots & -\tilde{d}_{J-1} \end{bmatrix}$$

$\mathbf{A}$ can be also written as $\mathbf{A} = \mathbf{M} - [\mathbf{D}(\mathbf{1}_{J-1}\mathbf{1}_J^T)]$ where $\mathbf{M}$ is unitriangular lower matrix of dimension $(J-1)\times J$, $\mathbf{D} = diag(\tilde{d_s})$, with $\mathbf{1}_{J-1}$ and $\mathbf{1}_J$ column vectors of one of dimension $(J-1)$ and J, respectively. The CSS-type Multiple Taguchi's statistic T^M_{CSS} is then given by

$$T^M_{CSS} = n\times||\mathbf{R}||^2_{\mathbf{D}_{IK}} = n\times||\mathbf{D}^{-1}_{IK}\tilde{\mathbf{P}}\mathbf{A}^T\mathbf{W}^{\frac{1}{2}}||^2_{\mathbf{D}_{IK}} = n\times trace\left(\mathbf{D}^{-\frac{1}{2}}_{IK}\tilde{\mathbf{P}}\mathbf{A}^T\mathbf{W}\mathbf{A}\tilde{\mathbf{P}}^T\mathbf{D}^{-\frac{1}{2}}_{IK}\right)$$

Let $GSVD(\mathbf{R})_{\mathbf{D}_{IK},\mathbf{I}}$ denotes the generalized singular value decomposition of matrix $\mathbf{R} = \{r_{ikj}\}$ of rank M such that $\mathbf{R} = \mathbf{U}\boldsymbol{\Lambda}\mathbf{V}^T$, where $\mathbf{U}$ is an $[I\times M]$ matrix of left singular vectors such that $\mathbf{U}^T\mathbf{D}_I\mathbf{U} = \mathbf{I}_M$, $\mathbf{V}$ is an $[(J-1)\times M]$ matrix of right singular vectors such that $\mathbf{U}^T\mathbf{U} = \mathbf{I}_M$ and $\boldsymbol{\Lambda}$ is a positive definite diagonal matrix of order M of singular values of $\mathbf{R}$ of general term λ_m $(m = 1,\dots,M)$. Total inertia is given by

$$||\mathbf{R}||^2_{D_{IK}} = trace(\mathbf{R}^T\mathbf{D}_{IK}\mathbf{R}) = \sum_{i=1}^{I}\sum_{k=1}^{K}\sum_{j=1}^{J} p_{ik.}r^2_{ikj} = \sum_{m=1}^{M}\lambda^2_m = \frac{T^M_{CSS}}{n}$$

Finally, row and column standard coordinates for the graphical representation of the association between predictors and response categorical variables are then given by $\mathbf{F} = \mathbf{U}\boldsymbol{\Lambda}$ and $\mathbf{G} = \mathbf{V}\boldsymbol{\Lambda}$, respectively.

According to the Nair's approach [3, 4] we show how the distribution of T^M_{CSS} is approximated using Satterthwaite's method [5]. Let $\boldsymbol{\Gamma}$ be the $(J-1)\times(J-1)$ diagonal matrix of the nonzero singular-values of $\mathbf{A}^T\mathbf{W}\mathbf{A}$ and consider the singular value decomposition $\mathbf{A}^T\mathbf{W}^{\frac{1}{2}} = \mathbf{Q}\boldsymbol{\Gamma}\mathbf{Z}^T$ with $\mathbf{Q}^T\mathbf{Q} = \mathbf{I}$ and $\mathbf{Z}^T\mathbf{Z} = \mathbf{I}$ such that $\mathbf{A}^T\mathbf{W}\mathbf{A} = \mathbf{Q}\boldsymbol{\Gamma}^2\mathbf{Q}^T$. The CSS-type Multiple Taguchi's statistic T^M_{CSS} is given by

$$\begin{aligned} T^M_{CSS} &= n\times trace\left(\mathbf{D}^{-\frac{1}{2}}_{IK}\tilde{\mathbf{P}}\mathbf{A}^T\mathbf{W}\mathbf{A}\tilde{\mathbf{P}}^T\mathbf{D}^{-\frac{1}{2}}_{IK}\right) = n\times trace\left(\mathbf{D}^{-\frac{1}{2}}_{IK}\tilde{\mathbf{P}}\mathbf{Q}\boldsymbol{\Gamma}^2\mathbf{Q}^T\tilde{\mathbf{P}}^T\mathbf{D}^{-\frac{1}{2}}_{IK}\right) \\ &= n\times trace\left(\mathbf{S}\boldsymbol{\Gamma}^2\mathbf{S}^T\right) \end{aligned}$$

where $\mathbf{S} = \mathbf{D}_I^{-\frac{1}{2}}\tilde{\mathbf{P}}\mathbf{Q}$. It is possible to show that the i-th elements S_{is} of column vector $\mathbf{S}_s$ are asymptotically iid with a $N(0,1)$ distribution as $n\rightarrow\infty$, with $s = 1,\dots,J-1$ and $i = 1,\dots,(I\times K)-1$. Then, under the hypothesis of homogeneity and given the row and column probabilities, the components $\mathbf{S}_s^T\mathbf{S}_s = \sum_{i=1}^{I\times K}S^2_{is}$ are asymptotically iid with a $\chi^2_{[(I\times K)-1]}$ distribution. Consequently, under the null hypothesis, the limiting distribution of the CSS-type Multiple Taguchi's statistic T^M_{CSS} is a linear combination of chi-squared distributions

$$T^M_{CSS} = n \times trace\left(\mathbf{S}\boldsymbol{\Gamma}^2\mathbf{S}^T\right) \xrightarrow[H_0]{d} \sum_{s=1}^{J-1} \gamma_s \times \chi^2_{[(I\times K)-1]}(s)$$

where $\chi^2_{[(I\times K)-1]}(s)$ is the chi-squared distribution for the s-th component $\mathbf{S}^T_s\mathbf{S}_s$ $(s = 1,\ldots,J-1)$ and γ_s are elements of matrix $\boldsymbol{\Gamma}$. By using Satterthwaite’s two-moment approximation [5], the asymptotic distribution of T^M_{CSS} can be then approximated [3, 4] by $d^M_{CSS} \times \chi^2_{\nu^M_{CSS}}$ with $\nu^M_{CSS} = (d^M_{CSS})^{-1}\sum_{s=1}^{J-1}\gamma_s$ degrees of freedom and $d^M_{CSS} = [(I\times K)-1]^{-1}(\sum_{s=1}^{J-1}\gamma_s^2/\sum_{k=1}^{J-1}\gamma_s)$.

5 Orthogonal decomposition of Multiple Taguchi’s statistic

The Multiple Taguchi’s statistic is a measure of association that contains both main effects and interaction term. The main effects represent the change in the response variables due to the change in the level/categories of the predictor variables, considering the effects of their addition. The interaction effect represents the combined effect of predictor categorical variables on the ordinal response variable.

The interpretation of MTA graphical results can be improved if we highlight the impact of these effects on the association. The Multiple Taguchi’s statistic can be then decomposed in different orthogonal quantities:

$$T^M_{CSS} = T^{A\cup B} + T^{A\times B} = T^A + T^{B|A} + T^{A\times B} = T^{A|B} + T^B + T^{A\times B}$$

where $T^{A\cup B}$ reflects the main effects and represents the change in the response variables due to the change on the levels/categories of the predictor variables considering their joining effects, T^A (or T^B) represents the Taguchi’s statistic calculated between Y and A (or B) after a row aggregation of variable B (or A), while $T^{B|A}$ (or $T^{A|B}$) is the Taguchi’s statistic between Y and B (or A) where the effects of variable A has been partialled out (or B). Finally, $T^{A\times B}$ is the interaction effect and represents the combined effect of predictor variables on the response variable. In particular, there is an interaction between two predictor variables when the effect of one predictor variable varies as the levels/categories of the other predictor vary. If the interaction is not significant, it is possible to examine the main effects. Instead, if the interaction is statistically significant and of strong entity, then, it is not useful to consider the main effects.

In order to separate the main effects and the interaction term, the approach starts from a constraints matrix. Let $\mathbf{T}_{A\cup B} = [\mathbf{T}_A|\mathbf{T}_B]$ be the matrix of dummy variables with $\mathbf{T}_A = (\mathbf{1}_K \otimes \mathbf{I}_I)$ (factor A), $\mathbf{T}_B = (\mathbf{I}_K \otimes \mathbf{1}_I)$ (factor B) and such that formula (4) can be written as $\mathbf{R} = \mathbf{D}^{-1}_{IK}\mathbf{H}^T_{1/D_{IK}}\tilde{\mathbf{P}}\mathbf{M}^T\mathbf{W}^{\frac{1}{2}}$ where $\mathbf{H}_{1/D_{IK}} = \mathbf{I}_{IK} - [\mathbf{1}_{IK}(\mathbf{1}^T_{IK}\mathbf{D}_{IK}\mathbf{1}_{IK})^{-1}\mathbf{1}^T_{IK}\mathbf{D}_{IK}]$ is the orthogonal projector onto the null space of $\mathbf{1}_{IK}$ in metric $\mathbf{D}_{IK}$ with $\mathbf{1}_{IK}$ unitary column vectors of dimension IK. $\mathbf{H}_{1/D_{IK}}$ eliminates the row marginal effect from the relationship between rows and columns. The main effects are given by

$$\mathbf{R}_{A\cup B} = \mathbf{H}_{1/D_{IK}}\mathbf{T}_{A\cup B}(\mathbf{T}_{A\cup B}^{T}\mathbf{H}_{1/D_{IK}}^{T}\mathbf{D}_{IK}\mathbf{T}_{A\cup B})^{-1}\mathbf{T}_{A\cup B}^{T}\mathbf{H}_{1/D_{IK}}^{T}\tilde{\mathbf{P}}\mathbf{M}^{T}\mathbf{W}^{\frac{1}{2}}$$

Since $\mathbf{R}_{A\times B} = \mathbf{R} - \mathbf{R}_{A\cup B}$ then we obtain the following norm decomposition

$$||\mathbf{R}||_{D_{IK}}^{2} = ||\mathbf{R}_{A\cup B}||_{D_{IK}}^{2} + ||\mathbf{R}_{A\times B}||_{D_{IK}}^{2} \tag{5}$$

Similarly, a double decomposition of the main effects in orthogonal quantities is

$$||\mathbf{R}_{A\cup B}||_{D_{IK}}^{2} = ||\mathbf{R}_{A}||_{D_{IK}}^{2} + ||\mathbf{R}_{B|A}||_{D_{IK}}^{2} = ||\mathbf{R}_{B}||_{D_{IK}}^{2} + ||\mathbf{R}_{A|B}||_{D_{IK}}^{2} \tag{6}$$

where $\mathbf{R}_{A} = \mathbf{H}_{1/D_{IK}}\mathbf{T}_{A}(\mathbf{T}_{A}^{T}\mathbf{H}_{1/D_{IK}}^{T}\mathbf{D}_{IK}\mathbf{T}_{A})^{-1}\mathbf{T}_{A}^{T}\mathbf{H}_{1/D_{IK}}^{T}\mathbf{P}\mathbf{M}^{T}\mathbf{W}^{\frac{1}{2}}$ and $\mathbf{R}_{B} = \mathbf{H}_{1/D_{IK}}\mathbf{T}_{B}$ $(\mathbf{T}_{B}^{T}\mathbf{H}_{1/D_{IK}}^{T}\mathbf{D}_{IK}\mathbf{T}_{B})^{-1}\mathbf{T}_{B}^{T}\mathbf{H}_{1/D_{IK}}^{T}\mathbf{P}\mathbf{M}^{T}\mathbf{W}^{\frac{1}{2}}$. Decomposition (6) shows that $A\cup B \neq (A+B)$ because $A\cup B = (A+B|A) = (B+A|B)$ since A and B are not orthogonal factors [9]. If we consider a balanced design then we have $R_{A|B} = R_{A}$ and $R_{B|A} = R_{B}$ so that we can write $||\mathbf{R}_{A\cup B}||_{D_{IK}}^{2} = ||\mathbf{R}_{A}||_{D_{IK}}^{2} + ||\mathbf{R}_{B}||_{D_{IK}}^{2}$ and decomposition (5) is now $||\mathbf{R}||_{D_{IK}}^{2} = ||\mathbf{R}_{A}||_{D_{IK}}^{2} + ||\mathbf{R}_{B}||_{D_{IK}}^{2} + ||\mathbf{R}_{A\times B}||_{D_{IK}}$.

Interaction	$T^{A\times B}$	$\tilde{d}^{A\times B} = \left(\frac{1}{\tilde{d}^{M}} - \frac{1}{\tilde{d}^{A}} - \frac{1}{\tilde{d}^{B\|A}}\right)^{-1}$	$T^{A\times B}/\tilde{d}^{A\times B}$	$v^{A\times B} = \frac{1}{\tilde{d}^{A\times B}}\sum_{s=1}^{J-1}\gamma_s$
Total	T_{CSS}^{M}	$\tilde{d}_{CSS}^{M} = \frac{1}{[(I\times K)-1]}\frac{\sum_{s=1}^{J-1}\gamma_s^2}{\sum_{s=1}^{J-1}\gamma_s}$	$T_{CSS}^{M}/\tilde{d}_{CSS}^{M}$	$v_{CSS}^{M} = \frac{1}{\tilde{d}_{CSS}^{M}}\sum_{s=1}^{J-1}\gamma_s$

Table 2 Alternative $T^{A\cup B}$ decompositions

Decomposition	Index	$\tilde{d}$	Statistic	degrees of freedom
Factor A	T^{A}	$\tilde{d}^{A} = \frac{1}{(I-1)}\frac{\sum_{s=1}^{J-1}\gamma_s^2}{\sum_{s=1}^{J-1}\gamma_s}$	$T^{A}/\tilde{d}^{A}$	$v^{A} = \frac{1}{\tilde{d}^{A}}\sum_{s=1}^{J-1}\gamma_s$
Factor A|B	$T^{A\|B}$	$\tilde{d}^{A\|B} = \frac{1}{(I-1)}\frac{\sum_{s=1}^{J-1}\gamma_s^2}{\sum_{s=1}^{J-1}\gamma_s}$	$T^{A\|B}/\tilde{d}^{A\|B}$	$v^{A\|B} = \frac{1}{\tilde{d}^{A\|B}}\sum_{s=1}^{J-1}\gamma_s$
Factor B	T^{B}	$\tilde{d}^{B} = \frac{1}{(K-1)}\frac{\sum_{s=1}^{J-1}\gamma_s^2}{\sum_{s=1}^{J-1}\gamma_s}$	$T^{B}/\tilde{d}^{B}$	$v^{B} = \frac{1}{\tilde{d}^{B}}\sum_{s=1}^{J-1}\gamma_s$
Factor B|A	$T^{B\|A}$	$\tilde{d}^{B\|A} = \frac{1}{(K-1)}\frac{\sum_{s=1}^{J-1}\gamma_s^2}{\sum_{s=1}^{J-1}\gamma_s}$	$T^{B\|A}/\tilde{d}^{B\|A}$	$v^{B\|A} = \frac{1}{\tilde{d}^{B\|A}}\sum_{s=1}^{J-1}\gamma_s$

Let $\mathbf{R}_{(A\cup B)} = \mathbf{U}_{A\cup B}\boldsymbol{\Lambda}_{A\cup B}\mathbf{V}_{A\cup B}^{T}$ denote $GSVD(\mathbf{R}_{A\cup B})_{D_{IK},I}$ where $\mathbf{U}_{A\cup B}$ is an $(I\times M)$ matrix of right singular vectors such that $\mathbf{U}_{A\cup B}^{T}\mathbf{D}_{IK}\mathbf{U}_{A\cup B} = \mathbf{I}_{M}$ $[M = rank(\mathbf{R}_{A\cup B})]$,

$\mathbf{V}_{A\cup B}$ is $[(J-1)\times M]$ matrix of right singular vectors such that $\mathbf{V}_{A\cup B}^{T}\mathbf{V}_{A\cup B}=\mathbf{I}_M$ and $\boldsymbol{\Lambda}$ is a positive definite diagonal matrix of order M of singular value of $\mathbf{R}_{A\cup B}$ with general term $\lambda_m^{A\cup B}$ with $m=1,\ldots,M$. Row and column standard coordinates of the main effects are given by $\mathbf{F}_{A\cup B}=\mathbf{U}_{A\cup B}\boldsymbol{\Lambda}_{A\cup B}$ and $\mathbf{G}_{A\cup B}=\mathbf{V}_{A\cup B}\boldsymbol{\Lambda}_{A\cup B}$, respectively. It’s also possible to plot the interaction term and the single effects in the same way.

6 Conclusion

Taguchi introduced his statistic as simple alternative to Pearson’s chi-squared test for two way contingency tables. Actually, χ^2 does not perform well when we have a contingency table cross-classifying at least one ordinal categorical variable. In this paper an extension of this statistic for three way contingency tables handled in two way mode has been introduced highlighting some properties. The approximated distribution of the CCS-type Multiple Taguchi’s statistic T_{CSS}^{M}, by using Satterthwaite’s method, has been also suggested. In this paper, an extension of Correspondence Analysis based on the decomposition of the CCS-type Multiple Taguchi’s statistic has been moreover proposed. The interpretation of the graphical results has been improved highlighting the impact of the main effects and the interaction terms on the association. This is obtained with a decomposition of statistic T_{CSS}^{M} according to orthogonal quantities reflecting several effects.
Finally, an extended version of this paper will include an application on real data about service quality evaluation. All the theoretical results will be used showing also the graphical outputs. We will be also able to evaluate the impact of the main effects and interaction term on association among the categorical variables.

A robust multinomial logit model for evaluating judges' performances

Un modello multinomiale robusto per valutare la performance dei giudici.

Ida Camminatiello and Antonio Lucadamo

Abstract Principal component multinomial regression is a method for modelling the relationship between a set of high-dimensional regressors and a categorical response variable with more than two categories. This method uses as covariates of the multinomial model a reduced number of principal components of the regressors. Because the principal components are based on the eigenvectors of the empirical covariance matrix, they are very sensitive to anomalous observations. Several methods for robust principal component analysis have been proposed in literature. In this study we consider ROBPCA method. The new robust approach will be applied for assessing judges' performances.

Abstract *La regressione multinomiale sulle componenti principali è un metodo per modellare la relazione tra un set di regressori ad alta dimensionalità e una variabile di risposta nominale con più di due modalità. Questo metodo usa come covariate del modello multinomiale un numero ridotto di componenti principali estratte dai regressori. Poiché le componenti principali si basano sugli autovettori della matrice di covarianza empirica, sono molto sensibili alle osservazioni anomale. Diversi metodi robusti per l'analisi in componenti principali sono stati proposti in letteratura. In questo studio consideriamo il metodo ROBPCA. Il nuovo approccio robusto sarà applicato per valutare la performance dei giudici.*

Key words: principal component analysis, multinomial logit model, outliers, judges' performances.

1. Introduction

The court computerization of the last decades allows us to create available databases with complete information about the judicial flows. Here, we aim to focus on the causes of different judges' performances in the court of Naples.

The dataset shows strongly correlated regressors, so the most proper statistic methodology to analyse this kind of data could be Principal component multinomial regression (Camminatiello, Lucadamo, 2010; Lucadamo, Leone, 2015).

A previous research on Florence Court (Camminatiello, Lombardo, Durand, 2017) highlighted the presence of outliers among judges.

The aim of the paper is to study the dependence relationship between the judges' performances and some indicators of the judges' workload taking into account multicollinearity and outlier problems which make the estimation of the multinomial model parameters inaccurate because of the need to invert nearsingular and ill-conditioned information matrices.

A robust method for logistic regression (Rousseeuw, Christmann, 2003) and robust logistic ridge regression (Ariffin, Midi, 2014) have been proposed in literature, we propose a robust approach for the principal component multinomial regression (PCMR).

We proceed in the following way. In the second section we describe the PCMR. In the third section we list the most important robust methods for estimating the variance/covariance matrix and propose a robust approach to PCMR. In the fourth section we apply our robust approach for evaluating the judges' efficiency and calculate the correct classification rate for comparing three different models.

2. From multinomial logit regression to robust methods for principal component multinomial regression.

Multinomial logit model (MNL) is the simplest model in discrete choice analysis when more than two alternatives are in a choice set. The model becomes unstable when there is multicollinearity among predictors (Ryan, 1997). To improve the estimation of the MNL parameters, Camminatiello and Lucadamo (2010) proposed the PCMR.

PCMR uses as covariates of the multinomial model a reduced number of principal components (PCs) of the regressors. Because these components are based on the eigenvectors of the empirical covariance matrix, they are very sensitive to anomalous observations. Several methods for robustifying principal component analysis (PCA) have been proposed in literature.

If the number of observations is sufficiently large with respect to the number of variables, the classical covariance matrix can be replaced by minimum covariance determinant (MCD) estimator, minimum volume ellipsoid (MVE) estimator (Rousseeuw and Leroy 1987), S-estimators (Davies 1987), reweighted MCD

(Rousseeuw and van Zomeren, 1990), FAST-MCD (Rousseeuw and Van Driessen, 1999).

For high-dimensional data, a ROBust method for PCA, called ROBPCA, has recently been developed (Hubert, Rousseeuw and Vanden Branden, 2012). ROBPCA starts by reducing the data space to the affine subspace spanned by *n* observations. A convenient way to perform it is by a singular value decomposition of the mean-centred data matrix. In the second stage $h < n$ "least outlying" data points are found by Stahel-Donoho affine invariant outlyingness. In the third stage, the algorithm robustly estimates the location and scatter matrix of the data points projected into a subspace of small to moderate dimension by using the FAST-MCD estimator. ROBPCA ends by yielding the robust principal components. Like classical PCA, the ROBPCA method is location and orthogonal equivariant.

2.1. Robust Principal Component Multinomial Regression - RobPCMR

Several authors applied ROBPCA to formulate other robust techniques (Hubert, Vanden Branden, 2003; Hubert, Verboven, 2003; Rousseeuw, Christmann, 2003). We investigate using ROBPCA before PCMR to deal with multicollinearity and outlier problems in MNL. We proceed in the following way.

Let $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_\mathrm{i}, \dots, \mathbf{x}_\mathrm{p}]$ be a set of *p* quantitative regressors and $\mathbf{y}$ a categorical response variable with more than two categories observed on *n* statistical units.

At first step, robust principal component multinomial regression (RobPCMR) creates the robust PCs of the regressors $\mathbf{Z} = [\mathbf{z}_1, \dots, \mathbf{z}_\mathrm{i}, \dots, \mathbf{z}_\mathrm{p}]$ which are linear combinations of the original variables $\mathbf{Z} = \mathbf{XV}$. At second step the multinomial model is carried out on the set of robust PCs. At third step, the number of robust PCs, $\mathrm{a} < p$, to be retained in the model, is selected according to different tools (Camminatiello and Lucadamo, 2010).

At fourth step, the multinomial model is carried out on the subset of robust PCs chosen. The probability, for the individual *i*, to choose the alternative *c* can be expressed in terms of *a* robust PCs as:

$$\pi_i^{(a)}(c) = \frac{\exp\left\{\sum_{j=1}^{p} \sum_{k=1}^{a} z_{ik} v_{kj} \beta_{jc}^{(a)}\right\}}{\left\{\sum_{b=1}^{s} \exp \sum_{j=1}^{p} \sum_{k=1}^{a} z_{ik} v_{kj} \beta_{jb}^{(a)}\right\}} = \frac{\exp\left\{\sum_{k=1}^{a} z_{ik} \gamma_{kc}^{(a)}\right\}}{\left\{\sum_{b=1}^{s} \exp \sum_{k=1}^{a} z_{ik} \gamma_{kb}^{(a)}\right\}} \qquad (1)$$

where $\gamma_{kb}^{(a)} = \sum_{j=1}^{p} v_{kj} \beta_{jb}^{(a)}$ are the robust coefficients to be estimated on the subset of *a* robust PCs and $\beta_{jb}^{(a)}$ are the robust PCMR parameters obtained after the extraction of the *a* components.

Finally, the robust MNL parameters can be expressed in function of original variables (**X** matrix)

$$\mathbf{Z}^{(a)}\boldsymbol{\gamma}^{(a)} = \mathbf{X}\mathbf{V}^{(a)}\boldsymbol{\gamma}^{(a)} = \mathbf{X}\boldsymbol{\beta}^{(a)} \tag{2}$$

where $\boldsymbol{\beta}^{(a)} = \mathbf{V}^{(a)}\boldsymbol{\gamma}^{(a)}$ is the matrix of robust parameters expressed in function of original variables; $\boldsymbol{Z}^{(a)}$ is the matrix of robust PCs; $\boldsymbol{\gamma}^{(a)}$ is the matrix of robust parameters on a robust PCs for the s alternatives; $\mathbf{V}^{(a)}$ is the matrix of robust eigenvectors.

To measure the performance of a method, several criteria can be utilised (Camminatiello, Lombardo, Durand, 2017; Camminatiello, Lucadamo, 2010). Here, we focus on rate of well classified which we expect higher compared to PCMR and MNL.

3. A robust model to predict judges' performances.

Our study concerns the causes of different judges' performances in the court of Naples. The performance evaluation is based, among others, on the time that each judge employs to solve the disputes. According to many available publications about similar problems (Camminatiello, Lombardo, Durand, 2017), we aim to study if number of: pendings, hearings, dossiers, incoming and defined proceedings can influence the judges' performances. The response variable is on categorical scale, with four modalities from 1 (Low) to 4 (High), measured for 136 judges.

To evaluate how judges' performances can be influenced by explicative variables, we divide our sample in two sub-samples. The first one, composed by the 70% of the observations, is the sample used to estimate the model parameters (estimation sample). The second one (validation sample) is considered to test the goodness of the obtained estimates. In both the cases we calculate the rate of well classified judges and we compare the results obtained by applying the MNL, the PCMR and the RobPCMR.

In table 1 the results obtained by the three methods on the estimation sample are shown. From the second to the fifth column we have the percentage of well classified, calculated for four different models: the MNL estimated on all the regressors and on the two significant ones (via stepwise regression); the PCMR run on the first PC (which accounts for 93.4% of the variance, has the eigenvalue higher than one and furthermore is the only significant regressor); the RobPCMR carried out on the first robust PC (which accounts for 89.8 % of the variance, has the eigenvalue higher than one and is the only significant regressor).

It is easy to observe that for the estimation sample the classical MNL performs better than other models: it could be due to an over-fitting problem.

Table 1: Percentage of correct classified calculated for four different models on the estimation sample

	MNL (all)	*MNL (sign)*	*PCMR (1)*	*RobPCMR (1)*
% correct classified	70.1%	63.9%	59.8%	58.8%

To verify the goodness of the techniques it is then necessary to consider the results on the validation sample (table 2).

In this case it is evident that for all the methods, but for the RobPCMR, the percentages are lower than before.

Table 2: Percentage of correct classified calculated for four different models on the validation sample

	MNL (all)	*MNL (sign)*	*PCMR (1)*	*RobPCMR (1)*
% correct classified	53.8%	56.4%	53.8%	59.0%

In fact, looking at the table 2, we can notice that the MNL, considering all the variables, leads to the same classification rate obtained by the PCMR with only one component, while for the MNL, taking into account only the two significant variables, the percentage of well classified increases. It is surprising that RobPCMR result shows a rate of correct classification higher than before (59.0% against 58.8%). This may indicate the ability of the method in parameter estimation.

It is also interesting to notice what happens when we consider more components in the analysis, both for PCMR and for RobPCMR.

For this reason we show in table 3 and 4 the results obtained when we consider a different number of components as explicative variables.

Table 3: Percentage of correct classified, at varying the number of components, for the estimation sample

Number of components	*PCMR*	*RobPCMR*
1	59.8%	58.8%
2	60.8%	60.8%
3	60.8%	63.9%
4	61.9%	63.9%
5	70.1%	62.9%

For the PCMR, the results on the estimation sample show that, when the number of components increases, the classification improves. Considering all the components the result is equal to that obtained using all the variables in the classical MNL (Camminatiello and Lucadamo, 2010).

For RobPCMR instead, there is an improving in the correct classification rate at beginning, but when we consider all the components, the result is lower than one obtained with 3 and 4 components.

If we consider the validation sample the results confirm both for the PCMR and for the RobPCMR that the selection of the significant components (in this case explaining the most part of the variability too) is an useful solution to obtain a good rate of correct classification.

Table 4: Percentage of correct classified, at varying the number of components, for the validation sample

Number of components	*PCMR*	*RobPCMR*
1	53.8%	59.0%
2	53.8%	59.0%
3	51.3%	56.4%
4	48.7%	58.9%
5	51.3%	56.4%

Obviously for RobPCMR, as already done in previous studies for PCMR, a complete simulation study is necessary to generalize the results.

4. Conclusion and perspective

In this paper we carried out a robust model for evaluating the judges performances in presence of outliers and strongly correlated covariates. .To solve these problems, we proposed to use as covariates of the multinomial model a reduced number of robust PCs of the predictor variables.

The application showed that the proposed approach is a valid alternative on real data. However, an extensive simulation study is needed in order to verify that it is resistant towards many types of contamination, to compare the results with other robust approaches for PCA proposed in literature and to select optimal dimension of the model. The procedure should lead to lower variance estimates of model parameters comparing to PCMR. The variance can be estimated by bootstrap resampling.

Finally, an extension to MNL of the approaches proposed in literature, for dealing with multicollinear and outlier problems in the logit model (Ariffin, Midi, 2014) could be interesting as well as an extension to ordinal logit regression of the approach here proposed.

Complex Contingency Tables and Partitioning of Three-way Association Indices for Assessing Justice Court Workload

Tabelle di Contingenza Complesse e Partizioni di Indici di Associazione per la Valutazione del Carico di Lavoro nei Tribunali Giudiziari

Rosaria Lombardo, Yoshio Takane and Eric J Beh

Abstract A comprehensive study is conducted on the partition of two common indices for three-way contingency tables under several representative hypotheses about the expected frequencies (hypothesized probabilities). Specifically, the partition of the classical (symmetrical) three-way Pearson index and of the asymmetrical three-way Marcotorchino index are considered under a general *Scenario 0* from which known different scenarios are derived: 1) where the hypothesized probabilities are homogeneous among the categories [12], and 2) when the hypothesized probabilities are estimated from the data [7, 6].

Abstract *In questo lavoro si presenta uno studio completo sulla partizione di due indici di associazione per le tabelle di contingenza a tre vie, in base a diverse ipotesi sulle frequenze attese (probabilitá ipotizzate). Nello specifico, si propone la partizione dell'indice di Pearson (simmetrico) e dell'indice di Marcotorchino a tre vie (asimmetrico) in uno Scenario 0 da cui derivano note partizioni: 1) dove le probabilitá ipotizzate sono uniformi [12] e 2) quando le probabilitá ipotizzate sono stimate dai dati [7, 6].*

1 Introduction

Measuring and assessing the association among categorical variables can be undertaken by partitioning a multi-way association index into bivariate, trivariate and higher order terms. The partitions presented in this paper are based on the work by Lancaster (1951) which considered an ANOVA-like partitions of Pearson's chi-squared statistic implemented for the analysis of a $2 \times 2 \times 2$ table. Here, we focus on Pearson's statistic [10] and on Marcotorchino's index [15] for studying the symmetrical and asymmetrical association among three categorical variables, respectively. In this paper we show that, under complete independence of the three categorical variables, a general scenario - called *Scenario 0* - is defined from which different known partitions of Pearson's statistic and Marcotorchino's index can be derived as special cases. Examples of these known partitions include those of [7, 6], [14], [3, 4] and [12]. In *Scenario 0*, the probabilities are prescribed by the analyst instead of being estimated by using the margins of the empirical distribution that underly the data. The reason is that *a priori* knowledge of phenomena can suggest differently; see [1, 12].

The paper is organised in the following manner. After introducing the notation, a general partition of a three-way array in $\Re^{I\times J\times K}$ is discussed in Section 2. The key scenarios of model dependence are described in Section 3. Section 4 presents the general partition for Pearson's statistic. A practical demonstration of this partition under *Scenario 0* is given in Section 5. Some concluding remarks are made in Section 6.

2 Partitioning three-way association indices

Consider a general three-way contingency table $\underline{\mathbf{X}} = \left(x_{ijk}\right) \in \Re^{I\times J\times K}$ (for $i = 1,...,I$, $j = 1,...,J$, and $k = 1,...,K$) that summarises the cross-classification of n individuals/units according to I row, J column and K tube categories. These sets of categories form the row, column and tube variables x_I,x_J, and x_K, respectively. Let $\underline{\hat{\mathbf{P}}} = (\hat{p}_{ijk})$ be the array of the observed joint relative frequencies (of dimension $I \times J \times K$), so that $\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} x_{ijk}/n = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} \hat{p}_{ijk} = 1$.

Let $\underline{\mathbf{P}} = (p_{ijk})$ be the array of the joint probability values of the cells in the three-way tables. Define $\mathbf{p}_I\{= p_{i\bullet\bullet}\}$, $\mathbf{p}_J\{= p_{\bullet j\bullet}\}$, $\mathbf{p}_K\{= p_{\bullet\bullet k}\}$ to be the vectors of the marginal probabilities associated with the three variables x_I,x_J, and x_K, respectively.

In case complete three-way independence is hypothesized, it holds that $p_{ijk} = p_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k}$, where p_{ijk} is the $(i,\ j,\ k)$th joint probability and $p_{i\bullet\bullet}$, $p_{\bullet j\bullet}$ and $p_{\bullet\bullet k}$ are the marginal probabilities of the ith row category, the jth column category, and the kth tube category, respectively.

When studying the association among variables that are symmetrically associated, Pearson's chi-squared statistic is always appropriate. Instead, when variables are asymmetrically associated (for example, x_I may be considered as the response variable while x_J and x_K are treated as the predictor variables) then Marcotorchino's index [15, 14, 4] may be considered more suitable.

Let $\underline{\boldsymbol{\Pi}}$ be a three-way array whose general element is $\pi_{ijk} = \left(\frac{\hat{p}_{ijk}}{p_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k}} - 1\right)$ and define $\underline{\boldsymbol{\Pi}}_M = \left(\frac{\hat{p}_{ijk}}{p_{\bullet j\bullet}p_{\bullet\bullet k}} - p_{i\bullet\bullet}\right)$. Let $\underline{\mathbf{M}} = \mathbf{D_I} \otimes \mathbf{D_J} \otimes \mathbf{D_K}$ and $\underline{\mathbf{M}}_{tau} = \mathbf{I} \otimes \mathbf{D_J} \otimes \mathbf{D_K}$, be the metric related to the arrays $\underline{\boldsymbol{\Pi}}$ and $\underline{\boldsymbol{\Pi}}_M$, respetively. Given the traditional definition of inner products and quadratic norm in the space $\Re^{I\times J\times K}$ [16, p. 7],[6], observe that the quadratic norm of $\underline{\boldsymbol{\Pi}}$ with metric $\underline{\mathbf{M}}$ represents Pearson's mean square statistic and can be expressed as

$$\frac{\chi^2}{n} = \Phi^2 = \| \underline{\boldsymbol{\Pi}} \|^2_M = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} p_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k}\pi^2_{ijk}, \tag{1}$$

which measures the overall discrepancy between a set of observed frequencies and the expected frequencies.

Similarly, the quadratic norm of $\underline{\boldsymbol{\Pi}}_M$ with metric $\underline{\mathbf{M}}_{tau}$ represents Marcotorchino's index numerator and can be expressed as

$$\tau_M^{num} = \| \underline{\boldsymbol{\Pi}} \|^2_{M_{tau}} = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} p_{\bullet j\bullet}p_{\bullet\bullet k}(\pi^M_{ijk})^2, \tag{2}$$

which measures the discrepancy between a set of conditional frequencies and the expected frequencies. The denominator of this index is considered a constant term, since it does not depend on the predictor variables, and is usually neglected. Marcotorchino's index, called τ_M, is a generalization of the τ index presented by [8] for studying the predictability issue in two-way contingency tables. For more information on this index, refer to [15, 14] and [4, p.461].

For partitioning purpose, examine the orthogonal projections of a general three-way array $\underline{\mathbf{X}}$ beloging to the space $\Re^{I\times J\times K}$ onto the subspaces $\Re^0$, $\Re^I$, $\Re^J$, $\Re^K$, $\Re^{JK}$, $\Re^{IJ}$, $\Re^{IK}$ and $\Re^{IJK}$. Then, according to the ANOVA-like decomposition of the elements of an array we get

$$x_{ijk} = a + b_i + c_j + d_k + e_{ij} + f_{ik} + g_{jk} + h_{ijk}, \tag{3}$$

so that there exists a fixed main term ($a = x_{\bullet\bullet\bullet}$), three univariate main terms ($b_i = x_{i\bullet\bullet} - x_{\bullet\bullet\bullet}$, $c_j = x_{\bullet j\bullet} - x_{\bullet\bullet\bullet}$ and $d_k = x_{\bullet\bullet k} - x_{\bullet\bullet\bullet}$), three bivariate terms ($e_{ij} = x_{ij\bullet} - x_{\bullet\bullet\bullet}$, $f_{ik} = x_{i\bullet k} - x_{\bullet\bullet\bullet}$ and $g_{jk} = x_{\bullet jk} - x_{\bullet\bullet\bullet}$) and a trivariate effect ($h_{ijk} = x_{ijk} - x_{ij\bullet} - x_{i\bullet k} - x_{\bullet jk} + x_{i\bullet\bullet} + x_{\bullet j\bullet} + x_{\bullet\bullet k} - x_{\bullet\bullet\bullet}$), defined onto the sub-spaces $\Re^0$, $\Re^I$, $\Re^J$, $\Re^K$, $\Re^{IJ}$, $\Re^{IK}$, $\Re^{JK}$ and $\Re^{IJK}$, respectively. The determination of the partition terms depend upon the definition of the array $\underline{\mathbf{X}}$ and on the metric related to each subspace, as it will be illustrated in Section 2.1

2.1 Index's partition term

In general, the uniqueness of each term of the partition in Equation 3, for example say b_i, is verified if the following two conditions are satisfied

1. each term belongs to the related space: $b_i \in \Re^I$
2. each term is orthogonal to the space vectors:

$$(\mathbf{x} - \mathbf{b}_M) \perp \Re^I \leftrightarrow < \mathbf{x} - \mathbf{b}, \beta >_M = 0 \qquad \forall \beta \in \Re^I$$

as consequence

$$< \mathbf{x}, \beta >_M = < \mathbf{b}, \beta >_M$$

By setting $\boldsymbol{x} = \boldsymbol{\pi}$, using the metric $\underline{\mathbf{M}}$ and expanding the inner product, we get

$$\begin{aligned}\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} p_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k}\pi_{ijk}\beta_i &= \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} p_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k}b_i\beta_i \\ \sum_{j=1}^{J}\sum_{k=1}^{K} p_{\bullet j\bullet}p_{\bullet\bullet k}\pi_{ijk} &= b_i \\ \pi_{i\bullet\bullet} &= b_i\,.\end{aligned}$$

So the projection of $\underline{\boldsymbol{\Pi}}$ onto the subspace $\Re^I$ is defined by

$$\begin{aligned} b_i &= \pi_{i\bullet\bullet} - \pi_{\bullet\bullet\bullet} \\ &= \sum_{j=1}^{J}\sum_{k=1}^{K} p_{\bullet j\bullet}p_{\bullet\bullet k}\left(\frac{\hat{p}_{ijk}}{p_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k}} - 1\right) \\ &= \left(\frac{\hat{p}_{i\bullet\bullet}}{p_{i\bullet\bullet}} - 1\right)\end{aligned}$$

The weighted quadratic norm of this term is equal to the first term on the right-hand side of Equation 4.
The orthogonal projections of $\underline{\boldsymbol{\Pi}}$ onto the remaining subspaces can be similarly defined.
Furthermore, changing the metric in $\underline{\mathbf{M}}_{tau} = \boldsymbol{I} \otimes D_J \otimes D_K$ and taking into account the array $\underline{\boldsymbol{\Pi}}_M$, we can get the orthogonal projections of Marcotorchino's index in a similar way.

3 The key scenarios of model dependence

Under the three-way model of complete independence, we present a new general scenario - referred to as *Scenario 0* - which can be applied to each variable of a three- or multi-way contingency table rather than to contingency tables as a whole (see Section 4). In *Scenario 0*, the marginal probabilities, $\mathbf{p}_I$, $\mathbf{p}_J$, and $\mathbf{p}_K$, can take on any prescribed values that satisfy the classical probability laws (e.g., $p_{i\bullet\bullet} \geq 0$, and $\sum_{i=1}^{I} p_{i\bullet\bullet} = 1$). We do not assume that the probabilities of $\mathbf{p}_I$, $\mathbf{p}_J$, and $\mathbf{p}_K$ are user-defined but are dictated by situational demand.

- *Scenario 1*. A special case of *Scenario 0* where it is hyphotesised the marginal homogeneity under independence such that $\mathbf{p}_I = \mathbf{1}_I/I, \mathbf{p}_J = \mathbf{1}_J/J$, and $\mathbf{p}_K = \mathbf{1}_K/K$, where $\mathbf{1}_I, \mathbf{1}_J$ and $\mathbf{1}_K$ are unitary vector of length I, J and K, respectively. In this case the degree of freedom, *df*, for the three-way chi-squared statistic is $IJK - 1$. This scenario is at the core of the chi-squared partition proposed by Loisel and Takane by using orthogonal transformations of variables [12].
- *Scenario 2*. A special case of *Scenario 0* in which the probabilities in $\mathbf{p}_I$, $\mathbf{p}_J$, and $\mathbf{p}_K$ are estimated from the data, so that $\mathbf{p}_I = \hat{\mathbf{p}}_I$, $\mathbf{p}_J = \hat{\mathbf{p}}_J$ and $\mathbf{p}_K = \hat{\mathbf{p}}_K$, are prescribed to be equal to the observed marginal proportions of the three categorical variables. In this scenario, the *df* for the three-way chi-squared statistic is $(IJK-1)-(I-1)-(J-1)-(K-1)$
- *Scenario 3*. A special case of *Scenario 0* in which the specification of the probabilities in $\mathbf{p}_I$, $\mathbf{p}_J$, and $\mathbf{p}_K$ can be a mix of both *Scenario 1* and *Scenario 2*.

For all scenarios, the partition terms of Pearson's mean square coefficient and Marcotorchino's index in the space $\Re^{I\times J\times K}$ are likely to be different. However, irrespective of which special case of *Scenario 0* is considered, these statistics and each term of their partition, can be tested (asymptotically) for statistical significance using a χ^2 distribution.

4 Partitioning Pearson's statistic

For a sake of brevity, here we illustrate only the partition of Φ^2 under *Scenario 0*. The row, column and tube marginal probabilities, $\mathbf{p}_I$, $\mathbf{p}_J$, and $\mathbf{p}_K$, respectively, can be *a priori* known or estimated from the data. This general partition is

$$\begin{aligned}
\Phi^2 &= \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} \frac{1}{p_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k}} \left(\hat{p}_{ijk} - p_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k}\right)^2 \\
&= \sum_{i=1}^{I} \frac{1}{p_{i\bullet\bullet}} \left(\hat{p}_{i\bullet\bullet} - p_{i\bullet\bullet}\right)^2 + \sum_{j=1}^{J} \frac{1}{p_{\bullet j\bullet}} \left(\hat{p}_{\bullet j\bullet} - p_{\bullet j\bullet}\right)^2 + \sum_{k=1}^{K} \frac{1}{p_{\bullet\bullet k}} \left(\hat{p}_{\bullet\bullet k} - p_{\bullet\bullet k}\right)^2 \\
&\quad + \sum_{i=1}^{I}\sum_{j=1}^{J} \frac{1}{p_{i\bullet\bullet}p_{\bullet j\bullet}} \left(\hat{p}_{ij\bullet} - \hat{p}_{i\bullet\bullet}p_{\bullet j\bullet} - \hat{p}_{\bullet j\bullet}p_{i\bullet\bullet} + p_{i\bullet\bullet}p_{\bullet j\bullet}\right)^2 \\
&\quad + \sum_{i=1}^{I}\sum_{k=1}^{K} \frac{1}{p_{i\bullet\bullet}p_{\bullet\bullet k}} \left(\hat{p}_{i\bullet k} - \hat{p}_{i\bullet\bullet}p_{\bullet\bullet k} - \hat{p}_{\bullet\bullet k}p_{i\bullet\bullet} + p_{i\bullet\bullet}p_{\bullet\bullet k}\right)^2 \\
&\quad + \sum_{j=1}^{J}\sum_{k=1}^{K} \frac{1}{p_{\bullet j\bullet}p_{\bullet\bullet k}} \left(\hat{p}_{\bullet jk} - \hat{p}_{\bullet j\bullet}p_{\bullet\bullet k} - \hat{p}_{\bullet\bullet k}p_{\bullet j\bullet} + p_{\bullet j\bullet}p_{\bullet\bullet k}\right)^2 \\
&\quad + \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K} \frac{1}{p_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k}} \left(\hat{p}_{ijk} - \hat{p}_{ij\bullet}p_{\bullet\bullet k} - \hat{p}_{i\bullet k}p_{\bullet j\bullet} - \hat{p}_{\bullet jk}p_{i\bullet\bullet}\right. \\
&\qquad \left. + \hat{p}_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k} + \hat{p}_{\bullet j\bullet}p_{i\bullet\bullet}p_{\bullet\bullet k} + \hat{p}_{\bullet\bullet k}p_{i\bullet\bullet}p_{\bullet j\bullet} - p_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k}\right)^2 \\
&= \Phi_I^2 + \Phi_J^2 + \Phi_K^2 + \Phi_{IJ}^2 + \Phi_{IK}^2 + \Phi_{JK}^2 + \Phi_{IJK}^2 .
\end{aligned} \tag{4}$$

Here we can see that there are seven terms in the partition. The first term is the row main effect which, when multiplied by n and under the null hypothesis $p_{ijk} = p_{i\bullet\bullet}p_{\bullet j\bullet}p_{\bullet\bullet k}$, asymptotically follows a χ^2_{I-1} distribution, whose $1-\alpha$ percentile is $\chi^2_{\alpha,I-1}$ with $I-1$ degrees of freedom. Similarly, the column main effect, $n\Phi^2_J$ asymptotically follows a χ^2_{J-1} distribution while the tube main effect, $n\Phi^2_K$, follows a χ^2_{K-1} distribution. The bivariate terms of the partition - $n\Phi^2_{IJ}$, $n\Phi^2_{IK}$ and $n\Phi^2_{JK}$ - are measures of the row-column, row-tube and column-tube association, respectively, and are asymptotically chi-squared random variables with $(I-1)(J-1)$, $(I-1)(K-1)$ and $(J-1)(K-1)$ degrees of freedom, respectively. The last term of the partition, $n\Phi^2_{IJK}$ is the measure of three-way, or *trivariate*, association between all three variables and is asymptotically a chi-squared random variable with $(I-1)(J-1)(K-1)$ degrees of freedom. This general framework allows one to consider a mixture of tests, in particular goodness-of-fit tests, and association tests of the various relationships among the variables.

5 Example

To illustrate our partition briefly, we consider Pearson's index under *Scenario 0*; see Equation (4). The data concerns a study about the justice court delay in Italy [5]. We investigate the association among *Trial length*, *Subjects* of trials and *Number of Hearings*. The *Trial length* has four categories *low* duration (from 88 to 596 days), middle-low (from 597 to 1130 days), *mlow*, middle-long (from 1131 to 1950 days), *mlong*, and *long* (from 1951 to 6930 days) duration. The column variable, *Sub-*

ject of trials, has three categories *Obbligation, Controversy*, and *Real Rights* and also the tube variable has three categories, low number of hearings (from 0 to 2), *Hlow*, middle number of hearing (from 3 to 5), *Hmedium*, and high number of hearings (from 6 to 25), *Hhigh*. For a priori knowledge of the problem, we set the row probabilities as estimated from the data, the column probabilities as uniform, i.e. $p_{\bullet j \bullet} = (1/3, 1/3, 1/3)$, and the tube probabilities as equal to $p_{\bullet\bullet k} = (0.4, 0.4, 0.2)$. The overall association is $n\Phi^2 = \chi^2 = 4122$ with df=32 there exists strong evidence to say that it is statistically significant (p-value < 0.0001). The size and percentage contribution to χ^2 and the eight terms are reported in Table 2.

Table 1 Justice data: Crosstabulation of *Trial length* by *Subject* and by *Number Hearing*.

Hlow- *Low number of hearings*			
	Subject		
Trial Length	**Obbligation**	**Controversy**	**Real Right**
low	123	26	8
mlow	63	23	19
mlong	161	27	33
long	69	69	22
Hmedium- *Middle number of hearings*			
	Subject		
Trial Length	**Obbligation**	**Controversy**	**Real Right**
low	110	9	9
mlow	82	7	4
mlong	74	6	15
long	32	11	10
Hhigh- *High number of hearings*			
	Subject		
Trial Length	**Obbligation**	**Controversy**	**Real Right**
low	181	0	8
mlow	241	4	28
mlong	126	1	27
long	183	6	70

Table 2 Partition of the three-way chi-squared association measure under Scenario 0.

	X^2_J	X^2_K	X^2_{IJ}	X^2_{IK}	X^2_{JK}	X^2_{IJK}	X^2
Index	1591.15	869.84	92.94	152.93	1202.43	212.92	4122.22
% of Inertia	38.59	21.10	2.26	3.71	29.17	5.17	100.00
df	2.00	2.00	6.00	6.00	4.00	12.00	32.00
p-value	0.00	0.00	0.00	0.00	0.00	0.00	0.00

This output shows that the most dominant contributor (38.6%) to the association among the univariate terms of Equation (4) is due to the inclusion of the *Subject* variable. The unique not significant term is due to the row variable *Trial Length* (whose hypothesized probabilities are set equal to the estimated frequencies), all the others are statistically significant and the most important concerns the *Subject* of trials. Of the bivariate association terms from the partition, the most important is due to the column and tube variables, *Subject* and *Number of Hearing*, it is about 29% of the total association, while the least important bivariate association concerns the row and tube variables, *Trial Length* and *Subject*, that is 2.3% of the total association among the variables. Finally, the contribute of the trivariate association term is low (around 5%).

6 Discussion

This paper has proposed a general expression of the partition for three-way association statistics, in particular for the traditional three-way Pearson statistic (see Equation 4) when hypothesising complete independence model. Further investigation of the partitions when considering complete and partial independence will lead to other quite distinct situations in partitioning symmetric and asymmetric three-way association indices [14, 13]. Comparisons with other goodness-of-fit statistics for large-sample, like the likelihood-ratio statistic or the Wald statistic [11] will be pursued.

Finding the best paths in university curricula of graduates to improve academic guidance services

Individuare i migliori percorsi di carriera universitaria per migliorare l'efficacia dei servizi d'orientamento d'Ateneo

Silvia Bacci and Bruno Bertaccini

Abstract Within the more general quality assurance pathways undertaken by the universities, inbound and on going guidance activities are assuming an increasingly strategic role with the aim to reduce the dropout rate and the time to qualification. In this contribution, the usefulness of some typical data mining solutions is evaluated in the context of students' careers analysis. More in detail, an analysis of graduates' careers paths is proposed, mainly based on the application and comparison of clustering procedures. With our proposal we aim at identifying career paths that are particularly virtuous in terms of average scores and time to qualification. Such type of information can be used by the university management for planning the career paths of freshmen.

Abstract *All'interno dei più generali percorsi di assicurazione della qualità intrapresi dagli Atenei, le attività di orientamento in ingresso e itinere stanno assumendo un ruolo sempre più strategico in ottica di riduzione del tasso d'abbandono e contenimento dei tempi di conseguimento del titolo. Questo lavoro intende valutare l'applicabilità di alcune soluzioni di data mining nel campo dell'analisi dei dati di carriera dei laureati; in particolare i percorsi scelti da coloro che hanno completato gli studi saranno analizzati attraverso alcune tecniche di clustering per l'identificazione di carriere virtuose (in termini di votazione media e tempo richiesto per il completamento del percorso) che possano essere proposte dagli organi di governo dei corsi di studio quale modello di riferimento per i nuovi iscritti.*

Key words: academic guidance services, cluster analysis, data mining, education, hidden Markov models, mixture models

1 Introduction

The Italian university system is characterized by some peculiarities, *in primis* that students can freely decide when taking an exam and the specific sequence of enrolled exams. The main relevant consequence of this organizative approach are the long times to qualification. In such a context identifying career paths that are particularly virtuous in terms of average grades and time to qualification as well as the exams representing "bottlenecks" in the career flows is especially relevant for the university management in order to plan the career paths of freshmen and to improve the academic guidance services.

In this contribution we aim at studying the sequences of exams taken by a cohort of graduated students, through the comparison of some clustering approaches.

2 Data

The analysis here proposed is based on a cohort of 189 students in Business Economics at the University of Florence that enrolled the degree course in year 2012 and completed it within year 2017. In Figures 1 and 2 the sequences of first-year exams are shown, by average grade (low-high; Figure 1) and time to qualification (low-high; Figure 2). In both cases, attention is captured by differences in the observed sequences: in particular, the first-year exams that are more problematic in terms of tendency to postpone are Private Law and Mathematics.

3 Clustering approaches

Behavioral homogeneity of the cohort of students at issue is investigated through some clustering approaches:

Hierarchical cluster analysis. This a well-known approach that does not require any model specification, even if some choices are necessary (e.g., number of clusters, grouping method, type of distance). The analysis is performed on the exams' cumulative average score and on the cumulative time to qualification. This approach suffers for the presence of sparse data due to a large number of exams that are taken only by few students: as a consequence a preliminary cleanup of data is necessary.

Latent class model-based cluster analysis [4]. This is the simplest model-based clustering approach. The analysis is performed on the same variables as the previous approach. This approach has the same drawbacks as the hierarchical clustering.

Mixture Luce-Plackett model-based analysis [5]. Differently from the two above approaches, this approach works on the students' partial ranking of exams, that is for each student the corresponding sequence of exams is formulated in terms of a rank, where missing values correspond to exams that are not in the student's degree curriculum. In such a way the sequence of exams is explicitly taken into account. As main result, this approach provides a measure of liking toward each exam, separately for each cluster. The main practical drawback of this approach is that the clustering process does not account for the exam grades and, only partially, for the time gaps between exams, so that clusters are likely to overlap a lot in terms of exam grades and times to qualification. Moreover, the liking measures tend to assume high values for the very first enrolled exams and values around zero for the following exams, such that differences between clusters in terms of sequences may not be well defined.

Mixture Hidden Markov (MHM) model-based cluster analysis [2]. Similarly to the mixture Luce-Plackett model-based approach, this approach directly models the sequences of exams. More in details, a multiple multichannel MHM model is specially suitable for data at issue, as it will be cleared in the next section. Terms "multiple" and "multichannel" refer to the presence of more than one individual (i.e., cohort of students) and of more than one sequence of data for each individ-

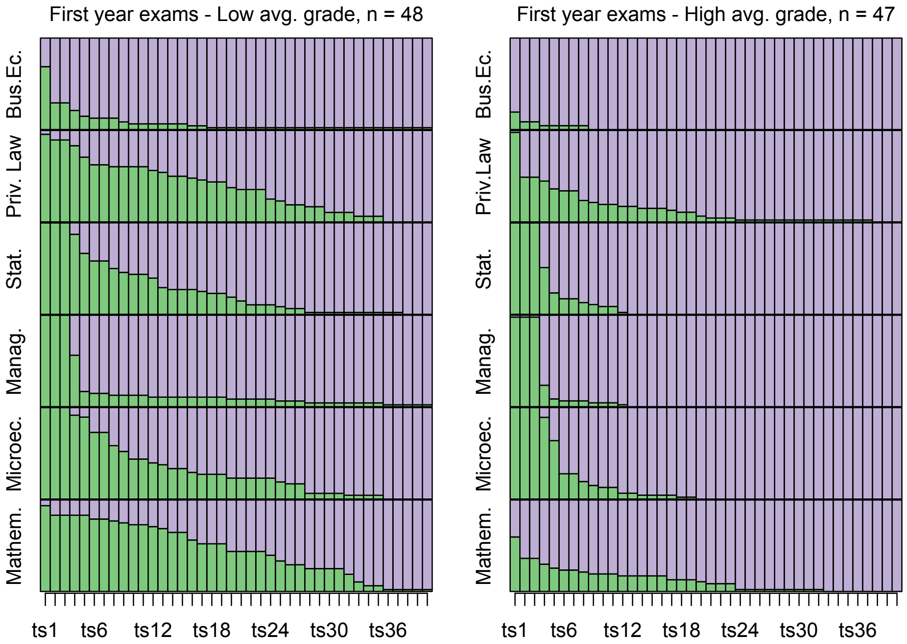

Fig. 1 Sequences of first-year exams by average grade: average grade less than first quartile (left panel) and average grade greater than third quartile (right panel). Legend: green = exam not taken; purple = exam taken.

ual (i.e., one sequence for each exam), respectively. In practice, the MHM model presents some specific advantages with respect to the other approaches: (*i*) the presence of sparse data is not a problem (exams that are not present in the degree curriculum of a student correspond to a sequence of 0s), (*ii*) the observed sequences of exams are explicitly modelled and individuals are clustered on the basis of these sequences, (*iii*) in addition to the other finite mixture approaches, it allows us an in-depth analysis of every exam within each cluster, such that weaknesses of the different typologies of students are highlighted, (*iv*) differently from the other approaches, it allows us to enclose in the analysis students that dropped out or that did not yet finished the exams of the degree course.

3.1 Mixture Hidden Markov model

HM models [3, 1] represent a nice frame to analyse sequence data. In such a context, a sequence of 0s and 1s represents the observed states, which are interpreted as

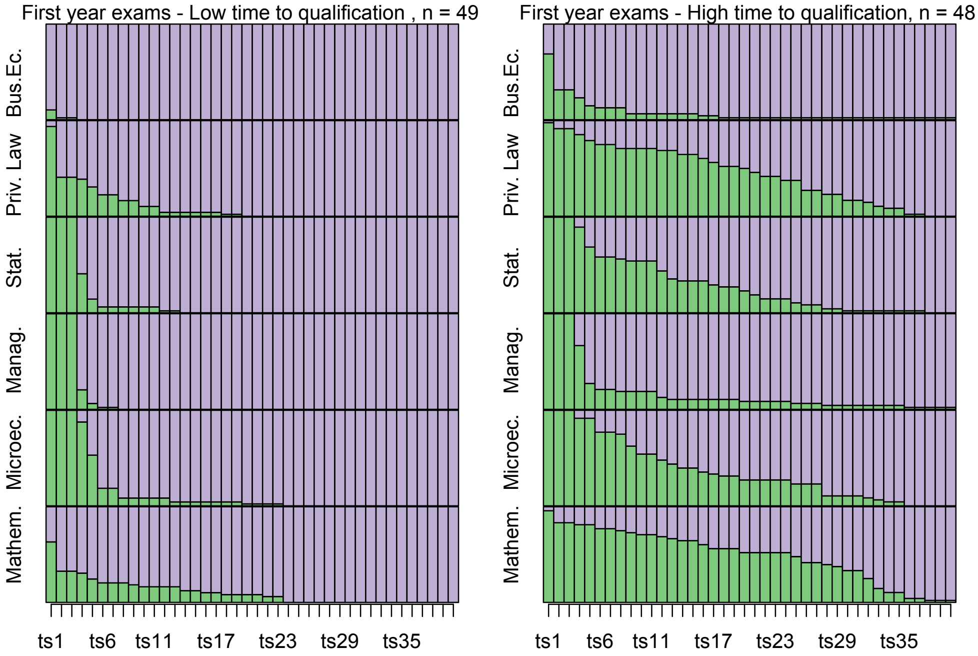

Fig. 2 Sequences of first-year exams by time to qualification: time less than first quartile (left panel) and time greater than third quartile (right panel). Legend: green = exam not taken; purple = exam taken.

probabilistic manifestations of a certain number of unobservable (i.e., hidden or latent) states. In our contribution, we assume that student i in any time point may belong to one of two hidden states: state $u_{it} = 1$ denotes a low propensity to take exams at time t and state $u_{it} = 2$ denotes a high propensity to take exams at time t. As usual in the HM models, students can move from a state to another one. In addition, we introduce the observed state $y_{itj} = y$, with $y = 1$ if student i takes exam j at time t or before, and $y = 0$ if student i did not yet taken exam j at time t; $j = 1,\dots,J$, with J denoting the total number of exams (it does not matter how many students choose an exam for their own degree curriculum), and $t = 1,\dots,T$ with T denoting the length of any sequence and corresponds to the number of exam sessions scheduled in the years 2012-2017.

Hence, we have two types of vectors for each student: vector $\mathbf{u}_i = (u_{i1},\dots,u_{it},\dots,u_{iT})$ of hidden state sequence and vector $\mathbf{y}_{ij} = (y_{i1j},\dots,y_{itj},\dots,y_{iTj})$ of observed state sequence; note that we have one vector $\mathbf{y}_{ij}$ for each exam.

The probability of observed sequence of data is formulated according to a time-homogeneous multivariate HM model:

$$p(\mathbf{Y}_{ij} = \mathbf{y}_{ij}) = \sum_{u=1}^{2} p(\mathbf{y}_{ij}|\mathbf{u}_i)p(\mathbf{u}_i) = \sum_{u=1}^{2} \left[p(y_{i1j}|u_{i1})p(u_{i1}) \prod_{t=2}^{T} p(y_{itj}|u_{it})p(u_{it}|u_{i,t-1}) \right], \tag{1}$$

with: $p(y_{itj}|u_{it})$ conditional probability of observed state given the hidden state (emission probability), $p(u_{i1})$ initial probability of starting from hidden state u_{i1}, and $p(u_{it}|u_{i,t-1})$ transition probability of moving from hidden state $u_{i,t-1}$ to hidden state u_{it}. This model is usually estimated through the maximization of the log-likelihood function, using the forward-backward algorithm.

A generalization of the HM model is represented by the MHM model, which is based on the assumption that the population is composed by homogenous groups of individuals and each of these groups follow a specific HM model. In such a context, model in equation 1 modifies as

$$p(\mathbf{Y}_{ij} = \mathbf{y}_{ij}) = \sum_{k=1}^{K} \pi_k \left\{ \sum_{u=1}^{2} p(\mathbf{y}_{ij}|\mathbf{u}_i)p(\mathbf{u}_i) \right\}, \tag{2}$$

where π_k denotes the prior probability that the sequence of observed states of an individual belongs to cluster k.

To synthetize, the mixture part of the model allows us to cluster students in groups that are homogenous in terms of observed sequences of exams and propensity to take exams. In this way a classification of students is obtained, which is comparable with those obtained in the previously described approaches. In addition, the HM part of the model allows us for an in-depth analysis of the performance of students on single exams.

4 Main results

To define homogenous sub-groups of students, we selected a number of clusters equal to three and we applied the clustering procedures above described. In Table 1 the results in terms of average grade, average time to qualification and cluster size are illustrated.

Table 1 Average grade and average time to qualification by cluster and clustering approach. In bold the best performances, in italic the worst performances.

Approach	Variables	Cluster 1	Cluster 2	Cluster 3
Hierarchical clustering				
	avg. grade (out of 30)	**26.14**	*23.69*	24.99
	avg. time (days)	**1037.04**	*1598.90*	1262.98
	# of students	54	48	87
Latent class clustering				
	avg. grade (out of 30)	25.35	*24.05*	**26.74**
	avg. time (days)	1171.83	*1436.12*	**1079.16**
	# of students	59	93	37
Mix. Luce-Plackett clust.				
	avg. grade (out of 30)	**25.59**	24.97	*24.13*
	avg. time (days)	**1305.47**	1382.06	*1447.91*
	# of students	30	148	11
MHM clustering				
	avg. grade (out of 30)	25.25	*23.99*	**25.81**
	avg. time (days)	1324.83	*1577.25*	**1219.21**
	# of students	46	68	75

It is worth to be noted that all approaches provide a cluster of best performers (in bold) and a cluster of worst performers (in italic) with respect to both criteria of average grade and time to qualification. The clustering approach based on partially ranked data is the least satisfactorily as concerns the level of separability among clusters.

Additional details about the cluster characteristics are provided by the estimated parameters of the MHM model. In Table 2 the emission probabilities of the first-year exams are shown, which describe the probability of taking an exam - in any time point - given the hidden state, that is, $p(Y_{itj} = 1|u_{it})$; these probabilities are cluster-specific. For the sake of clarity we remind that state 1 denotes a low propensity to take exams and state 2 denotes a high propensity to take exams; then, the lower $p(Y_{itj} = 1|u_{it})$, the higher the tendency to postpone exam j.

As shown in Table 1, the worst performers are allocated in cluster 2. In more detail 2, students of cluster 2 belonging to state 1 have a high tendency to postpone Mathematics and Private Law (emission probabilities equal to 26.6% and 33.3%, respectively), followed by Microeconomics (46.0%) and Statistics (57.8%). Mathematics and Private Law represent bottlenecks also for the colleagues in state 2 (emission probabilities equal to 79.1% and 83.8%, respectively).

Table 2 MHM model: Estimated emission probabilities by cluster (only first-year exams)

Exam	Hidden state	Cluster 1	Cluster 2	Cluster 3
Business Economics				
	State 1	0.893	0.925	0.983
	State 2	0.984	1.000	1.000
Private Law				
	State 1	0.636	0.333	0.655
	State 2	0.962	0.838	0.987
Statistics				
	State 1	0.609	0.578	0.740
	State 2	0.991	0.963	0.998
Management				
	State 1	0.704	0.763	0.804
	State 2	0.977	1.000	1.000
Microeconomics				
	State 1	0.493	0.460	0.677
	State 2	0.956	0.929	1.000
Mathematics				
	State 1	0.438	0.266	0.783
	State 2	0.885	0.791	0.989

On the opposite, the best performers are allocated in cluster 3. In such a cluster the main problems are observed for Private Law and Microeconomics: for both the exams the emission probabilities for state 1 are strongly smaller than 1 (65.5% for Private Law and 67.7% for Microeconomics).

Finally, cluster 1 lies in an intermediate position with respect to clusters 2 and 3 for all (the first-year) exams, with the exception of Business Economics, for which a certain tendency to postpone is observed for both the hidden states (emission probabilities are higher than those of cluster 2).

A synthetic representation of the three clusters is provided by Figure 3, where the estimated sequence of hidden states is displayed for each cluster. It is worth to be noted that around the centre of the time line cluster 2 presents a tail for state 1 that is heavier with respect to cluster 1 and, mainly, cluster 3.

5 Conclusions

The illustrated approaches of cluster analysis, with a special attention for the mixture Hidden Markov model, represent useful instruments for the academic management to detect critical exams for specific sub-groups of students and, more in general, to plan the career paths of freshmen and to improve the academic guidance services.

For the future development of this contribution we intend to extend the analysis to the entire cohort of students, including students that dropped out from the university

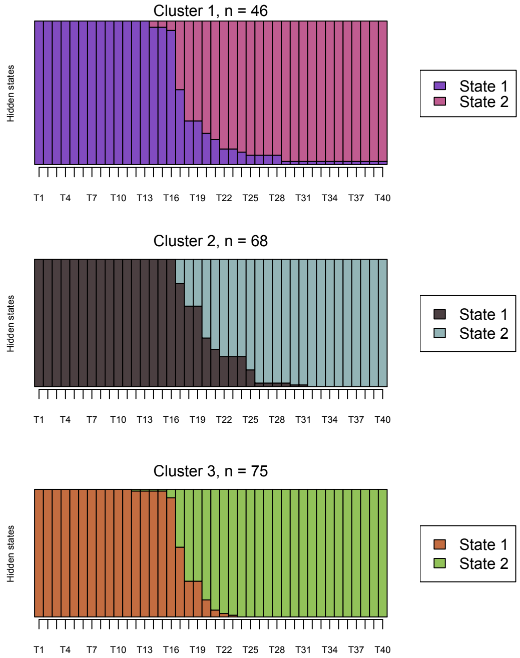

Fig. 3 MHM model: Sequences of hidden states by cluster.

and students that have to finish the exams of the degree course. We also intend to extend the analysis to account for individual characteristics (e.g., type of high school, high school graduation mark).

Statistical Modelling for Business Intelligence Problems

A nonlinear state-space model for the forecasting of field failures

Un modello state-space non lineare per la previsione di guasti post vendita

Antonio Pievatolo

Abstract We consider time series of field failure data (warranty claims) of domestic appliances, manufactured by different plants, with the aim of forecasting failures within the warranty period. The monthly failure profiles over two-year periods display variation across monitoring epochs and also batch-to-batch variation. A nonlinear state space model is developed to jointly represent the variation of the underlying failure rate parameters and the observed occurrence of failures, obtaining a dynamic Poisson-Lognormal model with a meaningful covariance structure of failure rates between monitoring epochs. An adaptation of the auxiliary particle filter is used for parameter learning and forecasting. A series of examples with data from two different production plants show that it is possible to obtain a small forecasting error for claims having very different patterns.

Abstract *Analizziamo serie storiche di riparazioni in garanzia di elettrodomestici, prodotti da impianti differenti, per prevedere la frequenza di guasti entro la fine del periodo di garanzia. I profili di guasto mensili in periodi di due anni mostrano variazioni sia tra periodi di monitoraggio sia tra lotti di produzione. Sviluppiamo un modello state space per rappresentare allo stesso tempo la variazione del parametro del tasso di guasto sottostante e l'apparizione dei guasti, ottenendo un modello dinamico Poisson-Lognormale con una appropriata struttura di covarianza tra periodi di monitoraggio. Utilizziamo un adattamento dell'auxiliary particle filter per la stima dei parametri statici e per la previsione. Alcuni esempi con dati da due impianti di produzione mostrano che è possibile ottenere un piccolo errore di previsione per serie di guasti post-vendita con profili molto diversi.*

Key words: Warranty claims, State-space model, Poisson-Dirichlet model, Poisson-Lognormal model, Particle learning, Covariance of failure rates

1 Introduction

Warranty data have long been recognized as a source of useful information for several purposes, some of which are prediction of future claims, comparison of groups of products and identification of faulty design or material defects or undetected production line problems. [5] provided one of the first review articles on this subject.

Claims are often aggregated by epoch index (e.g. by month) for every production batch, so that available data may be represented by n_t, for the number of items produced at epoch t, and y_{tj}, for the number of claims at epoch $t+j-1$ for batch t, $j=1,\ldots,d$, where d is the duration of the warranty period.

[5] proposed to model the claim arrival process of a given production batch as a sequence of independent Poisson random variables: $Y_{tj} \sim Poisson(n_t \lambda_j)$, as $j=1,\ldots,d$, where λ_j is the expected number of failures per produced item in batch t at epoch $t+j-1$. [9] used the same model for the early detection of reliability problems. Other works are focussed on the modelling of failure times instead ([3]; [4]).

The model based on independent Poisson counts has the main drawback that λ_j does not depend on t so it cannot adequately describe batch-to-batch variation, which could be attributed to: material defects due for example to a change of supplier; changes in the production line that may affect reliability; other unmeasured batch to batch heterogeneity.

This deficiency could be addressed following [6], who introduced a rate function for car warranty data, depending on a unit-specific random effect Z_t and a usage function modelled as $U_{tj} = jZ_t$. This approach requires to select a parametric form for the rate function and does not include possible dependence among unit failure rates at close t values. Furthermore it was developed for situations in which times of occurrence of failures of each unit are available, which is not our present situation.

In this work we have proposed a state space modelling framework in which the observation equation for (conditionally independent) describes a Poisson distribution, whereas the batch-to-batch heterogeneity and the possible dependence among failures of units from batches close in time is represented by a state transition equation on failure rates. In this way the failure rates are regarded as generated by a stochastic process and no assumption on their form is needed. On the other hand, we will focus on the specification of a meaningful dependence structure among failure rates and on a particle learning algorthm, which will provide forecasts on future failure rates before the end of the warranty period and also learn about unknown model parameters.

Our methodology has been applied to claims regarding home appliences manufactured by a multinational company with markets and production plants in several countries.

2 A state space model

Let $y_t = (y_{t1}, \dots, y_{td})^T$ and $\lambda_t = (\lambda_{t1}, \dots, \lambda_{td})^T$, where, unkile the introductory section, λ_t now denotes a vector of failure rates. We consider a state space model for claims

$$\begin{aligned} y_{tj} &\sim Poisson(n_t \lambda_{tj}), \quad j = 1, \dots, d \\ \lambda_t | \lambda_{t-1} &\sim f(\lambda_t | \lambda_{t-1}; \theta) \end{aligned} \tag{1}$$

where θ is an unknown parameter. This model is flexible enough to be able to describe batch-to-batch variation, dependence between batches, dependence between claim numbers in different epochs for the same batch, variation of claim reporting patterns. The task is now to select the form of the state transition equation, which we will do by examining observations from two production plants, where epochs are months, in Figure 2. The left-hand panels show a substantial batch-to-batch variation of observed failure rates for entire batches (number of failures in two years divided by the batch size). The right-hand panels highlight the within-batch variation, that is, how the overall number of failures in two years is distributed over the epochs (months) for all observed batches, with variablity in the shape of the curves.

A model which separates these two types of variation is the following Poisson-Dirichlet model

$$\begin{aligned} y_{tj} &\sim Poisson(n_t \mu_t p_{tj}), \quad j = 1, \dots, d \\ \log(\mu_t) &= \log(\mu_{t-1}) + \sigma w_t \\ p_t &= \gamma p_{t-1} + (1-\gamma) q_t \end{aligned} \tag{2}$$

where μ_t is a scalar, $q_t \sim Dir(M\eta)$, a d-dimensional Dirichlet distribution with mass parameter M and shape parameter $\eta = (\eta_1, \dots, \eta_d)$ such that $\sum_j \eta_j = 1$, and $\gamma \in (0,1)$, $w_t \sim N(0,1)$. The unknown parameter θ includes σ, η and M. The second equation describes the dynamics of the overall batch failure rate, whereas the third one describes the within-batch variation, also defining a covariance structure among epochs in the same batch via the Dirichlet error q_t.

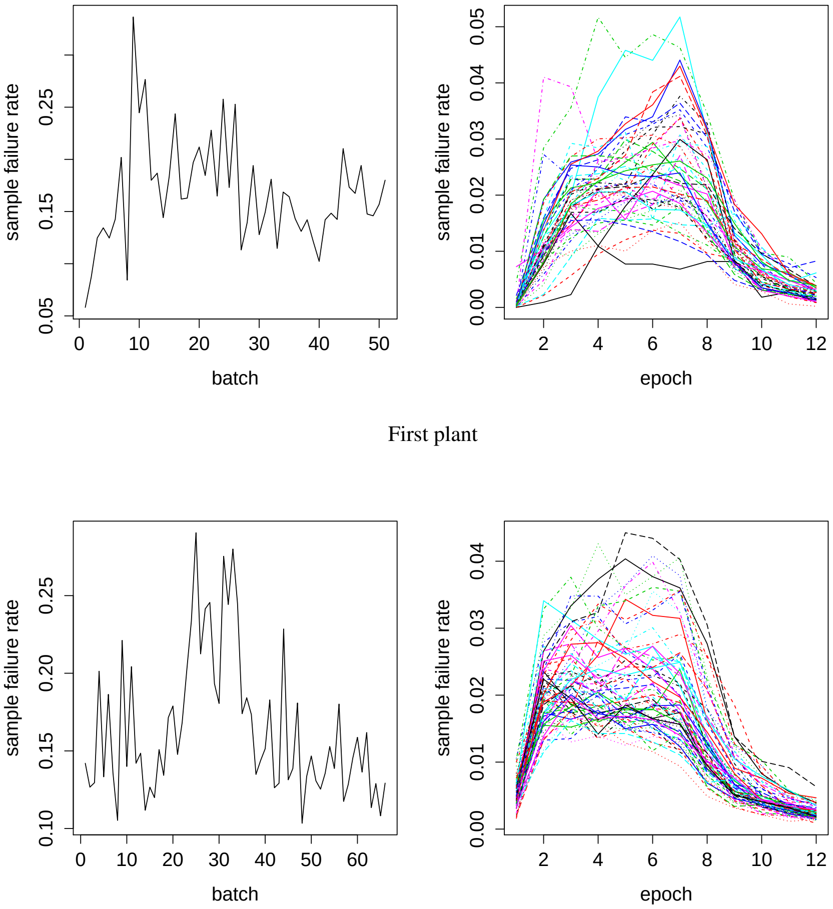
A more tractable version of this model, with a view to sequential Bayesian parameter update, can be obtained by collapsing the two state equations into one. Letting $\lambda_{tj} = \mu_t p_{tj}$, we derive the following:

$$\log \lambda_{tj} = \log \lambda_{t-1,j} + \varepsilon_{tj} \tag{3}$$

where $\varepsilon_{tj} = \log \lambda_{t-1,j} + \log(\gamma + (1-\gamma) q_{tj} / p_{t-1,j}) + \sigma w_t$ and the vector ε_t has a non-diagonal covariance matrix, which we can approximate via error-propagation formulas from the covariance structure of q_t. By doing so, we find

$$Var(\varepsilon_{tj}) \simeq \frac{(1-\gamma)^2 \eta_j (1-\eta_j)}{M+1} \frac{1}{(\gamma p_{t-1,j} + (1-\gamma)\eta_j)^2} + \sigma^2$$

which is further approximated by



First plant

Second plant

Fig. 2: First column: plot of pairs $(t, \sum_j y_{tj}/n_t)$; second column: plots of pairs $(j, y_{tj}/n_t)$, for all available values of t

$$\frac{(1-\gamma)^2}{M+1}\frac{(1-\eta_j)}{\eta_j}+\sigma^2=\tau^2\frac{(1-\eta_j)}{\eta_j}+\sigma^2$$

using η_j for $p_{t-1,j}$. Continuing with the covariances, by the error propagation formulas and using η_j for $p_{t-1,j}$, $Cov(\varepsilon_{tj},\varepsilon_{tr}) \simeq -\tau^2/2+\sigma^2$ and finally $E(\varepsilon_{tj}) \simeq 0$.

Then, the new Poisson-Lognormal state-space model is defined as

$$\begin{aligned} y_{tj} &\sim Poisson(n_t e^{\alpha_{tj}}), \quad j=1,\dots,d \\ \alpha_t &= \alpha_{t-1}+\varepsilon_t \end{aligned} \tag{4}$$

where $\alpha_t = \log\lambda_t$, $\varepsilon_t \sim N_d(0,\Sigma)$ and

$$\begin{aligned} \Sigma_{jj} &= \tau^2\frac{(1-\eta_j)}{\eta_j}+\sigma^2, j=1,\dots,d \\ \Sigma_{jr} &= -\frac{\tau^2}{2}+\sigma^2, j,r=1,\dots,d,\ j\neq r\ . \end{aligned} \tag{5}$$

Model (4)-(5) is not equivalent to the original model (2) and the normality of the error term has been assumed ex post, however this approximation procedure has provided a justification for applying a certain covariance structure to the logarithms of the failure rates. Furthermore, conditional on α_{t-1}, the model for (y_t,α_t) is the multivariate Poisson-lognormal model of [1], for which $Var(Y_{tj}) > E(Y_{tj})$, allowing for overdispersion relative to the Poisson distribution.

3 Particle filtering for claim forecasting

Let $\alpha^t = (\alpha_1,\dots,\alpha_t)$ and $y^t = (y_1,\dots,y_t)$. The filtering distribution at time t is

$$f(\alpha_t|y^t)$$

and it encodes the state of information on the claim rate vector given the observed claims. However, the needed warranty claim rate information for batch t is already provided by $\sum_j y_{tj}/n_t$, and the filter becomes useful for an early assessment of the overall claim when only a part of y_t is observed. So we seek to obtain

$$f(\alpha_t|y^{t-1},y_{t1},\dots,y_{tr_t}), \quad r_t<d,$$

where r_t is the latest observed epoch for batch t, taking advantage of the covariance structure of our state-space model.

By combining the methodology of the auxiliary particle filter (APL) of [8] and of the particle learning method of [2], we have obtained a new modified APL which also includes parameter learning on Σ and converges to the correct filtering and posterior distributions. The filter has not been applied to model (4)-(5), but to a relaxed version to allow for parameter updating using conjugacy. In particular, an inverse-Wishart initial distribution has been assigned to Σ_0, that is, $\Sigma \sim iW(\Sigma_0,\nu_0)$. Then, given that Σ is independent from y^t given α^t, its posterior distribution, conditional on the past history of the observations and of the states, is

$$\Sigma|s_t \sim iW(\Sigma_0+\sum_{r=1}^{t}(\alpha_r-\alpha_{r-1})(\alpha_r-\alpha_{r-1})^T, \nu_0+t) \tag{6}$$

where $s_t = \sum_{r=1}^{t} (\alpha_r - \alpha_{r-1})(\alpha_r - \alpha_{r-1})^T$. At time $t+1$ this distribution can then be updated by knowing only the sufficient statistics s_t and $(\alpha_{t+1} - \alpha_t)$, which, together, give s_{t+1}. The covariance structure (5) is not discarded, but is used to provide the Σ_0 parameter of the initial distribution of Σ, which, as experiments showed, must been assigned carefully.

The derivation of our modified APL is not shown here, for reasons of space. Instead we describe now the filtering algorithm, which provides, at each time t, a discrete approximation of the filtering density as a set of support points with associated weights. Additional yet undefined notation used for the algorithm, is L, the likelihood function determined by the observation equation in model (4) and the function f, which denotes a conditional density.

Given a step-t sample $(\alpha_t, s_t, \Sigma)^{(i)}$ and weights $w_t^{(i)}$, the modified APL goes through the following steps:

1. *Resampling step*: sample N index values k_i, $i = 1, \ldots, N$, using weights proportional to $L(\mu_{t+1}^{(k)}; y_{t+1}) w_t^{(k)}$, putting $\mu_{t+1}^{(k)} = \alpha_t^{(k)}$
2. *Propagation step*: sample N new particles $\alpha_{t+1}^{(i)}$ from $f(\alpha_{t+1} | \alpha_{t,ADJ}^{(k_i)}, \Sigma^{(k_i)})$ where $\alpha_{tj,ADJ}^{(k_i)} = \log(y_{t+1,j}/n_{t+1})$ if $j \leq r_{t+1}$, whereas $\alpha_{tj,ADJ}^{(k_i)} = \alpha_{tj}^{(k_i)}$ if $j > r_{t+1}$
3. Compute weights

$$w_{t+1}^{(i)} \propto \frac{L(\alpha_{t+1}^{(i)} | y_{t+1}) f(\alpha_{t+1}^{(i)} | \alpha_t^{k_i}, \theta^{(k_i)})}{L(\mu_{t+1}^{(i)} | y_{t+1}) f(\alpha_{t+1}^{(i)} | \alpha_{t,ADJ}^{k_i}, \theta^{(k_i)})}$$

   update sufficient statistics $s_{t+1}^{(i)} = s_t^{(k_i)} + (\alpha_{t+1}^{(i)} - \alpha_t^{(k_i)})(\alpha_{t+1}^{(i)} - \alpha_t^{(k_i)})^T$ and sample $\Sigma^{(i)} \sim iW(\Sigma_0 + s_{t+1}^{(i)}, \nu_0 + t + 1)$

4 Data examples

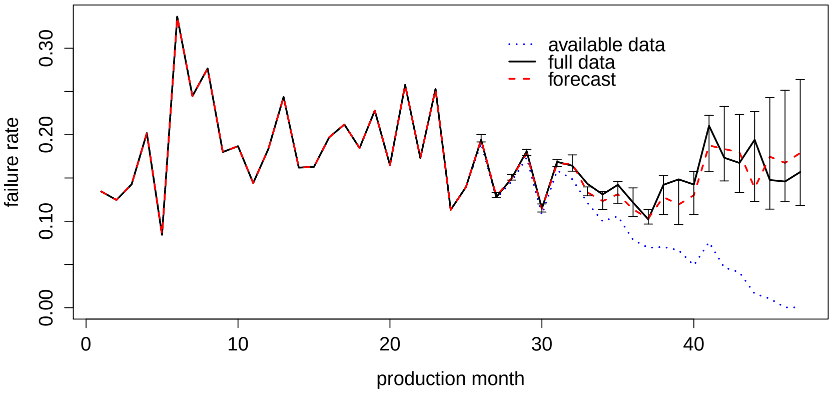
Because of the abundance of training data, the prior can be pretty informative. Therefore the initial distribution for Σ is $iW((R+1)\Sigma_0, R+d+2)$, with large R. With this parameterization, $E(\Sigma) = \Sigma_0$ a priori. The initial Σ_0 is computed using $\eta_j = \sum_t y_{tj} / \sum_t n_t$ from a training sample (such as another plant), then the filtered claim rate for batches with r_t observed claim epochs, $r_t < d$, is estimated as

$$\frac{1}{n_t} \left(\sum_{j=1}^{r_t} y_{tj} + \sum_{j=r_t+1}^{d} \sum_{i=1}^{N} w_t^{(i)} n_t \lambda_{tj}^{(i)} \right) .$$

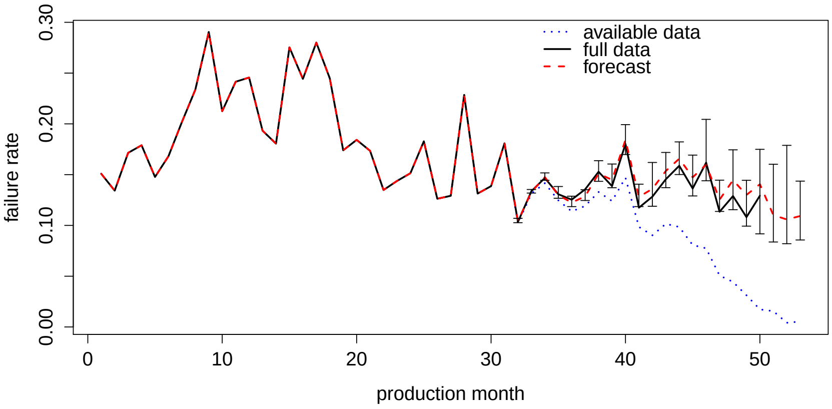
For predictive interval forecasts we resample particles and draw

$$\sum_{j=r_{t+1}}^{d} y_{tj}^{(i)} \sim Poisson(n_t \sum_{j=r_{t+1}}^{d} \lambda_{tj}^{(i)})$$

for every resampled particle. Then we take sample quantiles. The result of the forecasting procedure, including prediction intervals, is displayed in Figure 4, showing a good performance even with very little information on the current production batch.



First plant



Second plant

5 Conclusions

The state-space Poisson-Lognormal model developed in this work has shown a good potential for making early prediction of future claims from customers during the warranty period of a domestic appliance, thanks to the design of an appropriate covariance structure of within-batch failure rates and to parameter learning. This approach is ideal for the sequential monitoring and prediction of claims when they occur as counts in predefined monitoring intervals, without the need of any detailed modelling of known disturbances such as claim reporting delays and of the usage pattern of appliances. Experiments indicate that a good elicitation of the initial value of the covariance matrix is requested, which is possible in the present situation because of the abundance of data, therefore future work can be directed to the exploration of results using a less concentrated initial distribution, as well as to other parameter learning strategies that improve the convergence of the particle filter.

Does Airbnb affect the real estate market? A spatial dependence analysis

Il fenomeno di Airbnb influenza il mercato immobiliare? Un'analisi di dipendenza spaziale

Mariangela Guidolin and Mauro Bernardi

Abstract The problem of evaluating and forecasting the price variation of houses is a traditional one in economic statistics, and the literature dealing with it is very rich. Part of this literature has focused on spatial statistics models in order to account for the structure of spatial dependence among house prices, and studied the relationship between prices and house features, such as dimension, position and type of building. In this paper, we try to extend this approach by considering the effect of exogenous variables, that may exert a significant impact on price dynamics, namely the level of crime and the Airbnb phenomenon. In particular, to our knowledge, the evaluation of the Airbnb activity on the real estate market is still in its infancy, but we expect an increasing role of it. In doing so, we considered the case of New York city, for which this information is fully available as *open data*, and employed spatial autoregressive and spatial error models, in order to study the impact of these variables along with typical house features on the real estate market for each district of the city.

Key words: Bayesian methods, Spike–and–Slab prior, Spatial dependence, Open data, Forecasting.

1 Introduction

A traditional problem in the economic statistics literature has to do with the dynamics of the real estate market and the factors affecting it. An extensive stream of literature has devoted special attention to studying the price variation of houses. Part of this literature has employed spatial statistics models in order to account for the structure of spatial dependence among house prices, and studied the relationship

Mariangela Guidolin

Mauro Bernardi
Department of Statistical Sciences, Via Battisti 241, 35121, Padua e-mail: mbernardi@stat.unipd.it

between prices and house features, such as dimension, position and type of building. In this paper, we try to extend this approach by considering the effect of exogenous variables, that may exert a significant impact on price dynamics, namely the level of crime, the Airbnb phenomenon and the distance from a metro station. In particular, to our knowledge, the evaluation of the Airbnb activity on the real estate market is still in its infancy, but we expect an increasing role of it. In doing so, we considered the case of New York city, for which this information is fully available as *Open Data*, and employed spatial autoregressive and spatial error models, in order to study the impact of these variables along with typical house features on the real estate market for each district of the city. The obtained results confirm our hypothesis on the impact of such variables, opening new perspectives on spatial modelling in the real estate context. The rest of the paper is organised as follows. Section 2 describes the dataset that motivates our empirical analysis and methodological developments, Section 3 briefly review the class of spatial models that we vill employ to model our data while Section 4 deals with the problem of selecting the relevant regressors. Section 5 concludes presenting our main findings.

2 Data set description

The case study here analyzed aims to study the real estate market in New York city and test how some variables directly available as *Open Data* can have an impact on house prices within the different city districts, namely Bronx, Brooklyn, Manhattan, Queens and Staten Island. The main data set contains all the information about house sales in New York for the period 2014–2016, namely: district, type of building, address, size (m^2), year of construction, price, date of sale. Moreover, we considered as potentially significant variables the level of crime of each district, the proximity of a house to a metro station, and the presence of Airbnb in each district. Specifically, taking a temporal window of 6 to 24 months backward with respect to the date of sale, we considered the number of crimes committed, the number of announcements on Airbnb website, the number of positive reviews, the number of host subscriptions, the average price of houses on Airbnb, and the minimum distance to a metro station.

3 Spatial models

Because the data set considered has a spatial cross-section nature, it is necessary to account for spatial dependence between observations in our modelling. To this end, we may follow a wide accepted stream of literature in economics and urban studies, which ascribes such spatial dependence either to a *spillover* phenomenon, implying that prices of spatially close observations will be correlated, or to the *omission* of a variable, which is important for the model but difficult to measure or identify. Since both interpretations of spatial dependence appear plausible, we choose to employ two different modelling approaches incorporating the two, namely the Spatial Autoregressive Model, SAR, and the Spatial Error Model, SEM. The SAR model has the following structure

$$\mathbf{y} = \rho \mathbf{W}\mathbf{y} + \alpha \iota_n + \mathbf{X}\beta + \varepsilon, \tag{1}$$

where $\mathbf{y}$ is the response variables, ρ is a spatial autocorrelation coefficient, defining the intensity of spatial correlation, $\mathbf{W}$ is a $(n \times n)$ matrix of spatial weights, $\mathbf{W}$ is a $(n \times n)$ of explanatory variables, α denotes the intercept of the model, ι_n denotes a unit column vector of dimension n, β is a $(k \times 1)$ vector of regression coefficients associated to the $(n \times k)$ matrix $\mathbf{X}$, $\varepsilon \sim \mathsf{N}(0, \sigma^2 \mathbf{I}_n)$ is the error term. The SEM model incorporates spatial dependence in the error term, has the following structure

$$\mathbf{y} = \alpha \iota_n + \mathbf{X}\beta + \xi \tag{2}$$

$$\xi = \lambda \mathbf{W} \xi + \varepsilon, \tag{3}$$

where λ is the spatial autoregressive coefficient, measuring the effect of omitted variables and model misspecification, and $\varepsilon \sim \mathsf{N}(0, \sigma_\varepsilon^2 \mathbf{I}_n)$ is an error term. The next section will deal with the selection of the relevant regressors for both the SAR and SEM specifications. To this aim let us introduce the transformed variables $\tilde{\mathbf{y}}(\rho) = (\mathbf{I}_n - \rho \mathbf{W})\mathbf{y} = \mathbf{P}_\rho \mathbf{y}$ and $\xi = (\mathbf{I}_n - \lambda \mathbf{W})^{-1} \varepsilon = \mathbf{P}_\lambda^{-1} \varepsilon$ that allows to formulate the SAR and SEM specifications in the following compact way

$$\tilde{\mathbf{y}}(\rho) = \alpha \iota_n + \mathbf{X}\beta + \varepsilon \tag{4}$$

$$\mathbf{y} = \alpha \iota_n + \mathbf{X}\beta + (\mathbf{I}_n - \lambda \mathbf{W})^{-1} \varepsilon. \tag{5}$$

4 Spatial variable selection

Model selection is performed by extending the Stochastic Search Variable Selection (SSVS) algorithm of George and McCulloch (1993). Specifically we propose a SSVS algorithm based on dirac spike and slab Lasso prior specifically tailored to select relevant covariates in the spatial regression context here considered. As in Hans (2009) the main characteristic of the proposed method is that it does not rely on the stochastic representation of the Lasso prior as scale mixture of Gaussians and the associated Gibbs sampling approach. Before considering the Spike–and–Slab approach we introduce the Bayesian version of the Lasso regression problem. In what follows, we refer to the spatial SAR and SEM models defined in the previous Section.

4.1 Likelihood and prior

Assuming the Laplace prior structure specification as in Park and Casella (2008) for the vector of spatial regression parameters β, we get the following representation of the linear model

$$\pi\left(\mathbf{y} \mid \mathbf{X},\mathbf{W},\alpha,\beta,\rho,\sigma^2\right) = \mathsf{N}\left(\tilde{\mathbf{y}}\left(\rho\right) \mid \alpha\iota_n + \mathbf{X}\beta, \sigma^2\mathbf{I}_n\right) \tag{6}$$

$$\pi\left(\mathbf{y} \mid \mathbf{X},\mathbf{W},\alpha,\beta,\lambda,\sigma^2\right) = \mathsf{N}\left(\mathbf{y} \mid \alpha\iota_n + \mathbf{X}\beta, \sigma^2\mathbf{P}_\lambda^{-1}\right) \tag{7}$$

$$\pi\left(\alpha,\beta \mid \delta,\sigma^2\right) \propto \mathsf{L}\left(\alpha \mid \delta,\sigma\right)\prod_{j=1}^{k}\mathsf{L}\left(\beta_j \mid \delta,\sigma^2\right), \tag{8}$$

where equations (6) and (7) refer to the SAR and SEM specifications, respectively, and the Laplace prior specified in equation (8) has probability density function

$$\mathsf{L}\left(x \mid \delta,\sigma^2\right) = \frac{\delta}{2\sigma^2}\exp\left\{-\frac{\delta|x|}{\sigma^2}\right\}\mathbb{1}_{(-\infty,\infty)}\left(x\right), \tag{9}$$

which depends on the penalisation $\delta \in \mathbb{R}^+$ and scale $\sigma \in \mathbb{R}^+$ parameters. Due to its characteristics, the Laplace distribution is the Bayesian counterpart of the Lasso penalisation methodology introduced by Tibshirani (1996) to achieve sparsity within the classical regression framework. The original Bayesian Lasso, see also, e.g., Park and Casella (2008) and Hans (2009), introduces a univariate independent Laplace prior distribution for each regression parameters. The prior specification is completed by assigning a distribution to the hyper parameters $\left(\sigma^2,\delta\right)$ which controls for the scale and the Lasso penalty term. Specifically we assume an Inverse Gamma distribution for the scale parameter σ^2 and a Gamma distribution for the penalty parameter δ

$$\sigma^2 \sim \mathsf{IG}\left(\sigma^2 \mid \xi_\sigma,\eta_\sigma\right) \tag{10}$$

$$\delta \sim \mathsf{G}\left(\delta \mid \xi_\delta,\eta_\delta\right), \tag{11}$$

where $\xi_\sigma,\eta_\sigma,\xi_\delta,\eta_\delta > 0$ are given parameters. A direct characterisation of the full conditional distribution of the regression parameters of the SAR and SEM model specifications $\pi\left(\tilde{\beta} \mid \tilde{\mathbf{y}}\left(\rho\right),\mathbf{X},\mathbf{W},\rho,\sigma,\delta\right)$ and $\pi\left(\tilde{\beta} \mid \mathbf{y},\mathbf{X},\mathbf{W},\lambda,\sigma,\delta\right)$, where $\tilde{\beta} = \left(\alpha,\beta'\right)'$ that does not require the inclusion of latent variables is constructed as follows. Let $\mathsf{Z} = \{-1,1\}^{q+1}$ represent the set of all $2\left(q+1\right)$ possible $\left(q+1\right)$–vectors whose elements are ±1. For any vector $z \in \mathsf{Z}$, let $\mathsf{O} \cup \mathbb{R}^{q+1}$ represent the corresponding orthant: if $\tilde{\beta} \in \mathsf{O}_z$, then $\beta_j \geq 0$, if $z_j = 1$ and $\beta_j < 0$ if $z_j = -1$, for all $j = 1,2,\ldots,q+1$. Write the density function for the orthant–truncated Normal distribution and its associated orthant integrals as

$$\mathsf{N}^{[z]}\left(\tilde{\beta} \mid \mathbf{m},\mathbf{S}\right) = \frac{\mathsf{N}\left(\tilde{\beta} \mid \mathbf{m},\mathbf{S}\right)}{\mathsf{P}\left(z,\mathbf{m},\mathbf{S}\right)} \mathbb{1}_{\mathsf{O}_z}\left(\tilde{\beta}\right) \tag{12}$$

$$\mathsf{P}\left(z,\mathbf{m},\mathbf{S}\right) = \int_{\mathsf{O}_z} \mathsf{N}\left(\mathbf{t} \mid \mathbf{m},\mathbf{S}\right) d\mathbf{t}. \tag{13}$$

Having this notation in mind, we can characterise the full conditional distribution of the spatial regression parameters $\tilde{\beta}$ by exploiting the conjugacy between the augmented likelihood function in equations (6)–(7) and the ℓ_1–prior in equation (8) generalising Hans (2009) to the spatial regression framework.

Proposition 1. *Applying Bayes' theorem to the Lasso regression model defined in equations* (6)–(8)*, the posterior distribution in orthant–wise Normal*

$$\pi\left(\tilde{\beta}_a \mid \tilde{\mathbf{y}}\left(\rho\right), \mathbf{X}, \mathbf{W}, \rho, \sigma, \delta\right) = \sum_{z\in\mathsf{Z}} \varpi_z^s \mathsf{N}^{[z]}\left(\tilde{\beta}_a \mid \tilde{\hat{\beta}}_a^z, \Sigma_a\right) \tag{14}$$

$$\pi\left(\tilde{\beta}_e \mid \mathbf{y}, \mathbf{X}, \mathbf{W}, \lambda, \sigma, \delta\right) = \sum_{z\in\mathsf{Z}} \varpi_z^s \mathsf{N}^{[z]}\left(\tilde{\beta}_e \mid \tilde{\hat{\beta}}_e^z, \Sigma_e\right), \tag{15}$$

i.e., a finite mixture of 2^{q+1} *different truncated Normal distributions that are each restricted to a different orthant, where* $\tilde{\hat{\beta}}_s^z = \hat{\tilde{\beta}}_s - \delta\sigma^{-2}\Sigma_s\mathbf{z}$*, with* $s = \{a, e\}$ *for the SAR and SEM specifications, respectively, and*

$$\hat{\tilde{\beta}}_a = \left(\tilde{\mathbf{X}}'\tilde{\mathbf{X}}\right)^{-1} \tilde{\mathbf{X}}'\tilde{\mathbf{y}}\left(\rho\right) \tag{16}$$

$$\hat{\tilde{\beta}}_e = \left(\tilde{\mathbf{X}}'\mathbf{P}_\lambda\tilde{\mathbf{X}}\right)^{-1} \tilde{\mathbf{X}}'\mathbf{P}_\lambda\mathbf{y}, \tag{17}$$

with $\Sigma_a = \sigma^2\left(\tilde{\mathbf{X}}'\tilde{\mathbf{X}}\right)^{-1}$, $\Sigma_e = \sigma^2\left(\tilde{\mathbf{X}}'\mathbf{P}_\lambda\tilde{\mathbf{X}}\right)^{-1}$, $\tilde{\mathbf{X}} = \left[\iota_n\ \mathbf{X}\right]$, $\beta = (\alpha, \beta')'$ *and* $\varpi_z^s = \frac{\frac{\mathbb{P}\left(z,\tilde{\hat{\beta}}_s^z,\Sigma_s\right)}{\phi_{q+1}\left(0|\tilde{\hat{\beta}}_s^z,\Sigma_s\right)}}{\sum_{z\in\mathsf{Z}}\frac{\mathbb{P}\left(z,\tilde{\hat{\beta}}_s^z,\Sigma_s\right)}{\phi_{q+1}\left(0|\tilde{\hat{\beta}}_s^z,\Sigma_s\right)}}$ *where* $\phi_{q+1}\left(0 \mid \mu_z, \Sigma\right)$ *denotes the pdf of the multivariate Normal distribution with mean* μ_z *and variance–covariance matrix* Σ *evaluated at* 0*, and* $\mathbf{z} = \left(z_1, z_2, \ldots, z_n\right)'$.

4.2 Regressors selection using dirac spike–and–slab ℓ_1–prior

Using standard notation, let $\gamma = (\gamma_1, \gamma_2, \ldots, \gamma_q)$ be the q–dimensional vector where $\gamma_j = 1$ if the j–th covariate $\mathbf{x}_j = \left(x_{j,1}, x_{j,2}, \ldots, x_{j,n}\right)'$, for $j = 1, 2, \ldots, q$ is included as explanatory variable in the regression model and $\gamma_j = 0$, otherwise. Assuming that $\gamma_j \mid \pi_0 \sim \mathsf{Ber}\left(\pi_0\right)$, the prior distribution for β_j can be written as the mixture

$$\pi\left(\beta_j \mid \delta, \sigma^2, \pi_0\right) = \left(1 - \pi_0\right)\delta_0\left(\beta_j\right) + \pi_0\mathsf{L}\left(\beta_j \mid \delta, \sigma^2\right), \tag{18}$$

for $j=1,2,\dots,q$, where $\delta_0\left(\beta_j\right)$ is a point mass at zero and $\mathsf{L}\left(\beta_j\mid\delta,\sigma^2\right)$ denotes the Laplace density defined in equation (9). Under the spike and slab prior in equation (18), an iteration of the Gibbs sampling algorithm cycles through the full conditional distribution $\beta_j\mid\mathbf{y},\mathbf{X},\mathbf{W},\alpha,\beta_{-j},\delta,\sigma^2,\pi_0$, where β_{-j} denotes the vector of regression parameters without the j–th element, i.e., $\beta_{-j}=\left(\beta_1,\dots,\beta_{j-1},\beta_{j+1},\dots,\beta_q\right)$, for $j=1,2,\dots,q$. The next proposition provides analytical expression for the full conditional distribution of β_j, for $j=1,2,\dots,q$.

Proposition 2. *Applying Bayes' theorem to the spatial regression models defined in equations* (6)–(7) *with the Spike–and–Slab Lasso prior in equation* (18)*, the full conditional distributions of β_j, for $j=1,2,\dots,q$, is*

$$\begin{aligned}\pi\left(\beta_{j,a}\mid\mathbf{y},\mathbf{X},\mathbf{W},\alpha,\beta_{-j,a},\rho,\sigma^2,\delta,\pi_0\right)&=\varpi^0_{j,a}\left(\mathbf{y},\mathbf{X},\mathbf{W},\alpha,\beta_{-j,a},\rho,\delta,\sigma^2,\pi_0\right)\delta_0\left(\beta_{j,a}\right)\\&\quad+\left(1-\varpi^0_{j,a}\left(\mathbf{y},\mathbf{X},\mathbf{W},\alpha,\beta_{-j,a},\rho,\delta,\sigma^2,\pi_0\right)\right)\\&\quad\times\left[\left(1-\varpi_{j,a}\right)\frac{\phi\left(\beta_{j,a}\mid\hat{\beta}^-_{j,a},\sigma^2_{j,a}\right)}{\Phi_1\left(-\frac{\hat{\beta}^-_{j,a}}{\sigma_{j,a}}\right)}\mathbb{1}_{(-\infty,0)}\left(\beta_{j,a}\right)\right.\\&\quad\left.+\varpi_{j,a}\frac{\phi\left(\beta_{j,a}\mid\hat{\beta}^+_{j,a},\sigma^2_{j,a}\right)}{\Phi_1\left(\frac{\hat{\beta}^+_{j,a}}{\sigma_{j,a}}\right)}\mathbb{1}_{[0,\infty)}\left(\beta_{j,a}\right)\right],\end{aligned}\tag{19}$$

where $\sigma^2_{j,s}=\sigma^2\left(\mathbf{x}_j'\mathbf{A}_s\mathbf{x}_j\right)^{-1}$, $\mathbf{A}_a=\mathbf{I}_n$, $\mathbf{A}_e=\mathbf{P}_\lambda$, $\tilde{\varepsilon}_{j,a}=\tilde{\mathbf{y}}\left(\rho\right)-\alpha_a-\mathbf{X}_{-j}\beta_{-j,a}$, $\tilde{\varepsilon}_{j,e}=\mathbf{y}-\alpha_e-\mathbf{X}_{-j}\beta_{-j,e}$ *and*

$$\hat{\beta}^-_{j,s}=\left(\mathbf{x}_j'\mathbf{A}_s\mathbf{x}_j\right)^{-1}\left[\mathbf{x}_j'\mathbf{A}_s\tilde{\varepsilon}_{j,s}+\delta\right]\tag{20}$$

$$\hat{\beta}^+_{j}=\left(\mathbf{x}_j'\mathbf{A}_s\mathbf{x}_j\right)^{-1}\left[\mathbf{x}_j'\mathbf{A}_s\tilde{\varepsilon}_{j,s}-\delta\right]\tag{21}$$

$$\varpi_{j,s}=\frac{\varpi^+_{j,s}}{\varpi^-_{j,s}+\varpi^+_{j,s}},\tag{22}$$

with $\tilde{\mathbf{X}}_j=\left[\iota_n\ \mathbf{X}_{-j}\right]$, $\beta_{-j}=\left(\alpha,\beta_{-j}'\right)'$ *and*

$$\tilde{\varpi}_j^0 \left(\mathbf{y}, \mathbf{X}, \mathbf{W}, \alpha, \beta_{-j}, \delta, \sigma, \pi_0\right) = \left[1 + \frac{\pi_0}{(1-\pi_0)} \frac{\delta}{2\sigma} \times \left(\frac{\mathit{\Phi}\left(-\frac{\hat{\beta}_{j,s}^-}{\sigma_{j,s}}\right)}{\phi\left(0 \mid \hat{\beta}_{j,s}^-, \sigma_{j,s}^2\right)} + \frac{\mathit{\Phi}\left(\frac{\hat{\beta}_{j,s}^+}{\sigma_{j,s}}\right)}{\phi\left(0 \mid \hat{\beta}_{j,s}^+, \sigma_{j,s}^2\right)} \right)\right]^{-1}, \tag{23}$$

$$\begin{aligned}
\varpi_{j,s}^- &\equiv \varpi_{j,s}^- \left(\mathbf{y}, \mathbf{X}, \mathbf{W}, \alpha_s, \beta_{-j,s}, \delta, \sigma^2, \pi_0\right) \\
&= \int_{-\infty}^0 \pi\left(\mathbf{y} \mid \mathbf{X}, \mathbf{W}, \alpha_s, \beta_s, \sigma^2, \delta\right) \pi\left(\beta_{j,s} \mid \sigma^2, \delta\right) d\beta_{j,s} && (24) \\
&= \frac{\delta}{2\sigma^{2-p}} \frac{\mathit{\Phi}_1\left(-\frac{\hat{\beta}_{j,s}^-}{\sigma_{j,s}}\right) \phi\left(\tilde{\tilde{\mathbf{y}}}_s \mid 0, \sigma^2 \mathbf{A}_s\right)}{\exp\left\{-\frac{\tilde{\tilde{\mathbf{y}}}_s' \mathbf{A}_s \tilde{\mathbf{X}}_{-j} \tilde{\beta}_{-j,s}}{\sigma^2}\right\} \phi\left(0 \mid \hat{\beta}_{j,s}^-, \sigma_{j,s}^2\right)} && (25) \\
&\quad \times \frac{\phi_{p-1}\left(0 \mid \tilde{\beta}_{-j,s}, \sigma^2 \left(\tilde{\mathbf{X}}'_{-j} \mathbf{A}_s \tilde{\mathbf{X}}_{-j}\right)^{-1}\right)}{|\tilde{\mathbf{X}}'_{-j} \mathbf{A}_s \tilde{\mathbf{X}}_{-j}|^{\frac{1}{2}}} && (26) \\
\varpi_{j,s}^+ &\equiv \varpi_{j,s}^+ \left(\mathbf{y}, \mathbf{X}, \mathbf{W}, \alpha, \beta_{-j,s}, \delta, \sigma^2, \pi_0\right) \\
&= \int_0^{\infty} \pi\left(\mathbf{y} \mid \mathbf{X}, \mathbf{W}, \alpha, \beta_s, \sigma^2, \delta\right) \pi\left(\beta_{j,s} \mid \sigma^2, \delta\right) d\beta_{j,s} && (27) \\
&= \frac{\delta}{2\sigma^{2-p}} \frac{\mathit{\Phi}_1\left(\frac{\hat{\beta}_{j,s}^+}{\sigma_{j,s}}\right) \phi\left(\tilde{\tilde{\mathbf{y}}}_s \mid 0, \sigma^2 \mathbf{A}_s\right)}{\exp\left\{-\frac{\tilde{\tilde{\mathbf{y}}}_s' \mathbf{A}_s \tilde{\mathbf{X}}_{-j} \tilde{\beta}_{-j}}{\sigma^2}\right\} \phi\left(0 \mid \hat{\beta}_{j,s}^+, \sigma_{j,s}^2\right)} && (28) \\
&\quad \times \frac{\phi_{p-1}\left(0 \mid \tilde{\beta}_{-j,s}, \sigma^2 \left(\tilde{\mathbf{X}}'_{-j} \mathbf{A}_s \tilde{\mathbf{X}}_{-j}\right)^{-1}\right)}{|\tilde{\mathbf{X}}'_{-j} \mathbf{A}_s \tilde{\mathbf{X}}_{-j}|^{\frac{1}{2}}}, && (29)
\end{aligned}$$

and $\tilde{\tilde{\mathbf{y}}}_a = \tilde{\mathbf{y}}(\rho)$, $\tilde{\tilde{\mathbf{y}}}_e = \mathbf{y}$.

5 Results and conlusion

Overall, the obtained results show that the inclusion of the exogenous factors derived as Open Data variables is significant in all the city districts. With respect to these exogenous factors, the results show, as expected, a negative relationship between level of crime and level of prices, so that an increase in crime rate leads to a decrease in house prices in all districts. Interestingly, in the case of Airbnb diffusion, the relationship with prices is positive in Manhattan, Staten Island, Queens and Brooklyn, and negative in the Bronx district. This finding suggests that, depending on the district considered, Airbnb may be seen as a threat or an opportunity for the market. Indeed, the significantly negative relationship in Bronx may be taken as a sign that the presence of Airbnb can lead to an upgrading of the entire district, through a more accessible real estate market.

Bayesian Quantile Trees for Sales Management

Mauro Bernardi and Paola Stolfi

Abstract Sales management is a fundamental issue in retail commerce, being one of the main ingredient to maximise stores revenue. The huge amount of data accessible nowadays makes this task challenging. This paper proposes a new nonparametric method for predicting sales quantiles at different confidence levels, conditional on several explanatory variables such as the type of store, the location of the store, the type of product and its the price, etc, thereby providing a complete picture of the relation between the response and the covariates. Moreover, predicting extreme sales quantiles provide valuable information for building automatic stock management systems and for the sales monitoring. As concerns the methodology, we propose to approximate the conditional quantile at level $\tau \in (0,1)$ of the response variable using bayesian additive nonparametric regression trees. Decision trees and their additive counterparts are promising alternatives to linear regression methods because of their superior ability to characterise nonlinear relationships and interactions among explanatory variables that is of fundamental relevance to get accurate predictions.

Key words: Regression tree, bayesian methods, quantile regression, prediction.

1 Introduction

In empirical studies, researchers are often interested in analysing the behaviour of a response variable given the information on a set of covariates. The typical answer is to specify a linear regression model where unknown parameters are estimated using the Ordinary Least Squares (OLS). The OLS method estimates unknown parameters by minimising the sum of squared errors leading to the approximation of the mean function of the conditional distribution of the response variable. Although the mean represents the average behaviour of the response variable, it provides little or no information about the behaviour of the conditional distribution on the tails. As far as the entire distribution is concerned, quantile regression methods [Koenker and Bassett, 1978] adequately characterise the behaviour of the response variable at different con-

fidence levels. Moreover, the quantile analysis is particularly suitable when the conditional distribution is heterogeneous, non–Gaussian, skewed or fat–tailed, see, e.g., [Lum and Gelfand, 2012] and [Koenker, 2005].

Quantile models admitting a linear representation have been extensively applied in different areas, see, e.g., [Yu et al., 2003], such as, finance, as direct approach to estimate the Value–at–Risk, i.e., the loss–level a financial institution may suffer with a given confidence [Bassett Jr. and Chen, 2001], economics and social sciences [Hendricks and Koenker, 1992], medicine [Heagerty and Pepe, 1999], survival analysis [Koenker and Geling, 2001] and environmetrics [Pandey and Nguyen, 1999]. Futhermore, linear quantile models have been theoretically investigated from both a Bayesian, [Sriram et al., 2013] and a frequentist point of view, and the properties of the resulting estimates has been deeply studied. See [Koenker et al., 2017] and [Davino et al., 2014] for an extensive and up to date review latest theoretical results on quantile methods and their interesting applications. However, despite their relevance and widespread application in empirical studies, linear quantile models provide only a rough "first order" approximation of the relationship between the τ–level quantile of the response variable and the covariates. Indeed, as first recognised by [Koenker, 2005], quantiles are linear functions only within a Gaussian world, thereby stimulating many recent attempts to overcome this limitation. [Chen et al., 2009], [Faugeras, 2009], [De Backer et al., 2017] and [Kraus and Czado, 2017], for example, consider the copula–based approach to formalise nonlinear and parametric conditional quantile relationships. The copula approach, although quite flexible in fitting marginal data, forget to consider nonlinear interactions among the covariates. This paper try to overcome the traditional limitations of linear quantile methods by extending the quantile approach to the promising field of decision trees. Decision trees are regression techniques that are very popular within the machine learning community that try to mitigate the relevant problem of parsimoniously modelling interactions among covariates. Indeed, decision trees partition the space of relevant covariates into pieces, usually hyper–rectangles, where observations are homogeneous. For example, when the objective is to model the average response, observations with the same unconditional variance are clustered together, while for classification problems observations are partitioned according to the Gini index. Since their introduction several theoretical and applied papers have contributed to the diffusion of such idea in different contexts. Both the machine learners and the statistics communities contributed to the development of tools and methods. An up to date and comprehensive review of the methods developed in the machine learning literature can be found for example in [Loh, 2014a], [Strobl, 2014], [Ciampi, 2014], [Ahn, 2014], [Song and Zhang, 2014], [Rusch and Zeileis, 2014], [Loh, 2014b]. The main drawback of decision trees is related to the high variance of the resulting forecasts. The most promising alternative approach [Breiman, 2001], namely, the random forest, is an ensemble of bootstrap decision trees that reduces the variance and provides also a straightforward way to assess the relevant covariates. On the likelihood–based side, the Bayesian estimation of decision trees have been considered in [Chipman et al., 1998], [Denison et al., 1998], [Sha, 2002] and [Wu et al., 2007] and extended to additive trees by [Chipman et al., 2010]. The main novelty of this latter approach relies on exploiting the likelihood of parametric models where regressors splitting rules play the role of hard thresholding operators that partition the overall model into local models.

In this paper, we consider the Bayesian approach, namely, we extend the Bayesian Additive Regression Tree (BART) of [Chipman et al., 2010] to model the quantile of the response variable. The Bayesian Additive Quantile Regression Trees (BAQRT) exploits the data augmentation approach that relies on the Asymmetric Laplace working likelihood, see [Bernardi et al., 2015], to provide a Metropolis–within–Gibbs sampling method that efficiently explores the regressors space. The data augmentation approach allows to effectively marginalise out the leaf parameters of the trees when changing the tree structures. Section 2 formalises the likelihood function and the prior structure of the BAQRT method. Quantile random forest (QRF) methods have been previously introduced in the machine learning literature by [Meinshausen, 2006]. [Meinshausen, 2006] exploits the original version of random forest for modelling the conditional mean to infer the structure of the tree, while assigning the empirical quantile of the observations falling into each terminal leaf instead of the mean value. Therefore, the QRF algorithm is not highly flexible to adapt the structure of the generated trees according to the modelled quantiles.

Given their appealing perspective of discriminating observations below and above a given quantile threshold, the quantile approach is a promising method for solving many statistical problems usually encountered in business and industry. In Section 3 we apply BAQRT to strategic sales management in retail stores. Sales management is one of the main issues in retail commerce. Indeed, it is one of the main ingredient to maximise the income of stores. The huge amount of data accessible nowadays makes this task challenging. Indeed, there are many potentially predictors that could be useful to predict and monitor sales but there is not any model to reach this task. This is the usual situation in which machine learning algorithms represent a powerful instruments to extract insight from such heterogeneous data. We consider the dataset provided by BigMart, an international brand with both free home delivery services and outlet store of food and grocery, to show how quantile regression trees could be useful in selecting the most relevant variables and analyse their impact both for predicting and monitoring tasks.

2 Quantile regression tree

The linear quantile regression framework for independent and identically distributed data models the conditional τ–level quantile of the response variable Y, with $\tau \in (0,1)$, as a linear function of the vector of dimension $(q \times 1)$ of exogenous covariates $\mathbf{X}$, i.e., $\mathcal{Q}_\tau(Y \mid \mathbf{X} = \mathbf{x}) = \mathbf{x}'\boldsymbol{\beta}$, thereby avoiding any explicit assumptions about the conditional distribution of $Y \mid \mathbf{X} = \mathbf{x}$. From a frequentist perspective, within a likelihood–based framework, this is equivalent to assume an additive stochastic error term ε for the conditional regression function $\mu(\mathbf{x}) = \mathbf{x}'\boldsymbol{\beta}$ to be independent and identically distributed with zero τ–th quantile, i.e, $\mathcal{Q}_\tau(\varepsilon \mid \mathbf{x}) = 0$, and constant variance. Following [Yu and Moyeed, 2001] and [Bernardi et al., 2015], the previous condition is implicitly satisfied by assuming that the conditional distribution of the response variable Y follows an Asymmetric Laplace (AL) distribution located at the true regression function $\mu(\mathbf{x})$, with constant scale $\sigma > 0$ and shape parameter τ, i.e., $\varepsilon \sim \mathsf{AL}(\tau, \mu(\mathbf{x}), \sigma)$, with probability density function

$$\mathsf{AL}(Y \mid \mathbf{X}, \sigma, \tau) = \frac{\tau(1-\tau)}{\sigma} \exp\left\{-\frac{1}{\sigma}\rho_\tau(Y - \mu(\mathbf{x}))\right\} \boldsymbol{I}_{(-\infty,\infty)}(Y), \tag{1}$$

where $\mu(\mathbf{x})$ is the regression function and $\rho_\tau(u) = u\left(\tau - \boldsymbol{I}_{(-\infty,0)}(u)\right)$ denotes the quantile check function at level τ. The quantile regression model postulated in equation (1) assumes the AL distribution as a misspecified working likelihood that correctly identify the conditional quantile function.

Similarly to the Bayesian Additive Regression Tree approach of [Chipman et al., 2010] for modelling the conditional mean of the response variable, the quantile regression tree approach extends the linear quantile model defined in equation (1) by assuming a sum–of–trees ensemble for the regression function $\mu(\mathbf{x})$. Specifically, the Bayesian Additive Quantile Regression Tree (BAQRT) model can be expressed as

$$\begin{align} Y &= \mu(\mathbf{x}) + \varepsilon \tag{2}\\ &\approx \mathscr{T}_1^{\mathscr{M}}(\mathbf{x}) + \mathscr{T}_2^{\mathscr{M}}(\mathbf{x}) + \cdots + \mathscr{T}_m^{\mathscr{M}}(\mathbf{x}) + \varepsilon, \tag{3}\end{align}$$

where $\varepsilon \sim \mathsf{AL}(\tau, 0, \sigma)$. The assumption about the error term in equation (3) implies that $\mu(\mathbf{x}) = \mathcal{Q}_\tau(Y \mid \mathbf{X} = \mathbf{x})$. Furthermore, in equation (3) we assume that the quantile of the response variable is an additive function of

$m \geq q$ regression trees, each composed by a tree structure, denoted by $\mathscr{T}$, and the parameters of the terminal nodes (also called leaves), denoted by $\mathscr{M}$. Therefore, the j–th tree for $j = 1,2,\dots,m$, denoted by $\mathscr{T}_j^{\mathscr{M}}$, represents a specific combination of tree structure $\mathscr{T}_j$ and tree parameters $\mathscr{M}$, i.e., the regression parameters associated to its terminal nodes. The tree structure $\mathscr{T}_j$ contains information on how any observation y_i, in a set of n independent and identically distributed observations $\mathbf{y} = (y_1, y_2, \dots, y_n)$, recurses down the tree specifying a splitting rule for each non–terminal (internal) node. The splitting rule has the form $x_k \leq c$ and consists of the splitting variable x_k and the splitting value $c \in \mathbb{R}$. The observation y_i is assigned to the left child if the splitting rule is satisfied and to the right child, otherwise, until a terminal node is reached and the value of the leaf of that terminal node is assigned as its predicted value. Therefore, the quantile prediction corresponding to y_i assigned by the sum of regression tree specified in equation (3) is the sum of the m leaf values. Hereafter, we denote by $\mathscr{M}_j = \left\{\mu_{j,1}, \mu_{j,2}, \dots, \mu_{j,b_j}\right\}$ the set of parameters associated to the b_j terminal nodes of the j–th tree, where $\mu_{j,l}$, for $l = 1,2,\dots,b_l$ denotes the conditional quantile predicted by the model.

The additive quantile regression tree specified in equation (3) provides a natural framework for likelihood–based inference on the set of quantile regression parameters, i.e., the location parameters associated to the terminal nodes of each tree belonging to the ensemble. However, additional prior information should be imposed in order to infer the structure of the each tree. The next Section discusses the likelihood and the prior structure for both the model parameters and the trees.

2.1 Likelihood and prior

As discussed in [Yu and Moyeed, 2001], due to the complexity of the quantile likelihood function in equation (1), the resulting posterior density for the regression parameters does not admit a closed form representation for the full conditional distributions, and needs to be sampled by using MCMC–based algorithms. Following [Kozumi and Kobayashi, 2011] and [Bernardi et al., 2015], we instead adopt the well–known representation (see, e.g., [Kotz et al., 2001] and [Park and Casella, 2008]) of $\varepsilon \sim \mathsf{L}(\tau, 0, \sigma)$ as a location–scale mixture of Gaussian distributions:

$$\varepsilon = \zeta\omega + \varsigma\sqrt{\sigma\omega}\epsilon, \tag{4}$$

where $\omega \sim \mathsf{Exp}\left(\sigma^{-1}\right)$ and $\epsilon \sim \mathsf{N}(0,1)$ are independent random variables and $\mathsf{Exp}(\cdot)$ denotes the Exponential distribution. Moreover, the parameters ζ and ς^2 are fixed equal to

$$\zeta = \frac{1-2\tau}{\tau(1-\tau)}, \qquad \varsigma^2 = \frac{2}{\tau(1-\tau)}, \tag{5}$$

in order to ensure that the τ–th quantile of ε is equal to zero. The previous representation in equation (4) allows us to use a Gibbs sampler algorithm for sampling the trees parameters $\boldsymbol{\mu}_j$ of tree $j = 1,2,\dots,m$, detailed in the next subsection. Exploiting the augmented data structure defined in equation (4), the additive quantile regression tree in (3) admits, conditionally on the latent factor ω, the following Gaussian representation:

$$\begin{aligned} Y \mid \omega &= \mu(\mathbf{x}) + \zeta\omega + \varsigma\sqrt{\sigma\omega}\epsilon, && (6)\\ &\approx \mathscr{T}_1^{\mathscr{M}}(\mathbf{x}) + \mathscr{T}_2^{\mathscr{M}}(\mathbf{x}) + \cdots + \mathscr{T}_m^{\mathscr{M}}(\mathbf{x}) + \zeta\omega + \varsigma\sqrt{\sigma\omega}\epsilon && (7)\\ \omega &\sim \mathsf{Exp}\left(\sigma^{-1}\right). && (8)\end{aligned}$$

The hierarchical model representation in equations (6)–(8) has the advantage of being conditionally Gaussian, leading to a conjugate Bayesian analysis for the parameters associated to the terminal nodes and the scale parameter as well.

The Bayesian inferential procedure requires the specification of the prior distribution for the unknown vector of model parameters $(\boldsymbol{\mu},\sigma)$ and the structure of the tree. In principle, as discussed in the seminal paper of [Yu and Moyeed, 2001], non informative priors can be specified for the vector of regression parameters, i.e., $\pi(\boldsymbol{\mu}) \propto 1$. Alternatively, as in [Bernardi et al., 2015], the usual Normal–Inverse Gamma prior can be specified for regression and scale parameters, respectively, i.e.,

$$\mu_i \sim \mathsf{N}_1\left(\mu_0, \sigma_\mu^2\right) \tag{9}$$

$$\sigma \sim \mathsf{IG}\left(\frac{\eta_\sigma}{2}, \frac{\eta_\sigma \lambda_\sigma}{2}\right) \tag{10}$$

$$\mathbb{P}(\mathscr{T}) \propto \alpha(1+d)^{-\beta}, \tag{11}$$

where $\alpha \in (0,1)$ and $\beta \in [0,\infty)$ and d is the depth of the tree defined as the distance from the root. Here, N_1 denotes the univariate Normal density while IG is the Inverse Gamma distribution and $\left(\mu_0, \sigma_\mu^2, \eta_\sigma, \lambda_\sigma\right)$ are fixed hyperparameters, with $\eta_\sigma > 0$ and $\lambda_\sigma > 0$.

Now, let $\mathbf{y} = (y_1, y_2, \dots, y_n)$ be the vector of observations on the response variable Y and let $\mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_n)'$ be the associated matrix of covariates of dimension $(n \times q)$, then the joint prior distribution of the tree structure and tree parameters augmented by the latent factor ω, can be factorised as follows:

$$\begin{aligned}
\mathbb{P}\left(\mathscr{T}_1^{\mathscr{M}}, \mathscr{T}_1^{\mathscr{M}}, \dots, \mathscr{T}_1^{\mathscr{M}}, \boldsymbol{\omega}, \sigma\right) &= \left[\prod_{j=1}^{m} \mathbb{P}\left(\mathscr{T}_j^{\mathscr{M}} \mid \boldsymbol{\omega}\right)\right] \mathbb{P}(\sigma) \\
&= \left[\prod_{j=1}^{m} \mathbb{P}(\mathscr{M}_j \mid \mathscr{T}_j, \boldsymbol{\omega}) \mathbb{P}(\mathscr{T}_j \mid \boldsymbol{\omega})\right] \mathbb{P}(\boldsymbol{\omega}) \mathbb{P}(\sigma) \\
&= \left[\prod_{j=1}^{m} \prod_{l=1}^{b_j} \mathbb{P}\left(\mu_{j,\ell} \mid \mathscr{T}_j, \boldsymbol{\omega}\right) \mathbb{P}(\mathscr{T}_j \mid \boldsymbol{\omega})\right] \mathbb{P}(\boldsymbol{\omega}) \mathbb{P}(\sigma) \\
&= \left[\prod_{j=1}^{m} \prod_{l=1}^{b_j} \phi\left(\mu_{j,\ell} \mid \mathscr{T}_j, \boldsymbol{\omega}\right) \mathbb{P}(\mathscr{T}_j \mid \boldsymbol{\omega})\right] \mathbb{P}(\boldsymbol{\omega}) \mathbb{P}(\sigma),
\end{aligned} \tag{12}$$

where $\mu_{j,\ell}$ denotes the parameter (conditional quantile) associated to the ℓ–th terminal nodes of tree $j = 1, 2, \dots, m$, for $\ell = 1, 2, \dots, b$, $\boldsymbol{\omega} = (\omega_1, \omega_2, \dots, \omega_n, \sigma)$ is the vector of auxiliary variables $\omega_i \sim \mathsf{Exp}\left(\sigma^{-1}\right)$, $\sigma \in \mathbb{R}$ is the scale parameter which is common to all the trees, and $\phi(\cdot)$ denotes the gaussian probability density function.

3 Application

Retail stores invest much effort in high level strategy to maximise their income. The type of store, its location, the furnitures and the product proposal are some of the main ingredients driving strategic decisions. Sales product prediction is therefore one of the most challenging problem in retail commerce, fundamental for

Variable Name	Description
Item Identifier	Unique product ID
Item Weight	Weight of product
Item Fat Content	Whether the product is low fat or not
Item Visibility	The % of total display area of all products in a store allocated to the particular product
Item Type	The category to which the product belongs
Item MRP	Maximum Retail Price of the product (list price)
Outlet Identifier	Unique store ID
Outlet Estabilishment Year	The year in which store was estabilished
Outlet Size	The size of the store in terms of ground area covered
Outlet Location Type	The type of city in which the store is located
Outlet Type	Whether the outlet is just a grocery store or some sort of supermarket
Item Outlet Sales	Sales of the product in the particular store. This is the outcome variable.

Table 1: Variables and their description for the BigMart dataset.

instance for commercialising new products, opening new stores or monitor the income performance of the stores.

In this work we apply BAQRT to analyse data coming from BigMart. It is an international brand with both free home delivery services and outlet store of food and grocery. Data scientists at BigMart created a dataset containing sales for 1559 products in 10 different stores located in several cities. They also reported many features related both to products and stores, in table 1 we provide a list of all the variables together with a description. In particular, there are eleven predictors and a scalar response function that is the "Outlet Sales". Eight of the eleven predictors are categorical while the remaining are continuous. The main interest consists in the identification of the variables that mostly influence the sales and if the relevance of these features changes by considering the different quantiles of the response variable. Indeed, the tail behaviour of the sales is also useful in stock management.

The variables considered in this example are a small subset of all the possible variables that could be analysed by retail stores. The importance of the variables are however based on some hypothesis and there is not any model that can be used both for sales prediction and monitoring tasks. This motivates the application of our method to investigate the type of relations occurring between the predictors and the response variable.

In figure 1 we report the predictor importance for the confidence levels $\tau = (0.1, 0.5, 0.9)$. The first two quantiles show similar variables importance ranking, in particular, the most relevant variables are "Item MRP", "Item Type", "Item Visibility" and "Item Weight". The first variable represents the price, its relevance supports the fact that promotional offers makes the customers much more inclined to buy products. The second one is the "Item Type" that represents the category to which the product belongs to. This finding supports the idea that one of the main indicator of product's sale is its utility, that is daily use products have much more sales rate than others. The third one, the "Item Visibility", confirms the fact that the position of the products in the stores is fundamental for their sales. Finally, the last "Item Weight" supports the hypothesis that lighter (and often smaller) products are easier to carry and so people are more inclined to buy them even if they are not needed.

The higher quantile instead show a different situations for the predictors' importance. Indeed, the "Item Visibility" becomes the most relevant variable, while all the others have a quite similar importance.

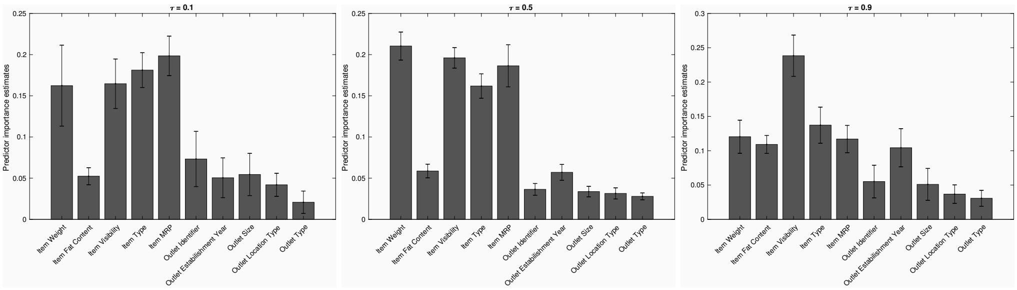

Fig. 1: Predictors' importance for different quantiles. The bottom figure in the left column refers to the mean behaviour.

Discrimination in machine learning algorithms

Discriminazione negli algoritmi di apprendimento automatico

Roberta Pappadà and Francesco Pauli

Abstract Machine learning algorithms are routinely used for business decisions which may directly affect individuals: for example, because a credit scoring algorithm refuses them a loan. It is then relevant from an ethical (and legal) point of view to ensure that these algorithms do not discriminate based on sensitive attributes (sex, race), which may occur unwittingly and unknowingly by the operator and the management. Statistical tools and methods are then required to detect and eliminate such potential biases.

Abstract *Sempre più decisioni, nei campi più vari, sono prese impiegando algoritmi a supporto o in sostituzione dell'intervento umano. Queste decisioni possono avere un effetto sulle persone che le subiscono, ad esempio quando un algoritmo di valutazione di solvibilit decide di rifiutare un prestito. Diventa quindi rilevante eticamente (e legalmente) assicurarsi che questi algoritmi non basino la loro decisione anche su caratteristiche sensibili, cosa che può avvenire senza intento e consapevolezza da parte del responsabile. Si apre dunque la necessità di studiare strumenti e metodi statistici per individuare e eventualmente eliminare queste potenziali distorsioni.*

Key words: machine learning; CEM; protected categories; sensible attribute

1 Introduction

The kind of discrimination we refer to consists in treating a person or a group depending on some sensitive attribute (s.a., *S*) such as race (skin color), sex, religious orientation, etc.

A human may discriminate either because of irrational prejudice induced by ignorance and stereotypes or based on statistical generalization: lacking specific in-

Department of Economics, Business, Mathematics and Statistics, University of Trieste, Trieste, Italy, e-mail: rpappada@units.it, francesco.pauli@deams.units.it

formation on an individual, he is assigned the characteristics which are prevalent in the sensitive attribute category he belongs to (for example in the US lacking information on education, a black person may be assumed to have relatively low level since this is the case in general for black people in the country) [7]. When a statistical/machine learning algorithm is used in the decision process, its behavior with respect to discrimination depends on the information it is given. In particular, if the sensitive attribute is available to the algorithm (that is, it is included in the learning data and can be used for predictions), it may discriminate either because the data it is taught by contain irrational prejudice (Fig. 1*(a)*) and because the sensitive attribute is associated to an unobserved attribute which is relevant for prediction of Y, the outcome of interest (Fig. 1*(b)*). An example of the former may occur if an algorithm is sought for screening job applicants and the learning data consist of selections made in the past by humans who, in some instances, based their decisions on irrational prejudice, consciously or not; as an example of the latter consider a credit scoring algorithm where the education of applicant is unknown but the race is, then due to the fact that education is relevant to assess reliability and is associated to the race the latter may be used in the decision. For an actual example consider car insurance (RCA), where the sex of the insured used to be a relevant factor in pricing likely because it is related to the number of km driven per year which is an unobserved variable strongly related to the outcome (liabilities). We note in pass that, although this is a rare circumstance, it may also be the case that the sensitive attribute is directly related to the outcome not because of human irrational prejudice, as it happens in life insurance for the gender attribute.

If the algorithm is constrained not to use the s.a. in the final rule (it is excluded from the data from which the algorithm learns) discrimination may still occur indirectly, either because a variable which is related to the outcome is also related to S (Fig. 1*(c)*) or because a variable included in the data which is unrelated to the outcome is related to S which is related to the outcome (either directly as in Fig. 1*(d)* or mediated as in Fig. 1*(e)* or in both ways as in Fig. 1*(f)*). In the first case the collective possessing the s.a. may experience the desired outcome less frequently than the rest whenever it differs from the population in the distribution of some relevant features included in the data. In the second case the collective possessing the s.a. may experience the desired outcome less frequently than the rest even if it were equal to the population as far as the other relevant features included in the data are concerned; in this second situation the discrimination may be due to a difference in the distribution of some relevant feature not included in the data but related to S and some variable in the sample.

Whether the situations described above are instances of undesired discrimination or not depends on how the concept is defined from a legal/ethical standpoint. In particular it depends on whether we require that the groups identified by S have the same treatment (rate of positive outcome) unconditionally or that they have the same treatment conditionally on some relevant characteristics different than S and which are deemed lawful to use to discriminate.

Which definition is more appropriate is a matter of ethic/law: a requirement of unconditional equal treatment means that the groups must be given equal treatment even if they are not equal (demographic parity, disparate impact), which may seem unjust from an individual point of view [2]. On the other hand, admitting the groups to be treated differently because one of them possesses desirable characteristics possibly amounts to perpetuating past unfair (S based) discrimination which may have lead the groups to be different. In fact, the first requirement may be an instance of affirmative action since it goes in the direction of eliminating the differences between groups, differences which are at least partly admissible within the second requirement. If conditional equal treatment is sought, one must decide which characteristics other than S but possibly correlated with it are ethical/lawful to use, which may be partly dictated by law, partly uncertain (for example in a civil law system such as in the US whether a characteristic is lawful to discriminate on may be for a jury to decide).

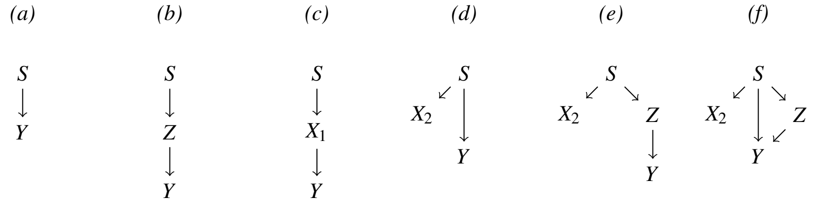

Fig. 1 Y is the outcome, S is the sensitive attribute, X_i denotes observed variables, Z denotes an unobserved variable. Example: S: race, Y: restitution of a loan, X_1: socioeconomic status, X_2: zip code residence, Z availability of family financial support.

In order to give precise definitions, from now on assume both S and Y dichotomous, $Y = 1$ be the desired outcome and $S = 1$ the belonging to a protected category. If unconditional equal treatment (demographic parity) is desired, data are apt if it is not possible to predict S from Y [1], that is, data are compatible with

$$P(Y = 1|S = 1) = P(Y = 1|S = 0).$$

If equal treatment should be conditional on X_1 then the requirement becomes

$$P(Y = 1|S = 1, X_1 = x_1) = P(Y = 1|S = 0, X_1 = x_1).$$

An extreme version of conditional equal treatment is advocated in [2], a rule is non discriminatory if the prediction errors are the same regardless of S

$$P(\hat{Y} = 1|S = 0, Y = y) = P(\hat{Y} = 1|S = 1, Y = y), \ \forall y;$$

or, which is the same, prediction and sensitive attribute are independent conditional on the outcome.

2 Measuring and avoiding discrimination by causal inference

The different strategies which can be used to avoid discrimination from an algorithm can be distinguished depending on the level at which action is taken: 1) learning data can be modified to ensure they do not imply discrimination; 2) the learning algorithm can be integrated with a non discrimination objective; 3) the final algorithm can be tampered with after it has been fitted; 4) the final predictions can be changed. The precise action to be taken depends on the definition of discrimination adopted; as outlined in the previous section, we may seek unconditional equality or conditional equality.

We focus on data preprocessing techniques. In a nutshell, this entails first establishing whether and to what extent the available data are discriminatory. If discrimination is detected data are modified in order to make them discrimination free before and then used with a standard algorithm [5]. Various ways of modifying data have been proposed including: 1) removing attributes (correlated with S); 2) changing the labels of some units; 3) weighing units; 4) resampling units We note that the precise implementation for both steps depends on the definition of discrimination which is adopted, presumably on legal/ethical grounds (see section 1).

In order to measure discrimination within a dataset it has been proposed to use causal inference techniques. Causal inference techniques aim at estimating the causal effect of a treatment–in this context, the belonging to a protected category–on an outcome. Generally speaking, causal inference methods aim at assessing the effect of a treatment based on observational data by matching treated units to untreated units which are similar with respect to their observed characteristics: a balanced dataset, suitable to draw causal inference, is built by restricting the original dataset to treated and untreated units which have been matched. Comparing a protected units outcome with the outcome of unprotected units which are similar with respect to the other observables is also a reasonable way to detect whether the unit has been discriminated (conditionally).

Following this idea, Luong *et al.* [6] propose to measure discrimination for unit (individual) i of the protected category ($S_i = 1$) as

$$\Delta_i = \frac{1}{k}\#\{j|j \neq i, x_j \in U_i^{k,1}, y_j = y_i\} - \frac{1}{k}\#\{j|j \neq i, x_j \in U_i^{k,0}, y_j = y_i\} \qquad (1)$$

where $U_i^{k,s}$ is the set of the k nearest neighbours of x_i within those units for which $S = s$, according to a Gower type distance (possibly, other measure of the difference between the two frequencies are used such as the ratio or the odds). Note that a positive Δ indicates discrimination against the protected category if y_i is the undesired outcome or discrimination in favour of the protected category if y_i is the desired outcome. The authors suggest fixing a threshold $\tau \in [0,1]$ to declare the individual i discriminated if $\Delta_i \geq \tau$, where τ. To prevent discrimination the dataset is changed by altering the value of y_i for those units fo which $\Delta_i > \tau$. τ is then a tuning parameter which regulates the trade off between residual discrimination and accuracy.

In what follows we focus on discrimination against the protected group, and so we compute a different version of the measure Δ:

$$\delta_i = \frac{1}{k}\#\{j|j \neq i, x_j \in U_i^{k,1}, y_j = 0\} - \frac{1}{k}\#\{j|j \neq i, x_j \in U_i^{k,0}, y_j = 0\} \qquad (2)$$

3 CEM based discrimination measure

Coarsened Exact Matching (CEM, [4, 3]) is based on coarsening continuous variables and match a treated unit to those untreated units which are equal with respect to the coarsened continuous variables and the categorical ones. In order to obtain a reliable estimate of the causal effect, CEM algorithm discards those units which can not be matched. Here, the objective is different in that we are not interested in a global estimate of the effect of the S, but rather whether unit i has experienced a different outcome because of it possesses the S: a comparison of unit i outcome with the outcome of units matched by CEM is a suitable measure of discrimination. In particular, let $\bar{y}_i^{(S=0)}$ be the relative frequency of positive outcomes among units matched with unit i (which possesses the s.a.) and not possessing the s.a., then $D_i = y_i - \bar{y}_i^{(S=0)}$ is a measure of discrimination which takes negative values when a unit is discriminated against and positive values when the unit is favoured (positive discrimination), so that the value of D_i is bounded between -1 and 1. However, in a standard implementation of CEM algorithm not all units are matched, which makes it unsuitable for our purpose. A possible strategy to exploit CEM technique is to apply it sequentially as follows. Suppose that all units are matched using k variables, it is possible that once an additional variable is considered in matching some units remain unmatched, we then measure the discrimination for those units based on the matching with k variables. Starting with an initial matching on 0 variables, that is, $D_i^{(0)} = y_i - \bar{y}^{(S=0)}$ where $\bar{y}^{(S=0)}$ is the relative frequency of the positive outcome for all units in the dataset not possessing the s.a., the sequential CEM allows to obtain a discrimination measure for all units. Clearly, the discrimination measures D_i depend on the order of addition of the variables, so the procedure is repeated for different (random) orders of addition and the final result is the average (See Fig. 2).

An alternative measure of discrimination based on CEM stratification which is more similar to (2), $\bar{D}_i$ in what follows is obtained by computing $\bar{D}_i = \bar{y}_i^{(S=1)} - \bar{y}_i^{(S=0)}$ instead of $\bar{D}_i$ (with obvious adaptations in the algorithm of Fig. 2). Note that, unlike D_i, $\bar{D}_i$ takes positive values when the unit is discriminated against (similar to δ).

4 Simulation experiment

We tested the procedure using the *adult* dataset as in [6]. The outcome is having an income greater than 50 000 USD, the sensitive attribute is being non white, other

```
Let
  • $x_1, \dots, x_K$ be the available variables;
  • let $\mathscr{M}^{(j_1,\dots,j_h)}$ be the set of units matched by CEM performed using variables $x_{j_1}, \dots, x_{j_h}$
    and let $C_i^{(j_1,\dots,j_h)}$ be the set of units belonging to the same CEM cell of unit $i$.
Repeat $M$ times

$-1$: select a random permutation $i_1, \dots, i_K$ of $1, \dots, K$;
  0: for all units $i$ let $D_i^{(0)} = y_i - \bar{y}$ where $\bar{y} = \hat{P}\{Y = 1|S = 0\} = \#\{i|y_i = 1, s_i = 0\}/\#\{i|s_i = 0\}$;
  $k$:   • for all $i \notin \mathscr{M}^{(i_1,\dots,i_k)}$ let $D_i^{(k)} = D_i^{(k-1)}$;
         • for all $i \in \mathscr{M}^{(i_1,\dots,i_k)}$ let $D_i^{(k)} = y_i - \bar{y}_i$ where $\bar{y}_i = \hat{P}\{Y = 1|S = 0, x_{i_1}, \dots, x_{i_k}\} =$
           $\#\{i|y_i = 1, s_i = 0, i \in C_i^{(i_1,\dots,i_k)}\}/\#\{i|s_i = 0, i \in C_i^{(i_1,\dots,i_k)}\}$;
$K+1$: $D_i^{(i_1,\dots,i_k)} = D_i^{(K)}$.

Set the final discrimination scores as $D_i = \frac{1}{M} \sum_{i_1,\dots,i_K} D_i^{(i_1,\dots,i_k)}$.
```

Fig. 2 Pseudo-code for repeated sequential implementation of CEM.

variables in the dataset include age, years of education, working hours, type of occupation (sector, type of employer), family status, sex, capital gain and loss, native country (redefined as areas of the world). The *adult* dataset is comprised of 45222 observations, the s.a. is possessed by 6319 units (13.97%), the outcome is favorable in 13008 (28.76%), 31.38% among those not possessing the s.a., 12.68% among those possessing it. For the analysis, the dataset is split in a learning (30162 units) and test (15060 units) subsamples (same as in [6]).

To check the stability of the procedure, we performed it twice for 100 iterations and compared the results, which showed a very good agreement ($\rho > 0.99$).

In order to explore how well the proposed measures detect discrimination against the protected group (i.e. $D < 0$, $\bar{D} > 0$ are relevant) under different circumstances we considered three different scenarios: *(a)* presence of a variable which is related to S but unrelated to Y (Fig. 1*(e)*); *(b)* discrimination free data (simulated); *(c)* discriminating data (simulated).

It is expected that if a variable we condition on is related to the s.a., then the level of conditional discrimination be lower. We added to the data a variable having a mild correlation with S (independent of the outcome). In Fig. 3*(a)* we compare the discrimination scores D and $\bar{D}$ (first and second row respectively) estimated by the procedure with and without the correlated variable: as expected, the discrimination scores are higher if the variable is omitted ($D_i^{(-p)}$, y-axis).

Further, we modified the dataset by adding and removing discrimination against the protected class to assess the sensitivity of the discrimination scores. Starting from a classification tree estimate of the probability of a positive outcome based on all variables but the S, we built a discrimination free dataset by simulating the outcome according to the estimated probabilities and a strong discrimination dataset by changing the outcome of 2200 units for which the probability of positive outcome is between 0.3 and 0.7 (in particular, we changed the outcome to negative for 200 units having the S and a positive outcome, and we changed the outcome to positive

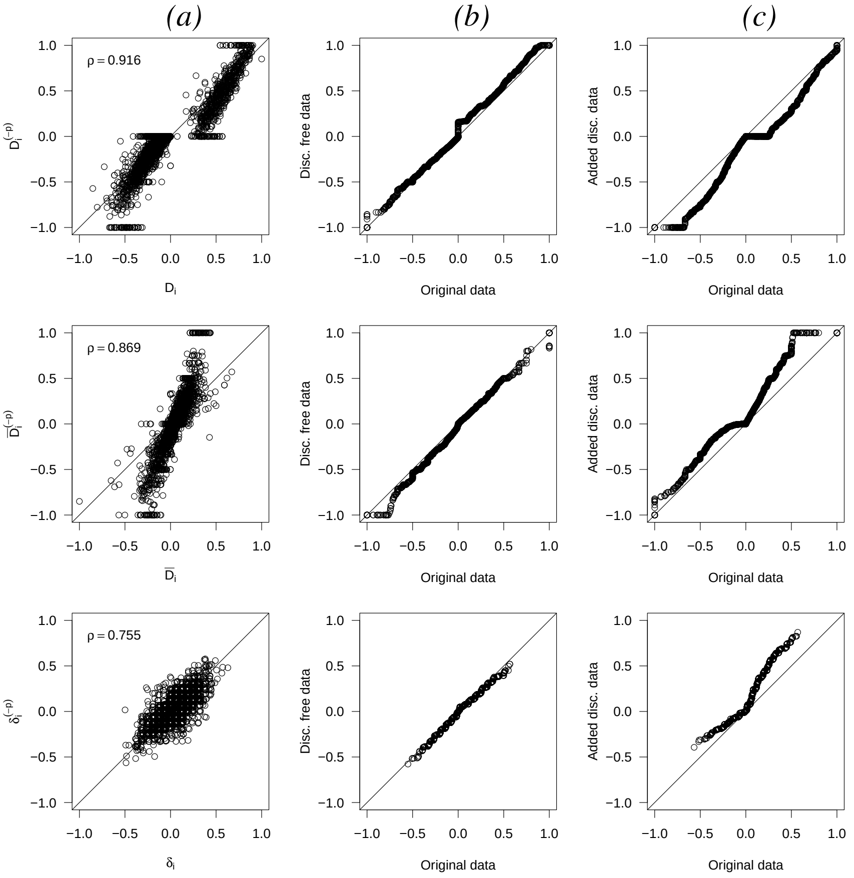

Fig. 3 Discrimination measures D_i, $\bar{D}_i$, δ_i (top, middle, bottom row respectively) performances: *(a)* scatter plots comparing discrimination measures obtained by including or omitting a conditioning variable simulated independently of the outcome to be correlated to S; *qq*-plots comparing the distributions of discrimination measures when discrimination is eliminated *(b)* and added *(c)*.

for 2000 units not having the S and a negative outcome). In Fig. 3*(b)* and *(c)* we compare the distributions of the discrimination measures using *qq*-plots.

Table 1 Classification accuracy after discrimination reductions.

% of S obs. changed	accuracy on testing data	accuracy on non S	accuracy on S
0	85.76	85.06	90.10
5	85.90	85.17	90.43
10	85.55	84.92	89.47
15	85.06	84.55	88.23
25	84.81	84.51	86.65

For comparison purposes we computed the measure δ of [6] (eq. (2) on the same datasets using 8, 16 and 32 as k values. Results are reported in Fig. 3 (bottom row) for $k = 16$, the other cases give qualitatively similar outputs. With respect to D, and to a minor extent to $\bar{D}$, the measure δ shows less variability since it is always based on groups of fixed size k, while very small (CEM) strata may contribute to the values of D ($\bar{D}$). Hence δ may be less sensitive to detect discrimination. This can be seen in scenario *(b)*, where only the D measure distribution differentiates between original and discrimination free data. Moreover, note that, contrary to D and $\bar{D}$, δ is weakly affected by the presence of a variable correlated to S.

The above discrimination measures can then be used to build a discrimination free dataset by changing the outcome of units with discrimination above a certain threshold. In Table 1 we report the performance of the classification (by a classification tree) after changing different numbers of units.

5 Conclusions

In order to detect inequality of treatment against protected classes in historical data it has been proposed to use the methods of causal inference to compare the treatment of statistical units belonging to the protected class to units not in the protected class which are similar with respect to the other observed characteristics. Similarity may be defined based on propensity scores or a distance metric. We argue that CEM stratification could be more apt to this task since it allows matching of units only if their characteristics are equal (possibly after coarsening of numerical variables), rather than relying on an overall distance. Preliminary results appear to confirm these expectations.

Statistical models for sports dat

The study of relationship between financial performance and points achieved by Italian football championship clubs *via* GEE and diagnostic measures

Lo studio della relazione tra risultati finanziari e punti realizzati delle squadre di calcio di serie A tramite GEE e misure di diagnostica

Anna Crisci, Sarnacchiaro Pasquale e Luigi D'Ambra

Abstract
Football is undoubtedly the most powerful and most popular sport in Italy, linking communities and stirring emotions. The main goal of any Football Championship club is to achieve sport results. The study of the relationship between sport and economic results attracts the interest of many scholars belonging to different disciplines. Very informative is considered the connection, over short or long periods of time, between the points in the championship and the resource allocation strategies. The aim of this paper is to give a interpretation of this last link using the Generalized Estimating Equation (GEE) for longitudinal data. Some diagnostic measures and graphical plots for checking the adequacy of GEE method will be presented and used.

Abstract
Il calcio in Italia è un fenomeno sociale che coinvolge intere comunità e continua ad aumentare il suo valore sociale ed economico. Lo studio della relazione tra i risultati sportivi ed economici riscuote l'interesse di tantissimi studiosi appartenenti a diverse discipline. Particolarmente stimolante è risultato il dibattito che lega, per ciascuna squadra di calcio, i punti in classifica alle capacità imprenditoriali del management sportivo in termini di allocazione delle risorse finanziarie e sportive. Obiettivo del presente lavoro è quello di dare un contributo in termini di interpretazione di quest'ultimo legame attraverso l'utilizzo delle Equazioni di Stima Generalizzate (GEE) per dati longitudinali. Alcune misure diagnostiche e metodi grafici per testare l'adeguatezza del metodo GEE saranno illustrati e utilizzati.

Key words: Italian Football championship clubs, sports and economic results, generalized estimating equations, Regression diagnostics

1. Introduction

Football is undoubtedly the most powerful and most popular sport in Italy, linking communities and stirring emotions. The main goal of any Football Championship club is to achieve sport results. Nevertheless, football has also become one of the most profitable industries, with a significant economic impact in infrastructure development, sponsorships, TV rights and transfers of players. Very informative is considered the connection between the points in the championship and the resource allocation strategies.

The Generalized Estimating Equation (GEE) methodology has been introduced to extend the application of generalized linear models to handle correlated data. For repeated measures, nowadays GEE represents a method based on a quasi-likelihood function and provides the population-averaged estimates of the parameters.

The aim of this paper is to give an interpretation of the link between the points in the championship and the resource allocation strategies using the GEE. In particular, we analyze the impact that some variables, including Income statement, Net equity and Team value, have on points made by football teams participating in the series A championship (2010-2015), by GEE for count data.

There are six sections in this study. A summary of GEE has been introduced in the second section. Section 3 deals with how to choose a working correlation structure and model selection in GEE. The Influential observation, Leverage and Outlier in GEE have been discussed in section 4. In section 5 the case study has been presented. Next, concluding remarks are presented in the final section of the paper.

2. Summary of the Generalized Estimating Equation method (GEE)

Let $\boldsymbol{y_i} = (y_{i1}, \dots, y_{it_i})'$ be a vector of responses value and let $\boldsymbol{X_i} = (\boldsymbol{X}'_1, \dots, \boldsymbol{X}'_n)'$ be a $t_i \times K$ matrix of covariates, with $\boldsymbol{x_{it}} = (x_{it1}, \dots, x_{itK})'$, i = 1,2, … ,n and t = 1,2, …,T. To simplify notation, let $t_i = t$ without loss of generality.

The expected value and variance of measurement y_{it} can be expressed using a generalized linear model:

$$E(y_{it}|\boldsymbol{x_{it}}) = \mu_{it}$$

Suppose that the regression model is $\eta_{it} = g(\mu_{it}) = \boldsymbol{x}_{it}^T\boldsymbol{\beta}$ where g is a link function and $\boldsymbol{\beta}$ is an unknown $K \times 1$ vector of regression coefficients with the true value as $\boldsymbol{\beta}_0$. The $Var(y_{it}|\boldsymbol{x_{it}}) = v(\mu_{it})\phi$, where v is a known variance function of μ_{it} and ϕ is a scale parameter which may need to be estimated. Mostly, v and ϕ depend on the distributions of outcomes. For instance, if y_{it} is continuous, $v(\mu_{it})$ is specified as 1, and ϕ represents the error variance; if y_{it} is count, $v(\mu_{it}) = \mu_{it}$ and ϕ is equal to 1.

Also, the variance-covariance matrix for $\boldsymbol{y_i}$ is noted by $\boldsymbol{V}_i = \phi \boldsymbol{A}_i^{\frac{1}{2}} \boldsymbol{R_i}(\boldsymbol{\alpha})$, $\boldsymbol{A}_i = diag\{v(\mu_{i1}), \dots, v(\mu_{iT})\}$ and the so-called "working" correlation structure $\boldsymbol{R_i}(\boldsymbol{\alpha})$ describes the pattern of measures within the subjects, which is of size $T \times T$ and depends on a vector of association parameters denoted by $\boldsymbol{\alpha}$. An iterative algorithm is applied for estimating α using the Pearson residuals $rp_{it} = \frac{y_{it}-\hat{\mu}_{it}}{\sqrt{v(\mu_{it})}}$ calculated from the current value of $\boldsymbol{\beta}$ (see section 4). Also, the scale parameter ϕ can be estimated by: $\hat{\phi} = \frac{1}{n-K}\sum_{i=1}^{n}\sum_{t=1}^{T} rp_{it}^{2}$. The parameters β are estimated by solving: $U(\boldsymbol{\beta}) = \sum_{i=1}^{n} \boldsymbol{D}_i'[V(\hat{\boldsymbol{\alpha}})]^{-1}\boldsymbol{s}_i = 0$ where $\boldsymbol{s}_i = (\boldsymbol{y}_i - \hat{\boldsymbol{\mu}}_i)$ with $\hat{\boldsymbol{\mu}}_i = (\mu_1, \dots \dots \mu_{iT})'$and $(\hat{\boldsymbol{\alpha}})$ is a consistent estimate of $\boldsymbol{\alpha}$ and $\boldsymbol{D}_i' = \boldsymbol{X}_i'\boldsymbol{\Lambda}_i$ and $\boldsymbol{\Lambda}_i = diag\ (\partial_{\mu_{i1}}/\partial_{\eta_{i1}} \dots \dots, \partial_{\mu_{it}}/\partial_{\eta_{it}})$. Under mildregularity conditions $\hat{\boldsymbol{\beta}}$ is asymptotically distributed with a mean $\boldsymbol{\beta}_0$ and covariance matrix estimated based on the sandwich estimator:

$$\hat{\boldsymbol{V}}_i^{\boldsymbol{R}} = (\sum_{i=1}^{n} \boldsymbol{D}_i'\boldsymbol{V}_i^{-1}\boldsymbol{D}_i)^{-1} \sum_{i=1}^{n} \boldsymbol{D}_i'\boldsymbol{V}_i^{-1}\boldsymbol{s}_i\boldsymbol{s}_i'\boldsymbol{V}_i^{-1}\boldsymbol{D}_i(\sum_{i=1}^{n} \boldsymbol{D}_i'\boldsymbol{V}_i^{-1}\boldsymbol{D}_i)^{-1}\ (\mathbf{1})$$

In GEE models, if the mean is correctly specified, but the variance and correlation structure are incorrectly specified, then GEE models provide consistent estimates of the parameters and also the mean function, while consistent estimates of the standard errors can be obtained via a robust “sandwich” estimator. Similarly, if the mean and variance are correctly specified but the correlation structure is incorrectly specified, the parameters can be estimated consistently and the standard errors can be estimated consistently with the sandwich estimator.

3. Criteria for choosing a working correlation structure and model selection

Unlike the GLM method, which is based on the maximum likelihood theory for independent observations, the GEE method is based on the quasi-likelihood theory and no assumption is made about the distribution of response observations. Therefore, AIC (Akaike's Information Criterion), a widely used method for model selection in GLM, is not directly applicable to GEE.

The QIC (Quasilikelihood under the Independence model Criterion) statistic proposed by Pan [8], and further discussed by Hardin and Hilbe [7], is analogous to the familiar AIC statistic used for comparing models fit with likelihood-based methods:

$$QIC = -2Q(\hat{\boldsymbol{\mu}}; \boldsymbol{I}) + \boldsymbol{2trace}(\hat{\boldsymbol{\Omega}}_{\boldsymbol{I}}^{-1}\widehat{\boldsymbol{V}_i^{\boldsymbol{R}}})$$

where $\boldsymbol{I}$ represents the independent covariance structure used to calculate the quasi-likelihood, $\hat{\boldsymbol{\mu}} = g^{-1}(\boldsymbol{x}_{it}\hat{\boldsymbol{\beta}})$. The coefficient estimates $\hat{\boldsymbol{\beta}}$ and robust variance (estimator $\hat{\boldsymbol{V}}_i^{\boldsymbol{R}}$ are obtained from a general working covariance structure. Another variance estimator $\hat{\boldsymbol{\Omega}}_I$ is obtained under the assumption of an independence correlation structure.

QIC can be used to find an acceptable working correlation structure for a given model. When trace $\hat{\boldsymbol{\Omega}}_{\boldsymbol{I}}^{-1}\hat{\boldsymbol{V}}_i^{\boldsymbol{R}} \approx trace\ (\boldsymbol{I}) = K$, there is a simplified version of QIC, called QIC_u [8]: $QIC_u = -2Q(\hat{\boldsymbol{\mu}}; \boldsymbol{I}) + 2K$. QIC and the related QIC_u statistics can be used to compare GEE models and aid model selection. QIC_u approximates QIC when the

GEE model is correctly specified. When using QIC and related QIC_u to compare two models, the model with the smaller statistic is preferred.

4. Regression diagnostics: Residuals, Influential and leverage points

Model checking is an important aspect of regression analysis with independent observation [9]. Unusual data may substantially alter the fit of the regression model, and regression diagnostics identify subjects which might influence the regression relation substantially. Therefore, GEE approach also needs diagnostic procedures for checking the model's adequacy and for detecting outliers and influential observations. Graphical diagnostic plots can be useful for detecting and examining anomalous features in the fit of a model to data.

Regression diagnostic techniques that are used in the linear model [3] or in GLM [4] have been generalized to GEE. Venezuela *et al.* [10] described measures of local influence for generalized estimating equations. Here, we extend such diagnostic measures of the regression model in GEE approach (Table 1). The diagnostic measures are numerous and can be classified into five groups:

a) Measures based on the prediction matrix

In GEE the Hat matrix is $\boldsymbol{H} = \boldsymbol{W}^{\frac{1}{2}}\boldsymbol{X}(\boldsymbol{X}'\boldsymbol{W}\boldsymbol{X})^{-1}\boldsymbol{X}'\boldsymbol{W}^{\frac{1}{2}}$ where $\boldsymbol{W} = diag(\boldsymbol{W}_1, \dots, \boldsymbol{W}_n)$ is a block diagonal weight matrix whose ith block corresponds to the ith subject. The leverage h_{it} as the ith diagonal element of the Hat matrix. Thus, h_{it} represent the high-leverage of ith observation y_i in determinig its own predicted value. It ignores the information contained in y. High-leverage can be rewritten by considering the Mahalonobis Distance (MD):

$h_{it} = MD_{it}^2 + \frac{1}{N}$ where $MD_{it} = \sqrt{(w_{it}^{1/2}\boldsymbol{x}_{it} - \bar{x})'(\boldsymbol{X}'\boldsymbol{W}\boldsymbol{X})^{-1}(\boldsymbol{x}_{it}'w_{it}^{1/2} - \bar{x})}$ and $\bar{x}$ is weighted mean. Cut off point: $2K/N$.

b) Measures based on residual

One method of detecting model failures is examining the residuals. There are many ways to compute residuals. The Pearson residual is a simple residual scaled by standard deviation of y_{it}. Pearson standardized residuals have been computed in order to have unit asymptotic variance. Anscombe residual have been introduced to make the distribution of the residuals as normal as possible [2].

c) Measures based on Influence Function

In this group we find CD [3, 4]; $\mathrm{SIC}_{\mathrm{it}}$ and $\mathrm{SC}_{\mathrm{it}}$.

d) Measures based on the volume of confidence ellipsoids

A measure of the influence of the ith observation on the estimated regression coefficients can be based on the change in volume of confidence ellipsoids with and without the ith observation. We consider:

a) The Andrews –Pregibon Statistic (AP) [1]: AP measures the volume of the confidence ellipsoid. It provides considerable information not only on outlying and influential observations but also on the remoteness of observations in the parameter space. We extend the AP in GEE approach. It is worth noting that this statistics does not assume the linear model and it therefore has a more general applicability. Indeed, it may be used not only as confirmative but also an exploratory tool and thus it may be extended to any data set independently of a model hypothesis.

b) The quasi-likelihood distance: Let $Q(\hat{\beta})$ is the quasi-likelihood estimate of the GEE parameters β using all response values and $Q(\hat{\beta}_{(it)})$ is the corrisponding estimate evaluate with the y_{it} observation deleted. A measure of the influence of the ith observation on $\widehat{\boldsymbol{\beta}}$ can be based on the distance between $Q(\widehat{\boldsymbol{\beta}})$ and $Q(\widehat{\boldsymbol{\beta}}_{(it)})$: $QD = 2[Q(\widehat{\boldsymbol{\beta}}) - Q(\widehat{\boldsymbol{\beta}}_{(it)})]$.

e) Measures based on total influence.

The overall influence [6] is based on the simple fact that potentially influential observations are outliers as either X-outliers, y-outliers, or both (see Table 1). Hadi recommends using "mean(HD_{it}^2)+ c$\sqrt{var(HD_{it}^2)}$" as a cut-off point for Hadi's measure, where c is an appropriately chosen constant such as 2 or 3.

5. Case study

The data used for our case study was obtained from the financial statements filed by the Serie A football teams. The period of study concerned the championship from season 2010/2011 up to 2014/2015. The focus of the analysis is to verify the impact that the income statement, Net equity and Team value variables have on the points achieved by football teams. We have started by previous paper where we selected the best model through *Cp* Mallows [5]. The independent variables considered in the final model are: Depreciation Expense of multi-annual player contracts(DEM); Revenue net of player capital gain (RNC); Net Equity (NE). Later, for this model, considering the diagnostic measures presented in section 4, we can note that the teams, Roma, Udinese and Genoa, exceed the cut of value of some measures (see table 2). In particular, the Roma team to the championship 2013-14 exceeds the cut off values related to the measures in table 2. For this reason, we consider a new GEE model with exchangeable work correlation structure (α = 0.612), without the observation related to Roma team to the championship 2013-14. The results are described in table 3.

Table 2: Diagnostic Measures

Teams	***Pearson***	***Leverage*** ***(h_{it}> 0,2454)***	***Cook-Distance*** ***(CD_{it}> 0,07272)***	***Hadi***
Roma (2013-14)	2,3079	0,3426	0,3966	0,7505 (HD^2>0,64)
Udinese (2012-13)		0,3083		0,4757 (HD^2>0,45)
Genoa (2010-11)		0,2558		

Table 3: The Poisson GEE Population-Averaged Model with Exchangeable Structure

Points	***Coef***	***St.err.***	***Z***	***P >| z|***
DEM	-0,0720	0,039	-1,84	0,066
RNC	0,3589	0,059	6,08	0,000**
NE	0,0539	0,017	3,17	0,002**
Cons	-2,2083	0,665	-3,32	0,009
Wald Stat.	93,56	Prob>chi^2 0,0000		

** significant at 5%.

Finally, we can note that the minimal working residual, computed by using correlation matrix, is obtained when we delete Roma Team. Concluding, we have discussed and reviewed the various measures which have been presented for studying outliers, high leverage points, and influential observations in the context of GEE approach. As an illustration, a data set about impact that some budget variables have on points achieved by football teams in the Serie A championship [5], has been presented, applying the methods developed in Section 4.

Table 1: Regression Diagnostics

Measures and Formula	***Interpretation and Cut off point***
a) Hat matrix h_{it} is the *i*-th diagonal element of the Hat matrix $\mathbf{H} = \mathbf{W}^{\frac{1}{2}}\mathbf{X}(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}\mathbf{X}'\mathbf{W}^{\frac{1}{2}}$	It allows to identify high leverage point $h_{it} \geq 2K/N$
$h_{it} = MD_{it}^2 + \frac{1}{N}$ where $\mathrm{MD_{it}} = \sqrt{(\mathrm{w}_{\mathrm{it}}^{\frac{1}{2}}\mathbf{x}_{\mathrm{it}} - \bar{\mathrm{x}})'(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}(\mathbf{x}_{\mathrm{it}}'\mathrm{w}_{\mathrm{it}}^{\frac{1}{2}} - \bar{\mathrm{x}})}$	High-leverage point can be computed by using the Mahalonobis Distance (MD) $h_{it} \geq 2K/N$
b) Residuals	
Square Pearson residuals $rp_{it}{}^2 = \sum_{i=1}^{n}(\boldsymbol{y}_i - \widehat{\boldsymbol{\mu}}_i)'\boldsymbol{\Lambda}_i{}^{-1}(\boldsymbol{y}_i - \widehat{\boldsymbol{\mu}}_i)$	rp_{it} is a simple residual scaled by standard deviation of y_{it} . Residuals are evalueted at the current value of $\boldsymbol{\beta}$. The matrix $\boldsymbol{\Lambda}_i{}^{-1}$ can be replaced by $\boldsymbol{V}_i$ and $\boldsymbol{R}_i$ in order to consider the correlation within subjects (working residual)
Pearson standardized residuals $(rpsd)_{it} = \frac{y_{it} - \hat{\mu}_{it}}{\sqrt{v(\mu_{it})(1 - h_{it})}}$	$(rpsd)_{it}$ is standardized in order to have unit asymptotic variance
Anscombe residuals for poisson distribution $r_{it}^A = \frac{\frac{3}{2}(y_{it}^{2/3} - \hat{\mu}_{it}^{2/3})}{\hat{\mu}_{it}^{1/6}}$	r_{it}^A: Anscombe (1953), proposed a residual using the function $G(y)$ in place of y where $G(\cdot)$ is chosen to make the distribution of as normal as possible. For univariate generalized linear models $G(\cdot)$ is given by: $G(\cdot) = \int \frac{1}{V^{\frac{1}{3}}(\mu)}\partial\mu$
c) Influence function	
Cook distance (CD) $(CD)_{it} = rpsd_{it}^2 \frac{h_{it}}{K(1 - h_{it})}$	$(CD)_{it}$ is a measure to detect clusters with a strong influence on parameter estimates $(CD)_{it} > 4/N$
$SIC_{it} = (\boldsymbol{N} - \boldsymbol{1})(\boldsymbol{X}'\boldsymbol{W}\boldsymbol{X})^{-\boldsymbol{1}}\boldsymbol{x}_{\boldsymbol{it}}'(\boldsymbol{y}_{\boldsymbol{it}} - \boldsymbol{x}_{\boldsymbol{it}}\widehat{\boldsymbol{\beta}}_{(\boldsymbol{it})})$ $SC_{it} = N(\boldsymbol{X}'\boldsymbol{W}\boldsymbol{X})^{-1}\boldsymbol{x}_{it}'\frac{r_{it}}{1 - h_{it}}$ where $r_{it} = (\boldsymbol{y}_i - \widehat{\boldsymbol{\mu}}_i)$	SIC_{it} and $SC_{it}$are easier to interpret; they are proportianal to the distance between $\widehat{\boldsymbol{\beta}}$ and $\widehat{\boldsymbol{\beta}}_{(\mathrm{it})}$
d) Volume of confidence ellipsoid	
Andrews/Pregibon Statistic (AP) $AP_{it} = \frac{\lvert \boldsymbol{X}_{(it)}^{*\prime}\boldsymbol{X}_{(it)}^{*}\rvert}{\lvert \boldsymbol{X}^{*\prime}\boldsymbol{X}^{*}\rvert}$	It provides considerable information not only on outlying and influential observations but also on the remoteness of observations in the parameter space. Small value of AP_{it} calls for special attention

The Quasi likelihood distance (QD): $QD = 2\left[Q\left(\widehat{\boldsymbol{\beta}}\right) - Q(\widehat{\boldsymbol{\beta}}_{(\boldsymbol{it})})\right]$	
e) Overall influence; $HD^2 = \frac{K}{(1-h_{it})}\frac{d_{it}^2}{(1-d_{it}^2)} + \frac{h_{it}}{(1-h_{it})}$ where $d_{it}^2 = \frac{\boldsymbol{r_{it}^2}}{\boldsymbol{r'r}}$	HADI is based on the simple fact that potentially influential observations are outliers as either X-outliers, y-outliers, or both. $HD^2 >$ mean(HD_{it}^2)+ c$\sqrt{var(HD_{it}^2)}$

Exploring the Kaggle European Soccer database with Bayesian Networks: the case of the Italian League Serie A

Maurizio Carpita and Silvia Golia

Abstract In the last decade, the application of statistical techniques to the sport field significantly increased. One of the most famous sports in the world is the soccer (football), and the present work deals with it, using data referred to the seasons from 2009/2010 to 2015/2016 of the Italian League Serie A extracted from the Kaggle European Soccer database. The players overall performance indicators, obtained on the basis of the players position or role (forward, midfielder, defender and goalkeeper), are used to predict the result of the matches by applying the Bayesian Networks as well as the Naive Bayes and the Binomial Logistic Regression models, considered as their competitors.

Abstract *Nell'ultima decade, l'applicazione di tecniche statistiche in ambito sportivo ha avuto un incremento significativo. In questo lavoro che riguarda il calcio, uno degli sport più famosi al mondo, si usano i dati relativi alle stagioni 2009/2010-2015/2016 del Campionato Italiano di Serie A estratti dal database Kaggle European Soccer. Gli indicatori di performance complessiva dei giocatori, ottenuti sulla base della loro posizione ovvero del loro ruolo (attaccante, centrocampista, difensore e portiere), sono utilizzati per prevedere il risultato delle partite utilizzando le Reti Bayesiane così come i modelli Naive Bayes e Logistico, considerati loro competitori.*

1 The Kaggle European Soccer database

In the last decade, the application of statistical techniques to the sport field and in particular to the European soccer (football) significantly increased, especially to predict matches' results [1, 15] using for example players performance statistics [10, 13] also for the Italian League [3, 4]. In the big data era, many databases are constructed and used to develop predictive models. On-line platforms for predictive modeling and analytics competitions, as Kaggle (www.kaggle.com), emerged and developed a meeting point for data scientists. This study uses data from the Kaggle European Soccer (KES) database [12], that contains data about 28,000 players and about 21,000 matches of the championship leagues of 10 countries and 7 seasons from 2009/2010 to 2015/2016, resulting in one of the biggest open database devoted to the soccer leagues of European countries, with data about players, teams and matches for several seasons [5].

The *Player Attributes table* of the KES database contains 33 variables, that represent player's performance indicators on the 0-100 scale with respect to overall and different abilities of the soccer play (power, mentality, skill, movement, attacking, goalkeeping), built with the experts classification of the EA Sports FIFA videogame. To develop the models of this study, only the players overall performance indicators and match result (in terms of goals scored by home and away teams) for the seasons from 2009/2010 to 2015/2016 of the Italian League Serie A are used. Given the presence of some missing values, the number of available matches is 2,587 instead of 2,660. The players overall performance indicator has been averaged based on the players' position or role, that is forward (FOR), midfielder (MID), defender (DEF) and goalkeeper (GOK), in each match according to the coach decisions before the match takes place. As explained in [5], the players' role is obtained from the *Match table* of the KES database, which contains X and Y coordinates representing the positions of the 22 players on the soccer pitch.

The aim of the study is twofold. First, one wants to explore these data using the Bayesian Networks (BN) as main model, to be compared to Naive Bayes (NB) and Binomial Logistic Regression (BLR) models, second, one wants to evaluate the power of overall performance indicators of the four roles in a soccer team (goalkeeper, defender, midfielder and forward role) in predicting the matches' results.

The paper is organized as follows. Sect. 2 contains a brief description of the theory underlying BN, NB and BLR models, whereas Sect. 3 reports the main results of the application of the three models to the data under study. Conclusions and ideas for future research follow in Sect. 4.

2 The three statistical models

Probabilistic networks are graphical models that explicit through a graph, the interactions among a set of variables represented as vertices or nodes of the graph. Any pair of unconnected nodes of the graph indicates (conditional) independence between the variables represented by these nodes under certain conditions that can be read from the graph itself. Hence, a probabilistic network captures a set of (conditional) dependence and independence properties associated with the variables represented in the network [8]. BN belong to the class of probabilistic networks. The underlined graph is called Directed Acyclic Graphs (DAG). A DAG $\mathscr{G}$ is a pair $\mathscr{G} = (\mathbf{V}, E)$, where $\mathbf{V}$ is a finite set of distinct vertices, $\mathbf{V}= \{V_i\}_{i=1}^k$, which correspond to a set of random variables $\mathscr{X} = \{X_{V_i}\}_{i=1}^k$ indexed by $\mathbf{V}$, $E \subseteq \mathbf{V} \times \mathbf{V}$ is the set of directed links (or edges) between pairs of nodes in $\mathbf{V}$. An ordered pair $(V_i, V_j) \in E$ denotes a directed edge ($\rightarrow$) from node V_i to node V_j; V_i is said to be a parent of V_j whereas V_j a child of V_i. The set of parents of a node V shall be denoted by $pa(V)$. A Bayesian Network (BN) over the variables $\mathscr{X}$ is defined as the triplet $\mathscr{N} = (\mathscr{X}, \mathscr{G}, \mathscr{P})$, where $\mathscr{G}$ is a DAG and $\mathscr{P}$ is a set of conditional probability distributions containing one distribution $P(X_v|X_{pa(v)})$ for each random variable $X_v \in \mathscr{X}$, where $X_{pa(v)}$ denotes the set of parent variables of variable X_v. The joint probability distribution $P(\mathscr{X})$ over the set of variables $\mathscr{X}$ is factorized as

$$P(\mathscr{X}) = \prod_{v \in \mathbf{V}} P(X_v|X_{pa(v)}). \tag{1}$$

So, a BN can be described in terms of a qualitative component, that is the DAG, and a quantitative component, consisting of the joint probability distribution (1).

The construction of a BN runs in two steps. First, one identifies the interactions among the variables generating a DAG, then the joint probability distribution has to be specified in terms of the set of conditional probability distributions $P(X_v|X_{pa(v)})$.

The DAG can be derived either manually or automatically from data. In order to automatically find the BN structure, several algorithms have been proposed in the literature, falling under three broad categories: constraint-based, score-based, and hybrid algorithms. Constraint-based algorithms make use of conditional independence tests focusing on the presence of individual arcs, score-based algorithms assign scores to evaluate DAGs as a whole, whereas hybrid algorithms combine constraint-based and score-based algorithms. The method used in this paper to derive the DAG is the Hill Climbing (HC), implemented in the R package `bnlearn` provided by Scutari [16]. It belongs to the class of the score-based algorithms and it consists in exploring the search space starting from an empty DAG and adding, deleting or reversing one arc at a time until the score considered can no longer be improved [17].

Given a BN, it can be used to answer questions (queries) related to the domain of the data that goes beyond the description of its behavior; for BN the process of answering questions is also known as probabilistic reasoning or belief updating. Basically, it focuses on the calculus of the posterior probabilities given a new piece of information called evidence. In fact, suppose to have learned a BN, it is used to compute the effect of new evidence Ev on one or more target variables X' using the knowledge encoded in the BN, that is to compute posterior distribution $P(X'|Ev)$. The procedure used in the paper makes use of the junction tree representation of a BN which is composed by cliques (a clique is a maximal complete subgraph of a moralization of the DAG $\mathscr{G}$). Belief updates can be performed efficiently using Kim and Pearls Message Passing algorithm [9].

Even if all the variables play the same role in the construction and usage of the BN, in the present paper one of the variables will be considered as target variable, similar to the variable Y used in the definition of the two competing models that follows.

In order to compare the performance of BN with the performances of competing models, the NB and BLR models are taken into account.

The Naive Bayes (NB) is one of the simplest restricted probabilistic graphical models [6]. It is characterized by a structure where one single class variable is parent of the remaining attribute variables, which are conditionally independent given the class variable. So, let Y be the class variable and let $\{X_i\}_{i=1}^{p}$ be the attribute variables, their joint probability is factorized as $P(Y,X_1,\cdots,X_p) = P(Y)\cdot\prod_{i=1}^{p} P(X_i|Y)$. From the definition of conditional probability, $P(Y|X_1,\cdots,X_p)$ is given by the following expression:

$$P(Y|X_1,\cdots,X_p) = \alpha\cdot P(Y)\cdot\prod_{i=1}^{p} P(X_i|Y), \tag{2}$$

where α is a normalization constant. Equation (2) is the common definition of a NB.

The Binomial Logistic Regression (BLR) model belongs to the family of the generalized linear models and it is used to estimate the probabilities of the two categories of a binary dependent variable Y using a set of covariates or predictors $\mathbf{X} = \{X_i\}_{i=1}^{p}$ [7]. The model assumes that the binary response variable is distributed as a Bernoulli with probability π and a logit link function. It can be expressed through the *logit transformation* as:

$$logit[\pi(\mathbf{X})] = log\left[\frac{\pi(\mathbf{X})}{1-\pi(\mathbf{X})}\right] = \mathbf{X}\boldsymbol{\beta} \tag{3}$$

where $\pi(\mathbf{X}) = P(Y = 1|\mathbf{X})$ and $\boldsymbol{\beta}$ is the vector of coefficients involved in the linear predictor $\mathbf{X}\boldsymbol{\beta}$. The BLR model was already applied to predict the result of soccer matches in other studies [2, 5, 11].

3 Statistical evidences for the Italian League Serie A

As explained in Sect. 1, the dataset used in this paper was obtained from the KES database and contains the overall performance indicators for the four roles in a soccer team (goalkeeper, defender, midfielder and forward role), used as predictors, and the matches' results reported in terms of goals scored by the home and away teams. The number of overall performance indicators is eight and corresponds to p for the NB and BLR models. From the goals scored by the two teams of the match, it is possible to determine the outcome of the match from the home team point of view, *result*, classified as win, draw and loss. Preliminary analysis, using this classification for the *result* variable, has shown a high difficulty of the BN in predicting the draw with respect to win and loss; similar performances were observed in previous studies [3, 4]. This finding could be due to the fact that a draw is an outcome characterized by a higher degree of uncertainty, as well as to class imbalance [14] as in this case, where percentage of wins is 46.1%, whereas percentages of loss and draw are 26.4% and 27.5% respectively. In order to partially overcome this problem, the *result* variable was dichotomized into two categories: WIN and NOWIN (that is loss or draw) of the home team. Clearly, a model that takes into account three categories for the outcome with satisfactory prediction accuracy should be preferred to a model that involves less categories. Nevertheless, a model based on a binary variable, as the dichotomized *result*, can be of interest for the home team (obviously interested to the WIN probability) as well as the away team (interested to the NOWIN probability of the home team, that is the NOLOSS probability of the away team). The *result* variable represent the target variable denoted by Y in the NB and BLR models. So, the variables used in all the analyses are nine and this number corresponds to k for BN; the link between p and k is the following: $k = p + 1$.

Given that the dataset under study contains continuous variables (averages by players role of the overall performance indicator on 0-100 scale) and a discrete variable (outcome of the match), it is necessary to discretize the continuous variables. In applying BN it is possible to manage hybrid database like the one under study, but it is necessary to constraint the relation parent-child, imposing that a discrete variable may only have discrete parents [8]. In the context of this paper, this kind of constraint implies that the overall performance indicators can not be parents of the outcome of the match and this constraint appears unrealistic.

The method used to discretize the players' performance indicators, is the Equal Frequency Discretizer that involves the quantiles of the variable's distribution. The number of categories was fixed to four.

In order to identify the best combination of score-based algorithm and score that gives a DAG with highest score, a cross-validation has been performed. The scores under evaluation were the Bayesian Information criterion (BIC) and the Bayesian Dirichlet Equivalent (BDE) uniform posterior probability of the DAG associated with a uniform prior over both the space of the DAGs and of the parameters [17]. The selected score was the BDE with imaginary sample size (iss) equal to 100; iss determines how much weight is assigned to the prior distribution compared to the data when computing the posterior. Fig. 1 shows the obtained DAG. It can be seen that the home and away teams are well separated and with a coherent structure of links. In fact, the goalkeeper role is connected with the defender and midfielder roles, the defender role is linked to the midfielder role and the forward role is related to the midfielder and defender roles. Moreover, the structure of relations between the performance indicators of both the home and away teams is the same, whereas the variables with a direct link with the variable *result* are different. For the home team the role directed linked to the variable *result* is the midfielder role whereas the one of the away team is the defender role. This finding is coherent with the match strategies chosen by the two coaches: generally, the home team goal is to win the match, so the midfielder role is important, whereas the away team goal is not to lose the match and in this case, the defender role is the strategic one.

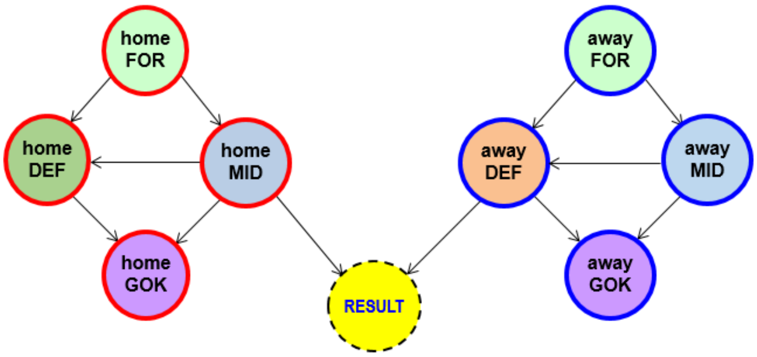

Fig. 1 DAG for the Italian League Serie A, Seasons 2009/2010-2015/2016

In order to compare the performance of the BN applied to the data, NB and BLR models were estimated. Table 1 reports the estimates of the parameters involved in the BLR model with the corresponding z-statistic. The performance indicators are maintained categorical in order to use the same data as the BN; same comments arise from the analysis of the results of the BLR model with continuous performance indicators. The most significant variables for the BLR model are *home_MID* and *away_DEF*, which are the ones with directed links to *result* in BN.

Table 1 Parameter estimates and z-statistics for the BLR Model

Perf. Indicator	$\hat{\beta}$	z-stat	Perf. Indicator	$\hat{\beta}$	z-stat
home_FOR2	-0.023	-0.181	away_FOR2	-0.094	-0.793
home_FOR3	0.029	0.206	away_FOR3	-0.021	-1.157
home_FOR4	0.319	1.959	away_FOR4	-0.289	-1.758
home_MID2	0.155	1.231	away_MID2	0.057	0.463
home_MID3	0.555	3.817	away_MID3	0.077	0.527
home_MID4	0.776	4.173	away_MID4	-0.466	-2.430
home_DEF2	0.086	0.693	away_DEF2	-0.260	-2.165
home_DEF3	0.336	2.286	away_DEF3	-0.420	-2.788
home_DEF4	0.478	2.689	away_DEF4	-0.672	-3.692
home_GOK2	-0.035	-0.288	away_GOK2	-0.078	-0.649
home_GOK3	-0.007	-0.060	away_GOK3	-0.153	-1.309
home_GOK4	-0.013	-0.087	away_GOK4	0.010	0.072

All the methods considered calculate the probability of win given new information. In order to predict the result of the match in terms of WIN-NOWIN of the home team, the simple majority rule is the most popular way to convert a probability into a predicted result; this is the rule used in the paper. Precision of model predictions can be evaluated by computing some indexes such as the *Accuracy*, which expresses how effectively the model predicts matches' results, the *Sensitivity*, which expresses how effectively the model predicts WIN matches and the *Specificity*, which expresses how effectively the model predicts NOWIN matches. Moreover, the accuracy of a model can be compared with the so called *null accuracy*, which measures the accuracy obtained without models and corresponds to the highest observed frequency of the two possible results of the match. Table 2 reports the prediction performances of BN, NB and BLR considering 500 random samples of 500 matches form the 2,587 available. For each sample of 500 matches, the DAG is the one reported in Fig. 1, whereas in applying NB and BLR, all the overall performance indicators are taken into account as predicting variables of *result*. All the conditional probabilities involved in BN and NB and the coefficients of BLR are computed making use of the remaining 2,087 matches.

Table 2 Mean predictive capability of the models based on the prediction of 500 matches' results randomly sampled 500 times (standard errors are in parenthesis)

Model	Accuracy	Sensitivity	Specificity
BN	0.623 (0.020)	0.550 (0.055)	0.688 (0.052)
NB	0.632 (0.021)	0.577 (0.032)	0.679 (0.030)
BLR	0.630 (0.021)	0.525 (0.031)	0.721 (0.031)

All methods have similar accuracy (about 63%), which is about ten percentage points greater than the null accuracy (53.9%). Moreover, BN and NB are more accurate in the WIN prediction (sensitivity) than BLR, which is more accurate in predicting NOWIN (specificity). Finally, standard errors for sensitivity and specificity of BN are greater than those of NB and BLR of about two percentage points.

4 Conclusions and future research

The paper shows some results obtained analyzing data regarding the Italian League Serie A extracted from the KES database; the aim was to explore these data using the BN and evaluate the power of overall performance indicators of the four roles in a soccer team (goalkeeper, defender, midfielder and forward role) in predicting the matches' results. A preliminary analysis suggested the necessity to collapse the match's results loss and draw in a unique category. Moreover, due to the fact that BN works with discrete variables, the overall performance indicators were discretized. In addition to BN, NB and BLR models were considered as competitors. All the three models have similar accuracy (around 0.63) significantly greater than null accuracy (0.54), so it is possible to conclude that the variables considered have some predictive power. Regarding the application of BN, the DAG expressed by the data shows coherent structure of links between the roles and maintains the home and away teams indicators well separated. Moreover the variables with a direct link with the variable *result* were the midfielder role for the home team and the defense role for the away team. This finding is coherent with the match strategies chosen by the two coaches: generally, the home team goal is to win the match, so the midfielder role is important, whereas the away team goal is not to lose the match and in this case, the defender role is the strategic one.

This study can be extended in various directions. For example, an advantage in using BN with respect of other models is the possibility to use partial information to predict a match's result, and this will be argument of future research. Moreover, another interesting development of this paper will be to extend the analysis to leagues of other countries in Europe in order to verify similarities in the results.

A data-mining approach to the Parkour discipline

Un approccio data-mining alla disciplina del Parkour

Paola Pasca, Enrico Ciavolino and Ryan L. Boyd

Abstract Parkour is a relatively new discipline. As an uncommon nexus between risk, resistance, and the philosophy of overcoming obstacles, it is continuously gaining interest and popularity. However, the “voice” of parkour practitioners has been explored only qualitatively, on small samples and from a phenomenological point of view. In this work, raw data from the official American Parkour forum (from 2005 to 2013) have been web-scraped and treated with the Meaning Extraction Method (MEM), a simple and flexible technique providing optimal dimension reduction and the identification of broader themes related to the parkour discipline, thus providing a broader vision of a phenomena which is configuring itself as a true life-style.

Abstract *Il parkour è uno sport piuttosto recente: come nesso tra rischio, resistenza e filosofia degli “ostacoli da superare”, è diventata una disciplina sempre più interessante e popolare. Tuttavia, la voce dei praticanti è stata esplorata solo in una ricerca qualitativa, effettuata su un piccolo campione, e solo da un punto di vista fenomenologico. In questo lavoro, per la prima volta, sono stati estratti dati provenienti dall'intero forum American Parkour (dal 2005 al 2013) e sono stati trattati con il Meaning Extraction Method (MEM), una tecnica semplice e flessibile che permette di ridurre la dimensionalità dei dati e di identificare i temi più ampi e caratteristici del parkour, una disciplina che si configura sempre più come uno stile di vita.*

1 An introduction to the Parkour discipline

Parkour is a relatively recent practice which is continuouly gaining interest and popularity, due to a significant presence on both tv and the *web*. Its first manifestations started as a game for its founders David Belle and Sébastian Foucault, in the context of the deprived parisian suburbs [3].

However, the roots of parkour can be dated back prior to the First World War: Georges Hébert, a military trainer of the French Navy, believing in intense physical training as a means for self-development, created a training method that combined physical obstacles with psycho-emotional barriers. The so-called *Natural Method* encouraged training in unconstrained, outdoor settings, where different terrain or obstacles could be faced and overcome. Grounded on ten main groups of exercises (walking, running, jumping, quadrupedal movement, climbing, balancing, throwing, lifting, defending and swimming), the *Natural Method* aims at making mind and body agile and adaptive in any situation: its fast, fluid and forward movements transposed into the urban environment are the essence of parkour [3, 17].

Despite its popularity, parkour is still permeated by prejudice. On a large scale, thoughtlessness, reckless behaviour and even suicide is sometimes attributed to it, even if there are no formal statistics related to deaths caused by parkour; moreover, training at one's own physical level is at the heart of the practice and practice itself starts from a ground level where falls are not life threatening. On a smaller scale, parkour practitioners, better known as *traceurs*, are often discouraged from practicing or banished by authorities, even if they almost always take care of their training spots by keeping them safe, clean and populated [17].

These controversial aspects make parkour an interesting topic for research and indepth exploration. Previous literature shed light on various aspects of the discipline [5, 19, 3, 13]. However, it is mainly focused on a small-group scale, based on qualitative data (interviews, narratives) on which no statistical processing has ever been performed.

This paper approaches the parkour discipline through simple data-mining techniques. It focuses on the entire American Parkour forum and lets the voice of *traceurs* and interested people emerge with the help of recent software developments for the treatment, processing and meaning extraction from linguistic data [10, 7].

A brief description of dataset, procedures and methods is reported in section 2. Some of the results of the natural language processing are reported in section 3.

2 Data and Methods

When it comes to the collection of unstructured data from the *web*, *web scraping* may help [16]. In the field of computer science, the term refers to several methods for data extraction and for their conversion into metadata which can further be processed and analyzed. In this case, one of the simplest, most intuitive software for efficient collection of *web* data has been used: *Helium Scraper* [2].

Through this software, linguistic data were exported from one of the biggest and most active online communities of parkour/freerunning practitioners: the American Parkour Forum [1]. There, *traceurs* and *freerunners* can share experiences, advices and ideas related to the discipline.

2.1 Dataset

The raw dataset covers a period of time ranging from 2005 to 2013. It consists of a .csv file containing *unique Id* of the post, *text in the post, number of responses, dates* and *times, author* of the thread, thread *title*.

On the raw dataset, a consistent amount of threads containing few hundreds of words could be noticed (precisely, 2692 threads contained an amount of words equals or inferior to 640 words).

In order to facilitate the information extraction in the text processing phase, authors decided to exclude from the analysis the threads with a word count lower than the minimum determined for segmentation, that is, 100 words. With respect to the whole corpus of data, this choice prevents from including threads likely to contain repetitions and comment citations, that is, less informative data. Building on these assumptions, we retained threads whose overall word count was above or equal to 5000 words.

Moreover, we excluded one thread which was in arabic language, and removed *links* and *urls* mentioned within the texts. Grouped by thread, the final dataset ($>$5000) included a total of 249 threads and 17275 comments.

2.2 Meaning Extraction Method

The Meaning Extraction Method (MEM), developed by Chung and Pennebaker [11] is based on the assumption that words related to a particular topic will tend to be used together. The mere observation of associated words allows researchers to draw inferences on how much people are talking, about what topics and in what way. This simple assumption makes application and interpretation procedures easier and more efficient.

MEM procedures start with a binary dataset of used-vs-non used words. This first step requires cleaning data from stop words (words that carry little to no meaning, such as ”the”, ”you”, ”did”), uncommon and non-informative words, in order to be sure that the most meaningful themes will be extracted. Then, a common factor analytic approach such as Principal Component Analysis can be applied to the word-by-observation table. Applied to natural language, results will provide word clusters reflecting broader themes emerged from the sample of text.

In order to speed up the front-end procedures used in this (and other) topic modeling approaches, Boyd released the Meaning Extraction Helper (MEH) [8], a free-ware that automates many of the steps described above. Its simplest application requires the user to make few basic selections, to point the software to the location of the .txt files and run the analysis. MEH efficiently converts unstructured linguistic data into structured matrices ready to be analyzed, leaving researchers to apply statistical techniques for meaning extraction [7].

In literature, several applications confirmed MEM as a promising method for uncovering information regarding psychological dimensions [11], personal values [9] and cultural self-schemas [18]. In particular, a recent application [6] proved MEM efficacy in catching how people think and talk online.

Building on previous literature, the American Parkour dataset has been processed with MEH through the following settings:

- upload a list of stop words (both the default one and another stop word list determined by the first author who, as a parkour practitioner, is familiar to parkour language);
- upload conversions (e.g. words such as *compete, competitive, competing* to be coded as *competition*);
- split files into equally sized segments (38 per thread). The number of segments is the ratio between the *mean by thread* value and a pre-determined words-per-segment value, that is 250. As said above, the minimum size (in terms of word count) admitted for a segment to be included in the output is set to 100 words.
- setting the minimum word percentage of word appearance in order to be included in the outputs to 3%.

The rationale for text processing choices is to make the most out of the combination of data descriptive statistics and MEH characteristics. The average number of segments (38) will split small threads into very small segments (in terms of word count) and bigger threads into big ones. However, the 3% required to a word to be included for analysis ensures to take the very essential from the smallest threads and more contents from bigger threads.

MEH uses a dictionary to identify common content words in each segment and systematically assigns a binary score to each word according to presence (”1”), or absence (”0”). After processing each word in each segment, MEH generates an output file that identifies the words and shows in which segments they are used.

Moreover, frequency of each common word across all the text observation is computed. The output file can be uploaded into statistical software (e.g. R, SPSS). A Principal Component Analysis with varimax rotation allows to extract components reflecting broader themes across all texts.

3 Results

Top 50 most frequently used words are reported in table 1.

Table 1 50 most frequent words across 9462 segments

Word	Frequency	Word	Frequency
competition	3357	friend	1311
work	3063	strong	1294
jump	2427	complete	1197
community	2338	technique	1181

movement	1350	human	879
love	1344	style	876

The top 50 most frequent words themselves reveal relevant aspects of parkour: words related to it as a concept (*competition, discipline, philosophy, sport*), as well as words reminding to social aspects (*community, friend, group, practitioner*) and more technical words (*jump, flip, vault, wall, roll*).

PCA results along with descriptives are reported in table 2. The parkour corpora can be summarized by 11 themes that globally accounted for the 26% of variance.

Table 2 Corpora descriptives

Component	1	2	3	4	5	6
Eigenvalue	2.95	1.81	1.69	1.62	1.59	1.47
Variance %	4.27	2.62	2.45	2.36	2.31	2.13

	efficient -.217		sport -.207

Values with an absolute value potentially rounded to .2 were used in order to identify PCA components [11, 9]. The themes emerged have been evaluated (in terms of meaning) by both the first author and an italian parkour instructor (see the *acknowlegdement* section for more info). They cover many facets of the parkour discipline, related both to the global status of being a practitioner (*component 1*), but also to more specific dimensions: the idea of parkour as discipine and philosophy (*component 2*) is largely reported by the most conservative practitioners on a smaller scale [12, 19].

The *outdoor* and *technique* components mention specific parkour moves (*vault, jump, wall, roll*) and environment words (*building, ground*). It is interesting to note that the word *efficient* loads positively within the *outdoor* component, whereas it loads negatively in the *competition* component suggesting, in agreement with literature [3, 12], that when it comes to moving in real environments, efficiency matters more than spectacularity or aesthetic . This is also coherent with Georges Hébert's principle that inspired parkour: *be strong to be useful* [19].

Also, references to parkour *jams*, that is, intensive training meetings, as well as a strong social component appeared: in the context of an open-minded attitude towards discipline and life, a precious contribution to personal and physical development comes from confrontation and advise of other *traceurs*, and from sharing both sweat and goals.

4 Conclusions

In this paper, Meaning Extraction Method was used to web-scrape and analyse data from the official American Parkour forum. The method provided an optimal dimensionality reduction and identify some latent themes that underlay the vision of a Parkour discipline.

The obtained results showed that the Parkour discipline confirmed and extended the vision of a phenomenon involving global existence and perceived as a way of life.

Acknowledgements A special thanks to Ryan L. Boyd for providing the first author with the largest parkour dataset so far and introducing her to MEM.

A special thanks to Alessandro Pennella, one of the best certified parkour trainers in Italy, for examining and commenting the themes emerged from the analysis.

Players Movements and Team Shooting Performance: a Data Mining approach for Basketball.

Movimenti dei giocatori e performance di squadra nella pallacanestro con l'uso di tecniche di Data Mining.

Rodolfo Metulini

Abstract In the domain of Sport Analytics, Global Positioning Systems devices are intensively used as they permit to retrieve players' movements. Team sports' managers and coaches are interested on the relation between players' patterns of movements and team performance, in order to better manage their team. In this paper we propose a Cluster Analysis and Multidimensional Scaling approach to find and describe separate patterns of players movements. Using real data of multiple professional basketball teams, we find, consistently over different case studies, that in the defensive clusters players are close one to another while the transition cluster are characterized by a large space among them. Moreover, we find the pattern of players' positioning that produce the best shooting performance.

Abstract *N*el dominio attinente Sport Analytics, i dispositivi di posizionamento globale vengono utilizzati intensivamente poiche' consentono di raccogliere e analizzare i movimenti dei giocatori. Managers e allenatori sono interessati a conoscere la relazione tra i movimenti dei propri giocatori e le prestazioni della squadra, al fine di gestire al meglio la loro squadra. In questo articolo proponiamo un approccio che utilizza la Cluster Analysis e il Multidimensional Scaling con l'obiettivo di identificare e descrivere specifiche dinamiche di movimento. Usando dati reali di più squadre di basket professionistiche, troviamo, consistentemente su diversi casi di studio, che le azioni di difesa si caratterizzano per avere giocatori tra loro vicini, mentre le azioni di transizione presentano un' ampia spaziatura tra di essi. Inoltre è stato trovato il posizionamento in campo che meglio si associa con una buona performance di tiro.

1 Introduction

Studying the interaction between players in the court, in relation to team performance, is one of the most important issue in Sport Science, as team sports' Managers, more and more in recent years, are becoming aware of the potential of Data Analytics in order to better manage their team. Recent years make it possible, thanks to the advent of Information Technology Systems (ITS), that permits to collect, store, manipulate and process a large amount of data. On the one hand, a sequence of relevant events of the match, such as passes, shots and fouls (player-specific) and time-outs (team-specific) takes the name of play-by-play. On the other hand, information on the movement of players on the court has been captured with the use of appropriate Geographical Positioning Systems (GPS) devices, for example the accelerometer, a device that measures proper velocity and positioning. Analysing players' interaction, however, is a complex task, as the trajectory of a single player depends on a large amount of factors related, among others, to coaches, single players and the whole team. The trajectory of a player depends on the trajectories of all the other players in the court, both teammates and opponents. Players interactions have been mainly studied in the new domain of ecological dynamics [1, 2]. Typically, there are certain role definitions in a sports team that influence movements. Predefined strategies are used by the coach to achieve specific objectives. A common method to approach with this complexity in team sport analysis consists on segmenting a match into phases, as it facilitates the retrieval of significant moments of the game. For example, Perin et al. [3] developed a system for visual exploration of phases in football, while, to the same goal, Metulini [4] propose motion charts. Cluster analysis methodology is widely used in team sports literature. To name a few, Sampaio and Janeira [5] applied a cluster analysis to investigate the discriminatory power of game statistics between winning and losing teams in the Portuguese Professional Basketball League, by using game final score differences, Ross [6] uses cluster analysis to segment team sport spectators identifying potential similarities according to demographic variables. Csataljay et al. [7] used cluster approach to the purpose of identifying those critical performance indicators that most distinguish between winning and losing performances. However, differently from the aforementioned papers, to the aim of segmenting game into phases, in this paper we cluster time instants. In doing so, we use GPS tracked data. In this regard, Goncalvez [8] applied a two-step cluster to classify the regularity in teammates dyads' positioning. Metulini, Manisera and Zuccolotto [9] used cluster analysis to an amatorial basketball game in order to split the match in a number of separate time-periods, each identifying homogeneous spatial relations among players in the court. They also adopt a Multidimensional Scaling to visually characterize clusters and analysed the switch from *defense* to *offense* clusters, by mean of transition probabilities. This paper aims to fill the gap in Metulini et al., by extending the analysis to multiple matches. Moreover: i) we apply our cluster analysis procedure to professional basketball games, ii) we use the data generated by the algorithm proposed in Metulini [10] in order to consider active game moments only, iii) we use a more detailed labelling scheme introducing *transition* moments, which permits a better interpretation of the transition probabilities. Last, we characterize clusters in term of team performance, by retrieving shooting events throughout a video analysis.

2 Data and Methods

Basketball is a sport generally played by two teams of five players each on a rectangular court. The objective is to shoot a ball through a hoop 46 centimeters in diameter and mounted at a height of 3.05 meters to backboards at each end of the court. According to FIBA rules, the match lasts 40 minutes, divided into four periods of 10 minutes each. There is a 2-minutes break after the first quarter and after the third quarter of the match. After the first half, there is a 10 to 20 minutes half-time break. In this paper we use tracked data from three games played by Italian professional basketball teams, at the Italian Basketball Cup Final Eight. MYagonism (https://www.myagonism.com/) was in charge to set up a system to capture these data during the games, trough accelerometer devices. Each player worn a microchip that, having been connected with machines built around the court, collected the player's position (in pixels of 1 cm^2 size) in the x-axis (court length), the y-axis (court width), and in the z-axis (height). Data, filtered with a Kalman approach, has been detected at a millisecond level. Available data contain information on players' positioning, velocity and acceleration during the full game length. Throughout the text we will call the three games case study 1 (CS1), case study 2 (CS2) and case study 3 (CS3). As the initial dataset is provided to us considering the full game length, we cleaned it by dropping the pre-match, the quarter- and the half-time intervals and the post match periods, as well as the time-outs and the moments when a player is shooting a free-throw. More information on this filtering procedure can be found in Metulini [10]. The final dataset for CS1 counts for $206,332$ total rows, each identifying the milliseconds in which the system captured at least one player. CS2 dataset counts for $232,544$ rows, while CS3 counts for a total of $201,651$ rows.

We apply a k-means Cluster Analysis in order to group a set of objects. Cluster analysis is a method of grouping a set of objects in such a way the objects in the same group (clusters) are more similar to each other than to those in other groups. In our case, the objects are represented by the time instants, expressed in milliseconds, while the similarity is expressed in terms of distance between players' dyads. In the analyses that follows we only consider moments when a particular lineup is on the court. More specifically, we only consider lineups that played for at least 5 minutes. According to this criteria, we consider two lineups (*p1, p3, p6, p7, p8* and *p1, p4, p5, p7, p10*) for CS1, two (*p1, p2, p4, p5, p6* and *p1, p2, p5, p6, p8*) for CS2, and one lineup for CS3 (*p2, p5, p6, p9, p10*, *p* stays for player). We chose number of clusters based on the value of the between deviance (BD) / total deviance (TD) ratio and the increments of this value by increasing the number of clusters by one. We consistently, and surprisingly, find k=6 (BD/TD= around 45% along the different lineups, and relatively low increments for increasing k, for $k \geq 6$) for almost all the lineups considered. Specifically, increasing the number of clusters from 5 to

6, BD/TD increments by around 11-12 % in all the five lineups, while increasing from 6 to 7, BD/TD increments by around 6-7 %.

3 Results

In this section we describe clusters for their dimension and their characteristics in term of pattern of player's positioning and team performance, along the five lineups. According to the first lineup of CS1, the first cluster (C1) embeds 13.31% of the observations (i.e. 13.31% of the total game time), the other clusters, named C2, ..., C6, have size of 19.76%, 3.40%, 29.80%, 6.41% and 27.31% of the total sample size, respectively. Consistently for all the five lineups, we find a couple of small clusters, with less than 10% of the total observations, and 2-3 larger ones, containing at least 20% of the observations.

Cluster profile plots have been used to better interpret the players' spacing structure in each group. Figure 1 reports profile plot for the first lineup of CS1, to characterize groups in terms of average distances among players. In this case, we find the smaller cluster (C3, 3.4% of observations) displaying large average distances among players (horizontal lines in Figure 1 represent the average value along the game time played by that lineup). On the contrary, the larger cluster (C4, 29.8%) displays all the average distances below the game average. These two facts are confirmed in the second lineup of CS1, as it presents the larger cluster (C5, 40.4%, which is not reported for the sake of space saving) displaying really small average distances, while its smaller cluster (C6, 3.2%) reports large average distances. Same evidences have been found in other case studies.

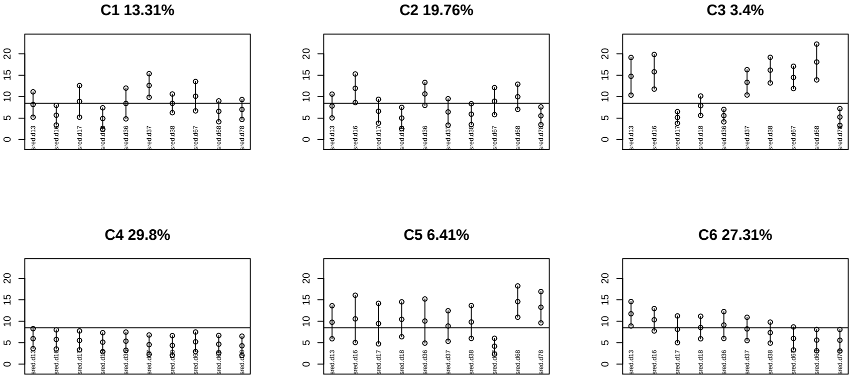

Fig. 1: Profile plots representing, for each of the 6 clusters, the average distance among players' dyads.

To the aim of producing further visual evidences, we used Multidimensional Scaling (MDS), which plots the differences between the groups in terms of positioning in the court. With MDS algorithm we aim to place each player in N-dimensional space such that the between-player average distances are preserved as well as possible. Each player is then assigned coordinates in each of the N dimensions. We choose N=2 and we draw the related scatterplots. Figure 2 reports the scatterplot for the first lineup of CS1. We observe strong differences between the positioning pattern among groups. The figure highlights large space among players in CS3, as also highlighted by the average distances in the profile plot. Moreover, moments in C4 are characterized by close to each others players. Despite not reported here, other lineups display similar MDS results: smaller clusters are characterized by large average distances and by a large space among players, while larger clusters by small average distances and by close to each others players.

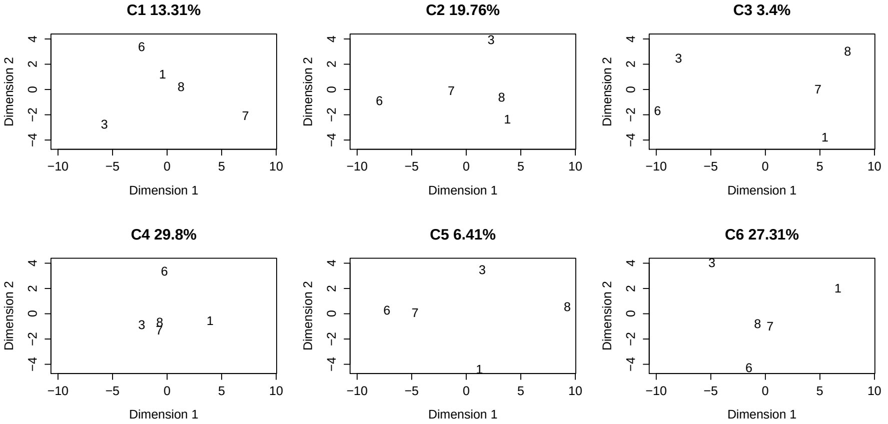

Fig. 2: Map representing, for each of the 6 clusters, the average position in the $x-y$ axes of the five players in the court, using MDS.

The filtered datasets label each moment as *offense*, *defense* or *transition* by mean of looking to the average x-axis positioning of the five players on the court. A moment is labelled as *transition* when the average x-axis is in within the interval [-4,+4], where 0 corresponds to the half court line. Throughout this information, we associate each cluster to offense, defense or to transition, according how many time instants in a specific cluster corresponds to the specific label.

Table 1 reports related percentages for the first lineup in CS1. Clusters C1, C2 and C6 mainly correspond to offense (respectively, for the 68.85%, 67.97% and 71.52% of the times), C3 and C5 correspond to defensive actions (82.11% and 54.49% of the times, respectively), while C4 corresponds to defense (70.48%). It emerges that large clusters with small average distances among players contains defensive moments. Moreover, the small cluster with large distances corresponds to transition. This result is consistent in all the five considered lineups. For example, in the sec-

Table 1 Percentages of time instants classified in Transition (TR) Defense (D) or Offense (O), for each cluster.

Cluster	**1**	**2**	**3**	**4**	**5**	**6**
TR	8.41	21.76	**82.11**	7.08	**54.49**	10.53
D	22.74	10.28	6.6	**70.48**	23.98	17.95
O	**68.85**	**67.97**	11.29	22.45	21.53	**71.52**
Total	100.00	100.00	100.00	100.00	100.00	100.00

ond lineup of CS1, the small cluster (C6) corresponds to transition moments for the 80.76% of the time. The large cluster with corresponding small distances (C5) contains moments classified as defense the 72.99% of the times.

Table 2 shows the transition matrix for the first lineup of CS1, which reports the relative frequency in which subsequent moments in time report a switch from a cluster to a different one. Main diagonal values of the matrix have been set to zero, so that each column percentages sum to 100% without including subsequent moments in which there isn't a switch.

Table 2 Transition matrix reporting the relative frequency subsequent moments $(t, t+1)$ report a switch from a group to a different one.

Cluster label	**C1**	**C2**	**C3**	**C4**	**C5**	**C6**
C1	0.00	11.27	10	8.45	15	10.34
C2	31.03	0.00	10	23.94	15	35.34
C3	0.00	1.41	0	0.00	0	7.76
C4	34.48	21.13	0	0.00	25	35.34
C5	3.45	4.23	0	4.23	0	11.21
C6	31.03	61.97	80	63.38	45	0.00

It emerges that, for the 34.48% of the times C1 switches to a new cluster, it switches to C4. It also switch to C2 and C6, respectively for the 31.03% and for the 31.03% of the times. We can note that C2, C4 and C6 are the three largest clusters. C3, marked as *Transition*, switches 80% of the times to C6 (a offensive cluster). Moreover, C2 switches most of the times (61.97%) to C6. C2 and C6 are both marked as offensive clusters. Since the total number of switches for this lineup is equal to 309, and this lineup played for a total of 8 minutes and 21 seconds, on average we have a switch every 2 seconds. For this reason we have frequent cluster switches during the same action. Switch from C2 to C6 is an example: players change patterns of positioning during the same action. Table 4 highlights that offensive clusters often switch to another offensive cluster (beside C2, C1 switches for the 31.03% of the times to C2 and for the 31.03% of the times to C6, C6 switches for the 35.34% of the times to C2). This evidence is confirmed in the other case studies, since, in the second lineup of CS1, we have three offensive clusters (C1, C2 and C3); C1 switches to C2 for the 33.33% of the times, C3 switches to C2 for the 40.91% of the times. In the first lineup of C2, we find three offensive clusters (C3, C4 and C6); C4 switches to C6 for the 75.86% of the times.

With this in mind, we can not associate a cluster with a whole action played with a particular tactic, instead, we have to interpret offensive clusters as subsequent players' positioning configurations, to the aim of finding the best positioning for a good shot.

In light of this, we collect the shooting events of the match. Since play-by-play data are not available for this tournament, we collect such events by watching the video of the game. Zuccolotto, Manisera, Sandri [11] analysed the shooting performance under pressure. Here we study shooting performance with respect to different players' positioning patterns, by associating shots to the cluster in which the team was (at the moment of the shot). We take into consideration only shots from the court, disregarding free throws. During the 8 minutes and 21 seconds players *p1, p3, p6, p7* and *p8* were in the court together, the team made 15 shots from the court, with 7 made shots and 8 missed, for a percentage of 46.67%. We find that most of these shots (8) has been attempted in moments that belongs to cluster C6. During this cluster, the team scored 5 out of 8 total attempts, with a really high percentage of 62.5%, ways higher than the average of 46.67%. Moreover, the team attempted only 4 shots (2 of them made) during cluster C1, only 2 shots (both missed) during cluster C2 and it missed a shot during cluster C5. So, 14 out of 15 shots have been attempted during the clusters labelled as offensive (i.e. C1, C2 and C6) while only one during a transition cluster (C5). Looking to bottom-right chart in Figure 2 (C6), we find player 3 far away from the others. We could suppose that the tactic of the team was to leave that player free to shot on the weaker side of the court. Results support the idea that C6 represents the cluster of (good) shooting moments. Furthermore, the other offensive (C1, C2) and transition (C3, C5) clusters often switch to cluster C6, which support our hypothesis of subsequent game configurations to the aim of finding the best positioning for a good shot: the best positioning to shot is that in C6 moments.

4 Conclusions

In recent years, the availability of ‘big data" in Sport Science increased the possibility to extract insights from the games that are useful for managers and coaches, as they are interested to improve their team's performances. In particular, with the advent of Information Technology Systems, the availability of players' trajectories permits to analyse the space-time patterns with a variety of approaches. With this paper we pursue the points raised by Metulini et al. [9] as suggestions for future research, by analyzing multiple professional games and relate clusters with team shooting performance. We segmented the game into phases of play and we characterized each phase in terms of spacing structure among players, relative distances among them and whether they represent an offensive, a defensive or a transition play, finding substantial differences among different phases. Moreover, we analysed this structure in terms of shooting performance, finding the cluster corresponding to the best shooting performance. These results shed light on the potentiality of data-mining methods for players' movement analysis in team sports. In future research we aim to better explain the relation between players' positioning and team performance, adding more play-by-play data and analysing this relationship for a larger amount of time and for multiple matches.

Supporting Regional Policies through Small Area Statistical Methods

Survey-weighted Unit-Level Small Area Estimation

Jan Pablo Burgard and Patricia Dörr

Abstract For evidence-based regional policy making, geographically differentiated estimates of socio-economic indicators are the basis. However, national surveys are often conducted under a complex sampling design due to diverse reasons. Often small sample sizes result within regions of interest leading to too inefficient classical design-based estimators for policy making. In this case, the methodology of small area estimation (SAE) is applicable. Classical SAE relies on the assumption of a multi-level regression model underlying the population data and presumes the sample design to be non-informative. These assumptions are hard to verify in practice. Under an informative sample design, estimated regression parameters are biased and the model-consistency of SAE gets lost. We correct for the sample informativeness in the parameter estimates, and construct design- and model-consistent estimates for regional indicators. Besides the estimation procedure we also propose a MSE estimator. In a simulation study, we illustrate the necessity of survey weights under the violation of typical SAE assumptions. Furthermore, we show that the proposed method is also applicable to generalized linear mixed model settings, allowing also for non-continuous dependent variables.

Key words: Small area estimation, generalized linear mixed models, survey-weighting

1 Introduction

National Statistical Institutes often conduct surveys using a complex survey design, either due to costs or due to optimality considerations at the national level. This may lead to small sample sizes in certain geographic regions for which an estimate can be of interest, though. Small sample sizes lead to high variances of the classical design-based estimators and lead to the tradional set-up of the small area estimation (SAE) framework. In SAE borrowing strength across small domains and thus an increased efficiency is attained using a regression model. The inclusion of a random effects term - whose realization is area-specific - the regression model is called mixed. SAEs are usually composite of such random effects predictions and the realized sample's estimate. However, when the model - that is estimated on the realized sample - does not correspond to the population model for some reason, these procedure returns biased estimates. Complex survey designs or model misspecification may contribute to such non-correspondence between the sample and population model. In general, survey weights contain information about the sampling design and thus, their inclusion in the regression model component can reduce possible model bias.

We consider the case where the mixed model is estimated on the sampling unit, i.e. unit-level SAE in the sense of [2]. Usually, estimation is done using the sample log-likelihood, which requires integration over unit-likelihoods in a given area such that unit-specific weighting is not straight forward (cf, for example [13]). Existing proposals require units sharing one random effect to have the same weight, because the likelihood is expressed as a nested integral and elements within an integral cannot be weighted differently. This implies that the random effects structure reflects the sampling clustering and thus are nested [12], [13]. This is quite restrictive and furthermore, access to sampling stage specific inclusion probabilities is seldom for final data users. Therefore, a more general estimation procedure that allows for crossed and nested random effects and that requires only final survey weights is needed. The Expectation-Maximization (EM) methodology ([5]) that is applicable to mixed effects models in general ([7]) provides a framework that is applicable to these needs. However, as one could also think of dependent variables stemming from other exponential family distributions such as binary or count data, we employ a Monte-Carlo version (Monte-Carlo EM algorithm, MCEM) that replaces the E-step by a Monte-Carlo approximation ([10], [3]). The specific survey-weighting application is outlined in [4].

Section 2 introduces the algorithm and turns on problems of the MC-integration. Section 3 handles consistency considerations and Mean Squared Error (MSE) estimation. Afterwards, a simulation study demonstrates the possible gains of the survey-weighted SAE estimator. The final section discusses possible further research and concludes.

2 Proposed Estimators

2.1 Likelihood Set-up

We use the Monte-Carlo EM-algorithm adapted to survey-weighted Generalized Linear Mixed Models (GLMMs) as proposed in [4]. Here, we give a brief review of the set-up from which the SAE point estimator result. Consider as data generating process (DGP) a GLMM described through

$$\eta_i = \mathbf{x}_i^T \beta + \mathbf{z}_i^T \gamma \tag{1}$$

$$\mu_i = g(\eta_i) \tag{2}$$

$$Y_i \sim F(\mu_i, \varphi) \tag{3}$$

$$G \sim N(\mathbf{0}, \Sigma) \quad , \tag{4}$$

where γ is a realization of the mulitvariate normal random variable G (with normal density function $\phi(\cdot|\sigma)$), $X = (\mathbf{x}_1, \ldots, \mathbf{x}_N)^T$ and $Z = (\mathbf{z}_1, \ldots, \mathbf{z}_N)^T$ being matrices of explanatory variables in $\mathbb{R}^{N \times p}$ and $\mathbb{R}^{N \times q}$ respectively, β a superpopulation parameter vector of fixed effects and F a distribution from the exponential family. Consequently, g denotes the inverse link function between expectation μ_i and linear predictor η_i. We consider here the canonical link functions under which

$$\log f(y_i, \eta_i) = \frac{y_i \eta_i - b(\eta_i)}{a(\varphi)} + c(y_i, \varphi) \tag{5}$$

is the logarithmic density function. The covariance matrix Σ only depends on a parameter vector σ of length $q^\star$. Define the vector of model parameters by $\psi = (\beta^T, \sigma^T)^T$. Let $\mathscr{U}$, $|\mathscr{U}| = N$ be an index set and for $i \in \mathscr{U}$, let y_i be a realization of Y_i. Then, the population log-likelihood is

$$\mathscr{L}\mathscr{L}(\mathbf{y}, \psi, \gamma) = \sum_{i \in \mathscr{U}} \log f(y_i|\gamma, \beta) + \log \phi(\gamma|\sigma) \quad , \tag{6}$$

and if the random effect vector γ was known, a natural survey-weighted version of (6) would be the Horvitz-Thompson estimator for totals ([6]). However, this is not the case. But a γ simulated from the correct distribution may serve as a plug-in and then (6) can be estimated through a HT-estimator. Repeating the simulation and averaging yields then the (model) expectation of the HT-estimator (denoted by $\mathrm{E}(\widehat{\mathscr{L}\mathscr{L}_{\mathscr{S}}})$), that is maximized in the M-step. Computational and conceptual difficulties that must be taken into account with that procedure are discussed in [4]. As the EM-algorithm applied on the expectation of the estimand of (6) converges to a saddlepoint of the likelihood and the latter is the weighted sum of strictly convex unit-likelihood: The first summand is a generalized linear model component, whose maximum likelihood (ML) estimator is unique for the canonical link (cf. [16]) and the second summand in (6) is a normal log-density, whose ML is unique, too. The proposed procedure thus converges to the maximum likelihood (ML) estimator of the population likelihood if the survey-weights reflect the selection process into the sample. In contrast, an unweighted sample log-likelihood rather converges to the ML of the *sample's* data generating process, composed of the population DGP and the sample randomization. Thus, the survey weighting may protect against some violations of the SAE assumptions (cf. [14]): A non-ignorable sample design.

2.2 SAE Estimator

Having the estimates of the model components, $\hat{\psi}$, we can define our estimator, a weighted unit-level estimator (wUL) of the finite population mean of variable Y. For the pairwise disjoint subpopulations $\mathscr{U}_d$, $|\mathscr{U}_d| = N_d$ and $\mathscr{U} = \uplus_{d=1}^{D} \mathscr{U}_d$, we propose three alternative estimators for the finite population mean in domain d, $\bar{y}_d = N_d^{-1} \sum_{i \in \mathscr{U}_d} y_i$. The notation $\bar{y}_d$ is chosen in order to differentiate between the expectation under the superpopulation model, μ_d, and the finite population realization, which is the focus here. The first alternative is

$$\hat{\mu}_d^{wUL} = N_d^{-1} \sum_{i \in \mathscr{U}_d} \hat{\mu}_i, \tag{7}$$

which is similar to [14, eq 5.3.7] in the linear case and [14, eq 9.4.20] for binary data. This version does not include any finite population correction, which however, might be negligible in a small area setting where the sampling fractions are rather small. Another version that incorporates the sampled observations y_i is

$$\hat{\mu}_d^{wUL} = N_d^{-1} \left(\sum_{i \in \mathscr{U}_d} \hat{\mu}_i + \sum_{i \in \mathscr{S} \cap \mathscr{U}_d} (y_i - \hat{\mu}_i) \right). \tag{8}$$

In both equations, $\hat{\mu}_i$ is the prediction of individual i's variable Y_i expectation under the estimated vector $\hat{\psi}$ and the mode $\hat{\gamma}$ of the weighted sample likelihood under $\hat{\psi}$

$$\hat{\mu}_i = g(\mathbf{x}_i^T \hat{\beta} + \mathbf{z}_i^T \hat{\gamma}), \tag{9}$$

where the random effects only can be predicted for those areas that have at least one observation in the sample. In the LMM setting, (8) is a generalization of the classical unit-level estimator introduced in [2], which only incorporates a random intercept and does not include any additional survey information. That means, in [2], the survey weights are considered to be equal across areas and units.

Another option for SAE would be a model-assisted version

$$\hat{\mu}_d^{wUL} = N_d^{-1} \left(\sum_{i \in \mathscr{U}_d} \hat{\mu}_i + \sum_{i \in \mathscr{S} \cap \mathscr{U}_d} w_i (y_i - \hat{\mu}_i) \right). \tag{10}$$

Estimator (10) is similar to the Generalized Linear Regression Estimator proposed in [15] and [8] in the logistic regression setting. However, note that the version (10) is based on a GLMM in lieu of GLM and incorporates area-specific information through the random effect prediction $\hat{\gamma}$, which makes this model-assisted estimator especially applicable to SAE settings.

2.3 MSE Estimation

As our proposed estimators are smooth functions of ψ and γ, asymptotic MSE estimation fits into the framework of [11] who even deal with non-smooth SAE estimators for poverty analysis. Therefore, under the (common) regularity conditions given in [11] (that we also partially assume in the previous sections in order to establish design-consistency of the point estimators), an asymptotic MSE of (10) consists of the design variance of the model residuals in the domain under consideration. For the model-based estimators (7) and (8), however, MSE estimation is more difficult. We suggest a first-order Taylor approximation of the predictions $\hat{\mu}_i$ at the population parameters $(\beta^{pop}, \gamma^{\star})^T$ - $\gamma^{\star}$ being the population likelihood mode and then calculating the variance of the linearized predictions. This requires variance estimators for the fixed effects estimates and the random effect predictions. [9] gives a formula on how to approximate the Hessian of the observed data matrix in the EM-algorithm and its application for the fixed effects parameter is also proposed in [3]. A lower bound of the prediction error of $\hat{\gamma}$, on the other hand, is the inverse Hessian of the log-likelihood evaluated at the ML-estimates of $\hat{\beta}$. An approximation of the inverse Hessian is readily available from the specific MCEM-estimation algorithm discussed in [4]. However, note that this suggestion is only a lower bound for MSE estimation and hold only asymptotically.

3 Simulation Study

We present a small simulation study in order to demonstrate the necessity of survey-weighting when the non-informativeness assumption is violated. We therefore generate a fixed population $\mathscr{U}$, $|\mathscr{U}| = 3000$ under the following superpopulation model where the population is made up of 50 pairwise disjoint domains $\mathscr{U} = \dot{\cup}_{d=1}^{50} \mathscr{U}_d$, $|\mathscr{U}_d| = 60$, and $X_1 \sim N(6, 3^2)$ and $X_2 \sim \text{Exp}(3)$. The DGP is

$$\eta_i = 30 - 3x_{1,i} - 8x_{2,i} + \gamma_d, \quad i \in \mathscr{U}_d \tag{11}$$

$$\gamma_d \sim N(0, 2^2) \tag{12}$$

$$\mu_i = g(\eta_i), \qquad g \in \{\text{id}, \text{logit}^{-1}\} \tag{13}$$

$$Y_i \sim \begin{cases} N\left(\mu_i, (2.3)^2\right) \\ \text{Ber}(\mu_i) \end{cases} . \tag{14}$$

We draw $B = 1500$ (equally allocated) stratified samples $\mathscr{S}$ of size $n = 200$ of a finite population generated in this way. Consequently, $\mathscr{S} \cap \mathscr{U}_d = \mathscr{S}_d$ and $|\mathscr{S}_d| = n_d = 4$. This is a relatively easy set-up and if the sampling design is non-informative, the estimation conditions for the BHF ([2]) are optimal.

We contrast a πps design (which is under the correct model specification non-informative) where the inclusion probability π_i for a unit in domain d equals

$$\pi_i = \max\left\{\frac{x_{2,i}}{\sum_{j\in\mathscr{U}_d} x_{2,j}} \cdot n_d, 1\right\} \tag{15}$$

and an informative design where the inclusion probability of unit i in domain d is calculated in three steps:

$$e_i = y_i - \mu_i \tag{16}$$

$$q_i = \begin{cases} 0.1 \text{ if } e_i \text{ is below the 0.25 quantile} \\ 0.2 \text{ if } e_i \text{ is between the 0.25 and 0.5 quantile} \\ 0.4 \text{ if } e_i \text{ is above the 0.5 quantile} \end{cases} \tag{17}$$

$$\tilde{\pi}_i = \max\left\{\frac{q_i}{\sum_{j\in\mathscr{U}_d} q_j} \cdot n_d, 1\right\} \quad . \tag{18}$$

As observations with a bigger residual tend thus to be oversampled, the intercept estimator of the unweighted model estimation is expected to be overestimated which in return should yield biased predictions.

We compare the proposed estimator (8) (that has conceptually the closest similarity to the traditional BHF) to the Generalized Regression estimator (GREG), the BHF estimator and another survey-weighted SAE estimator, the You-Rao estimator (YR, cf. [17]). In the case of the binary outcome, we consider the logistic regression estimator (LGREG, cf. [8]), too, and the BHF is estimated like (8), but the underlying regression is a generalized linear mixed model estimated with the R-Package `lme4` ([1]). Due to construction, the GREG and the YR estimate a linear model for the binary outcome, too.

The quality criteria that we assess are the relativeempirical bias and the relative empirical mean squared error (MSE) of an estimator $\hat{\mu}$ over all domains:

$$\text{relBias} \quad = \tfrac{1}{50}\sum_{d=1}^{50} \tfrac{1}{1500}\sum_{b=1}^{1500} \tfrac{\hat{\mu}_{d,b}-\mu_d}{\mu_d} \tag{19}$$

$$\text{relMSE} = \tfrac{1}{50}\sum_{d=1}^{50} \tfrac{1}{1500}\sum_{b=1}^{1500} \left(\tfrac{\hat{\mu}_{d,b}-\mu_d}{\mu_d}\right)^2 \tag{20}$$

Results are listed in table (1). The results under the non-informative design and the gaussian outcome variable are standard: Survey-weights are not needed for consistent estimation and inflate the estimators. Consequently, the BHF is the most efficient estimator with respect to relative mean squared error. However, we note that the loss of efficiency when applying survey weights is low and thus might be recommended as the model assumptions are usually not verifiable. Furthermore, we find that the proposed estimator wML can compete with YR.

Under a binary variable of interest, we find that results are similar to the linear mixed model case and both GREG and YR perform well though they employ a linear regression model. Nonetheless, the LGREG is the less biased estimator and has a lower relative MSE than the GREG.

Table 1 Simulation Results

Sampling design	Outcome Variable	Estimator	relBias	relMSE
Non-informative	Normal	GREG	0.00457	0.10959
		wML	0.00974	0.0248
		YR	0.0212	0.02504
		BHF	0.01264	0.01759
	Binary	GREG	0.00466	0.07273
		LGREG	0.00242	0.02196
		wML	0.00682	0.00456
		YR	0.01076	0.00752
		BHF	0.00647	0.00454
Informative	Normal	GREG	0.00312	0.04289
		wML	0.04555	0.02394
		YR	0.05136	0.02402
		BHF	0.12068	0.03189
	Binary	GREG	0.00594	0.04658
		LGREG	0.00742	0.02256
		wML	0.02744	0.00564
		YR	0.05692	0.01108
		BHF	0.06463	0.01033

Under the informative sampling design, results change remarkably, though. As expected, the unweighted traditional BHF has an unacceptable high relative bias, although the relative MSE may compete with the GREG. In the continuous dependent variable case, wML and YR return comparable results. But when the dependent variable is binary, the suggested method outperforms BHF due to the inclusion of survey weights and the YR due to the GLMM framework employed. Thus, wML gives any of the four presented cases a good balance between bias and variance.

4 Conclusion

In this paper, we propose the use of a GLMM estimation framework that allows the inclusion of unit-specific survey weights in the estimation process in order to protect unit-level based SAE estimators against sampling informativeness. A linearization and/ or residual based MSE estimation of the suggested estimators is discussed. Finally, a simulation study demonstrates the necessity of survey weights in the model estimation step in order to reduce the SAE estimators' bias, both in a continuous variable set-up as well as for a binary variable of interest. We find that the loss in efficiency when survey weights need not be included in the model estimation but are nonetheless, is marginal. In contrast there are important gains when the sampling is informative. To conclude, we would like to note that the informativeness of the survey design is hard to verify in real world application and may also depend on the analyzed variable. Thus, we highly recommend the inclusion of survey weights in SAE analysis.

Robust and model-assisted small area estimation methods: an application to the Banca d'Italia Survey of Industrial and Service Firms

Stimatori robusti e assistiti dal modello nelle piccole aree: un'applicazione ai dati dell'indagine Banca d'Italia Survey sulle Imprese industriali e dei servizi

Bottone Marco, Casciano Maria Cristina, Fabrizi Enrico, Filiberti Salvatore, Neri Andrea and Salvati Nicola

Abstract The Banca d'Italia survey of Industrial and Service Firms gathers information many relevant economic variables relating to Italian industrial and service firms with 20 or more employees. In paper we study small area estimation of parameters describing sub-populations of this survey. We consider small area models based on specifying a regression model for the relationship between the target and the auxiliary variable at the unit (firm) level. As normality is likely to fail because of skewness and the presence of outliers we focus on robust methods and specifically on M-quantile regression methods as they allow for the estimation of pseudo-area effects without recourse to any distributional assumptions. Our approch is model assisted in the sense that although motivated by regression models are evaluated with respect to design-based properties.

1 Introduction

The accurate estimation of aggregates such as total or average turnover, investments, value added for subsets (domains) of the population of small and medium enterprises is very relevant to to the economic debate and policies.

Estimates obtained from the Banca d'Italia survey of Industrial and Service Firms are of special relevance because of the Bank institutional role. Estimates produced in the framework of this survey are reliable for the nation as a whole or large domains. The Banca does not publish or use in outlook analyses estimates for sub-population smaller than those for which reliable design-based estimates are available. In the survey data analysis when when estimates are needed also for small domains small methods can be helpful. This research is part of a project aimed at exploring a suitable small area methodology for the survey of Industrial and Service Firms.

The key idea behind small area estimation is that of complementing sample data with auxiliary information obtained from external sources. This can be done in several ways: we assume that auxiliary information is in the form of known totals or means for variables that are recorded also in the sample and that can be used to predict the variables of interest provided that a regression model express them as function of the auxiliary.

For a review of recent applications of small area estimation methods to business data see [5].

In this paper we are interested in a model-assisted approach, which means that, altough motivated by a regression model, the small area estimators make use of survey weights and are evaluated with respect to design properties. Specifically, we want the estimators to be design-consistent, a form of guarantee against possible model failures when the sample size is from moderate to large. Various small area estimators with good design properties have been proposed in the literature. The interested reader can find a review in [4].

A well known estimator in this class is the adaptation of the GREG to small area estimation (sae-GREG) reviewed in [7], (section 2.5). This estimator is design-unbiased but suffers from two limitations: it is very efficient and it is not robust to outliers that are quite often met in the analysis of business data.

A design-consistent estimator relying on the theory M-quantile regression [2] was proposed by [4]. This estimator is robust-projective in the sense of [3], is characterized by a small bias as the sae-GREG, but somewhat more efficient as it accounts for *area heterogeneity*. Its very small bias is nonetheless paid at the price of instability (relatively high mean square error) when large outliers are present. This problem has been studied by [3] who proposed robust-predictive estimators to improve efficiency of bias-corrected M-quantile estimators at the price of a moderate bias increase.

In this research we extend the [3] methodology, that was proposed in a model-based framework, to the model-assisted approach. This new methodology is applied to the analysis of a data set from the Banca d'Italia survey of Industrial and Service Firms. Although the data are real, the application is only for explorative purposes. We also present the results of a limited simulation exercise.

2 The Banca d'Italia survey of Industrial and Service firms

Banca d'Italia conducts the Survey of Industrial and service firms (INVIND, thereafter) since 1972 to collect yearly information on investments, gross sales, workforce, expectations and other economic variables relating to Italian industrial and service firms. From 2002 onwards, the sample is made up of about 4000 companies. The survey adopts a cut off stratified sample design. The sample excludes all units that have less than 20 employees. Strata are combinations of branch of activity, size class (in terms of number of employees) and region in which the firm's head office is located. Firms with more than 5,000 employees are self-representative units. Firms that have been interviewed in past waves and which are still in the target population are always eligible for a new interview. The survey was initially designed to produce accurate estimates at national level of total turnover and investments.

Recently, the Italian National Statistical Institute (Istat) has created a new statistical register for the annual production of profit-and-loss accounts of small and medium enterprises (SMEs). This register, called Frame SBS, makes use of firm-level administrative and fiscal data as primary sources of information to annually estimate the main variables of the economic accounts of Structural Business Statistics (SBS), while the traditional survey on SMEs is used as complementary source of information for estimating those variables which cannot be directly obtained from administrative sources. We use the Frame SBS register as a source of auxiliary information for our analysis.

3 Three model-assisted small area estimators

Suppose that, from a population U partitioned into m domains $U_1,\dots,U_i,\dots,U_m$ a sample s is drawn according to a possibly complex design; the design is characterized by first order inclusion probabilities π_{ij}, $(j = 1,\dots,n_{s_i}, i = 1,\dots,m)$ and sampling weights $w_{ij} = \pi_{ij}^{-1}$. Let's denote with $s_1,\dots,s_i,\dots,s_m$ the domain-specific samples. Although unplanned, we assume for simplicity that $|s_i| > 0$. Let y_{ij}, $\mathbf{x}_{ij}$

denote the sample values for the target and a p-vector of auxiliary variables for which we also assume that $\bar{\mathbf{x}}_i = N_i^{-1}\sum_{j\in U_i}\mathbf{x}_{it}^T$ are known from an external source. We assume that the target of our inference is $\bar{Y}_i = N_i^{-1}\sum_{j\in U_i} y_{ij}$.

Among the many model-assisted small area estimators proposed in the literature, we review those relevant to this paper. A first example in this class is the adaptation of the popular sae-GREG estimator discussed in [7] (section 2.5):

$$Y_i^{greg} = N_i^{-1}\sum_{j\in U_i}\mathbf{x}_{it}^T\hat{\beta}_w + N_i^{-1}\left\{\sum_{j\in s_i} w_{ij}(y_{ij}-\mathbf{x}_{ij}^T)\hat{\beta}_w\right\} \qquad (1)$$

where $\hat{\beta}_w = \left(\sum_{j\in s_i} w_{ij}\mathbf{x}_{ij}\mathbf{x}_{ij}^T\right)^{-1}\left(\sum_{j\in s_i} w_{ij}\mathbf{x}_{ij}y_{ij}^T\right)$. The first addend in (1) is a *synthetic* estimator that it is very likely to be have a small variance, but a potentially large bias as it does not consider any area heterogeneity beyond that explained by the auxiliary variables. Moreover the estimator β_w can be unduly influenced by outliers. The second addend corrects the ponential bias, but in doing so, it will produce an higher MSE. [7] notes that, for this reason the GREG is not very efficient and its variances is of order $O(n_{s_i}^{-1})$.

In a line of research stemming from [2], [4] propose an estimator based on M-quantile regression theory. An introduction to M-quantile regression and its application to small areas is beyond the scope of this short presentation. The interested reader is redirected to the last two quoted papers. We simply note how the recourse to M-estimation instead of plain quantile regression adds a degree of freedom in selecting the level of robustness we want for our procedure: it can be less or more than ordinary quantile regresssion according to the choice of an influence function $\psi(.)$. The estimator of [4] is as follows:

$$Y_i^{WMQ} = N_i^{-1}\sum_{j\in U_i}\mathbf{x}_{it}^T\hat{\beta}_{w\bar{\theta}_i} + N_i^{-1}\left\{\sum_{j\in s_i} w_{ij}(y_{ij}-\mathbf{x}_{ij}^T)\hat{\beta}_{w\bar{\theta}_i}\right\} \qquad (2)$$

The difference between (2) and (1) is in the slope coefficient. $\hat{\beta}_{w\bar{\theta}_i}$ is a design-consistent quantile-specific slope estimator (see [4], theorem 1) referred to the $\bar{\theta}_i$ quantile. This quantile is chosen assuming that, if there is area heterogeneity in the regression residuals, units within the same area will lie on close quantile regression planes. Thereby, observation specific quantiles are calculated for all sample observations from the same area and then averaged. The first addend in (2) is a *robust projective* synthetic estimator that projects sample non-outliers in out-of-sample prediction, while the second addend is a bias correction similar to that of (1). The estimator (2) is more efficient than (1) in most situations as the choice of an area-specific quantile regression plane incoroporates the idea of *borrowing strength* across areas. Nonetheless, the bias correction, although very effective is liable to the effect of outliers and reduces efficiency.

[3] introduce a new quantile based estimator that is *robust projective* in the synthetic component and *robust predictive* in the bias correction. The idea is to robustify the bias correction in order to curb down the impact of big outliers according to some influence function $\phi(.)$ with suitable properties. The methodological puropose

of this paper is to extend this estimator, that was developed in the context of a model based framework to the model-assisted approach:

$$Y_i^{WMQ-bc} = N_i^{-1} \sum_{j \in U_i} \mathbf{x}_{it}^T \hat{\beta}_{w\bar{\theta}_i} + N_i^{-1} \left\{ \sum_{j \in s_i} w_{ij} \hat{\sigma}_i \phi \left(\frac{y_{ij} - \mathbf{x}_{ij}^T \hat{\beta}_{w\bar{\theta}_i}}{\hat{\sigma}_i} \right) \right\} \qquad (3)$$

In the second addend of (3), $\phi(.)$ is a bounded monotone non-decreasing function over the real line with $\phi(0) = 0$ and $\hat{\sigma}_i = median|y_{ij} - \mathbf{x}_{ij}^T \hat{\beta}_{w\bar{\theta}_i}|/0.6745$. With respect to the influcence function implicitly adopted in the estimation of $\hat{\beta}_{w\bar{\theta}_i}$, in line with [3] we impose $|\phi(.)| \geq |\psi(.)|$.

With the same assumptions and regularity conditions assumed by [4] it can be proved that (2) is a design-consistent estimator of $\bar{Y}_i$.

As for the variance estimation, in view of the nearly unbiasedeness of (1) and (2) the simple weighted residuals estimator of [8] can be used provided second order inclusion probabilities are available. [4] prove that it works very well. Nonetheless in this research we use the bootstrap procedure illustrated in [4]. Also for (3) [3] introduced an analytical estimator that can be extended to the model assisted framework. Nonetheless we consider the same boostrap procedure as before.

4 A simulation exercise

In this Section we report results from a simulation that is based on the the Australian Agricultural and Grazing Industries Survey (AAGIS) data as in [4]. A sample of 1652 Australian broad-acre farms spread across twenty-nine regions of Australia is studied. A population of $N = 81982$ farms is generated by bootstrapping the original AAGIS sample. The synthetic AAGIS population consists of 15 variables for 81982 farms. The size of regions in terms of farms ranges from 79 to 10930. The variable of interest is the Total cash costs (`TCC`; Y); its distribution exhibits strong positive skewness. Auxiliary information available ($\mathbf{X}$) for each farm includes the total revenues received by the business during the financial year (`TTR`) and the total area of the farm in hectares (`FarmArea`); we also consider a group of six binary variables created cross-classifying the farms by climatic zone and size (`SizeZone`). We use two combinations of auxiliary variables to obtain two models with different values of R^2 calculated upon fitting an ordinary linear regression model: 1) low linear relationship with $R^2 = 0.40$ ($\mathbf{X}_1 = $ (`SizeZone,FarmArea`), `low` scenario), 2) high linear relationship between Y and $\mathbf{X}_2 = $ (`SizeZone,TTR`), $R^2 = 0.90$ (`high` scenario). Note that this strong correlation between Y and $\mathbf{X}_2$ is not due to the presence of outliers, as the inclusion of `TTR` reduces their size.

Samples are selected according to a fixed size, unequal probability without replacement sampling design using the maximum entropy method [9] implemented in the `Sampling` package [10] in `R`. We consider a sample size of $n = 578$ corresponding approximately to a 0.7% sampling rate. Two alternative sets of inclusion probabilities are defined to be proportional to two different size variables Z: *i*) livestock (beef, sheep and wool - `livestock`) and *ii*) a Uniform variable on the interval $(1,20)$. More specifically, in case *i*), we define $\pi_j = 0.2 \times z_j + 0.05$, $\forall j \in U$ to avoid that too many inclusion probabilities are equal to one. In our setting the first scenario is labelled non-ignorable design while the second one is called ignorable design.

The estimators of the small area means that we compare are the proposed bias corrected weighted M-quantile estimator (3), the weighted M-quantile estimator (2), the 'direct' estimator, the unweighted M-quantile estimator (MQ) and the sae-GREG estimator (1). The 'direct' estimator of the mean is a Hájek type estimator, i.e. $\hat{\bar{Y}}_i = \sum_{j \in s_i} \breve{w}_{ij} y_{ij}$. Note that for the M-quantile model the ψ function is set to be the Huber Proposal 2 with $c_\psi = 1.345$. If the reader would like to compare the performance of the estimator in the simulation experiment with other predictors that use sampling weights, as the pseudo-EBLUP estimator [12] and the GREG-LV estimator [6], see the results in Table 1 in [4].

The Monte-Carlo experiment consists of drawing $R = 5000$ samples from this population and calculating small area estimates of the mean of `TCC`. The performance of the different small area estimators is evaluated using the relative bias (RB) and the relative root mean squared error (RRMSE) of estimates of the small area parameters. The averages across the areas of the RB and RRMSE are reported for the considered estimators and the two scenarios in Tables 1. The comparisons include also an estimator labelled as MQ, which a the unweighted M-quantile regression based small area estimator that ignores the design. It is defined in [11].

Focusing on the proposed estimator we observe that, as expected, it shows a small bias. The WMQ is nearly design unbiased. We note that average relative biases are higher for the unweighted estimator (MQ) or for estimators that include unweighted components such as GREG-LV and pseudo-EBLUP, and this is particularly true when the design is non-ignorable. In terms of RRMSE, the proposed bias corrected predictor WMQ-bc is the most efficient estimator.

Table 1 Design-based simulation results using the AAGIS data. Results show the mean Relative Bias (RB) and Relative Root Mean Squared Error (RRMSE) averaged across areas under the two scenarios.

Predictors	Average RB			
	non-ignorable design		ignorable design	
	`low`	`high`	`low`	`high`
MQ	10.13	7.86	-0.34	-0.83
WMQ	-0.41	0.84	-0.58	-0.59
WMQ-bc	-2.88	-0.79	-4.28	-2.63
sae-GREG	-0.21	1.54	-1.23	-0.22
Direct	1.01	1.01	-0.91	-0.91
	Average RRMSE			
MQ	27.53	20.23	18.43	14.13
WMQ	26.79	15.09	21.72	15.94
WMQ-bc	21.84	14.03	19.65	13.71
sae-GREG	35.59	16.73	25.40	16.86
Direct	40.35	40.35	35.43	35.43

5 Application to Banca d'Italia's data and discussion

In this section we compare the Horwitz-Thompson and the three model assisted design based estimators of Section 3 in two exercise data set with data from the Banca d'Italia survey of Industrial and Service firms. In both datasets we define domains to be a cross-classification of firms below 5000 employees by geography (19 regions), 2 sectors (industry, services) and size (below and above 100 employees). The target parameter is given in both cases by the average turnover.

In the first dataset the covariate is given by the lagged turnover (whose population total becomes available from the Frame SBS archive with delay with respect to survey data collection and analysis). This is a situation where a very powerful linear predictor is available ($R^2 = 0.98$, although influenced by points with high leverage). This scenario is called `high`.

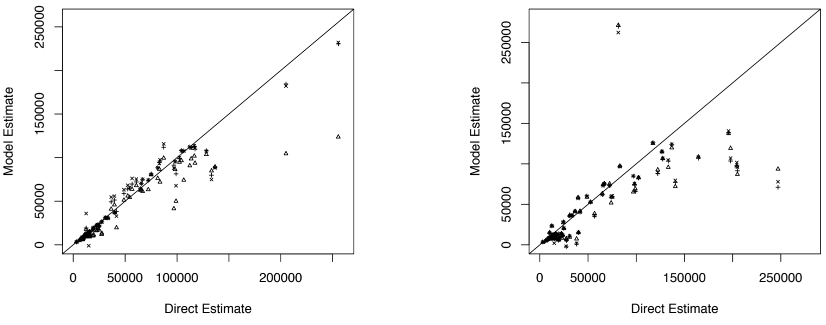
In the second dataset the covariate is given by the number of employees, a much weaker predictor of the turnover ($R^2 = 0.32$). This latter situation will allow us to explore what happens when, with a weaker predictivity, non-normality of the residuals' distribution and outliers are more likely. This scenario is called `low`.

In Table 2 we report the mean values across areas of the ratios of the estimated MSE of the WMQ, WMQ-bc and sae-GREG estimators to the estimated MSE of the direct estimator. The MSEs are estimated using the bootstrap procedure by [1]. In both scenarios the ordering of the MSEs is the same, with WMQ-bc being the most efficient. The scale of the efficiency improvement depends of course on the predictivity strength of the auxiliary information. The sae-GREG performs quite well relatively to the WMQ because in this application the intra-cluster correlation, i.e. area heterogeneity of the residuals is apparently small.

Table 2 Mean values across areas of the ratios of the estimated MSE of the weighted M-quantile (WMQ, WMQ-bc) and saeGREG estimators to the estimated MSE of the direct estimator.

Predictors	Scenario	
	`low`	`high`
WMQ	0.855	0.158
WMQ-bc	0.581	0.101
sae-GREG	0.918	0.182
Direct	1.000	1.000

Figure 1 compares the model-based estimates of the average turnover for each small area with the corresponding direct estimates. We note that the WMQ-bc estimates appear to be generally consistent with the direct estimates, with the correlation between the two sets of estimates being 0.92 in the low case and 0.95 in the high scenario. The corresponding correlation between the direct estimates and the WMQ estimates is 0.97 in low case and 0.94 in high case. Few remarkable differences can be seen on the right of both plots: they correspond to areas characterized by the presence of big outliers in the residuals. Curbing down these outliers can introduce some bias but protects estimates from instability that may translate in large year to year variations when these units enter or leave the sample.



(a) (b)

Fig. 1 Direct estimates versus corresponding WMQ (+), WMQ-bc (△) and sae-GREG (×) estimates in low (a) and high (b) scenarios.

The Second Generation at School

Resilient students with migratory background

Studenti resilienti di origine immigrata

Anna Di Bartolomeo and Giuseppe Gabrielli

Abstract Numerous research has shown that there is direct relationship among high educational outcomes, employment, income and integration. Immigrants' children do show, on average, lower educational performances than natives' ones in addition of being more socio-economically disadvantaged. Countries' success in helping and integrating immigrants' children needs to find new educational policies and strategies. Using PISA survey data, we aim at providing further elements of discussion looking at "resilient" students. Given the strong impact of the students' social, cultural and economic family background, we aim at analysing how "disadvantaged" students can overcome their socio-economic and cultural obstacles and achieve good educational performances. Applying multilevel logit models, the paper analyses the factors linked to the probability of being resilient with a focus on parental and individual motivations and on school characteristics.

Abstract *Numerose sono le ricerche che hanno mostrato nel tempo la relazione diretta esistente tra rendimento scolastico, occupazione, reddito e integrazione. I figli di immigrati hanno, in media, un rendimento scolastico inferiore a quello dei figli di autoctoni e vivono in famiglie socio-economicamente svantaggiate. Sono necessarie nuove strategie e politiche in grado di raggiungere un miglior inserimento scolastico dei figli di immigrati. Utilizzando i dati dell'indagine PISA, lo scopo del presente lavoro è fornire ulteriori elementi di discussione analizzando gli studenti "resilienti". Nello specifico, l'intento è quello di definire come gli studenti, con un basso background socio-economico delle famiglie di origine, possano raggiungere risultati scolastici positivi. Applicando modelli logistici multilivello, sono analizzate i principali fattori legati all'essere studenti resilienti considerando nello specifico le motivazioni individuali e genitoriali e le caratteristiche scolastiche.*

Keywords: integration, second generation, school performances, resilience, multilevel

1 Introduction

Many studies in Europe have been devoted to the educational outcomes and social mobility pathways of immigrant descendants [among the others, 3, 7]. International research showed that positive educational paths and successful integration of immigrants' descendants promote social cohesion and development. There is direct relationship between high educational outcomes, employment, income and health.

However, immigrants' children have, on average, lower educational performances than natives' children in addition of being more socio-economically disadvantaged [8, 13]. When compared to their native peers, children of immigrants exhibit important signs that they are experiencing difficulties when integrating into the school system. These signs include more frequent school dropouts, less effective performances, and higher concentration of children of immigrants in vocational high schools where students enter the labour market immediately [3]. Scholars have tried to explain the worst immigrants' educational performances [among the others, 6, 11]. However, after controlling for variables at the individual level and the school level, differences between migrants and natives' children are still significant in different European countries [10, 11].

Countries' success in helping and integrating immigrants' children needs to find new educational policies and strategies to remove obstacles to student achievement and to help immigrant students fully develop their potential.

On average across OECD countries, students with migratory background are socio-economically disadvantaged compared to native students. Differences in socio-economic status explain over one-fifth of the gap between students with and without migratory background in the likelihood of obtaining academic skills [14]. It is debatable how disadvantaged students can overcome these obstacles and achieve good performance. Although most applied work identifies socio-economic disadvantage as a risk factor for poor academic performance [among the others, 15, 16], some disadvantaged (resilient) students beat the odds against them and achieve good academic.

Using PISA survey data, we aim at providing further elements of discussion looking at "resilient" students. Applying multilevel logistic models, we analyse the main determinants to be resilient students in EU countries considering both individual motivations and school resources by sex and migratory background. Resilient students are compared to other disadvantaged low achievers in order to individuate the main factors (such as environment, individual ability or motivation ability) to achieve positive school performances among "disadvantaged" students with immigrant background.

Which are the determinants associated with the probability of being resilient? What role is played by individual and parents' aspirations in having positive educational performance? Do schools' characteristics, activities and resources policies make a difference? To what extent do such patterns differ between children of natives and children of immigrants?

2 Data and methods

Data come from the Programme for International Students Assessment (PISA) dataset carried out in 2015 and developed by the Organisation for Economic Co-operation and Development (OECD). The Italian survey involves 11,583 students aged 15+ (15.8% with migratory background) attending 474 schools.

The PISA survey is conducted every three years with the aim of assessing the educational achievement of fifteen-year-old students in the most advanced economies. These cognitive skills are measured through standardized tests which aim not only at testing pupils' theoretical competencies but also – and especially – at assessing whether pupils are ready to enter their adulthood. These tests are later evaluated and synthesised into a continuous scale by a pool of international experts through the *Item Response Theory* (IRT), which gives five plausible values of pupils' performance for each student [12]. For the sake of country comparability, these scores are then standardized to an international mean of 500 and a standard deviation of 100.

Apart from test scores, data from students, parents and school characteristics were collected in separate questionnaires. A major limitation of PISA surveys relies, instead, on the fact that in Italy there are no detailed info on students' country of origin while it is well known as origin is likely to strongly affect immigrants' children trajectories in several fields.

Methodologically, the paper is based on multilevel regression analyses. This methodology is one of the most suitable methods for interpreting this interaction between levels [9] and frequently used in the analysis of student performances and behaviour patterns as it allows to understand the different levels in which students are grouped: classes, schools and educational systems [among the others, 7, 10].

In order to identify the – individual and school – determinants associated to the probability of being a resilient, a two-level logistic random intercept model is adopted. Specifically, we run the following model:

$$logit\{P[y_{ij} = 1|x_{ij},\zeta_j]\} = \beta_0 + \beta_1' x_{1ij} + \beta_2' x_{2j} + \zeta_{j,}$$

where y_{ij} is the response for student *i* in school *j* (y_{ij}=1 if i-th student in j-th school is resilient, y_{ij}=0 otherwise); x_{1ij} are the individual level covariates for student *i* in school *j*; x_{2j} are the school level covariates for school *j*.

Two separate models are run for children of immigrants and children of natives, respectively, for assessing – if any – immigrants' children specificities. Both models do only include students from a low socio-economic background (disadvantaged students), i.e. those with an ESCS index below the 40th percentile of whole distribution. The dependant variable equals 1 when students are resilient, i.e. when achieving performance higher or equal the 60th percentile and 0 when students are not resilient, i.e. do achieve performance below the 60th percentile. The performance subject of interest is science.

Independent variables at an individual level are related to socio-demographic aspects including sex and migrant generation (in the model of immigrants' children) and to the motivation dimension including students and parents' educational aspirations. At a school level, the following dimensions were considered: a) size of the school location; b) school resources and extra-curricular activities; c) school management; d) homework support. Annex Table 1 details the construction of variables.

3 Results

Overall, the share of resilient students is higher among children of immigrants (30.6%) than among children of natives (26.9%).

The first fundamental step when launching a multilevel model is verifying whether this approach is an added-value to the analysis, i.e. making sure that the uncorrelatedness assumption in the data is violated. By the null model, it is possible to decompose variance and to appreciate the quotes of variance to be attributed to each level of analysis, as measured by the Intraclass coefficient (ICC). The higher the ICC, the higher the importance of adopting multilevel tools as most of the differences observed across subjects on the response are actually derived from group differences. In our case, the quote of variance to be attributed to the school context is very high for both populations equalling 31% for children of natives and 42% for children of immigrants. This means that belonging to one school or another produces a strong selection and that multilevel techniques are extremely useful in the analysis (especially for immigrants' children).

Table 1 reports the results of the analysis including covariates at a student and school level. At an individual level, gender and generation' effects are in line with the literature. Being male denotes a higher probability of being resilient (for both groups) while being children of mixed couples is an advantage with respect to being second-generation and (even more) to first-generation students.

As far as parental aspirations are concerned, previous studies have shown as they have a positive effect on students' performance [2]. Our study adds that they are also positively associated with the probability of being resilient and thus help overcoming socio-economic gaps. This effect is strong and significant for both groups: the odds ratios are around 2. This clearly shows that even if parents are unable to assist their children with specific subjects or skill they can still play a vital role by encouraging students' feeling of competence and positive scholastic attitudes. Conversely, it is worth noticing that individual aspirations do play a significant role only for children of natives. In the case of children of migrants, once controlled for parental aspirations, the positive effect of students' motivations disappears. This may suggest that parental role tend to assume a pivotal role in affecting students' trajectories in this group by even prevailing over individual motivations.

Table 1: Determinants of resilience among Italian students and students with migratory background. Odd-ratios and p-values of two-level logistic regression analyses.

School variables do clearly show that scholastic resources and characteristics may play the difference for developing virtuous paths. In other words, in line with other studies [1], we found that all students may profit from attending schools which develop certain kind of promoting activities and which may count on a number of resources. In particular, interestingly enough, students benefit from being inserted in schools where extra-curricular activities are promoted, regardless of whether they are related or not to science. In both groups, indeed, the probability of being resilient is positively and significantly associated with belonging to schools that develop two or more of these activities: the odd ratios of extra-curricular science activities equal 1.9 for children of migrants and 2.4 for children of natives. The same values for extra-curricular non-science activities stand at 2.1 and 2.3. Along the same line, a higher support to children to homework also provide strong benefits for being resilient. This suggest that supporting these activities – regardless of whether they are curricular oriented or not – may help students in being less reliant on their (scarce) home resources. School support thus enables to fill the gap of belonging to familiar disadvantaged conditions by enhancing positive educational trajectories.

Children outcomes are also similar with respect to the effect of selection school mechanisms: higher degree of entry-selection criteria is positively associated with the probability of being resilient especially in the case of children of migrants (odd ratio=2.4 vs. 1.3 of children of natives). The contrary occurs instead with more "authoritative" schools: the higher the principal leadership Index, the lower the quotes of resilient students.

Interesting enough are the results concerning school resources and location. As to the former, school resources have a positive effect on children of natives' resilience abilities while no effect is found for children of migrants. With respect to the latter, the only significant (positive) effect is found for children of migrants attending schools located in large cities (with more than 100thousand inhabitants).

4 Discussion

The impact of socio-economic disadvantages on educational trajectories is one of the most alarming form of inequality. Poor scholastic performance and the consequent difficulties in integrating into the labour market would indeed ensure that the unequal distribution of power resources between classes is transmitted through generations.

This is particularly worrying for immigrant families. Most migrants have low skills and lack established family businesses, accumulated wealth and long-standing local social networks. For them education represents a unique opportunity for social mobility with respect to the next generation. Success in the education system would allow their children to obtain higher-paying, higher-status jobs with a contemporaneous rise in the family's social standing [5]. In spite of this, some disadvantaged students succeed in overcoming such obstacles and achieve good performance results, i.e. the so-called resilient students.

Our main result supports the idea that, among both children of migrants and children of natives, parental motivations are a strong predictor of "resilience". Not surprisingly, parental expectations on children future careers represent a support for exiting their initial background disadvantage and well perform at school. As far as personal motivations are concerned, they result significantly associated with the probability of being resilient only for children of natives. At a school level, there seem to exist several strategies through which students can be supported in overcoming their structural socio-economic gap and develop virtuous mechanisms. Among them, extracurricular activities focusing on science topics and homework support tools seem are worth noticing. However, not only school-oriented but also extra-curricular activities do show a positive impact for both groups. The time spent in activities such as being involved in developing school yearbooks, newspapers or magazines, in participating to school musicals, art or science clubs or even sporting teams is useful in helping students to achieve good performance. This is possibly linked to the fact that taking part to these initiatives would stimulate students' cultural profiles by reducing the time they spent in less motivating familiar contexts. Interestingly enough, school material and cultural resources do represent an input only for children of natives. Conversely, children of migrants seemed to be advantaged when attending schools located in large cities. Possibly, in such big contexts, immigrants' children tend to be less stigmatized by both teachers and schoolmates by so enhancing their self-esteem and performance.

To conclude, this analysis show that motivations and schools can make the difference in overcoming social mobility inequalities within the Italian context. Accordingly, the necessity of investing on school autonomy tools for implementing more and diverse activities directed at targeted – more disadvantaged – groups seem favourable. On the other hand, it should be also guaranteed that school policies are not the privilege of few and selective schools, but to the whole scholastic population. School autonomy is positive but need to be monitored, as also suggested from the result concerning school leadership.

Annex Table 1: Description of variables.

Variable	Description

Migratory generation	It includes the following items: a) Students with one Italian parent; b) Students borne in Italy or arrived before secondary school; c) Students arrived during secondary school or later.
PISA Index of students' motivations	Students’ statements about themselves on a four-point Likert scale to the four following items: a) I want top grades in most or all of my courses; b) I want to be able to select from among the best opportunities available when I graduate; c) I want to be the best, whatever I do; d) I see myself as an ambitious person.
Parents' expectations about children scientific career	Do you expect your child will go into a science-related career? No, Yes.
Extra-curricular non-science activities	It includes the following activities: a) Band, orchestra or choir; b) School play or school musical; c) School yearbook, newspaper or magazine; d) Volunteering or service activities; e) Chess club; f) Club with a focus on computers/ Information and Communication Technology; g) Art club or art activities; h) Sporting team or sporting activities.
Extra-curricular science activities	It includes the following activities: a) Science club; b) Science competitions; c) A big share of extra-funding goes into improvement of our school science teaching; d) School science teachers are among our best educated staff members; e) Compared to similar schools, we have a well-equipped laboratory; f) The material for hands-on activities in school science is in good shape; g) We have enough laboratory material that all courses can regularly use it; h) We have extra laboratory staff that helps support school science teaching; i) Our school spends extra money on up-to-date school science equipment.
School resources	Students’ statements about themselves on a four-point Likert scale with respect to the following question: Is your school’s capacity to provide instruction hindered by any of the following issues? a) A lack of educational material (e.g. textbooks, IT equipment, library or laboratory material); b) Inadequate or poor quality educational material (e.g. textbooks, IT equipment, library or laboratory material); c) A lack of physical infrastructure (e.g. building, grounds, heating/cooling, lighting and acoustic systems); d) Inadequate or poor quality physical infrastructure (e.g. building, grounds, heating/cooling, lighting and acoustic systems).
Presence of school-entry selection criteria	It includes the following factors that are considered when students are admitted to the school: a) Student’s record of academic performance (including placement tests); b) Recommendation of feeder schools; c) Parents’ endorsement of the instructional or religious philosophy of the school; d) Whether the student requires or is interested in a special programme; e) Preference given to family members of current or former students; f) Residence in a particular area; g) Others.

Residential Proximity to Attended Schools among Immigrant-Origin Youths in Bologna

Vicinanza residenza-scuola fra i ragazzi di origine immigrata a Bologna

Federica Santangelo, Debora Mantovani and Giancarlo Gasperoni

Abstract This paper explores home-school proximity among students attending lower secondary schools and identifies student and school characteristics associated with proximity differences. After having implemented a geolocation procedure to a data-base supplied by the Italian National Institute for the Evaluation of the Educational System for Schooling and Training (INVALSI), distances between students' homes, their schools and other schools are examined for evidence of differences between native- and immigrant-origin students.

Abstract *Questo paper esplora la vicinanza casa-scuola tra gli studenti che frequentano le scuole secondarie di primo grado e individua le caratteristiche degli studenti e delle scuole associate alle differenze di distanza. Dopo aver implementato una procedura di geolocalizzazione su una base di dati fornita dall'Istituto nazionale per la valutazione del sistema educativo di istruzione e di formazione (INVALSI), viene esaminata la distanza tra la residenza dell'alunno, la scuola ad essa più vicina e la scuola effettivamente frequentata, per rilevare differenze tra studenti di origine nativa e immigrata.*

Keywords: Italy, home-school proximity, immigrant-origin students, socio-economic status

1 Home-school distance as an indicator of immigrant-origin student educational disadvantage?

This paper examines residential proximity to schools among students attending lower secondary schools in the city of Bologna, Italy, and in particular focuses on home-school distance differences between native- and immigrant-origin pupils. Several studies stress that school choice of students from lower social classes is mainly ascribable to area of residence and distance from school. More precisely, socially disadvantaged students are more likely to attend the nearest school to their home, since school selection depends more on convenience rather than on an evaluation of multiple schools' pros and cons in a medium/long-term perspective [4]. The decision may be shaped by several aspects, such as: the degree to which values, norms and beliefs are shared by parents and teachers; parents' level of understanding of the school system; economic, cultural and social resources. Since immigrant-origin students are overrepresented in working class families, we might expect that: i) they are more likely to attend the nearest school to their home; ii) immigrant-origin status is irrelevant after controlling for social origins.

Therefore, differential home-school distance is a potential indicator of school segregation mechanisms, possibly reflecting both residential separation among native and immigrant populations and more specific school-based mechanisms that reinforce (or weaken) the residential component of segregation. To this end, the analysis will distinguish between (aggregations of) neighbourhoods in the Bologna area. The main data, provided by the Italian National Institute for the Evaluation of the Educational System for Schooling and Training (INVALSI), involves a sample of about 2,000 students living and attending schools in Bologna in the 2014/15 school year. Other data is drawn from the 2011 Italian Population Census conducted by the Italian National Institute for Statistics (ISTAT).

Residence-school proximity has often been studied as a factor influencing adolescents' levels of physical activity and health [1,2], but here we reflect on its capacity to convey differences between native and immigrant-origin families' strategies as regards their children lower secondary school choices and the potential for ensuing school segregation, which has received little attention in Italy [5]. We remind readers that in Italy lower secondary education is mandatory and comprehensive in nature (vertical tracking begins with upper secondary education).

More specifically, this paper will address the following questions with a primarily exploratory approach. Do immigrant-origin children attend the closest school to the same degree as children of Italian nationality? Do they travel the same distance? Do differences vary according to area of residence within the city, and/or are they associated with other student, family or area characteristics?

The preliminary findings reported here are part of a research project titled "Social Exclusion and Selection in Lower Secondary Education: School Segregation Dynamics and Criteria Concerning Immigrant-Origin Students". The project is financed by the University of Bologna, through its Alma Idea grant programme supporting basic research. The overall aim of the project is to explore the segregation of native- and immigrant-origin students in lower secondary schools in larger cities in Central and Northern Italy, via an account of foreigners' presence in these territorial contexts, a description of how non-Italian students are distributed among schools and classes, the identification of mechanisms underlying such differential allocation, and the explanation of these mechanisms' effects on learning levels. This paper is a preliminary effort developed within this project.

2 Data and Variables

The following subsections describe the source of the data-base (and its limits) used for our analyses, as well as the dependent variables, the main explanatory variables and other covariates, and the basic data analysis strategies implemented.

2.1 Sources of data

The data primarily used in our analyses were provided by INVALSI and refer to students enrolled in the final year of lower secondary schools, in the 2014/15 school year, across 36 Italian provinces (chosen in such a way as to include major cities with a significant immigrant-origin population). The data included, most importantly, students' home addresses as well as the addresses of the schools they attended at the time, but also comprises other information, including students' native/immigrant-origin status (and, if applicable, their belonging to so-called first or second generations), gender, and other socio-demographic characteristics concerning the pupils themselves, their families, their schools and their classes. The current analysis focuses only on students living and attending schools in the city of Bologna. A major limit of the INVALSI data-base is an underrepresentation of immigrant-origin pupils as compared to the MIUR (Italian Ministry of Education) data-base, comprising the entire student population.

The data-base was submitted to an extensive cleaning and augmentation process, including the georeferentiation of home and school addresses, which required an initial reformatting of addresses (in order to adapt them to the requirements of the geolocation software) and the use of the QGIS platform and its MMQGIS geocoding plug-in. The data-base was also enriched with census-area information (2011 ISTAT census data) concerning selected features of the resident population, including its composition broken down by citizenship.

2.2 Dependent variables

Comparatively short distances from residence to school may reflect families' choosing to enrol their children in the most readily available learning institution and thus adhering to school catchment boundaries, whereas selecting a comparatively distant school may correspond to a more discerning behaviour based on information-gathering and evaluation strategies. It could be argued that the distinction roughly mirrors a passive versus active choice dynamic. On the other hand, greater distances also imply, other things being equal, greater travel times and efforts. The selection of a school distant from one's residence might also depend on other convenience criteria, such as ease of access due to a school's proximity to a parent's workplace or grandparents' home. Available data do not permit exploration of these aspects.

The georeferentiation of home and school addresses allows for the estimation of a (Euclidean) distance for each student's home-school dyad. Indeed, the association of each address to its geographical coordinates makes it possible to calculate the distance between a pupil's home and *any* school and thus to ascertain whether the school he/she actually attends is the closest to home. Also, it is possible to compare actual proximity with the greatest theoretical proximity (difference between actual home-school distance and the shortest possible distance from the pupil's home to a lower secondary school).

This information puts at our disposal a set of potential dependent variables:

- D1. Attendance of school closest to home: no = 0, yes = 1 (binary variable);
- D2. Actual home-school distance (cardinal variable, with no 0 values);
- D3. Supplementary home-school distance, i.e., the difference between actual home-school distance and the distance between home and nearest school (cardinal variable, equal to 0 when the nearest school and the actual school coincide).

The sample's students are enrolled in 28 schools (an additional 2 schools are located in the city of Bologna, but they are not attended by any students in the INVALSI data-set).

2.3 Explanatory variables and covariates

We focus on two main explanatory variables. The first is *immigrant/native status*. Our sample, once cases with missing values have been eliminated, comprises 1,917 units, of which 1,615 defined as native Italians, 150 members of the so-called second generation (G2) and 152 first-generation immigrants (G1). G1s are expected to display a weaker degree of acculturation in the destination country, which may lead to less informed school choices.

[2] Each dependent variable features two major limits. The first one is computational: home-school road distance may considerably differ from the Euclidian one, in terms of both kilometres travelled and travel times. The second is methodological: the closest school to home is not necessarily the school that the student "should" select considering his/her residence, since our analyses do not take into account formal catchment areas. Future efforts will address these issues.

The second variable is *area of residence*. Figure 1 highlights Bologna's administrative zones, in use from 1966 to 1985 and still widely employed in everyday experience. These 18 *quartieri* were subsequently grouped into 9 larger areas and, more recently, into just six, but we've used the older boundaries as the basis for a different 8-area aggregation, that takes into account social similarities as well as the number of immigrant-origin students in our data-base:

- Bologna West: Borgo Panigale, Barca, Santa Viola, Saffi;
- Historic Centre: Marconi, Irnerio, Malpighi, Galvani;
- Costa-Saragozza / Colli / Murri;
- San Ruffillo / Mazzini;
- San Vitale;
- San Donato;
- Corticella / Lame;
- Bolognina.

Analyses at the local level are crucial for examining possible school segregation effects. In fact, analyses conducted at the national or regional level might suppress forms of school segregation in play. Only a detailed examination of local areas' characteristics (socio-economic and ethnic features, distribution of schools) may reveal operative segregation [3,6].

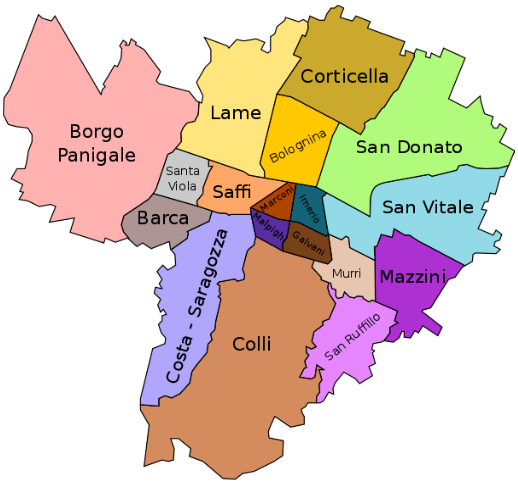

Figure 1: Bologna neighbourhoods

Table 1 displays some basic information about the 8 areas used in our analysis. The more socially disadvantaged areas are San Donato and Bolognina, as reflected by the relatively lower incidence of residents with a university degree, the higher unemployment rates and the higher concentration of foreign-origin residents. The INVALSI data-base shows that San Donato and Bolognina have the highest residential concentration of immigrant-origin students. Some differences exist between these two ex-*quartieri*: in San Donato, the incidence of first and second generations is relatively similar, even if G1s exceed G2s (respectively 16.5 and 12.4%), whereas in Bolognina G2s are more numerous than G1s.

The multivariate analyses will involve the following covariates: student gender and parents' highest education level.

Table 1: Some socio-economic characteristics of population residing in Bologna's areas (2011 Census data) and students' distribution in lower secondary schools per areas and migratory status (INVALSI data)

	Population (2011 Census)				INVALSI data-base				
	Pop. (000s)	% Non-Italians	Unempl. rate	% univ. graduates	No. pupils	No. schools	% Non-Italians	% G1	% G2
Bologna West	75,482	12.2	5.4	15.0	399	5	9.8	5.3	4.5

Total	371,174	11.9	5.6	22.4	1,917	28	15.7	7.9	7.8

3 Preliminary findings

As a whole, Italian and immigrant-origin students show a high propensity towards school mobility: over two students out of five attend the closest school to home (Table 2). Aggregate data suggest that immigrant-origin students are slightly more likely than natives to choose the school closest to home.

Nonetheless, analyses broken down by area reveal noteworthy differences: Italian students residing in Bologna West and the Historic Centre are more likely to be less mobile, whereas the same behaviour is more common among immigrant-origin students living in San Donato, one of the city's most socio-economically disadvantaged outskirts. A lower propensity towards mobility is also evident in both groups of students residing in Corticella / Lame.

Table 2 also highlights differences between G2s and G1s. In particular, G1s have a higher propensity to opt for the nearest school to home (D1). This result could be explained by the fact that G1s (and their families) have a lower knowledge of the Italian school system due to their more recent (as compared to G2s's families) arrival in Italy. However, G1s' likelihood of attending the school closest to home is evident only in some areas, such as San Donato and Corticella / Lame.

Table 2: Students attending the closest lower secondary school to home (D1), overall and supplementary home-school distances (in km) travelled by students (D2 and D3) by area and migratory status

	D1 (% closest school)				D2 (mean distance)				D3 (mean suppl. distance)[*]

[*] D3 calculated only for students not attending school closest to home.

As far as the home-school distance is concerned (D2), on average an Italian student travels 1.34 km, whereas an immigrant-origin student 1.28 km. Differences between G1s and G2s are negligible. Analysis by *quartiere* reveals some distinct features: immigrant-origin students, especially G1s, are more likely to travel longer distances than Italians if they reside in Bologna West. In this case, higher mobility (D1) is associated with greater travelled distance. On the contrary, although G1s residing in the Historic Centre show a similar propensity to school mobility (37.5%), they travel very short distances to reach their schools (0.49 km). This finding might reflect a process of school segregation: in the more socio-economically prestigious area of the Historic Centre, students are relatively mobile and may travel short distances to reach the school that fits their needs. As a result, Italian students might be concentrated in some schools and immigrant-origin students in other schools, which are very close to each other and located in the same area.

In order to explore the different propensity to mobility in selecting schools among Italian and immigrant-origin students, two multivariate analyses have been developed: a logistic regression on the probability to choose the closest school (D1) and a linear regression on the additional distance (D3).

The former suggests if – all other things being equal (student gender, family's level of education and area of residence) – migratory background is associated with selection of the closest school to home. The latter focuses on a cardinal dependent variable, with values determined as follows: the difference between the distance from home to the selected school and the distance from home to the closest school. The linear regression was estimated only on the subsample of students who do not attend the nearest school in order to investigate if specific characteristics are detectable among students travelling an additional distance to go to school.

[3] Analyses control for all interactions between parents' highest level of education, immigrant status and area of residence, but average marginal effects have been calculated as if several regressions had been

Preliminary results show that G2s are more similar to Italians than to G1s with respect to both the choice to attend a school on a distance basis and the additional distance that students travel in order to attend a school that does not coincide with the closest to home. Furthermore, G1s exhibit a lower probability than Italians to select a school far from home when they reside in San Donato. On the contrary, they are more inclined to travel farther than Italians when they live in Mazzini-San Ruffillo. As far as the additional distance is concerned, G1s tend not to traverse a longer distance than Italians.

Irrespective of immigrant status, two mechanisms appear to be in play: with the only exception of Bolognina inhabitants, families living in the most disadvantaged neighbourhoods are less likely to adopt school choice strategies other than convenience. Families living in wealthier neighbourhoods, like the Historic Centre, have the same behaviour; in this case, however, they live in areas which are the preferred destination for families who decide to place their children in non-near schools. Despite the fact that families residing in Corticella / Lame are comparatively less willing to enrol their children in distant schools, more educated parents are also the most willing to have their children travel longer distances.

To tentatively conclude, data does not reveal any operational process of school segregation on an ethnic basis, and school selection seems to be driven more by family's socio-cultural and economic traits. As a consequence, immigrant-origin students' (especially G1s) school choice patterns are more associated with their over-representation in working class families than with their migratory status.

developed for each area of residence. Level of education, migrant status and the area of residence could possibly be correlated to the socio-economic status, causing an endogeneity problem.

From school to ... future: strategies, paths and perspectives of immigrant immediate descendants in Naples

Dalla scuola al …. futuro: strategie, percorsi e prospettive di giovani immigrati di seconda generazione a Napoli

Giustina Orientale Caputo and Giuseppe Gargiulo

Abstract: The study subject presented here is the school inclusion process of immigrant immediate descendants enrolled in some middle schools of Naples. The research's general objective was to study the immigrant immediate descendants integration and, in particular, to identify the determinants of the choice, once achieved the compulsory school title, to continue studies or enter the labour market by using a qualitative approach. In fact, it seemed interesting to study this transition phase, which is crucial for adolescents, because they are in constant evolution in terms of aspirations, constraints and opportunities. First results have shown how it is important to consider the simultaneous interconnections between several factors such as: the territorial context; the individual and family characteristics; the family migratory history; schools institution and educational policies on theme about intercultural education and pedagogy. We have seen how the interweaving between the weaknesses of each of the characteristics we mentioned above, could often define paths different from those imagined - by themself or by their families. These weaknesses are also cause of biographical shocks in the delicate transition from school to the future due to not understood, not supported, disincentive and obstructed aspirations.

Abstract*: Oggetto dello studio di cui qui presentiamo i primi risultati è il processo di inclusione scolastica dei giovani immigrati iscritti in alcune scuole secondarie di primo grado a Napoli. Obiettivo generale della ricerca era studiare l'integrazione degli immigrati di seconde generazioni ed in particolare, attraverso un approccio qualitativo, cogliere le determinati relative alla scelta, successiva al conseguimento*

del titolo di studio dell'obbligo, di proseguire gli studi o di entrare nel mercato del lavoro. Ci è sembrato infatti interessante studiare una fase di passaggio che in generale per tutti gli adolescenti è cruciale poiché pone i ragazzi in un continuo confronto tra desideri, vincoli e opportunità disponibili. Dai primi risultati emerge come sia stato significativo considerare le simultanee interconnessioni tra più fattori quali: il contesto territoriale; le caratteristiche individuali e familiari; la storia migratoria del nucleo familiare; l'istituzione scuola e le politiche educative in tema di educazione e pedagogia interculturale. Nello specifico, si è visto come siano spesso proprio i punti di debolezza di ciascuno di questi elementi che nel loro intrecciarsi in modi diversi possono definire percorsi diversi da quelli immaginati – dal soggetto o dalle loro famiglie – e anche provocare shock biografici nel delicato passaggio dalla scuola al futuro dovuti ad aspirazioni non comprese, non sostenute, disincentivate o, al limite, ostacolate.

Key words: immigrant immediate descendants, educational insertion, secondary school, Naples.

1 Introduction

Over time Migrant phenomenon has taken different structures and traits, shaped by economic, social and political variables typical of the different phases(stages) of European and World History. Comply with Ambrosini's Periodization (1999), the transition from temporary migration and for job reasons to long-term settlement proposal, changes the own nature of the migrant phenomenon. Subsequently is the permanent and growing presence of the migrant families, reunited or newly created, and children in the society of residence (Ambrosini 2005) with a deep change in the human and social territorial geography and social spaces involved (Basteneir, Dasetto 1990). The steady presence, increase in number the relations and the new subjects demand to become part of the social context surrounded (bringing out the demand of the new subjects in the territory to become part of the social context surrounded); and also stimulate the institutions and civil society to provide responses to the migrant demands. Parents and children are faced with an unknown and complicated situation, going through different ways (Bindi 2005).

Migration involves the questioning of minors born in Italy from foreign parents, in that case it shows a dis-identification from the parents' s culture and an identity transfer more closed (projected) to the birth country. Children, whether they are young with family reunited or born in Italy, are in a different phase compared to their parents, in which the socialization process and identity definition is still flowing (or has just begun) and it happens in a different system of expectations shaped from another culture that either does not be part (belong to) of them or is not very immediate, but in which every day they do experiences.

The local school system is an essential socialization context with the surrounding world and, at the same time, a unique opportunity to glean the necessary training for social inclusion (Strozza, de Filippo, Buonomo 2014). The educational insertion of migrant descendants is the primary aim of the modern, multinational and multicultural European societies because the accumulation of human resource is a basically requirement for the social inclusion. This has inflamed the debate of the Italian schools context on topics as: multiculturalism, organization in the school, educational content, pedagogy and teaching methods (Strozza 2015). The multicultural transformation of Italian school groups imposes to the school system a lot of civic and educational dares if it would like to keep his aims of equity, inclusion and democratic citizen education. The research we are going to discuss in this paper, intends implementing an perspective shown relationships between the practice education, often taken for granted - or not problematized - in the political-academic and professional debate and the assumption on which such practices are founded (Serpieri, Grimaldi 2014). Our cognitive object, in the first time, will be to analyze the integration / inclusion level of the second-generation migrant children in the Italian schools; the second question, it will be to understand this youngsters future orientations – continue to study or have a job - and it also concerns educational practice. Therefore, one of our aims it will be to bring out the existence of an equity problem in the educational system; linked to inequalities of opportunity and result that systematically disadvantage not-Italian pupils; disadvantage exacerbating in the higher school levels. In fact, considering the evolutions of the school system, a marked shift of school selection emerges from the secondary school of first degree towards the first years of secondary school so that for this order of school we can speak of deferred selection (Besozzi, Colombo 2014). For that reason our attention was shaped to the transition from secondary school to grade II.

The sociological approach through a qualitative methodology intends to achieve primarily the goal of reading the new needs they bring immigrant children and consequently those of the families where they belong, in the belief that "Children of immigrants (...) could (or should) be the main actors in the construction of the future society "(Strozza, Serpieri, de Filippo, Grimaldi (eds. 2014, p. 34). And if these companies must be "multicultural and low-low level of conflict"(Zincone 2000) then it must be built primarily from the integration of children in schooling and training. Just these paths must therefore carefully studied because they provide to young subjects - immigrants or not - on the one hand the tools for better construction and understanding of themselves and their own abilities and the other keys to access opportunities - that the context inside living can offer them - in terms of further training and / or integration into the labour market.

2 Methodology, technique and research phases

Our sociology-driven qualitative research perform the task of surveying, integrating and putting into context the statistical data and information collected during the first part of the research. Through field analysis we actually try to describe the conditions and experiences of minor immigrants and their families in migrants reception contexts, in order to identify the variables which have greater influence – whether negative or positive – on school, and later on social, integration of minor immigrants to prevent situations of marginalization, social exclusion and on their future choices. Immigrant immediate descendants represent, indeed, a growing trend both from the numerical point of view and from that of social importance The analysis take into account the different nationality groups to which the minors belong, their wider family background, the length of their stay in Italy, the links their families have with the labour market, so as to better understand minors' school progression and their successes and failures.

The project aim is to fill gaps in research on the subject of immigration in the Italian context through the providing understanding of the school inclusion process of children and youths of not Italian origins. The contribution which this part of the research provide looks rather remarkable to us, given the lack of surveys on the extent of the phenomena we are going to investigate, and of studies on the conditions, strategies, difficulties, changes and adaption to our schooling system foreign minors have to face while they are here. In other words, we intend analyse the determinant of the school drop-out and failures, the risk of perceived school discrimination, the school insertion, the training and employment expectations. On the other hand, this step is all the more necessary since the current cohort of second-generation is also the first, especially in Naples where they were defined as "frontrunners social category" (Spanò 2011). The analysis is also be oriented at understanding the present state of educational and social policies implemented by the individual schools for these foreign pupils, who can be defined somehow non standard, since they do not always possess the pre-requisites and base knowledge held by native minors. In our opinion, all that acquires further value in a context such as the city of Naples with a structurally weak educational offer, a common condition in Southern Italy (Landri, Milione, Vecchione 2014).

Even though data show a lower presence of minor immigrants in Naples schools compared to the other big Italian cities, we are witnessing here as well, ongoing changes in the presence of immigrants, and as a consequence we are facing rapid changes in the composition of the pupils mix. The research group is obviously aware that this rapidity does not always correspond with a rapidity in the transformation of the social policies applied locally and, most of all, with the institutions' capability of identifying rapidly the most effective actions to implement for the school inclusion of foreign minors. However, we are going to examine and illustrate these actions.

For a deeper understanding of these aspects, we have chosen the Neapolitan schools with a strong presence of immigrant minors, in the city centre, to be able to represent the weight of local contexts, at the analysis stage.

Therefore our object was the process of school inclusion of second-generation migrants attending the secondary schools of first degree in the historical center of Naples. Our aim was to understand the elements that determined processes of their scholastic and social inclusion and identifying if there are any problematic aspects of the process not already solved. The specific objectives of the qualitative research are the identification of the strong points and weak points of the school inclusion process and academic insertion. The aim will be to produce recommendation for any future interventions of integration policies developed.

The research question was: what are the determinants of the school inclusion process of the second-generation children attend the three-year period of secondary schools first degree? What are their training needs in the educational path? What are the variables that guide their choices of continuation or interruption their studies at the end of the course?

First of all, we are going to study the theoretical contribute of the statistical, pedagogical, sociological approaches and obviously the analysis of public policies. The data analysis from the available databases was preparatory for the field survey, made through qualitative research tools including: participant observation, interviews with privileged observers, autobiographical texts, focus group. About focus groups, actually we just made meeting separately children and their parents.

The survey has been performed as following:

- mapping secondary schools of first degree (level); consultation, contact and identification of those available to participate for the research;
- partake planning and/or interviews with school chief in order to identify specific detection areas, shared construction of survey tools and the identification of the class of each school.

Focus group made with:

- class group, with the aim to show the intergenerational questions in a peer to peer contest ; identify the role of peer relationships, the trans-generational relationship, the socialization contexts; observe the training needs and expectations of this age group;
- parents of second-generation migrant pupils with the aim to understand which was the impact and the influences of the family migration project on the children's educational career; representations, causal attributions in relation to the choice of scholastic paths and to the educational success; parental styles; models, beliefs and educational aims; requests and expectations with respect to training institutions.

At the first time, the phenomenon we want to understand was superior to the individual, therefore it was circumscribed to a group, even if not representative can be considered significant in order to understand our interested dynamics. The investigation method as through the focus group technique was the approach used in this phase and we are going to show this in the paper as first results. This investigation technique does not allow to reach the phenomenon quantification and not to their generalization but it is considered incisive for obtaining a lot of information on little-known or delicate subjects.

In the type of group interview, the stimulus is invariant and the reactions are recorded individually and in the same way. Moreover, in addition to the content of the reporting, the interactions between the members of the group are observed. The recent diffusion of this interview technique is contemporary with the rediscovery of the community, as a reaction to globalization and depersonalization and indicates a growing interest in implicit and explicit negotiation processes in the everyday sphere (Besozzi, Colombo, 2014) It is good to remember that, especially in socio-educational contexts, the interviewed subjects require particular caution. With children and adolescents some elements must be considered, such as: mastering a more or less restricted vocabulary; lower ability to use abstract concepts; asymmetrical relationship with the adult interviewer; limited time of attention to purely intellectual activities; lack of understanding of the situation; respond mechanically or in a complacent manner. For these reasons, until the nineties, children and young people were mostly excluded from large-scale investigations. However, in recent years, also in Italy, research has taken place with the children active protagonists in the consideration that minors are social subjects endowed with their own agency capacity and therefore able not only to report themselves with a language and a peculiar reflexivity but to affirm cultural needs and contents in the public sphere.

Specifically, the topics discussed during the meetings were:

- Family / cultural educational models
- School inclusion and discrimination
- Linguistic aspects
- Free time, relationships with the peer group, as represented in the speech of peers.

Field research started in September 2017.

Starting from city schools mapping, those institutes were contacted, due to the numerous and heterogeneity of enrolled student stalls of not-Italian origin, could better serve to understand the themes of the research. Not without difficulty, the schools that showed their availability were 6 and represent precisely those from the most complex and articulate student groups. Moreover, these institutions all insist on the vast territory of the historic center of Naples.

Received the availability of school leaders, the subsequent contacts were made with representatives of the institutes, with whom they shared the subsequent stages of identification of specific areas of research detection and identification of classes participating in the focus groups. At this point, the subsequent contacts were with the teacher coordinators of the classes identified in the six schools with which, through preliminary meetings, the knowledge of the composition of the group of students was deepened.

At present, meetings have been held with teachers and managers, with whom it is important to return to speak at the end of the meetings with pupils and parents in order to be able to make an overall assessment of the issues raised; all the focus has been completed with the boys and the first three focuses with the parents were conducted.

3 Preliminary research results

Although the research is still going, the material collected so far and the observations made may be the object of some consideration.

School, family, peer group and future, in fact, are the spaces - sometimes physical, sometimes even mental - with which the participants expressed their ability to "interpretive reproduction" (Corsaro, 2003).

The first possible observations are related to the social context in which the schools are located and the children live. The quarters of the Neapolitan historical centre in which the schools analysed by us fall are a common and varied space crossed by similar social phenomenon but quite peculiar to each neighbourhood. San Lorenzo, Vicaria, Zona Industriale and Montecalvario are neighbourhoods in which the presence of students of non-Italian origin, and therefore of foreign families, helps to make the typing of the Neapolitan historical centre. These areas are generally characterized by the presence of a particularly difficult social fabric, in which poverty, unemployment, the presence of multi-problem families in great difficulty appears high. This affects the growth of children and constitutes an element that defines a large part of their lives, as emerged from our survey. The urban and architectural structure of the neighbourhoods, the almost total absence of public green and equipped for children, the high population density, the school structures often inadequate and poorly equipped are just some of the problems that the area shows at first glance. And minors immediately reported their weight on their daily lives. Not less than their families did.

Present for several years in our country, mostly born in Italy, foreign children we heard all express themselves in Italian quite correctly, often speak very well the dialect and have a frequency of bilingualism in everyday use or otherwise express themselves and they understand both languages - the family (which often keep talking at home) and the Italian one. The most significant relationships that the boys have established in the classroom are in most cases with other boys of their same origin and in some cases even with Italians these relationships also continue outside the classroom and are an important part of their free time.

Refers to the aspects of daily interaction and the issue of discrimination, it can be said that the children felt cannot be touched by the problem: a problem of discrimination exists - where it is stronger where it is milder - and this strongly recalls the body's responsibility teacher and the choices that they often make in everyday life: diversifying the expectations among Italian and foreign students, also physically distancing the good guys from the less, not favouring and in some cases hindering the interactions between the groups. The success or failure of the study and the different disciplines is somehow predictive of the orientation towards the future that the boys show. And so the boys who have a better education (Italian or foreign) have a stronger orientation to continue their studies than others. In general all indicate that they want to continue their studies, even with the approval of their parents and no one has declared that they will interrupt them (the obligation of the other party will lead them to continue at least two more years after the conclusion of the cycle they currently attend), as well as in general foreign children more than the Italians put higher expectations in the study compared to professional achievement. In general, children of foreign origins have declared desires for higher professions and professional achievements of their Italian peers. If young Italians want to play all the players (the males) and the dancers or the hairdressers (the females), the young foreigners want to be a veterinarian, an anatomical pathologist, an engineer, a tour guide. These statements seem to indicate not only a different horizon between Italian parents (of classes strongly deprived as mentioned) and foreign parents, but also a different degree of confidence in the future and in the possibility of growth and improvement of the condition of departure of the children through the study.

Tourism Destinations, Household, Firms

The Pricing Behaviour of Firms in the On-line Accommodation Market: Evidence from a Metropolitan City

Andrea Guizzardi and Flavio Maria Emanuele Pons

Abstract The widespread diffusion of on-line travel agencies has opened the possibility, for hoteliers, to update continously quality and prices offered along the advance booking. We study firms' pricing behaviour in a business-oriented environment considering time series of daily best available rates for 107 hotels in Milan, over a period of 9 months, from 0 to 28 days of advance booking. Throught a panel-VAR approach we assess if the typical planning of the price trajectory, including dummies for holidays and fairs as covariates. Results suggest that strategies put into effect by firms reflect some of the basic principles of the online revenue management. Price trajectories are planned considering both firms expectations on the prices they hope to charge last-minute, and their need to guarantee price stability along the advance booking. Fairs and holidays show a different impact on price dynamics. While the response caused by an ”holiday shock” tends to be flat, room rates during fairs raise in the immediate future, then accommodate to the equilibrium in about three days.

Key words: RevPOR, RevPAR, Dynamic Pricing, panel-VAR

1 Introduction

In recent years, rapid technological progress and the proliferation of on-line booking platforms have deeply modified the behaviour of touristic firms, in particular concerning pricing and the management of the occupation rate. The opportunity to

update quality and prices of the room offered on-line in real time has boosted the development of new methods and algorithms to perform an effective revenue management. Moreover, the great availability of free data deriving from on-line travel agencies increases the transparency of the market and the possibility to study firm competition.

Considering the industry characteristics (perishable inventory, short-term constrained capacity, high fixed costs respect to variable costs) managers are motivated to adjust prices in real time in order to sell all the rooms out by the target day emphasizing maximization of daily revenues ([Wang and Brennan, 2014]). However, hotels operate a segmentation of the room market, considering that there exists a negative correlation between the ability to purchase and the advance between booking and arrival date. In fact, clients with higher spending possibility, in general business travellers, tend to make a reservation on the target day or with a short notice of one or two days ([Guo et al., 2013]).

This situation induces a trade-off between the strong incentive to sell all the rooms by the target day (minimizing strategically - unsold capacity) and the higher profitability of the rooms sold with a short advance booking (maximizing tactically - average Revenue Per Occupied Room (RevPOR)). In the on-line market, the advance booking enables firms to mix strategic and tactic pricing, in order to maximize Revenue Per Available Room (RevPAR). This operation is not straigtforward, particularly in a location, such as Milan, where the low elasticity to price of business customers concurs in differentiating the economic effect of tactic and strategy in revenue management.

Previous researches (e.g. [Abrate and Viglia, 2016]) have exploited the full potential of a panel dataset to explain both cross-section and time variability of prices considering also contextual variables like: room and hotel quality, offered services, restriction placed on prices or the spatial density of competitors or destination occupancy. Price is taken as response variable in a random-effect regression model and advance booking is an explicative variable. However, [Guizzardi et al., 2017] found that price trajectories can be seen as a stationary AR(1) process, suggesting that dynamics is present not only between successive arrival dates, but also along the advance booking, the role of which cannot then be properly assessed simply considering the booking lag as a covariate.

In this article, we overcome this issue by considering a panel-VAR model. The VAR setting enables us to consider the price trajectory as a multivariate endogenous variable, modelling also the interdependencies between different advance bookings, other than the serial correlation in each time series. The panel generalization of VAR models lets us build consistent GMM estimators considering the cross-sectional nature of the dataset. Moreover, the computation of the impulse response functions (IRF) enables us to interpret the effect of exogenous shocks (in our case holidays and fairs) in terms of forecasted price response. Thanks to this approach, we assess: if and how hotel managers account for demand patterns and exogenous shocks in their price competition on the on-line market; if and when they change from strategy to tattic along the advance booking.

The rest of the paper is organized as follows: in Section 2 we describe the dataset and the modellistic framework, introducing the general formulation of panel-VAR models, and discussing the techniques adopted for model selection and estimation. In Section 3 we present the main results, which include significant model coefficients and the relevant impulse response functions; in Section 4 we discuss briefly our findings, linking them to the existing literature about dynamic pricing, and present our concluding remarks and an outline of future extensions of this work.

2 Data and Methods

We consider a dataset consisting of best available rates (BARs) recorded every day at 00:00 AM for a panel of 107 hotels in Milan, from January, 1st to September, 30th, 2016. The data source was `Expedia.com`. For each arrival date, the room price has been recorded from 28 to 0 days of advance booking.

Let $i = 1,2,\dots,N = 107$ index the hotel, $t = 1,2,\dots,T = 274$ the arrival date and $k = 0,1,\dots,K = 28$ the number of days of advance booking: let us denote the natural logarithm of the BAR for hotel i, arrival date t and advance booking k as $y_{it}^{(k)}$. We call *price trajectory* for the arrival date t at hotel i the vector of values $y_{it} = \{y_{it}^{(k)}\}_{k=0}^{28}$. In order to reduce dimensionality, we consider a sub-sample of the price trajectory, including a limited number of values of the advance booking to sample short, medium and long term with respect to the arrival date. In particular, we only consider lags = 0, 1, 7, 14, 21, 28, so that we reduce the dimension of the dependent variable from $K = 29$ to $K = 6$.

Given the panel nature of our dataset, and that for each hotel y_{it} is a vector time series, it is natural to consider the extension to panel-VAR models, which permits to take simultaneously into account the longitudinal and multivariate time series nature of the data. From our preliminary analysis, we establish that none of the hotel-specific VARs contains cointegration, so that no differencing is needed to achieve stationarity.

The panel-VAR model of order p reads ([Abrigo et al., 2016])

$$y_{it} = \sum_{j=1}^{p} y_{it-j}A_j + x_{it}B + u_i + \varepsilon_{it} \tag{1}$$

where y_{it} is a $(1 \times k)$ dependent vector, x_{it} is a $(1 \times l)$ vector of exogenous variables, u_i is a $(1 \times K)$ vector of hotel-specific fixed effects and ε_i is a $(1 \times K)$ vector of idiosyncratic errors, such that $E(\varepsilon_{it}) = 0$, $E(\varepsilon_{it}'\varepsilon_{it}) = \Sigma$, $E(\varepsilon_{it}'\varepsilon_{is}) = 0$ for all $t > s$. A_j and B are, respectively, $(K \times K)$ and $(l \times K)$ matrices of parameters to be estimated.

The covariates x_{it} consist of four dummies indicating weekend nights (from Friday to Sunday), national holidays, fairs, and the month of August, during which business activity in Italy is considerably reduced. From a preliminary analysis of their marginal effects, we found that seasonal variability is not very evident, except for the months of August and September, during which prices are, respectively, lower and higher than the annual average. However, we can only link to tourism seasonality the lower price levels during August, while the higher fares in September are expectedly due to particular events, such as an high number of fairs during the month. Moreover, weekend nights appear to be associated to prices lower that the weekly average, including Fridays. Regarding short events displacing demand from its equilibrium state, fairs are associated to significantly higher room rates, while holidays do not seem to marginally affect room prices in Milan.

Estimation

We use the package `pvar` in `Stata`, described in [Abrigo et al., 2016], to specify the panel-VAR model in Eq. 1. Model estimation is conducted in a GMM framework, while model selection is based on model and moment selection criteria (MMSC).

Concerning the estimation of the coefficient matrices A and B in Eq. 1, the package follows a GMM approach which generalizes the bivariate procedure introduced by [Holtz-Eakin et al., 1988]. As suggested by [Arellano and Bover, 1995], we remove fixed effects through forward orthogonal deviation (FOD), which consists of subtracting the mean of only the future observations at any time and for any unit. This way, the variables transformed to remove fixed effects and the lagged dependent variables remain orthogonal, allowing to use the latter as instruments for estimation. The FOD procedure results in the following transformed variables, which are subsequently used for GMM estimation: $y^*_{it} = \frac{y_{it} - \overline{y_{it}}^+}{\sqrt{T_{it}/(T_{it}+1)}}$, where $\overline{y_{it}}^+$ is the mean of the future observations at time t, T_{it} is the number of remaining future observations at time t, and y^*_{it} is a $(1 \times K)$ vector $y^*_{it} = [y^{*1}_{it}\, y^{*2}_{it} \cdots y^{*K}_{it}]$.

Considering the model as a system, rather than equation-by-equation, makes it possible to achieve efficiency. In practice, this is obtained by writing the model equation in reduced form, $y^*_{it} = \tilde{y}^*_{it} A + \varepsilon^*_{it}$. The resulting GMM estimator for A is obtained stacking observations over panel and then over time, $\hat{A} = (\tilde{y}'^* z \hat{W} z' \tilde{y}^*)^{-1} (\tilde{y}'^* z \hat{W} z' \tilde{y}^*)$ where z are the available instruments, and $\hat{W}$ is a $(L \times L)$ weighing matrix, with $L = Kp + l$, assumed to be nonsingular, symmetric, positive semidefinite, and can be chosen to maximize efficiency according to [Hansen, 1982]. The GMM estimator is consistent if the orthogonality condition between instruments and idiosyncratic errors $E(z'\varepsilon) = 0$ holds and $rank E(\tilde{y}'^*_{it} z) = Kp + l$

Model selection

Panel-VAR model selection is based on the choice of a maximum lag for the set of instrumental variables and for the autoregressive model. For our dataset, we choose $P = 8$ as maximum autoregressive order; this choice is made considering that we may observe weekly dependencies which could be better caught by an AR(7) model, so that we want $p = 7$ to be among the eligible values. The selection of the maximum lag of the endogenous variables to be used as instruments is less arbitrary. With a view to testing the validity of the restrictions imposed by the postulated model, [Hansen, 1982] proposed an extension of the specification test introduced by [Sargan, 1959]. Such test requires over-identification, i.e. the number of available instruments must be larger than $kP+l$: since the exogenous variables provide the l valid instruments, we need to choose a number $q > p$ of lagged endogenous K-dimensional variables. Moreover, to avoid consistency loss due to endogeneity, instrumental variables are valid if incorrelated to the estimation variables, so that the smallest lag available as a valid instrument for y_{it-1} is y_{it-2}, and the smallest lag available for y_{it-2} is y_{it-3}. In practice, the minimum set of instruments for a panel-VAR(p) model is $[y_{it-2} \cdots y_{it-p-2}]$, which also implies that, while conducting the model selection, for every set of q instruments, we can only achieve over-identification up to $p = q-1$.

The order selection is based on model and moment selection criteria (MMSC) introduced by [Andrews and Lu, 2001] to include the number of parameters p, the number of instruments q and the test statistics $J(p,q,K)$ for over-identification defined by [Hansen, 1982].

3 Results

The procedure described in the previous section leads to the final selection of a panel VAR(2) with $[y_{it-2}, \cdots, y_{it-6}]$ as instruments to guarantee overidentification. The modulus of all the eigenvalues of the companion matrix lies inside the unit circle, so that the model is stable. Sargan's test does not reject the null hypothesis of correctly specified model, with a p-value = 0.080. Estimation results are shown in Table 3, only for the exogenous variables and significant coefficients of endogenous variables.

The only endogenous variables that are significant in an explanatory sense are prices at advance booking 0, 1 and 21. Prices at advance booking 0 and 1 are significant "predictors" of prices at larger advance bookings for arrival dates in the immediate future (which have been fixed several days or weeks earlier). This indicates that hotel managers not only practice revenue management in a dynamic pricing framework, but also that along the considered advance booking they make an implicit prediction of the last-minute occupation rate and of competitors' prices.

Concerning the exogenous variables, we can notice that periodic effects, such as month and day of week, have significant effects at all the considered lags of advance booking. Also fairs significantly affect price levels at all advance bookings along the trajectory, always with positive coefficients. On the other hand, while holidays do not show significant marginal impact on prices, a small positive holiday effect can be recognized for advance bookings in the close proximity to the arrival date. The weakness of this holiday effect and its limited extension along the trajectory, opposed to the stronger and always significant impact of fairs reflect the vocation of Milan as a business destination. We can also notice that the negative effect due to weekends is stronger for last-minute deals, while discounts associated to Summer holidays are stronger for early purchasers. Finally, the positive effect of fairs seems to be higher for larger advance booking. This highlights, for the examined period, a tendency of managers to be too optimistic about the increase in occupation rates stimulated by fairs, and then on feasible prices. This reflects a recent decline in the fair market in Milan, as noted by [Guizzardi, 2016].

Thanks to the possibility to compute impulse response functions (IRF), we can interpret the role of these effects also in a forecasting setting. Dynamic multipliers, i.e. the IRFs for exogenous variables, are shown in Fig. 1 and 2: while the IRF of the holiday dummy is flat on zero at all future lags, fairs clearly result in higher prices in the immediate future (i.e. the duration of the event), with a return to equilibrium around three days later. The estimated IRFs are shown with 95% Monte Carlo (500 replicates) confidence intervals.

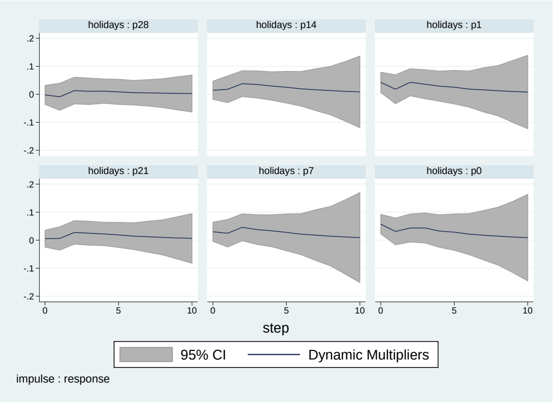

Fig. 1 Impulse response function on a 10 days horizon for holiday shocks. The gray shaded area marks the 95% confidence intervals obtained from 500 Monte Carlo replications.

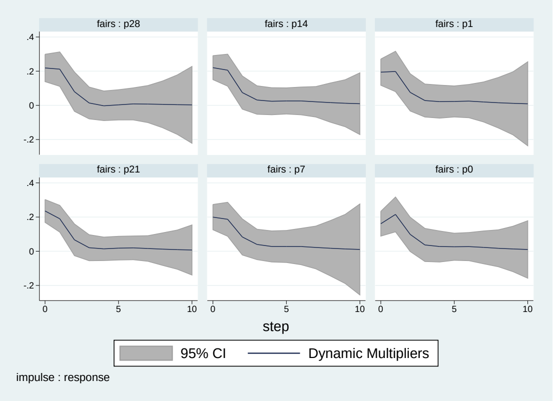

Fig. 2 Impulse response function on a 10 days horizon for fair shocks. The gray shaded area marks the 95% confidence intervals obtained from 500 Monte Carlo replications.

4 Discussion

In this work, we have shown that hotels of the high rating segment in Milan determine on-line BARs on the base of both their intentions about planning last-minute prices and the need to guarantee a certain stability of the price trajectory along the advance booking. In particular, the causality structure resulting from the VAR estimation suggests the significance of both last-minute and mid-term (three weeks in advance) room rates to explain the price dynamics. Prices in the mid-range of the trajectory (7-14 days) are not significant in an explanatory sense. The balance between tactic and strategic pricing holds up until short advance booking, where the tactic gains importance. Rates at advance booking 0 and 1, become negatively correlated with pricing strategies pursued at 21 days of advance booking. This negative correlation reflects tactic price adjustments in response to under/overbooking levels, caused by improper pricing choices in the mid-term, or an incorrect assessment of competitors on-line last-minute pricing. This behaviour is amplified by the prevalence of business travellers, who tend to make reservation with short advance booking while having low elasticity towards price.

We included four exogenous variables, all controlling for periods or events that modify the destinations business activity, so that we expect them to change the level of aggregate demand for the destination, occupation rates and, consequently, the pressure on firms to discount or increase prices. We find that fairs have a positive effect on prices, slightly higher for larger advance bookings, while the negative coefficients corresponding to weekends and the month of August call for a discount strategy. It is worth to notice that the negative effect due to Summer holidays is stronger for early purchasers, while discounts associated to weekends are stronger for last-minute deals. This suggest that managers have high confidence in planning pricing during August, while they give less weight to strategic pricing regarding weekends, given the unpredictability of weekend occupation rates, and lacking early information about: weather, events for leisure tourists and/or the concomitance with other significant events (also in the adjacent days) that interest the business segment. Also the effect of national holidays is significant only in short-term, while positive, for the reasons just mentioned regarding weekend pricing and for the fact that holidays are irregularly placed during the year. Overall, it appears that offer is not saturated until the advance booking is very small, so that pricing strategies defined three weeks in advance are only adjusted very close to the target date.

Concerning shock propagation, the impulse response functions for fairs and holidays show a different impact on price dynamics. While the response caused by a holiday tends to be zero at all future lags, fairs clearly result in higher prices in the immediate future (i.e. the average duration of the event), with a return to equilibrium around three days later.

In synthesis, we show that the actual strategies put into effect by the hotel managers reflect some of the basic principles of the online revenue management. Further development of this work will assess the question if, how, and to what extent, while practicing this mixture of tactical and strategic dynamic pricing, firms base their on-line pricing behaviour on the observation of prices published online by their competitors.

The Migration-Led-Tourism Hypothesis for Italy: A Survey

Rassegna sull'evidenza empirica a sostegno della relazione tra turismo e fenomeno migratorio in Italia

Carla Massidda, Romano Piras and Ivan Etzo[1]

Abstract Over recent decades, the literature on trade and factor mobility has shown an increasing interest in the relationship between migration and tourism. This literature has favored the demand side perspective, leaving the supply dimension almost entirely overlooked. Among the countries interested to investigate the tourism-migration nexus, Italy represents an attractive case to study. The present contribution provides a brief survey of the main empirical findings regarding this Country.

Abstract Nel Corso degli ultimi decenni, la letteratura sul commercio internazionale ha mostrato un interesse crescente verso la relazione tra turismo e fenomeno migratorio. In seno a tali studi, il maggior interesse si è concentrato sulla prospettiva della domanda, mentre la dimensione dell'offerta turistica è stata quasi completamente trascurata. Tra i paesi particolarmente interessanti da analizzare, per la sua storia passata e recente, vi è certamente l'Italia. Il presente contributo ha lo scopo di offrire una rassegna dei principali risultati finora raggiunti per questo paese.

Key words: tourism, migration, migration-led-tourism

1. Introduction

Starting from the works of Jackson (1990) and Williams and Hall (2002), the literature on trade and factor mobility has shown an increasing interest in the relationship between migration and tourism. Williams and Hall (2002) discuss three mechanisms that can link tourism demand to migration: a causal relationship running from migration to tourism trips (migration-led-tourism, MLT) motivated by the pleasure to visit friends and relatives (VFR); a causation from tourism to migration (tourism-led-migration, TLM); a bi-directional causal link between these

[1] Carla Massidda, University of Cagliari; massidda@unica.it
Romano Piras, University of Cagliari, pirasr@unica.it
Ivan Etzo, University of Cagliari, ietzo@unica.it

two phenomena. Although empirical findings effectively places migration among the major determinants of VFR flows, more recent studies favour an extensive interpretation of the MLT hypothesis (cf., inter al., Etzo et al., 2014). Accordingly, immigrants can pull arrivals and push departures, whether or not VFR is the main motivation. In the footsteps of this initial work, empirical studies on this issue have grown considerably and, almost unanimously, they conclude in favour of the MLT (Cf. *inter al*., Boyne et al. (2002), Prescott *et al*. (2005), Seetaram and Dwyer (2009), Gheasi *et al*. (2011), Seetaram (2012a,b), Tadesse and White (2012), Leitão and Shahbaz (2012), Genç (2013), Law et al. (2013), Massidda *et al*. (2015), Etzo et al. (2014), Massidda and Piras (2015), Balli *et al*. (2016), Etzo (2017), Massidda *et al*. (2017).

Surprisingly, this literature has almost entirely overlooked the supply-side perspective. This point is discussed in Massidda et al. (2017) on the base of the recent literature regarding the general impacts of immigration on host economies (cf. *inter al*., Ottaviano and Peri, 2012; Olney, 2013). The main issue is that, taking fully into account the skill complementarities between workers, immigrants can be an opportunity for receiving countries. On the one hand, immigrants, pulling tourist inflows, stimulate the demand for goods and services and, therefore, the production activities aimed at its fulfilment. On the other hand, foreign population represents workforce, mostly low-skilled, which often allows firms to pay lower wages and increase the scale of production. At the same time, immigrants can be entrepreneurs that, again, contribute to raise the number of firms and their employees.

Among the countries that are potentially interested to investigate the tourism-migration nexus, Italy represents an interesting case to study. This is because tourism and migration have strongly characterised the history of this Country, influencing its current social and economic shape. Italy has been an important source of international migration and, during the last decades, it has also become a country of immigration. At the same time, today Italy ranks among the top tourism destinations and top spenders worldwide. In spite of these features, there is a lack of empirical research on the determinants of Italian tourism flows (outbound, inbound and domestic) and, above all, a lack of investigations on the mechanisms linking tourism to migration. Only recently, has the literature started to fill this gap with the works of Massidda *et al*. (2015), Etzo *et al*. (2014), Massidda and Piras (2015) and Massidda *et al*. (2017). The aim of the present paper is to provide a survey of the main empirical findings provided until now.

2. Tourism and migration in Italy: an overview

The Italian tourism sector has increased steadily over time becoming one of the largest worldwide. In 2016, domestic tourism accounts for about 51% of the total industry for both arrivals and nights. With respect to arrivals (ISTAT, 2017), the Northern macro-area registers the highest share (55%), followed by Centre (23%) and South (22%). These shares are only slightly different in term of nights (52%, 23%, 25%, respectively). Regional market shares highlight Emilia Romagna, Lombardia, Veneto and Toscana amongst the most popular destinations for arrivals, whereas Emilia Romagna, Veneto, Toscana and Trentino are amongst the regions with highest number of nights. Holiday purpose is the main factor driving Italian domestic tourism, followed by VFR. As far as inbound tourism (UNWTO, 2017), among the top world destination countries, in 2016 Italy ranks 5th for arrivals and 6th for receipts. Germany is the main sending country, followed by France and United Kingdom (Bank of Italy, 2017). In terms of percentage variation, the eastern European countries show the highest growth rates, in particular Russia and Poland. Expenditures are mainly motivated by holiday purposes (68%), followed by business visits (14%) and VFR (10%). Turning the attention to outbound tourism, Italy ranks 8th among the main source markets in terms of expenditure (UNWTO, 2017). In 2016 the number of total outbound travellers has grown by approximately 1.6% and the European countries are the preferred destinations (Bank of Italy, 2017). Expenditure are higher in France, USA and Spain. With regard to the main purpose of visit, expenditures are mainly motivated by holiday purposes (40%), followed by business visits (34%) and VFR (9%).

Turning the attention to immigration flows, as it is well known, during the last decades of the 20th century Italy experienced a transition from being one of the most important sending countries to become also one of the principal destinations. According to the Registry of Italian citizens Residing Abroad, the stock of Italians abroad has reached 4.9 million in 2016, while the stock of immigrants residing in Italy is slightly above 5 million (Fondazione Leone Moressa, 2017). Romania is the first sending country, followed by Albania and Marocco. As far as internal migration is concerned, it started to boom after WWII: as it is well known in about twenty years (1951-1975), more than three million of individuals moved from the South to the Central and Northern areas of the country. During the seventies up to the mid-eighties, the internal migration flows started to decrease, to re-gain momentum from the mid-nineties onward (Piras, 2005). In particular, estimates show that the stock of internal migrants climbed to over 13 million in 2010, approximately one fifth of the Italian population. Lombardia, Piemonte and Lazio are the regions with the highest stocks of immigrants. Conversely, the lowest stocks are reported by Valle d'Aosta, Molise and Basilicata.

3. Migration and inbound tourism flows in Italy

The present section provides evidence of the channels through which migration stocks, defined at both origin and destination, affect Italian inbound tourism. The main source of this analysis is the contribution of Massidda *et al.* (2015). The model of tourism demand is specified in terms of total arrivals and arrivals disaggregated by purpose of visits, i.e. Visiting Friends and Relatives (VFR), Holiday and Business. The other covariates have been chosen following the extant literature. The investigation is performed over the period 2005-2011 and considers a panel of 65 countries. Data are taken from Bank of Italy, ISTAT, AIRE (Archivio degli italiani residenti all'estero) and World Bank.

To perform the analysis, with lower-case letters that indicate log-transformed variables, the following dynamic econometric model is specified:

(1) $y_{i,t,m} = \beta_0 + \beta_1 y_{i,t\text{-}1,m} + \beta_2 m\_ita_{i,t} + \beta_3 m\_for_{i,t} + \beta_4 gdp_{i,t} + \beta_5 rer_{i,t} + \beta_6 dist_i + \beta_7 cont_i + \gamma_t + \mu_i + \varepsilon_{i,t}$

where the subscript i=1, 2, … 65 denotes the countries of origin, the subscript t=1, 2, … 7 refers to the time period and m stands for the purpose of the visit. The empirical estimation is carried out by means of the one step system GMM estimator and the variables are defined as follows:[2]

- $y_{i,t,m}$ indicates arrivals;
- $m\_ita_{i,t}$ is the stock of Italian citizens residing in country i;
- $m\_for_{i,t}$ is the stock of country i's foreign citizens residing in Italy;
- $gdp_{i,t}$ is the real per capita GDP in the source country;
- $rer_{i,t}$ is the real exchange rate.
- $dist_i$ is the distance between Rome and the Capital of country i;
- $cont_i$ is a dummy variable that controls for common border effects;
- μ_i and γ_t are country-specific and time-specific fixed effects, respectively;
- $\varepsilon_{i,t}$ is the stochastic error term.

The main empirical findings provided by the cited study is that the stocks of Italian citizens residing abroad have a positive and statistically significant impact on total arrivals, on VFR (with the highest estimated coefficient) and on Holiday tourism. As for $m\_for_{i,t}$, the estimated coefficient is positive and statistically significant for all the trip categories. The highest impact is detected for Holiday tourism. A positive impact is detected also for $gdp_{i,t}$. Holidays demand, with an above unity estimated coefficient, seems to behave as a luxury good, whereas VFR and Business trips report the characteristic of a normal good. Among the other covariates, distance, when significant, report a negative influence on tourism flows, while the real exchange rate seems to not having any influence on international arrivals. Further comments on results are avoided for the sake of space.

4. Migration and outbound tourism flows from Italy

This section focuses on the relationship between migration and Italian outbound tourism. The main source for this analysis is the investigation proposed by Etzo *et al.* (2014). The empirical setting is closely related to the study proposed in Section 3, whereas now the dependent variable is specified in terms of departures. Data are

[2] For a more detailed description of the variables, data source and empirical methodology, see the original paper.

taken from Bank of Italy, ISTAT, AIRE (Archivio degli italiani residenti all'estero) and World Bank. The dynamic econometric model is specified as follows, with lower-case letters that indicate log-transformed variables:

$$(2)\quad y_{i,t,m} = \beta_0 + \beta_1\, y_{i,t\text{-}1,m} + \beta_2\, m\_ita_{i,t} + \beta_3\, m\_for_{i,t} + \beta_4\, p_{i,t} + \beta_5\, gdp_t + \beta_6\, dist_i + \beta_7\, cont_i + \beta_8\, crt_i + \beta_9\, (p_{i,t} \times crt_i) + \gamma_t + \mu_i + \varepsilon_{i,t}$$

where the subscript i=1, 2, … 65 denotes the destination country, the subscript t=1, 2, …7 refers to the time period and m stands for the purpose of visit. Again, the empirical estimation is carried out by means of the one step system GMM estimator and the variables are defined as follows:[3]

- $y_{i,t,m}$ represents the number of Italian outbound tourism trips;
- $m\_ita_{i,t}$ is the stock of Italian citizens residing in country i;
- $m\_for_{i,t}$ is the stock of country i's foreign citizens residing in Italy;
- $p_{i,t}$ is the log of the price competitiveness index $P_{i,t}$ (destination i is cheaper than Italy with a value of $P_{i,t}$ lower than one);
- gdp_t is the annual Italian real *GDP per capita*;
- $dist_i$ is the distance between Rome and the Capital of country i;
- $cont_i$ is a dummy variable that controls for the presence of common border effects
- crt_i is a dummy variable which takes on the value of one if real GDP per capita at destination is equal to or higher than Italian's real GDP per capita;
- $(p_{i,t} \times crt_i)$ is the interaction that allows to differentiate the effect of price depending on the development level at destination.

The main results is the positive impact of the stocks of Italian citizens residing abroad on all tourist groups. The highest effect is registered for Holiday. As for the effect of $m\_for_{i,t}$, the impact is statistically significant for all groups of tourists, but for Holiday. VFR trips seem to show the highest estimated impact. Turning the attention to the other covariates, it is interesting to observe the coefficient reported by the price competitiveness index. In line with expectations, when significant, it reports a positive coefficient for countries less developed than Italy and negative for countries as developed as Italy. The remaining covariates report the expected estimated impacts. Further comments are avoided for the sake of space.

5. Migration and domestic tourism in Italy

This section is devoted to the discussion of the relationship between internal migration and domestic tourism in Italy. The main source for this analysis is the contribution of Massidda and Piras (2015) where it is proposed a heterogeneous dynamic panel investigation of the role of interregional migration on domestic

[3] For more details, see the original paper.

tourism for the twenty Italian regions over the period 1987-2010. For the scope, the Pool Mean Group (PMG) panel estimation procedure is applied. The main sources of the data are ISTAT (various sources and years) and Svimez (2011).

The analysis is performed within a tourism demand theoretical framework. The number of per capita domestic bed nights in region *i* and time *t* ($NP_{i,t}$) is assumed to depend on the ratio of the stock of internal migrants to resident population in the region of destination ($Imp_{i,t}$). This variable, in absence of official data, has been constructed following the approach of White (2007). Other determinants are[4]:

- $Pr_{i,t}$ is the relative prices index;
- $Yp_{i,t}$ is real per capita gross domestic product at destination;
- $Hp_{i,t}$ is the number of per capita hotels;
- $Dens_{i,t}$ captures the population density calculated as the ratio of population per square kilometre.

Since the variables are proved to be $I(1)$ and cointegrated, the following error-correction model can be considered (lower-case letters indicate log-transformed variables):

$$(3) \quad \Delta np_{i,t} = \phi_{\mathrm{i}} \, (np_{i,t\text{-}1} - \beta_{0,i} - \beta_{1,i}\, pr_{i,t} - \beta_{2,i}\, yp_{i,t} - \beta_{3,i}\, imp_{i,t} - \beta_{4,i}\, hp_{i,t} - \beta_{5,i}\, dens_{i,t}) + \gamma_{11,i}\, \Delta pr_{i,t} + \gamma_{21,i}\, \Delta yp_{i,t} + \gamma_{31,i}\, \Delta imp_{i,t} + \gamma_{41,i}\, \Delta hp_{i,t} + \gamma_{51,i}\, \Delta dens_{i,t} + \varepsilon_{i,t}$$

where all coefficients are obtained as re-parameterization of an ARDL (1, 1, 1, 1, 1, 1). In Eq (3), ϕ_i represents the error correction coefficient, whereas $\varepsilon_{i,t}$ indicates the remainder disturbance term which is assumed to be independently distributed across *i* and *t*, with mean 0 and variance $\sigma_i^2 > 0$.

The main outcome of this study is the positive long-run nexus between internal migration and domestic tourism nights. Moving to the other covariates, Italian residents seem highly discouraged by price fluctuations (*pr*), whereas they are attracted by the general wellbeing of a region (*yp*), by tourism infrastructure (*hp*). A positive impact is also estimated for the variable *dens*.

6. Migration and tourism firms in Italy

The relationship between immigration and the Italian tourism supply has been the issue of the recent contribution of Massidda *et al.* (2017). This work provides an investigation of the relationship between the share of working age foreign-born population and the number of local units and their employees in the Hotel and Restaurant sector. The investigation is carried out at nation-wide level and, separately, for Centre-Northern and Southern macro-areas. Data refer to a panel of 103 Italian provinces during the 2004-2010 time period and are taken from the Statistical Archive of Active Enterprise (ASIA-ISTAT) for local units, from ISTAT

[4] For details on variables definition, data source and econometric issues, see the original paper.

archives for immigrants and from ISTAT data warehouse for unemployment and population density.

The empirical model is specified as follows (lower-case letters indicate log-transformed variables):

$$(4) \quad y_{i,t} = \beta_0 + \beta_1 sh\_Imm_{i,t} + \beta_j x_{i,t} + \gamma_t + \mu_i + \varepsilon_{i,t}$$

where the dependent variable $y_{i,t}$ is, alternatively, the log of the number of establishments and of the number of employees, in province *i* at year *t*. The variable of interest ($sh\_Imm_{i,t}$) is the log of the share of working age foreign born population resident in province *i* at year *t*, whereas $x_{i,t}$ is a set of three control variables including population density, unemployment rate and the growth rate of value added per capita. Fixed effects μ_i and temporal dummies γ_t are also included in the model. Finally, $\varepsilon_{i,t}$ is the error term uncorrelated with the covariates. To avoid inconsistency due to the potential endogeneity of the migration variable, estimates are obtained through the two stages least square (2SLS) estimator.

The main outcome of this analysis is that the share of immigrants positively affects the number of establishments, at both national and macro-area level. At macro-area level, this relationship appears to be stronger in the South. As for the effect of the other covariates, population density always reports a positive and statistically significant coefficient, whereas the unemployment rate seems to negatively affect only the number of local units in Southern provinces. Results on employees again highlight the positive influence of the provincial share of immigrants. Here again, Southern provinces are more responsive than Centre-Northern ones. As for the other covariates, population density keeps its positive role in the H&R sector and the unemployment rate negatively affects employment in the South.

Conclusions

Recent empirical studies demonstrate that in Italy the two phenomenon of tourism and migration show important connections. From the demand side perspective, it seems that the foreign-born communities residing in Italy and Italian emigrants leaving abroad stimulate both inbound and outbound tourism flows. A strong relationship also exists between interregional migration and the domestic tourism demand. On the supply side perspective, it seems that, besides opening new establishments and/or re-locating existing ones, Italian tourism firms respond to the relatively abundancy of foreign workers by increasing the labor demand.

Tourism Statistics: development and potential uses

Le Statistiche sul turismo: sviluppi e possibili utilizzi

Fabrizio Antolini

Abstract The paper aims at highlighting the role and importance of tourism statistics in describing tourism sector but also the business cycle. So far, despite WTO recommendations, and the EU regulations on the European statistics on tourism (Reg. 692/2011), there is no standardized Tourism Statistics System (TSS) across countries.

This study systematically and critically examines metadata of tourism statistics for a significant group of countries, aiming at highlighting those methodological issues that are afflicting tourism statistics

Abstract *Il presente lavoro intende evidenziare il ruolo e l'importanza delle statistiche sul turismo nel descrivere il settore del turismo, ma anche l'andamento del ciclo economico. Finora, nonostante le raccomandazioni del WTO e gli appositi regolamenti UE (Reg. 692/2011), non esiste un sistema di statistiche sul turismo (STS) standardizzato per i vari paesi. Questo studio analizza i metadati delle statistiche sul turismo di alcuni Paesi, con l'obiettivo di evidenziare le principali differenze metodologiche esistenti.*

Key words: Tourism statistics; metadata; quality of statistics.

1. "Tourism statistics" and "statistical information about tourism": the NSI and the ONT organizations.

Tourism is connected to nearly all areas of human social activity although, for its contribution to economic growth, it is considered an economic activity itself,

[1] Fabrizio Antolini, Università degli Studi di Teramo; fantolini@unite.it

prevalently concentrated in the services sector. Tourist behaviour depends on several reasons, and tourism is originated from different purposes that are not only the motivation of the people who originate the decision to travel, but also the specific characteristics of the place or country visited (Cunha, 2014). Actually, for a better comprehension of tourism sector and tourist behaviour, researchers needs and subjective preferences suggest to have a detailed and integrated statistical information. It follows the opportunity to build a System of Tourism Statistics (STS) at national and sub national level (OECD, 2011). The construction of a STS should be a part of the National Statistical System (NSS) "providing reliable, consistent and appropriate statistical information on the socio-economic aspects related to tourism, integrated within all the economic and social statistics related to other fields, at different territorial levels (national – or federal, where appropriate - infra national and international)" (UNWTO, 2011).

In the perspective of building a comprehensive STS, it is important to distinguish the statistical information on tourism from tourism statistics, the latter being only a part of the statistical information useful to evaluate tourism sector. While each National Statistical Institute (NSI) has the primary goal to transmit to Eurostat, data on the variables provided in Reg.692/2011 (Annex I and II), differently ONTs should organize a dashboard to evaluate the competitiveness of tourist destinations. In fact: "the National Tourism Observatories (ONT) could be considered as a one stop-stop shop for analysing economic and statistical data provided by different stakeholders so that to create a tourism intelligence centre for increased statistical co-operation with the local authority and the tourist operators" (OECD, 2011, p. 17). At present, in some countries, there are independent ONTs, while in others we find ONTs inside NSIs. Among the 27 EU Countries, 16 have an ONT, but only 10 have an independent ONTs (EC2010).

Moreover, ONTs can be organized in a very flexible way, depending on the needs of national or local stakeholders, thus covering topics that are not assigned to NSI. For instance, tourist operators and policy makers are interested in forecasting tourism figures in the long and short term (nowcasting), while such needs are not generally met by NSI as, according to Reg.692/2011, they do not fall within NSI duties. The availability of a STS creates a benefit also in the interpretation of other phenomena, not strictly linked to the tourism field. For instance, considering the attributes that a short-term indicator must have (Eurostat, 2006), the number of holiday trips can be used as a proxy of the household confidence about their future expectations, as well as the change in the "average length of stay" has proved to be an indirect measures of economic crisis in Italy.

2 The framework of tourism statistics: the past, the present and the future

The shift from the directive EC 95/57 to the EU Regulation 692/2011 cannot be considered as occasional. It represents the answer to the changing nature of tourism behavior with: the growing importance of short trips and same-day visits, the increasing importance of non-rented accommodations or accommodation in smaller establishments, as well as the growing impact of the internet on the tourism industry. Then the production of tourism statistics should be adapted (EC, 2011). For instance, in the new definition, the day visitors are inside the tourism sector, although they are not tourists. The nomenclature of economic activity is more detailed in its application, in particular for the code 55.3 of NACE REV.2 (Camping grounds recreational vehicle parks and trailer parks) . Furthermore, a specific classification of territories is provided (densely, intermediate and thinly areas), as well as it is also possible to classify the local administrative units in coastal and non-coastal. Tourism statistics have, as their primary goal, "to recognized the role of tourism as a tool of development and socioeconomic integration" (EC95/57), so that "monthly data is needed in order to measure the seasonal influences of demand on tourist accommodation capacity and thereby help public authorities and economic operators develop more suitable strategies and policies for improving the seasonal spread of holidays and tourism activities or to enable assessment of the macroeconomic importance of tourism in the economies of the Member States by Satellite Accounts" (EC 692/2011). With the "Agenda for a sustainable and competitive European tourism" (EC, 2007) the right balance between the welfare of tourists, the needs of the natural and cultural environment, linked competitiveness with sustainability were connected. Competitiveness and sustainability, during the years, have become the main concepts that guide the policies on tourism and, indirectly, the production of tourism statistics. While a set of indicators has been found to measures sustainability (EC, 2016), providing a sounded system of tourism information by ETIS indicators, for competitiveness the goal seems to be more complex to achieve. In fact, although some key elements of competitiveness are shared by countries, measuring competitiveness can be more difficult because of a lack of data. In fact, in many countries, the variables needed to build the indicators are not produced. For instance, researchers or politicians do not know the level of price of many services (and goods). Originally the volume of arrivals or of nights spent have been used as a proxy to measure competitiveness but now, with a significant change in mobility (Wang 2000; White and White, 2007) those aggregates cannot be used in the same way . Finally, it is important to point out the attractiveness of a territory in order to highlight its capacity to become a gravitational area, and that is why we need an integrated tourism statistical system.

3 Tourism statistics: operational definitions and different methodology across countries

Tourism statistics cover the internal tourism, in terms of capacity and occupancy of tourism accommodation establishment and national tourism, in terms of tourism demand, that concerns the characteristics of tourism trips and visitors and same day visits. The statistical unit is the visitor. In fact 'tourism' means the activity of visitors taking a trip to a main destination outside their usual environment, for less than one year, for any main purpose, including business, leisure or other personal purpose, other than to be employed by a resident entity in the place visited" (EC, 2011, p. 19). Thus (Table 1), a visitor is a traveller out his/her usual environment, which" identifies the geographical area, though not necessarily a contiguous one, within which an individual conducts his regular life routines" (EC, 2011, p. 19). The history of the definition of "usual environment" and "visitor" starts in the 1963 United Nations Conference (IUOTO, 1963). The conceptual meaning of usual environment (or, conversely, unusual environment) is "as residential place or as a part of physical space that can be defined in relation to people's individual experience and its routine activities" (Govers, Van Hecke & Cabus, 2008). Thus, the detection of "visitor" (and, consequently, "usual environment") is obtained excluding those people that every day or every week go from their home to their workplace or study-place (Cunha, 2014). The relationship between usual environment, space and place (Tuan, 1974; Cresswell, 2004) is crucial for demand side tourism statistics, considering the usual environment not as a spatial continuum, but as a collection of places with different surface areas.

Table 1: Action for travellers and visitors

Action	*Traveller*	*Visitor*
Movements	Between geographical locations	Destination outside his/her usual environment
Purposes	Any	Any purpose other than to be employed by a resident entity in the placed visited
Duration	Any	Less than year

A number of issues emerge from UN (UN, 2016, p. 19):

- the usual environment concept as a respondent category: "it introduces subjectivity, confusion and unsystematic variation in reported travel activity":
- the travel distance criterion: "introduces a false appearance of objectivity by masking subjective differences in respondents' abilities to recall and accurately measure travel distance thereby contributing to increased uncontrolled variance and volatility in subsequent data";
- crossing an administrative boundary: "could potentially provide an arbitrary gross standard as a 'minimum basis of comparison' for the purposes of international reporting, cumulative statistics and analysis".

Table 2 provides the operational definition of unusual environment for a representative set of EU countries. That table is partially different from the one (dated 2011) included in the publication UN (2016, p. 22) as it comprises also Italy and other EU countries. Data for the compilation of Table 2 are derived from Eurostat metadata and the examination of the questionnaires available at the Eurostat web pages.

It is clear that any combination of the criteria illustrated shifts the classification of visitors/non-visitors. For instance, traveller A who makes a unusual trip (suppose less than one a week) that exceeds 30 Km (hypothetical limit), with a duration of more than 2 hours (hypothetical limits), but does not pass any administrative border could not be considered a visitor. The second critical element regards how to recognize the "tourism trip" that requires "the stay in the place visited" but does not necessarily involve any "overnight", and that is why tourism visit is conceptually different from tourist. The notion of stay, implies a stop, in fact entering into a geographical area without stopping there, does not qualify, as a visit to that area, but a common limit to identify the minimum duration has not been found yet.

Looking at internal tourism data provided by the census on capacity and occupancy of tourist accommodation establishments (supply side source), the process design is different across countries. According to the Eurostat metadata, is possible (Table 3) to cluster the countries as those with a:

- dedicated and autonomous census survey (Italy, Portugal Malta);
- census survey from business register (Germany; Croatia; Finland);
- stratified sample survey (France and Spain).

The distinction between "autonomous" census survey and census survey from business register can have important effect on the quality of the data (Santoro and Petrei, 2015), and on the measure proposed. In Italy, for the year 2015, the Business Register ASIA reports 27330 Local Units of hotels (ATECO code 55.1, overall 53106), whilst the tourism administrative archives count 33199 establishments (overall 167718). Also comparing the number of overnight stays from supply and demand side sources, there are deep inconsistencies as shown for example in Guizzardi and Bernini (2012).

Table 2*: Operational definitions of unusual environment*

Country	*Distance threshold (km)*	*Administrative borders*	*Respondents' self-evaluation*	*Frequency of visit*	*Duration threshold (hours)*
Austria		X	X	Less than twice per month (*)	
Finland	30			Less than once a week	3 (+)
France	100 (*)		X

4. Conclusions

The present analysis reveals the implementation of different process designs, different data collection modes and different operational definitions for two types of tourism data: the ones collected from the supply side ("capacity and occupancy data") and the ones from the demand side (households surveys). As illustrated in the article, the population frames of supply side data can be administrative, statistical or mixed (Business Register). Differently, for demand side data, the main operational problem is the definition of "usual environment". The definition of "usual environment" is crucial even in the integration of official statistics with new data sources like mobile phone data. In fact, the use of mobile phone data should respect the basic definitions of usual environment given by the international regulations (Raun & Ahas, 2016).

Tourism attractiveness in Italy. Some empirical evidence comparing origin-destination domestic tourism flows.

L'attrattività turistica in Italia. Alcune evidenze empiriche confrontando metodi per flussi origine-destinazione.

Francesca Giambona, Emanuela Dreassi, and Alessandro Magrini

Abstract This paper aims to model tourism attractiveness for the twenty Italian regions by using origin-destination flows. To this purpose we consider the Italian domestic tourism flows and a wide range of determinants within the theoretical framework referring to the destination competitiveness theories. Using the same set of covariates (selected from Istat and Enac), we propose a comparison between the Gravity model (commonly used in tourism research) and the Bradley-Terry modelling approach (to date not yet used for tourism). Using different model specifications different empirical findings are obtained. Strengths and weaknesses of both modelling approaches will be analysed and explained.

Abstract *Questo lavoro intende modellare l'attrattiva turistica per le venti regioni italiane utilizzando i flussi turistici interregionali origine-destinazione. A tal fine sono stati considerati i flussi turistici nazionali italiani e una vasta gamma di determinanti all'interno del quadro teorico che si riferisce alle teorie della competitivitá di destinazione. Utilizzando lo stesso set di covariate (selezionato da Istat ed Enac), proponiamo un confronto tra il modello Gravity (comunemente usato in ambito turistico) e il modello Bradley-Terry (fino ad oggi non ancora utilizzato per il l'analisi dell'attrattivit turistica). Usando diverse specificazioni teoriche si otterranno risultati empirici diversi. I punti di forza e di debolezza di entrambi gli approcci di modellazione verranno analizzati e spiegati.*

Key words: Tourism attractiveness, Domestic tourism flows, Bradley-Terry model, Gravity model.

1 Introduction

Domestic tourism represents about 80% of internal (inbound and domestic) tourism consumption in the OECD area [1]. The determinants of both domestic and international tourism flows have been extensively studied and results are documented by empirical literature [2]. As far as local development is concerned, domestic tourism is a key driver also in a mature country like Italy. The recent strategic plan for tourism of the Italian government [3] explicitly includes domestic tourism among the targets and interventions related to the reinforcement of the Italian brand's positioning and attractiveness. A deepen understanding of domestic tourism at subnational level is a condition for a more affective national policies planning.
Tourism attractiveness is an attribute of tourism competitiveness as competitiveness for a destination is ”about the ability of the place to optimize its attractiveness for residents and non-residents, to deliver quality, innovative, and attractive (e.g. providing good value for money) tourism services to consumers and to gain market shares on the domestic and global market places, while ensuring that the available resources supporting tourism are used efficiently and in a sustainable way” [4] ; consequently, attractiveness has a key role in competitiveness as the increase of tourist flows (and more general tourism demand) is one target of competitiveness. Tourism attractiveness, in this paper, is analysed by using a model-comparison approach, by comparing the widely used gravity model (GM) respect to the Bradley-Terry model (BTM) not yet used in tourism issue. Both, BTM and GM are used to modelling origin-destination flows, but with different model specification and results interpretation. Gravity models have often been used to analyse tourism flows [5, 6, 7] with extensions to panel data [8, 9, 10] and spatial modelling [11]. Gravity models consider that bilateral flows between two countries are directly proportional to the countries economic masses and inversely proportional to the distance between them. However, the availability of origin-destination flows also allows the use of alternative models. The best-known model in the pairwise framework is the BTM [12]. It has been widely used in empirical applications when the structure of the data and the research questions have to be analysed using a pairwise comparison model [13]. In this paper we compare these modelling approaches in order to analyse the determinants of regional tourism attractiveness and to assess differences between GM and BTM.

2 Data and Models

Following the OECD definition domestic tourism is the tourism of resident visitors within the economic territory of the country of reference. In order to make a comparison between models used for O-D flows we use as dependent variable the Italian domestic flows between regions (NUTS2) available for the year 2016. The choice of covariates that could affect tourism attractiveness refer mainly on the push-pull factors theory. Push factors are related to individual motivations and even perceptions

of the destinations quality of life and image [14, 15, 16], so they are generally represented by individual level data. Pull factors are characteristics of the destination that arouse the desire for travel in the potential tourist and attract tourists to specific destinations. (generally include destination variables like natural attractions, cultural resources, recreational activities, and so on [17, 18]). Covariates are chosen on the basis of the theoretical framework by [19] who identified the main dimensions of competitiveness. In particular, we defined the following five dimensions within the supply side model: environment and scenery, heritage and culture, general infrastructures, tourism activities and situational conditions. For each dimensions several variable have been taken into account, but the final subset of explanatory variable is selected through a stepwise procedure (forward selection), considering the reduction of residual standard deviation.
Gravity model and the Bradley-Terry model are statistical tools to analyse flows when origin-destination matrix is available although they deal with data in a very different way. The basic differences between the two models are mainly due to the different belonging to two groups of different models, as GM belongs to the models with complementarity, whilst BTM refers to the models with competition [20]. In the following a more detailed methodological explanation will be provided.

2.1 Bradley-Terry model

The standard Bradley-Terry model [12, 22] considers the regions as players (e.g., i and j) with different abilities. If the ability of i (for $i = 1,\dots,M$) is higher than the ability of j (for all j), the number of times that i beats j is expected to be higher than the number of times j beats i, that is the number of tourists who prefer the region i coming from the area j. The model specifies the probability that in a pairwise comparison between i and j (for j that range from 1 to $M-1$) tourists prefer the region i to j, as follows:

$$P(i \text{ beats } j) = \pi_{ij} = \frac{\alpha_i}{\alpha_i + \alpha_j} \tag{1}$$

where α_i and α_j represent the ability parameters that measure the intensity of an unobservable (latent) trait in the two players. In the analysis of tourism the ability parameters are the attractiveness parameter of the competing regions. By expressing the model in the logit form, equation 1 becomes

$$\text{logit}(\pi_{ij}) = \lambda_i - \lambda_j \tag{2}$$

where $\lambda_i = \log \alpha_i$ and $\lambda_j = \log \alpha_j$ may be fixed or random parameter.

The basic model allows to make generalisations in several directions (Turner and Firth, 2012), for example, to specify ability as a function of covariates. If player covariates ($r = 1,\dots,p$) are used to explain differences in players' abilities, the parameters λ_i and λ_j are related to the covariates by a linear predictor

$$\lambda_i = \sum_{r=1}^{p} \beta_r x_{ir} + U_i \tag{3}$$

where U_i (and U_j) are normally distributed random terms. Following, equation 2 becomes

$$\text{logit}(\pi_i) = \sum_{r=1}^{p} \beta_r (x_{ir} - x_{jr}) + U_i - U_j \tag{4}$$

In the framework of the Bradley-Terry models, differences in attractiveness parameters (as measured by a fixed or random parameter shared by all pairs in which the same region is involved) are the factors that lead tourists to prefer one region over another. We call them ”ability” of the region to attract tourists.

2.2 Gravity model

Let Y_{ij} the flow from the i-th origin region to the j-th destination region. We consider a Poisson Generalized Linear Mixed Model (GLMM). We consider a set of fixed effects and a set of random intercepts and slopes (one for each destination region). The slopes relate to the logarithm of the distance between the centroid of the origin and destination regions. This, represents a gravity model [21]. The set of random slopes (exponentialized) describes the multiplicative effect of the logarithm of the distance for each destination region on the logarithm of the flow. Fixed effects are considered accordingly with covariates included o the Bradley-Terry model. However, a weakly linear relation is suggested for these and the logarithm of the flows. So, we consider $Y_{ij} \sim Poisson\,(\mu_{ij})$, then the linear predictor

$$\log \mu_{ij} = V_j + W_j \log(\text{distance}_{ij}) + \beta_1 x_i + \sum_{r=2}^{p} \beta_r x_{jr} \tag{5}$$

where V_j and W_j represent, respectively, sets of random intercepts and slopes (each referred to a destination j). A set of $p-1$ covariates, i.e. x_{jr}, are referred to the destination j, another, i.e. x_i, to the origin i. We estimate the model considering or not the internal regional flows. The classical Gravity model include these latter, but to compare results with the BTM we decided to estimate also the GM without the internal regional flows. The distance for internal regional flows are settled considering the radios of the circle with the same area of the region.

3 Results

The final subset of explanatory variable is selected through a stepwise procedure (forward selection), considering the reduction of residual standard deviation for the BTM. The analysis considers the twenty regions (level-2 units) and compares the

BTM and GM models. Random effects for the BTM have a standard deviation equal to 0.23788. For GM the estimate of standard deviation is 10.5737 for the intercepts and 0.8085 for the slopes. When we consider also the within flows we obtain a standard deviation of 12.9196 for intercepts and 0.9715 for slopes. Covariates are representative of local resources (*VILLAGES*= landscapes with historical villages (counts/1 000 km2) and *CULTENDOW*= cultural endowment index (counts/100 km2)), the tourism supply (*BEDS*= number of bed places over number of inhabitants) and transport services (*LOWCOST*=percentage of passengers of low-cost flights). Furthermore, we account for regional population size (*POP*=resident population (thousands) adjusted for outgoing flows). The signs of the covariates are as expected except for the *VILLAGES* variable. Its negative sign can be interpreted as follows: what matters is the presence of attractive historical villages although they are sparse over the territory. However, this result can be also the consequences of a heterogeneity across regions that is not taken into account trough a fixed effect. Table 1 reports the fixed effects estimates from both models. For the gravity model we have considered also the possibility of including internal regional flows. In GM the linear relations between the included covariates and the logarithm of the mean of the flows, are very weak, while in BTM are stronger. Figure 1 displays GM fitted flows (without internal regional flows) random intercept and slopes respect to the distance. Friuli and Trentino are more affected to distance than (on the contrary) Sicily or Molise.

Figure 2 describes the intercept random effects for the two models; both models do not consider internal regional flows. In is interesting the different positioning of Italian regions referring to the fitted values of GM and BTM: i) regions with concordant values as Molise and Lazio (low, low) or Trentino (high, high) or Toscana (medium, medium), ii) regions with different values as Piemonte or Friuli (low, high) or Marche (medium-low, high). Considering the standard GM (i.e. with internal flows) the discrepancy between the fitted flows using GM and BTM is more marked (Figure 3).

4 Conclusions

Although domestic tourism is only a part of total tourism flows, it remains a key driver of competitiveness in Italy. Recent economic crises have revealed a weakness of domestic tourism, which has undergone a period of stagnation and decline, recovering only since 2013, and only in some regions. From a destination point of view, if tourists are likely to find attractive and unattractive a specific destination is a key topic, as this is the key to improving destination performance and assisting, in this case, the Italian tourism industry to regain its attractiveness (competitiveness). In this contribution, a measurement of domestic attractiveness for the twenty Italian regions has been proposed based on an analysis of regional origin-destination tourism flows, by comparing two modelling approaches: the well-known Gravity model and the less-known (especially in tourism) Bradley-Terry model. The

Fig. 1 Random intercepts and slopes from the Gravity model without internal regional flows (the Poisson linear mixed model)

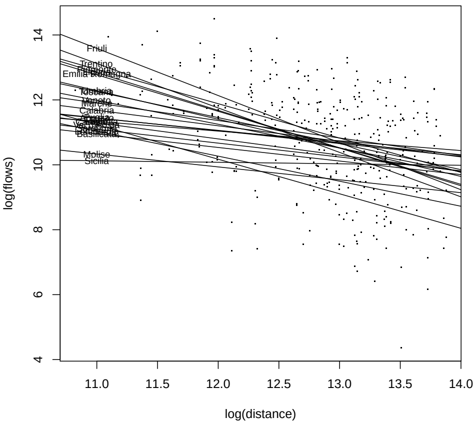

Fig. 2 Random intercepts from Gravity model *versus* the ability parameters from the Bradley-Terry model

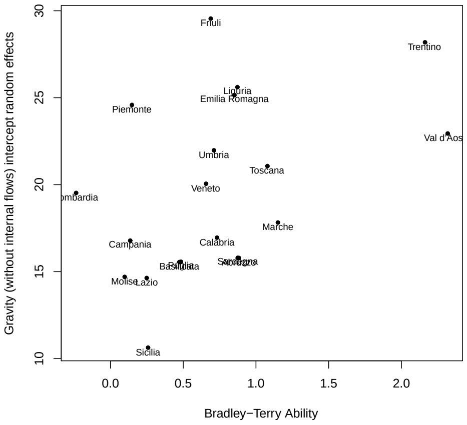

Bradley-Terry model found new application on tourism system evaluation, and compared to the usual Gravity model, the Bradley-Terry model changes drastically point of view as it specify attractiveness in a competition point of view. There are many differences between the two models. Mainly, the gravity model, compared to the Bradley-Terry model: *i*) models a flow and not a probability, as it belongs to the category of models with complementarity (nor competition), *ii*) takes into account the distance between origin and destination, *iii*) by including slope random effects for the distance between origin and destination, evaluates for each destination the decay effect of attraction of tourism respect to the distance, *iv*) it can consider also within flows (flows of tourists that move inside each region), *v*) includes covariates,

lowcost	2.008e-05	1.158e-05	0.083

referring them to the origin or destination, accordingly to their meaning. The use of GM or BTM is not a trivial issue, indeed empirical findings highlight that regions are more or less attractive on the basis of model specification, even if for some regions, i.e. the better and the worst in attractiveness terms, results are very similar.

The availability of a more detailed tourist flows matrix (at the provincial level, for example) could be useful to investigate more deeply the determinants of tourism attractiveness. However, at present, only provincial information is recorded only for the destination, i.e. we would have only region-province tourism flows.

What’s Happening in Africa

Environmental shocks and internal migration in Tanzania

Shock ambientali e migrazioni interne in Tanzania

Maria Francesca Marino, Alessandra Petrucci, and Elena Pirani

Abstract There is substantial evidence that climate has been changed in recent decades, and this trend will intensify in the near future. Climate changes are expected to exert additional pressure on areas which mainly rely on agricultural activities and, as result, act as push factors for population movements. By implementing a gravity-type model, in this study we aim at examining migration flows across Tanzanian districts. We analyze the potential impact of climate changes on inter-district migration in Tanzania, while controlling for socio-economic and geo-physical features for both the district of origin and destination.

Abstract Numerosi studi dimostrano come il clima sia cambiato negli ultimi decenni e come questa tendenza si intensificherà nel prossimo futuro. Si prevede che tali cambiamenti avranno ripercussioni soprattutto su aree la cui attività economica è prevalentemente basata sull'agricoltura e, in tali aree, agiranno come fattore di spinta per le migrazioni. Implementando un modello gravitazionale, in questo studio si propone un'analisi delle migrazioni interne in Tanzania. In particolare, si analizza l'effetto di shock ambientali sui flussi migratori inter-distrettuali in Tanzania, tenendo conto delle diverse caratteristiche socio-economiche e geofisiche delle aree interessate dal processo migratorio, ovvero quella di partenza e quella di arrivo.

Key words: Climate change, gravity-type models, population flows, socio-economic conditions.

1 Introduction

Recent studies have clearly shown that climate has been changed in recent decades and that this trend will not only persist but will also intensify in the near future. Climate changes are expected to have an impact especially on those areas whose economy mainly relies on agricultural activities; here, they are expected to exert additional pressure on the economy and, as a result, act as push factors for population movements. Despite the growing acknowledgement that the environment is becoming increasingly important in explaining large-scale movements of migrants, some of whom have been described as environmental refugees [5, 6, 8], understanding the association between migrations flows and changes in climate conditions remains a challenging task, especially in developing countries. Most of the previous studies are based on a micro approach [10, 7]. That is, they focus on the individual migrating unit (person, group or household) and study those factors that influence the decision of the potential migrant to remain in the current location or to move. In contrast, when considering a macro perspective, the interest is in analyzing aggregated migration flows, and understanding the relation between migration and objectively-determined macro variables, such as population sizes, economic descriptors of the context, and/or environmental conditions.

In this study, we follow the macro approach and focus on migration flows across Tanzania districts. This country represents an interesting case study due to its diversity in terms of agro-climatic conditions and ecological zones, and for the richness of available data on climate conditions. In this respect, our aim is that of analyzing the potential impact of climate changes on inter-districts migration in Tanzania via a gravity-type model. This also allows us to properly control for socio-economic and geo-physical features of both the district of origin and destination.

2 Tanzania National Panel Survey

Tanzania National Panel Survey (TNZPS) is a longitudinal survey carried out in Tanzania between October 2008 and January 2016. The survey collects information on a wide range of topics, including agricultural production, non-farm income generating activities, consumption expenditures, and other socio-economic features, with the aim of monitoring poverty dynamics in the country. The survey is made up by three different questionnaires: (*i*) the household questionnaire, which collects information on households economic conditions (expenditures, loans and credits, crimes and justice, etc...) and on education, labor, and health conditions of household members; (*ii*) the agriculture questionnaire, which collects information on household's agricultural activities in terms of production and sales; (*iii*) the community questionnaire, which provides information on physical and economic infrastructure and events in surveyed communities. The first wave of the survey (October 2008 - September 2009) provides information on $3,265$ households; the second (October 2010 - November 2011) and the third (October 2012 - November 2013) provide information on $3,924$ and $5,010$ households, respectively. At the last wave (October 2014 - January 2016), $3,352$ households were involved in the study. In the following, we will focus on data from the household questionnaire coming from the third wave of the survey, that is, that providing the highest sample size.

Combining information on the household's district of residence with the answers provided by the household's head to items "For how many years have you lived in this community?" and "From which district did you move?", we derive information on: (*i*) the migration status of the household (the household migrated if the household's head moved from one district to another in the 5 years prior to the interview); (*ii*) the district of origin and of destination of the household. By aggregating these information at the district level, we are able to build a migration variable, M_{ij}, counting the number of households migrating between district i and j during the five years prior to the interview, with $i = 1,\dots,129$, $j = 1,\dots,129$, and $j \neq i$.

3 A gravity-type model for migration flows across Tanzanian districts

The use of gravity models represents a well-established practice in the economic literature. Recently, thanks to the enhanced availability of migration data, this class of models has attracted researcher's interest also for the analysis of migration flows. The traditional gravity model (e.g. [11] , so-called by analogy with Newtons gravity law) is defined as

$$M_{ij} = \frac{P_i P_j}{d_{ij}},$$

where, as before, M_{ij} denotes the number of recorded migrants between area i and j, P_i and P_j the corresponding population size, and d_{ij} denotes the distance between the centroids of i and j. This equation has the nice property that, taking the logarithm of both sides, we end up with a multiple linear regression model, which is simply to fit and to interpret. However, the restrictive assumptions upon which the log-normal model is built have led researchers to consider more elaborated gravity-type models. Two main extensions have been explored: (*i*) migration flows are assumed to follow a Poisson distribution, rather than a log-normal one; (*ii*) together with the origin and destination populations and the corresponding distance, additional environmental, demographic, and socio-economic factors are included in the model with the aim of providing a better description of the phenomenon under investigation. See e.g. [4, 2, 3]. In this framework, migration flows are modeled according to the following regression model:

$$\log M_{ij} = \beta_0 + \beta_1 P_i + \beta_2 P_j + \beta_3 d_{ij} + x_i'\gamma_1 + x_j\gamma_2 + w_i'\phi_1 + w_j'\phi_2,$$

where x_i and x_j denote the vector of environmental covariates for the area of origin and destination, respectively, and γ_1 and γ_2 the corresponding vectors of parameters. Here we focus on three environmental shock variables: for each district, we consider the percentage of households in the survey indicating to have been affected by (*i*) drought or floods, (*ii*) crop disease or pests, (*iii*) severe water shortage, on the total number of households. These events have been cited as negative important events for a relevant part of the Tanzanian population in the period 2007/08 – 2012/13, with a substantial variation across districts (Table 1).

On the other hand, w_i and w_j denote the vector of socio-economic covariates, with ϕ_1 and ϕ_2 summarizing the corresponding effects on the (transformed) response M_{ij}. Given the scarcity of information on contextual socio-economic characteristics at district level from external databases, we decided to derive such information directly from the TNZSP survey. Based on previous theoretical and empirical literature [9], we built some indicators describing the demographic structure, the level of social and economic development and urbanization, and some geo-physical features of each district. In preliminary analyses, we tested a large set of indicators. At end, the variables included in the model are those listed and described in Table 1, together with their distribution across Tanzanian districts.

Table 1: Gravity-type model for migration flows: variables description

Variable	**Description**	**Mean**	**Std dev.**	**Min**	**Max**
Environmental variables					
Drought or floods	n. of household indicating to have been affected by drought or floods in the last 5 years	22.5	16.5	0	78.1
Crop disease or pests	n. of household indicating to have been affected by crop disease or crop pests in the last 5 years	13.0	14.4	0	87.9
Severe water shortage	n. of household indicating to have been affected by severe water shortage in the last 5 years	20.7	11.7	0	63.6
Demographic and socio-economic variables					
Cultivated area	% under agriculture in the area	27.4	15.9	0.8	84
Mean age	Mean age of the population	23.3	3.1	17	33.5
Urbanization	% of persons living in urbanized areas	22.5	28.4	0	100
Education	% of people with secondary of higher education	16.6	15.9	0	74.9
Tenure status	% of households of property	74.5	17.2	30.6	100

4 Model results

To evaluate the role of environmental shocks in internal migration, we estimated a set of models. First, we considered the basic gravity model (Model 1) including only the population size of the district of origin and of destination and the distance between them. Second, we added to Model 1 the variables associated to perceived environmental shocks in the district of origin and of destination (Model 2). Finally, we included also those variables describing the socio-economic context of the districts involved in the migration (Model 3). Model parameter estimates are reported in Table 2. In the last lines of the table, we also report the value of the log-likelihood function, the deviance, and the AIC index [1] of all three models under investigation to be used for model comparison.

Deviance	975.774			931.291			856.831		
AIC	3049.133			3016.651			2962.190		

By looking at the last three lines of Table 2, we may observe that the optimal specification includes in the linear predictor both environmental and socio-economic factors. In particular, by comparing the deviance of Model 2 with that of Model 1, we obtain a Likelihood Ratio Test (LRT) equal to 44.48 with 6 degrees of freedom; the low p-value (< 0.001) associated to such a statistic leads us to prefer the more complex model specification (i.e. Model 2). Similarly, when comparing Model 3 with Model 2, we obtain a LRT equal to 74.46 with 10 degrees of freedom. Once again, the low p-value (< 0.001) of such a test statistic leads us to retain the more complex model specification which includes in the linear predictor the population size of the district of origin and destination, the distance between then, the environmental variables, as well as the socio-economic ones. Identical conclusions can be drawn when looking at the AIC values reported in the last line of Table 2. Based on these findings, we will discuss in the following only results obtained under Model 3.

By looking at the estimates derived under the optimal model specification, we may firstly observe that the largest the population of destination, the biggest the migration flow, whereas, the population of origin seems to be negatively linked to migratory movements (significance level at 5%). In agreement with the standard theory behind gravity-type models, longer distances discourages movements (coefficient equal to -0.23); that is, when Tanzanian inhabitants migrate, they generally tend to prefer districts which are not that far from the district of origin.

As for environmental factors, we found that being affected by crop diseases or crop pest, or by a severe water shortage are important factors in pushing internal migrations (both coefficients equal to 0.020): as expected, the higher is the number of households experiencing one of such environmental shocks, the higher is the likelihood for them to move. On the other hand, experiencing droughts or floods does not seem to have a significant effect on migration flows. Also crop-related shocks associated to the district of destination are positively associated to migration flows, even if the magnitude of this effect is lower (coefficient equal to 0.015). This result may be possibly related to the negative sign of the parameter associated to the distance between districts. Tanzanian households tend to prefer closer destinations, which are more likely to be affected by similar problems in term of crop disease or pests with respect to the area of origin. Overall, estimated parameters suggest that environmental variables mainly act as as pushing factors for migration. Similarly, we found that the percentage of cultivated area of the district of origin – a characteristic which is related to the environment, although not representing a shock – is negatively related to inter-districts migrations: the average number of migrants is lower for those districts characterized by a low percentage of cultivated areas.

As for the variables describing the demographic, the social and the economic characteristics of the district, we found that migrants prefer destinations where the population is younger (probably the more dynamic areas). The variables referring to the percentage of population living in urban areas and the percentage of people who are owner of their home can be interpreted as proxies of the richness and development of an area. In this sense, the higher these indicators are for the districts of destination, the higher is the incoming migration flow they attract. Finally, in line with the literature, the attractiveness of an area increases when the corresponding educational level is higher. Generally, when considering demographic and socio-economic factors, it seems that they are relevant especially for the district of destination; in other words, such factors appear to be important as pull factors rather than as pushing ones.

We tested the effect of other objective climatic variables, coming from external databases, such as temperature and rainfall, but none of them were statistically significant. In the analysis, we also considered other demographic and socio-economic variables (such as the percentage of household headed by a woman; the illiteracy rate; the proportion of male population), but once again they were not significant.

5 Conclusions

The results of this analysis highlight that, as expected, demographic and socio-economic characteristics of Tanzanian districts are correlated to migration patterns, and that environmental variables are also significant. In particular, the contribution of environmental variables is mainly important in explaining the departure from a given district, whereas demographic and socio-economic characteristics are especially relevant in explaining the destination of the migration process. It is also worthwhile noticing that the distance remains the most important factor in determining the district of destination (the coefficient, equals to -0.23, has the biggest magnitude). In conclusion, Tanzanian inter-districts migrations are especially pushed by crop-related shocks and severe water shortage. At the same time, migrants generally prefer closer destinations, where they can expect to improve their social and economic situation (i.e., more developed and higher educated areas).

In the next steps of the analysis, we aim at adding a contiguity variable in the model specification, which is expected to better characterize migration flows (previous literature stated that areas that share a boundary tend to have more migration between them because this migration will include a proportion of short-distance moves from one side of the boundary to the other). Moreover, we aim at improving the description of the origin and destination districts, testing the effect of other environmental and socio-economic variables.

Determinants and geographical disparities of BMI in African Countries: a measurement error small area approach.

Determinanti e disparità geografiche del BMI nelle regioni africane: un modello di piccola area con errore di misurazione.

Serena Arima and Silvia Polettini

Abstract Food insecurity remains one of the greatest challenges in many African countries, hindering their economic development. Among related indicators, women's body mass index (BMI), measuring women's nutritional status, is a key indicator of the socio-economic development of a country. Despite recent intervention programmes, geographic and socio-economic disparities remain in the BMI distribution. Therefore, it would be important to rely on accurate estimates of women's mean BMI levels across domains. We consider a small area model with area-specific random effects that capture the regional differences in BMI levels. We propose a Bayesian model to investigate the role on BMI of a number of socio-economic characteristics such as age, wealth, parity, education, while accounting for regional variation. Since it is reasonable to assume that some of these variables are measured with error, we develop a suitable methodology and investigate the effect of neglecting measurement error in covariates on the assessment of the regression effects and on the prediction of area-specific BMI mean levels. We apply the proposed model to DHS data to explore the geographical variability of the BMI in two different regions, namely Ethiopia and Nigeria, and compare the determinants of women's nutritional status in these countries.

Abstract *L'insicurezza alimentare rimane una delle maggiori sfide per molti paesi dell'Africa. L'indice di massa corporea (BMI) femminile non fornisce solo una indicazione sullo stato di salute delle donne, ma è uno degli indicatori più utilizzati per valutare lo sviluppo culturale ed economico dei paesi. Nonostante le numerose azioni intraprese dai governi, ancora oggi permangono grandi disparità geografiche e socio-economiche a livello nutrizionale. Per la valutazione e la pianificazione delle politiche occorrono stime accurate dei livelli medi del BMI delle donne a livello regionale; a tale scopo, il lavoro propone un modello bayesiano di*

piccola area con effetti casuali atti a cogliere la variabilità intra-regionale della risposta. Il modello lega la variabile di interesse a una serie di caratteristiche socio-economiche individuali quali età, indice di benessere economico, livello di istruzione, numero di figli, tenendo conto della variabilità geografica del BMI. Tuttavia per alcune di tali variabili è ragionevole ipotizzare che siano state misurate con errore. Il modello proposto è stato quindi esteso includendo nella sua formulazione anche la presenza di errore di misurazione nelle covariate. Utilizzando i dati indiviuali risultanti dalle indagini DHS, il modello proposto viene applicato per stimare e confrontare i livelli medi del BMI delle donne di due Paesi, Etiopia e Nigeria, che presentano caratteristiche molto diverse. Le stime dei parametri del modello consentono inoltre di valutare e confrontare le determinanti dello stato nutrizionale delle donne nei due Paesi.

Key words: BMI, Food insecurity, measurement error, small area models

1 Introduction

Although the proportion and absolute number of chronically undernourished people has declined worldwide, progress has been uneven among developing countries. Women are clearly the most critical target group from a nutrition standpoint, therefore data on women's nutritional status is essential in monitoring the socioeconomic development of a country. Indeed it has a direct impact on women's health status, and several indirect effects through the multiple roles of women in generating income inside and outside the household, bearing children and being responsible for their families' nutrition and care. Not surprisingly, for many countries this aspect has been the object of prioritized interventions in the achievement of the Millennium Development Goals.

In this paper we study the Body Mass Index (BMI) in two African countries: Ethiopia and Nigeria. These two countries are very different from several points of view. First of all their geographical position: Nigeria is located in West Africa while Ethiopia is located in the Horn of Africa. Nigeria is often referred to as the "Giant of Africa", owing to its large population and economy. With 186 million inhabitants, Nigeria is the most populous country in Africa and the seventh most populous country in the world. With over 102 million inhabitants, Ethiopia is the most populous landlocked country in the world and the second most populous nation on the African continent.

Despite progress toward eliminating extreme poverty, Ethiopia remains one of the poorest countries in the world, due both to rapid population growth and a low starting base. More than 70% of Ethiopia's population is still employed in the agricultural sector, but services have surpassed agriculture as the principal source of GDP. According to the 2016 World Bank figures, life expectancy in Ethiopia is about 65 years while in Nigeria it is about 53. However, the human development index has been estimated to be equal to 0.448 in Ethiopia and 0.527 in Nigeria, where the

GDP per capita is more than three times as high as Ethiopia (5861$ vs 1734$, data in constant 2011 international dollars). Also, the literacy rate among the population aged 15 years and older is much lower in Ethiopia (39% in 2007) than in Nigeria (55% in the same year).

The figures published for Nigeria by the National Population Commission & ICF International in 2014 based on the 2013 DHS survey data indicate that the mean BMI among women aged 15-49 is 23.0 kg/m2. Instead, the 2011 Ethiopia DHS data give a mean BMI of 20.2 kg/m2. While rural/urban disparities exist in both countries, small geographical differences emerge from the figures published for Nigeria, although the North West has the lowest mean BMI (21.9 kg/m2). Invariably, mean BMI increases with increasing education level and shows a steady increase with increasing wealth. In Nigeria, 11% of women of reproductive age are thin or undernourished (BMI less than 18.5 kg/m2), as opposed to Ethiopia, where, according to the 2011 DHS figures, the same percentage amounts to 27%. Besides this, in Nigeria obesity is a public health problem, with a 17% of women being overweight (BMI of 25-29 kg/m2), and 8% obese (BMI of 30 kg/m2 or above). Notice that in Ethiopia only 6% of women are overweight or obese. In both countries the prevalence of overweight and obesity among women of reproductive age increases with age and is reportedly higher in urban areas than in rural areas. In addition, the wealth index seems to be strongly associated with being overweight or obese.

In this work we study the BMI of women aged 15-49: we consider data from the 2011 Ethiopia DHS and 2013 Nigeria DHS. Data are available at `www.measuredhs.com`. Both surveys were designed to provide population and health indicators at the national (urban and rural) and regional levels (for Ethiopia, the following 11 regions: Tigray, Affar, Amhara, Oromiya, Somali, Benishangul-Gumuz, SNNP, Gambela, Harari, and two city administrations, Addis Ababa and Dire-Dawa; for Nigeria, the 36 states plus the Federal Capital Territory are planned domains, but we consider for comparison the following 6 geo-political zones: South East, South South, South West, North Central, North West and North East). For both countries, the number of observations sampled in each region of interest is not particularly small. However, especially for Ethiopia, high geographical variability and the large population size make the problem of estimating the mean BMI at the domain level worth to be framed in a small area context. This also allows us to investigate the individual determinants of BMI while accounting for geographical variability.

We develop a small area model for studying the effect on BMI level of several potential explanatory variables: for each women, we have considered the number of sons, the education level, if they live in urban or rural centers, the age and the wealth index. The wealth index is built from from sample information on asset ownership, housing characteristics and water and sanitation facilities; it is obtained via a three-step procedure, based on principal components analysis, designed to take better account of urban-rural differences in wealth indicators. Being the result of a complex procedure, we treat the wealth index as a categorical covariate subject to misclassification. We also consider age, being self reported, as a continuous variable observed with error.

2 Small area models

In recent years, small area estimation has emerged as an important area of statistics as a tool for extracting the maximum information from sample survey data. Sample surveys are generally designed to provide estimates of totals and means of variables of interest for large subpopulations or domains. However, governments and policy makers are more and more interested in obtaining statistical summaries for smaller domains such as states or provinces. These domains are called small areas and are usually unplanned so that a small number of units is allocated in each of these areas. *Indirect estimators* are often employed in order to increase the effective domain sample size by borrowing strength from the related areas using linking models, census, administrative data and other auxiliary variables associated with the small areas. Depending on the type of data available, small area models are classified into two types: area-level and unit-level. Area level models relate the small area means to area-specific auxiliary variables. Such models are essential if unit level data are not available. Unit level models relate the unit values of the study variable to unit-specific auxiliary variables with known area means. In this paper we focus on unit-level models within a Bayesian framework. See [9] for an up-to-date review.
In this paper we focus on unit-level small area models given the availability of record-level data, described in Section 1.
Suppose there are m areas and let N_i be the known population size of area i. We denote by Y_{ij} the response of the $j-$th unit in the $i-$th area ($i = 1,...,m$; $j = 1,...,N_i$). A random sample of size n_i is drawn from the $i-$th area. The goal is to predict the small area means

$$\theta_i = N_i^{-1} \sum_{j=1}^{N_i} Y_{ij} \tag{1}$$

based on the observed sample. To develop reliable estimates, auxiliary information, often in forms of covariates, measured at the unit or at the area level, may be exploited.Adopting a superpopulation approach to finite population sampling, a unit-level small area model is defined as

$$Y_{ij} = \alpha + \beta x_i + u_i + \varepsilon_{ij} \qquad i = 1,...,m; \quad j = 1,...,N_i \tag{2}$$

where x_i is an auxiliary variable observed for each area. ε_{ij} and u_i are assumed independent, $\varepsilon_{ij} \overset{\text{iid}}{\sim} N(0,\sigma_e^2)$ and $u_i \overset{\text{iid}}{\sim} N(0,\sigma_u^2)$. A random sample of size n_i is selected from the $i-$th small area ($i = 1,...,m$).
The model in (2) may be estimated based on maximum likelihood [2, 8], Empirical Bayes [5] and hierarchical Bayes approaches [3].
As stressed in [6, 7] auxiliary variables may be measured with error: It is well recognized that the presence of measurement error in covariates causes biases in estimated model parameters and leads to loss of power for detecting interesting relationships among variables. Several solutions exist, also in the small area literature: indeed corrections of the unit-level and area-level estimators have been proposed both in a frequentist and Bayesian context [10, 4, 1]. Relying on the model proposed in

[6], we extend it in order to account for measurement error in both continuous and discrete covariates and explore the impact of our procedure in the assessment of covariates' effect in a small area model designed to estimate regional mean BMI level in Nigeria and Ethiopia.

3 Measurement error small area models

Consider a finite population, whose units are divided into m small areas. As in the previous section, let the population size of the i-th area be N_i, $i = 1, \ldots, m$. Let Y_{ij} be the value of the variable of interest associated with the j-th unit ($j = 1, \ldots, N_i$) in the i-th area ($i = 1, \ldots, m$). A random sample of size $n_i \geq 1$ is drawn from the $i-$th area population and the sample data are denoted by y_{ij} ($i = 1, \ldots, m$; $j = 1, \ldots, n_i$). For each area, we consider the following covariates: t_{ij} – the vector of p continuous or discrete covariates measured without error, w_{ij} and x_{ij} – respectively, a vector of q continuous covariates and h discrete variables (with a total of K categories), both measured with error. Denote by s_{ij} and z_{ij} the observed values of the latent w_{ij} and x_{ij}, respectively. We assume that the perturbation only depends on the unobserved category of the latent variable, so if $h > 1$ we assume independent misclassification. Without loss of generality, in what follows we assume $h = 1$.
Following the notation in [6], the proposed measurement error model can be written in the usual multi-stage way: for $j = 1, \ldots, n_i$, $i = 1, \ldots, m$ and for $k, k' = 1, \ldots, K$

$$\text{Stage 1. } y_{ij} = \theta_{ij} + e_{ij} \qquad e_{ij} \overset{\text{iid}}{\sim} N(0, \sigma_e^2)$$

$$\text{Stage 2. } \theta_{ij} = t_{ij}^{'}\delta + w_{ij}^{'}\gamma + \sum_{k=1}^{K} I(x_{ij} = k)\beta_k + u_i \qquad u_i \overset{\text{iid}}{\sim} N(0, \sigma_u^2)$$

$$\text{Stage 3. } S_{ij}|w_{ij} \overset{\text{iid}}{\sim} N(w_{ij}, \sigma_s^2), \qquad w_{ij} \overset{\text{iid}}{\sim} N(\mu_W, \Sigma_w)$$

$$\mu_W \sim N(0, \sigma_\mu^2 I)$$

$$Pr(Z_{ij} = k|X_{ij} = k') = p_{k'k} \qquad p_{k'.} \sim \text{Dirichlet}(\alpha_{k',1}, \ldots, \alpha_{k',K})$$

$$Pr(X_{ij} = k') = \frac{1}{K}$$

We also assume that $\beta, \delta, \gamma, \sigma_e^2, \sigma_u^2, \sigma_s^2$ are, loosely speaking, a-priori mutually independent; in particular, $\beta \sim N(\mu_\beta, \sigma_\beta), \delta \sim N(\mu_\delta, \sigma_\delta), \gamma \sim N(\mu_\gamma, \sigma_\gamma)$, $\sigma_u^{-2} \sim Gamma(a_u, b_u)$, $\sigma_e^{-2} \sim Gamma(a_e, b_e)$, $\sigma_s^{-2} \sim Gamma(a_s, b_s)$.
Hyperparameters have been chosen to have flat priors. Finally, we assume $\Sigma_w = \sigma_w^2 I$, and σ_w^2, σ_μ^2 and $(\alpha_{k',1}, \ldots, \alpha_{k',K})$ all known.
Stage 3 describes the measurement error model for both continuous and discrete covariates: we assume that the continuous observable covariates S_{ij} are modeled as Gaussian variables centered at the true unobservable value w_{ij} with variability σ_s^2. The model for the unobservable continuous variables w_{ij} is assumed normal with

unknown mean and known variance.
Thanks to the multilevel model formulation, the measurement error mechanism need not to be assumed, which is a useful characteristic of our proposal. For the discrete covariates, the misclassification mechanism is specified according to the unknown $K \times K$ matrix P; we denote its $k'-$th row by $p_{k',}$, whose entries, $p_{k'k}$, represent the probabilities $P(Z_{ij} = k|X_ij = k')$, $k = 1,\ldots K$ that the observable variable Z_{ij} takes the $k-$th category, $k = 1\ldots,K$when the true unobservable variable X_{ij} takes the $k'-$th category. We also assume that the misclassification probabilities are the same across subjects and that all the categories have the same probability $\frac{1}{K}$ to occur.
Over each $p_{k',}$, $k' = 1,\ldots,K$, we place a Dirichlet$(\alpha_{k',1},\ldots,\alpha_{k',K})$ prior distribution, with known parameter. According to the above assumptions, we can estimate the transition matrix P jointly with all the other model parameters.
Using the Bayes theorem, the posterior distribution of the unknown parameter is proportional to the product of the likelihood and the prior distributions specified in Stage 4. As the posterior distribution cannot be derived analytically in closed form, we obtain samples from the posterior distribution using Gibbs sampling.

4 Results and comments

For each country we consider the estimates of the regression parameters obtained under the two models, with and without accounting for measurement error. Previous studies show that not accounting for measurement error may lead to inaccurate estimation of regression coefficients, which in turn may affect small area predictions. Figures 1 and 2 report the posterior distributions of the regression parameters under both models for Ethiopia and Nigeria, respectively. Under the measurement error model (top panels), the covariates' effects are all consistent with expectations. The BMI increases with the wealth index category: the poorest women are more likely to be underweight than the richest ones. Although expected, such an important effect of the wealth index has not been always confirmed in previous studies. Also, in both countries more educated women show a larger BMI than less educated ones, with an effect that increases with the educational level. The model also highlights the great disparity between urban and rural areas, where the women's undernutrition problem is more severe. The number of children ever born (parity) is found to affect women's nutritional status significantly only in Ethiopia, where the BMI decreases with parity. With respect to age, the model highlights positive linear association with BMI: younger women are more likely to be underweight than older ones, as well documented in the literature. On the other hand, under the model that ignores the measurement error in wealth index and age, the strong differential effect of the wealth index is lowered or, in the case of Ethiopia, disappears (see the bottom panel of Figure 1). This is also consistent with findings in the literature, that sporadically identifies this variable as important. With respect to the other parameters, while the meaning of the coefficients is coherent with those obtained with the proposed model, the variables' effects are considerably inflated. Noticeably, for the Nigeria data parity is only significant under the unadjusted model. On the other hand, a linear effect of the wealth index on the BMI emerges quite clearly from the measurement error models in both countries, but not from the naive model. Moreover, the measurement error plays a different role in the two models: in the Ethiopia data, it strongly affects the parameters' estimates and, as expected, the posterior distribution of the P matrix is far from the diagonal one. On the other hand, in the Nigeria data the measurement error has a smaller impact on the estimates as the posterior distributions of the diagonal elements of P are concentrated around 0.9. In conclusion, the proposed model seems to be fairly robust with respect to misspecification of the measurement error mechanism.

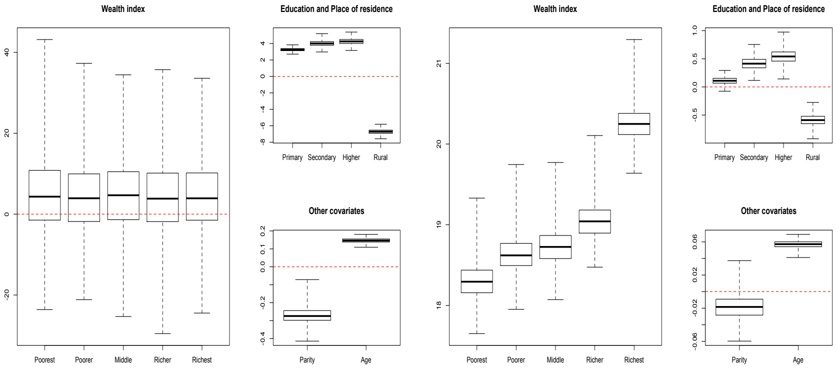

Fig. 1 Ethiopia data: posterior distributions of the model parameters under the proposed model (left panel) and under the assumption that the covariates are measured without error (right panel).

Brexit in Italy

Text Mining of Social Media

Francesca Greco, Livia Celardo, Leonardo Salvatore Alaimo

Abstract The aim of this study is to identify how Italian people talk about Brexit on Twitter, through a text mining approach. We collected all the tweets in Italian language containing the term "Brexit" for a period of 20 days, obtaining a large corpus on which we applied multivariate techniques in order to identify the contents and the sentiments within the shared comments.

Abstract *Questo studio ha lo scopo di identificare in che modo Brexit viene discussa su Twitter dagli Italiani attraverso l'analisi automatica del testo. A questo scopo sono stati raccolti tutti i messaggi in lingua italiana contenenti i termini "Brexit" per 20 giorni, ottenendo un corpus di grandi dimensioni su cui sono state applicate delle tecniche statistiche multivariate al fine di individuare i contenuti e i sentimenti relativi al tema in esame.*

Key words: Brexit, Twitter, Emotional text mining, Co-clustering

Introduction

There is a growing increase in Euroscepticism among EU citizens nowadays, as shown by the development of the ultra-nationalist parties among the European countries. Regarding to European Union membership, public opinion is divided between Eurosceptics and pro-Europeans, as clearly shown by the results of the 2016 British referendum. Many studies about Brexit are focused on the analysis of the electoral result, trying to highlight the effects of possible determinants - such as immigration, economic crisis, socio-economic and demographic characteristics of the voting population - on the electoral choices (Gietel-Bastel, 2016; Goodwin & Heath, 2016; Clark et al., 2017; Alaimo, 2018). Other studies analyse the possible consequences of Brexit, focusing on the economic consequences for United Kingdom (Dhingra et al., 2016; Dodds, 2016; Vikers, 2017). Although Brexit has shaken the European public opinion, there are few studies about how the referendum is actually

perceived by the citizens of European Member States. Moreover, not many analyses are available concerning how Brexit is discussed on the social media.

The wide diffusion of the internet increases the opportunity for millions of people to surf the web, create account profiles and search or share information every day. The constant rise in the number of users of social media platforms, such as Twitter, makes a large amount of data available; these data represent one of the primary sources for exploring people's opinions, sentiments, and emotions (Ceron et al., 2013; Pelagalli et al., 2017).

Due to that, we decided to perform a quantitative study where online discourses regarding Brexit are analysed using two text analysis techniques in parallel: Content Analysis and Emotional Text Mining. The aim is to explore not only the contents but also the sentiments shared by users on Twitter. In this paper we focused only on the analysis of the sentiments and contents published in Italian, in order to understand how Brexit is treated in Italy.

Methods

In order to explore the sentiments and the contents related to Brexit, we scraped from Twitter all the messages written in Italian containing the word *Brexit*, produced from January 23rd to February 18th, 2018. The data extraction was carried out with the TwitteR package of R Statistics. From the data we extracted, we decided to create two sub-corpora: the first one including the retweets and the other one excluding all the retweets. We chose to use two different corpora for the analyses because we were studying both sentiments and contents within our texts; for the analysis of sentiments and emotions it is important to consider also retweets, while for content analysis retweets are just the repetition of the same concepts. Then, the first corpus was composed of 13,662 messengers, including 76.4% of retweets, resulted in a large size corpus of 211,205 of tokens, which underwent the Emotional Text Mining (Greco et al., 2017). A second corpus was extracted excluding all the retweets, resulting in a large size corpus of 46,458 tokens, which underwent the content analysis. In order to check whether it was possible to statistically process data, two lexical indicators were calculated: the type-token ratio (TTR) and the hapax percentage ($TTR_{corpus\ 1}$ = 0.04; $Hapax_{corpus\ 1}$ = 42.2%; $TTR_{corpus\ 2}$ = 0.16; $Hapax_{corpus\ 2}$ = 61.3%). According to the large size of the corpora, the lexical indicators indicate the possibility to proceed with the analyses.

Then, on the first corpus was performed a sentiment analysis, which is a technique used to investigate the sentiments of a text. In text mining, many methods exist to analyse it automatically, which are supervised and unsupervised (e.g., Carli & Paniccia, 2002; Hopkins & King, 2010; Bolasco, 2013; Ceron et al., 2016). We performed the Emotional Text Mining (ETM) (Greco, 2016; Pelagalli et al., 2017; Greco et al., 2018), which is an unsupervised method derived from the Emotional Textual Analysis of Carli and Paniccia (Carli & Paniccia, 2002; Bolasco, 2013); it is based on the idea that people emotionally symbolize an event or an object, and socially share this symbolisation. The words they choose to talk about this event or object is the product of the socially-shared unconscious symbolization. According to this, it is possible to detect the associative links between the words to infer the symbolic matrix determining the coexistence of these terms in the text. In order to perform ETM, first corpus was cleaned and pre-processed with the software T-Lab (version T-Lab Plus 2018) and keywords were selected. In particular, we used lemmas as keywords instead of types, filtering out the lemma *Brexit* and those lemmas of the low rank of frequency (Greco, 2016). Then, on the tweets per keywords matrix, we performed a cluster analysis using the bisecting *k*-means algorithm, limited to twenty partitions (Savaresi & Boley, 2004) and excluding all the tweets having less than two keywords co-occurrence. The eta squared index was used to evaluate and choose the optimal solution in terms of number of clusters. To complete the analysis, a correspondence analysis (Lebart & Salem, 1994) on the keywords per clusters matrix was made, in order to explore the relationship between clusters and identify the emotional categories. The main advantage connected with this approach is the possibility in interpreting the factorial space according to words polarization, thus identifying the emotional categories that generate Brexit representations, facilitating the interpretation of clusters and exploring their relationships within the symbolic space.

On the other hand, content analysis is a technique used to investigate the subjects treated within a text; in text mining, many methods exist to analyse the contents automatically. One of these is the Text Clustering; it consists of splitting the corpus in different subgroups based on words/documents similarities (Iezzi, 2012). In this paper, a text co-clustering approach (Celardo et al., 2016) for contents analysis is used. The objective is to simultaneously classify rows and columns, in order to identify groups of texts characterized by specific contents. To do that, data were pre-processed with Iramuteq software: we lemmatized the texts and we removed stop words and terms with frequency lower than 2. The weighted terms-documents matrix was then co-clustered through the double *k*-means algorithm (Vichi, 2001); the number of clusters for both rows and columns was identified using the Calinski-Harabasz index.

Results

The results of the ETM show that the 240 keywords selected allowed us to classify the 79% of the tweets. The eta squared index was calculated on different partitions – from 3 to 9 clusters, and the values we found showed that the optimal solution is four clusters. The correspondence analysis detected three latent dimensions (Table 1). In figure 1, we can see the emotional map of Brexit emerging from the Italian tweets. It shows how the clusters are placed in the factorial space. The first factor represents the evaluation of the Brexit deal, considering the exit from the EU a bad deal or a good one; the second factor reflects the British political strategy, differing the partisan strategy – which is led by specific political and economic interests, from the public strategy, which is carried on by the government; finally, the third factor represents the post-Brexit effects evaluation, distinguishing the forthcoming impact from the future one. The four clusters are of different sizes (Table 2), and they reflect the Italian sentiments toward Brexit. The first cluster represents the Soros scandal as a conspiracy that disregards the democratic expression of Britons' choice; the second cluster reflects Italian satisfaction in considering Brexit as a bad deal for Britons, who are punished for their betrayal; the third cluster concerns the negative European economic impact of the British policy, which is perceived as an unfair British advantage causing a loss for EU citizens; and the fourth cluster highlights the hope for a British comeback through a new referendum. By clusters interpretation, no group highlights a positive sentiment in the direction of British exit from the EU. Nevertheless, we have considered as positive or satisfactory (51.5%) the British punishment and the hope for a British comeback, and negative the other two (48.5%), the unfair British advantage and the citizen right violation.

Table 1 - *Explained inertia for each factor*

The first six keywords of the clusters are ordered by the number of context units (CU) classified in each cluster

For the content analysis, we firstly pre-processed the corpus, removing all the noise – i.e. stop-words – cutting the messages contents by 83%. Then, on the terms-documents matrix (where documents are represented by the tweets) we calculated the Calinski-Harabasz index, in order to find the number of groups, for both the rows and the columns. The index indicated five groups for words and five for tweets; the results of the co-clustering procedure are shown in the Table 3. The first group of words identifies the common language, representative of all the messages; it is about the general conditions and aspects of Brexit. The 35% of the tweets has, in addition to this, a specific language. Almost the 30% of messages is about the impacts and the effects of Brexit on the local economies and on the political systems. A smaller share of tweets deals with the Soros scandal (5%), while just few messages are about what is going to happen in the near future in Italy.

Table 3: *Centroids matrix resulting from the co-clustering procedure*

Cluster - Label	***1***	***2***	***3***	***4***	***5***
	(65%)	(14%)	(13%)	(5%)	(3%)
1- Brexit	0.005	0.001	0.002	-0.001	0.001

3 - Economic Effects	0.005	**0.066**	0.004	-0.003	0.002
4 - Soros Scandal	0.005	0.004	0.006	-0.007	**0.668**
5 - Forthcoming	0.009	0.004	0.001	**0.624**	0.028

Discussion and conclusion

The results of our analyses showed how “Brexit” is represented by Italians both in terms of sentiments and contents. The Emotional Text Mining revealed the presence of positive and negative sentiments in respect to the consequences of Brexit, but not directly toward the UK exit. A positive sentiment is connected to the punishment of the British choice and the hope of a rethink concerning the UK exit, which is basically perceived as a betrayal. In fact, negative opinions rely on the unfair British advantage and the disregards of the Britons’ referendum choice.

Regarding the content analysis, it identified in the first cluster the common language shared within Twitter, used to describe what happened and is continuing to happen in Europe after Brexit. The other four clusters underline the presence of a specific language. In particular, the second and third clusters focus on the current political and economic effects of Brexit in Europe.

The results of the two analyses showed that Brexit is a theme with a strong emotional charge in the Italian context. Italian people seem to focus their attention mainly toward the economic and political effects of the British choice. This subject is treated negatively from the users, probably because of the worries for the consequences of the British vote in Europe.

Distance based Depth-Depth classifier for directional data

DD-classifier per dati direzionali basati su funzioni di distance-depths

Giuseppe Pandolfo and Giovanni C. Porzio

Sommario The DD-classifier, which has been extended to the classification of directional objects, is here investigated in the case of some new distance-based directional depths. The DD-classifier is a non-parametric techniques based on the depth vs. depth (DD) plot. Its main advantages concern the flexibility and the independence from specific distribution parameters. The new depth functions adopted here allow using them for high-dimensional directional data sets.
Sommario *Il DD-classifier, che è stato esteso alla classificazioni di dati direzionali, viene qui analizzato nel caso di due nuove funzioni di depth recentemente introdotte. Il classifier è un metodo non parametrico basato sul depth vs. depth plot. I maggiori vantaggi riguardano la flessibilità e l'indipendenza da specifiche ipotesi distribuzionali. La nuove funzioni di depth, essendo particolarmente vantaggiose in termini computazionali, permettono di utilizzare questa metodologia anche nel caso di insiemi di dati direzionali a dimensioni elevate.*

Key words: Angular data depth, Chord depth, Classification, Cosine depth.

1 Introduction

Directional data arise when observations are measured as directions or angles, and observations are represented as points on the circumference of the unit circle, or on the surface of the unit hyper-sphere. Simple examples are directions on a compass ($0^\circ - 360^\circ$), and times of the day ($0 - 24$ hours). Higher dimensional directional data arise in text mining and gene expression analysis.

Giovanni C. Porzio
University of Cassino and Southern Lazio, Cassino e-mail: porzio@unicas.it

They play thus an important role in many fields such as biology, meteorology, neurology and physics. Within the literature, directional data are presented and discussed in books by Mardia (2000) and Batschelet (1981). They provide a wide survey about specific features and problems we have to face when dealing with them.

Specific statistical methods are needed to analyse directional data. This is due to the periodicity and boundness of the sample space. To make it clearer, one may consider two angles of 10° and 350° which are 20° far away from each other. If treated as linear data, their arithmetic mean would be equal to 180°, while their correct directional mean is 0°. Hence, to avoid misleading results, appropriate techniques are necessary to perform directional data analysis, and this applies to classification in directional spaces as well.

In this work, the focus is on supervised classification (also called discriminant analysis), where the aim is to assign observations to classes (or groups), given a previous knowledge on their structures obtained through some preliminary observed data.

Specifically, we consider the directional non-parametric DD-classifier introduced in Pandolfo (2014, 2015), and further investigated in Pandolfo (2017).

The classifier evaluates the depth of a new observation with respect to some previously collected samples (a depth wrt each of the groups), and then uses its value as a basis for a classification rule. While Pandolfo (2014, 2015, 2017) investigated such a tool adopting different notions of depth functions already available within the literature, this work focuses on the advantages that can be obtained if some new depth functions are adopted. Pandolfo et al. (2017) recently introduced a new class of functions based on directional distances. It seems one of the main advantages of these functions is their computational feasibility. For this reason, they might be particularly suitable to deal with non-parametric classification problem in high-dimensional spaces. This essentially motivates this work, whose aim is to present a performance analysis of the directional DD-classifier under these two new depth functions.

The paper is organized as follows: Section 2 briefly recalls the definition of these new directional depth functions and presents the related classifier; Section 3 offers some concluding remarks.

2 Non-parametric classification using data depth

The literature on nonparametric discriminant analysis for directional data is not particularly extensive. Liu and Singh (1992) discussed methods for ordering directional data and suggested a possible solution for discriminant analysis. That is, an observation can be classified according to its center-outward ordering with respect to two given competing distributions. Later, following the linear approach by Stoller (1954) a circular discriminant analytical method was proposed by Ackermann (1997). This method, which looks for the pair of splitting angles which maximizes the probability of correct classification. Unfortunately, this solution requires solving an NP-complex problem, and hence it is quite computationally infeasible.

Several tools are available for classification problems in standard multivariate analysis. Assuming normality, linear discriminant analysis is probably the most used. Many other methods, both parametric and non-parametric, are available as well. Non-parametric classifiers have the important advantage to be more flexible, given that they do not require any distribution assumptions. Amongst them, this work focuses on classifiers based on data depth. Considering their full non-parametric nature, they can be used in many different contests.

The depth of a point $x \in \mathbb{R}^q$ (for dimension $q \geq 1$) is a function that measures the "centrality" or "deepness" of it with respect to a multivariate distribution F or a multivariate data cloud, and it is denoted by $D(x, F)$.

Some notions of angular data depth are available within the literature: the *angular simplicial depth*, the *angular Tukey's depth* and the *arc distance depth*. All these were given in Liu and Singh (1992). More recently Pandolfo et al. (2017) introduced a class of depth functions for directional data based on angular distances. The class is defined below.

Let $\mathscr{S}^{q-1}$ be the unit sphere in a $q-1$ dimensional space. A particular member of the class will be obtained by fixing a particular (bounded) distance $d(\cdot,\cdot)$ on $\mathscr{S}^{q-1}$. For such a distance, $d^{\sup} := \sup\{d(\theta,\psi) : \theta,\psi \in \mathscr{S}^{q-1}\}$ will denote the upper bound of the distance between any two points on $\mathscr{S}^{q-1}$. We have the following definition (Pandolfo et al., 2017).

Definition 1 (Directional distance-based depths) *Let $d(\cdot,\cdot)$ be a bounded distance on $\mathscr{S}^{q-1}$ and H be a distribution on $\mathscr{S}^{q-1}$. Then the* directional d-depth of $\theta(\in \mathscr{S}^{q-1})$ with respect to H *is*

$$D_d(\theta, H) := d^{\sup} - E_H[d(\theta, W)], \tag{1}$$

where E_H is the expectation under the assumption that W has distribution H.

Accordingly, two new easy-to-compute directional depth functions can be obtained if the distance in (1) is chosen to be the chord or the cosine distance, respectively. While the main properties of these functions have been investigated in Pandolfo et al. (2017), their use within a DD-classifier is investigated here.

2.1 Depth-based classifiers and the DD-plot

After the first suggestion in Liu and Singh (1992), the use of data depth to perform supervised classification has been suggested and investigated by many authors. Two main approaches have been adopted in the literature: the *maximum depth classifier* and the *Depth vs Depth* (*DD*) classifier. The latter (that is a refinement of the former) is based on the *DD*-plot (Depth vs Depth plot), introduced by Liu et al. (1999).

The *DD*-plot is a two-dimensional scatterplot where each data point is represented with coordinates given by its depth evaluated with respect to two distributions. A classification rule $r(\cdot)$ is then directly applied in this latter. The same procedure can be applied to any kind of data, providing that a corresponding depth function exists. For istance, DD-plot for functional data have been developed.

For directional data, the following questions arise. First, it is of interest to investigate if some depths perform better than others. Second, the classification rule to be adopted within the plot may also affect performances. A proper simulation study has been thus developed in order to suggest under which conditions one depth function should be preferred over the other.

3 Concluding remarks

The depth vs. depth classification method extended to directional data has been investigated here when some new distance based depth functions are adopted. The idea of depth provides a criterion to order a directional sample from center-outward, providing a new way to classify directional objects. The performance in terms of average misclassification rate of the classifiers is evaluated by means of a simulation study. Furthermore, their use is illustrated through a real data example. First results are promising, calling for further investigation on the performance under different directional settings.

Approximate Bayesian Computation for Forecasting in Hydrological models

Metodi Bayesian approssimati per le previsioni nei modelli idrologici

Jonathan Romero-Cuéllar, Antonino Abbruzzo, Giada Adelfio and Félix Francés

Abstract Approximate Bayesian Computation (ABC) is a statistical tool for handling parameter inference in a range of challenging statistical problems, mostly characterized by an intractable likelihood function. In this paper, we focus on the application of ABC to hydrological models, not as a tool for parametric inference, but as a mechanism for generating probabilistic forecasts. This mechanism is referred as Approximate Bayesian Forecasting (ABF). The abcd water balance model is applied to a case study on Aipe river basin in Columbia to demonstrate the applicability of ABF. The predictivity of the ABF is compared with the predictivity of the MCMC algorithm. The results show that the ABF method as similar performance as the MCMC algorithm in terms of forecasting. Despite the latter is a very flexible tool and it usually gives better parameter estimates it needs a tractable likelihood.
Abstract *In questo articolo, il metodo chiamato Approximate Bayesian Computation (ABC) viene applicato ai modelli idrologici, non come uno strumento per l'inferenza parametrica, ma come un meccanismo per generare previsioni probabilistiche, dando luogo all'Approximate Bayesian Forecasting (ABF). L'ABF è applicato a un caso studio sul bacino del fiume Aipe in Colombia. Viene considerato un modello idrologico semplice per dimostrare l'applicabilità di ABF e confrontarlo con la predittività del metodo MCMC. Nonostante i risultati mostrano che il metodo ABF e l'algoritmo MCMC non differiscono in termmini di previsioni ottenute, l'ABF è comunque uno strumento molto flessibile e fornisce risultati utili anche quando si è in presenza di una verosimiglianza intrattabile.*

1 Introduction

In hydrological models, predictions are crucial for supporting decision-making and water management. Reliability of prediction of hydrologic outcomes is affected by several sources of uncertainty such as input or forcing data uncertainty, initial conditions, model uncertainty or epistemic error, parameters inference, output uncertainty. So several sources of uncertainty affect the full predictive uncertainty, that is the probability of occurrence of a future value of a response variable (streamflow, water level) conditional on all the covariates, usually provided by forecasting models [9]. Therefore, the forecast approaches, rather than looking for deterministic predictions, essentially aim at quantifying predictive uncertainty. Predictive uncertainty estimation in hydrological models is a challenge when dealing with intractable likelihoods. The Approximate Bayesian Computation (ABC) overcomes the likelihood-based approach via the use of sufficient statistics and simulated data [1]. The idea behind the ABC approach was first introduced in population and evolutionary genetics [6, 7]. The ABC has a wide range of application domains because it is useful when an explicit likelihood function cannot be justified [10]. The main focus, of the most of the studies about the ABC, is the quantification of uncertainty about parameters [2]. Together with the increasing applications of ABC (see [4] for recent surveys), attention has recently been paid to the theoretical properties of the method, including the asymptotic behaviour of: the ABC posterior distributions, the point estimates derived from those distributions, and the Bayes factors that condition on summaries (see for instance [4]). The ABC approach in hydrological models is introduced in [11], using the ABC to estimate posterior distributions of parameters for simulation-based models.

The aim of this paper is to introduce the ABC as an approach for generating probabilistic forecasts in hydrological models. This approach is referred to Approximate Bayesian Forecasting (ABF) [2]. A streamflow forecasting on a case study of the Aipe river basin in Columbia is used to show the potential strength of the ABF. Predictions derived from the ABF algorithm are compared to prediction derived from the MCMC algorithm.

This paper is structured as follows. In the first section, we describe a simple hydrological model. In the second section, we describe the application of the ABC for the hydrological model. In the third section, we compare the ABF and the MCMC algorithm.

2 Approxiamte Bayesian Forecasting for the hydrological model

The abcd water balance model is a hydrological model for simulating streamflow (see [8]). This model is a fairly general conceptual rainfall-runoff model which transforms rainfall and potential evapotranspiration data to streamflow at the catchment outlet. The model is comprised of two storage compartments: soil moisture and groundwater. The soil moisture gains water from precipitation and loses water to evapotranspiration, surface runoff, and groundwater recharge. The groundwater compartment gains water from recharge and loses water as discharge. The total streamflow, which is the outcome we are interested in, is the sum of surface runoff from the soil moisture and groundwater discharge. It applies the continuity equation to a control volume representing the upper soil zone, from which evapotranspiration is assumed to occur, so that

$$Sw_t + ET_t + Q_t + R_t = Sw_{t-1} + P_t, \tag{1}$$

where P_t is a total precipitation for the month, ET_t is actual evapotranspiration, R_t is recharge to groundwater storage, Q_t is upper zone contribution to runoff, and Sw_t and Sw_{t-1} represent upper soil zone soil moisture storage at the current and previous time steps respectively. For the groundwater component, the mass balance equation is

$$Sg_t + Qg_t = Sg_{t-1} + R_t, \tag{2}$$

where Qg_t is groundwater discharge, Sg_t and Sg_{t-1} represent groundwater storage at the current and previous time steps, respectively. More details about the abcd water balance model are in [8] and [5]. Equations (1) and (2) produce the streamflow output for t times. We denote this variable by $\tilde{\mathbf{y}} = \{\tilde{y}_1, \ldots, \tilde{y}_t, \ldots, \tilde{y}_T\}$. Starting from this result, the ABC is used as hydrologic post-processor. Hydrologic post-processing works directly on hydrologic model outputs by using a statistical model to represent the relationship between model outputs and corresponding observations. It serves the purpose of removing model biases from all upstream uncertainty sources. In this paper, we use the ABC to estimate the parameters of the linear model

$$y_t = \beta_0 + \beta_1 \tilde{y}_t + \varepsilon_t, \tag{3}$$

where y_t is the observed streamflow at time t, β_0 and β_1 are parameters, $\tilde{y}_t$ is the output form the abcd model (equations (1) and (2)). The random variable ε_t is the error term in the model, representing random fluctuations, i.e. the effect of factor outside of our control or measurement, such that $\varepsilon_t \sim N(0, \sigma^2)$, i.i.d. Specifically, the ABC produces draws from an approximation of the posterior distribution of $\theta = (\beta_0, \beta_1, \sigma^2)$, i.e.

$$p(\theta|\mathbf{y}) \propto p(\mathbf{y}|\theta)p(\theta),$$

where $p(\theta)$ is the prior, $p(\mathbf{y}|\theta)$ is the distribution of $\mathbf{y}$ conditional on the parameters. Even though we can use ABC with intractable likelihood $\ell(\theta|\mathbf{y})$, we must be able to simulate data from $p(\theta)$ and $p(\mathbf{y}|\theta)$. We assume flat normal priors for β_0 and β_1 and $Y_t|\theta \sim N(\mu_t = \beta_0 + \beta_1 \tilde{y}_t, \sigma^2)$. The pseudo code for the ABC is summarized in Algorithm 1. Algorithm 1 thus samples θ and pseudo-data $\mathbf{z}$ from the joint posterior:

$$p_\varepsilon(\theta, \mathbf{z}|\eta(\mathbf{y})) = \frac{p(\theta)p(\mathbf{z}|\theta)\mathbb{I}(\mathbf{z})}{\int_\Theta \int_\mathbf{z} p(\theta)p(\mathbf{z}|\theta)\mathbb{I}(\mathbf{z})d\Theta d\mathbf{z}} \tag{4}$$

The ABF produces the approximate predictive uncentanty formally defined as

Algorithm 1 ABC accept/reject algorithm

```
1: $\theta^i$, $i = 1,\ldots,N$ from $p(\theta)$
2: $\mathbf{z}^i = (z_1^i, z_2^i, \ldots, z_T^i)^\top$, $i = 1,\ldots,N$, from the likelihood, $p(\cdot|\theta^i)$
3: Select $\theta^i$ such that:
       $d\{\eta(\mathbf{y}), \eta(\mathbf{z}^i)\} \leq \varepsilon$
   where $\eta(\cdot)$ is a vector statistic, $d\{\cdot\}$ is a distance criterion, and, given $N$, the tolarence level $\varepsilon$ is chosen to be small.
```

$$g(y_{T+1}|\mathbf{y}) = \int_{\Theta} p(y_{T+1}|\theta, \mathbf{y}) p_{\varepsilon}(\theta|\eta(\mathbf{y})) d\theta, \tag{5}$$

where $p_{\varepsilon}(\theta|\eta(\mathbf{y})) = \int_{\mathbf{z}} p_{\varepsilon}(\theta, \mathbf{z}|\eta(\mathbf{y})) d\mathbf{z}$.

3 Streamflow data analysis

We use monthly data of mean areal precipitation, mean areal potential evaporation, and so the other variables of the abcd model, from the Aipe river basin at Huila, Colombia, that is a tropical basin described in the study by [3]. Fig. 1 represents some characteristics of the hydrological behavior of the Aipe river basin. We ap-

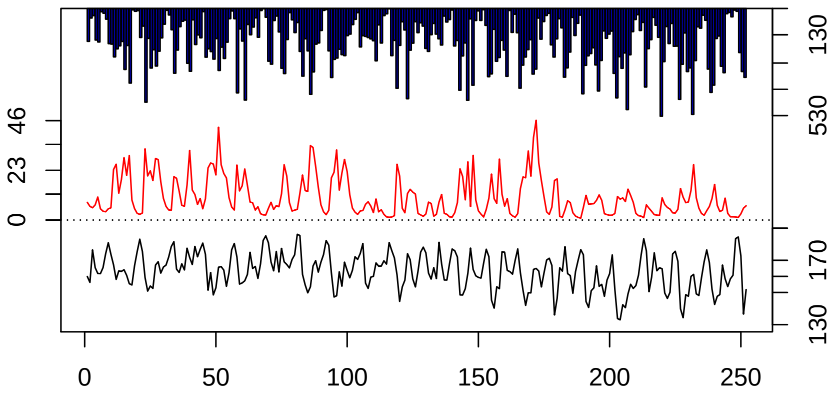

Fig. 1 Monthly time series of Aipe river basin. The blue histogram corresponds to the rainfall (mm), the red line corresponds to the runoff $(m^3 s^{-1})$ and the black line corresponds to the potential evaporation (mm).

ply both the ABC and the MCMC algorithm to obtain parameters estimation of the model (3). Moreover, the ABF is used to assess the predictive uncertainty and compared to the MCMC predictive distribution. The MCMC algorithm is used as a benchmark, since it takes advantage of the likelihood which, for the model we are dealing with, is tractable. To produce the results for the ABF we set the Euclidean distance and choose the mean and the standard deviation as sufficient statistics. In Fig. 2 we show the results of the MCMC and ABC approaches. Although the MCMC and ABC posteriors for both the elements of $\theta = (\beta_0, \beta_1)$ are quite a different one from the other (panel on the left and in the middle), the predictive distributions are quite close and similar.

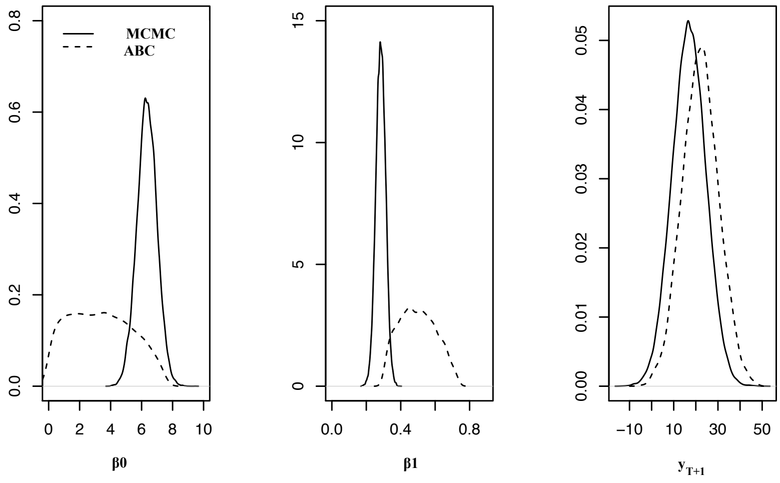

Fig. 2 Marginal posteriors fro the parameters, both considering the MCMC and ABC methods for the monthly time series of Aipe river basin (on the left and in the middle). Predictive density functions both MCMC and ABC (on the right).

4 Conclusion

In this paper, we discuss the use of the Approximate Bayesian Forecasting for hydrological models. The advantage of this tech niche is the applicability for intractable likelihood. This characteristic can make this model very appealing in hydrological forecasting. Even though the ABC seems inappropriate for parameter estimation (probably due to the choice of sufficient statistics) it shows good performance (similar to the MCMC algorithm) in terms of prediction.

Customer Churn prediction based on eXtreme Gradient Boosting classifier

Previsione della probabilità di non ritorno della clientela attraverso il metodo di classificazione eXtreme Gradient Boosting

Mohammed Hassan Elbedawi Omar and Matteo Borrotti

Abstract Nowadays, Machine Learning (ML) is a hot topic in many different fields. Marketing is one of the best sectors in which ML is giving more advantages. In this field, customer retention models (churn models) aim to identify early churn signals and recognize customers with an increased likelihood to leave voluntarily. Churn problems fit in the classification framework, and several ML approaches have been tested. In this work, we apply an innovative classification approach, eXtreme Gradient Boosting (XGBoost). XGBoost demostrated to be a powerful technique for churn modelling purpose applied to the retail sector.

Abstract *Al giorno d'oggi, il Machine Learning (ML) è un argomento estremamente importante in differenti settori. Ad esempio, il marketing rappresenta uno dei settori più vivi per l'applicazione di metodi di ML. In questo settore, i modelli di customer retention (modelli di churn) analizzano il comportamento dei clienti per individuare quali di questi non torneranno a effettuare acquisti. Questo problema può essere tradotto in un problema di classificazione e molti modelli di ML sono stati testati. In questo lavoro applicheremo un innovativo approccio di classificazione, eXtreme Gradient Boosting (XGBoost) al settore del commercio al dettaglio. Dai risultati ottenuti, si può notare che XGBoost può essere considerato come una tecnica molto efficace per i modelli di churn.*

1 Introduction

Machine learning (ML) is gaining momentum due to a virtually unlimited number of possible uses and applications. ML is capable to produce models that can analyse bigger and more complex data and deliver accurate insights in order to identify profitable opportunities or to avoid unknown risks. As more data becomes available, more ambitious problems can be tackled. ML is widely used in many fields, such as: recommender systems, credit scoring, fraud detection, drug design, and many other applications.

An important sector where ML is widely applied is marketing. An important topic is related to customer segmentation [6]. In customer segmentation, clustering approaches are used to group customers based on their purchase behaviour. Another important ML application is customer retention. The cost of customer acquisition is much greater than the cost of customer retention and companies are interested in improving customer retention models (churn models). Churn models aim to identify early churn signals and recognize customers with an increased likelihood to leave voluntarily [8, 4].

In this work, we evaluate the performance of a novel approach, eXtreme Gradient Boosting (XGBoost) [2] classifier, on the churn problem. XGBoost is a scalable machine learning system for tree boosting. XGBoost differs from classical tree boosting algorithms for handling sparse data and a theoretically justified weighted quantile sketch procedure, which enables handling instance weights in approximate tree learning. XGBoost algorithm is compared with a classical Decision Tree classifier [7]. The two algorithms are applied to the problem of customers churning in the retail sector. XGBoost outperforms the Decision Tree classifier demonstrating to be a promising approach for customer retention models.

2 eXtreme Gradient Boosting (XGBoost)

The XGBoost algorithm [2] is based on the Gradient Boosted Decision Tree (GBDT) [3]. The following description is based on the work of [9]. XGBoost efficiently deals with sparse data and is suitable for large-scale dataset since implements distrubuted and parallel computing flexibility. XGBoost estimates the target feature by a series of decision tree and defining quantised weight for each leaf node. The prediction function is defined as follows:

$$\hat{y}_i = \sum_{k=1}^{K} f_k(\mathbf{x}_i), \tag{1}$$

where $\hat{y}_i$ is the predicted class of the $i-th$ observation, $\mathbf{x}_i$ is the corresponding feature vector, K is the total number of decision trees. The function f_k is defined as

$$f_k(\mathbf{x}_i) = \omega_{q_k(\mathbf{x}_i)}, \tag{2}$$

where $q_k(\mathbf{x}_i)$ is the structure function of the $k-th$ decision tree that map $\mathbf{x}_i$ to the corresponding leaf node and ω is the vector of the quantised weight.

The accuracy and complexity of the model are taken into account by a regularisation term added to the loss function. The learning process is based on the minimisation of the following loss function:

$$L_t = \sum_{i=1}^{n} l(y_i, \hat{y}_i) + \sum_{k=1}^{K} \Omega(f_k), \tag{3}$$

where l is the loss function. The loss function measures the differences between the observed and predicted classes. Ω denotes the complexity of the model.

3 Experimental settings

We consider a dataset composed of 7013 customers belonging to a pet shop. Sensible data were anonymised for privacy purpose. For each customer, the following features are considered: (1) Total net amount of money spent in the considered period, (2) Total amount of discount in the considered period, (3) Number of receipts in the considered period, (4) Number of days since last purchase, (5) Number of days between first and last purchases in the considered period, (6) Average number of days between purchases and (7) Label that is equal to 1 if the customer made at least a purchase in a precise period or 0 otherwise (target feature). It should be noticed that features number (1), (3) and (4) correspond to the Recency (R), Frequency (F) and Monetary (M) features of the well-known RFM model [5].

Features were computed considering the transactions from 29^{th} October 2017 to 21^{th} January 2018. The target feature was identified considering the transactions from 22^{th} January 2018 to 2^{nd} February 2018.

The dataset is divided in three parts: 65% training set, 20% validation set and 15% test set. The validation set is used for parameters optimisation purposes. The Decision Tree and XGBoost's parameters considered for optimisation are the maximum depth of a tree (*max_depth*: $\{2,6,10\}$) and the number of trees (*n_estimators*: $\{100,500,900\}$). For both algorithms, the maximum number of iterations (*nrounds*) is fixed to 100. The XGBoost's learning rate (*eta*) is fixed to 0.01 to avoid early convergence.

XGBoost and Decision Tree were implemented in Python 3.5.4 using XGBoost package version 0.7 and scikit-learn package version 0.19.1.

3.1 Performance metrics

The XGBoost and Decision Tree's performance were evaluated using two metrics: accuracy and logarithmic loss (log-loss) [10]. The confusion matrix (see Table 1) is also used to analysed the general behaviour of the approach.

Accuracy is defined as $Accuracy = \frac{T_p+T_n}{T_p+F_p+T_n+F_n}$.

Table 1 Confusion matrix.

	Observed class 1	Observed class 0
Predicted class 1	True positive (T_p)	False positive (F_p)
Predicted class 0	False negative (F_n)	True negative (T_n)

Log-loss is defined as $l_n = -\frac{1}{n}\sum_{i=1}^{n}\sum_{j=1}^{c} y_{ij}log(\hat{y}_{ij})$, where n is the number of observations to be predicted, c is the number of classes (i.e. $c = 2$), y is the observed class and $\hat{y}$ is the predicted probability class. Log-loss should be minimized.

In simple words, accuracy is the count of predicted classes correctly classified among the observed ones. Log-loss takes into account the uncertainty of the predicted class based on how much it varies from the observed class.

These metrics were used to compare XGBoost and Decision Tree on the validation set. Furthermore, we considered the Receiver Operating Characteristic (ROC) curve [1] as a performance metric on the test set. Receiver Operating Characteristic (ROC) curve is based on true positive rate, $P(Tp) = \frac{T_p}{T_p+F_n}$, and false positive rate, $P(Fp) = \frac{F_p}{T_n+F_p}$. ROC curve is used to show in a graphical way the trade-off between true positive rate and false positive rate. The area under the ROC curve is a measure of accuracy.

4 Results

XGBoost and Decision Tree were compared on the validation set. Table 2 shows the performance metrics for all the possible parameters configurations considered in this study. Decision Tree has the best performance with number of trees (*n_estimators*) equal to 500 and maximum depth of a tree (*max_depth*) equal to 10. More precisely, an accuracy of 0.834 and log-loss 0.396. Decision Tree has a similar behaviour also increasing the number of trees. XGBoost reaches the best accuracy (0.895) and log-loss (0.317) with number of trees (*n_estimators*) equal to 900 and maximum depth of a tree (*max_depth*) equal to 10. XGBoost outperforms Decision Tree in all parameters configurations except when the number of trees (*n_estimators*) is set to 100.

Given the obtained results, XGBoost were deplyed on the test set with the best configuration previously found (*n_estimators* = 900 and *max_depth* = 10). Table 3

Table 2 Performance results of Decision Tree classifier on the Validation set.

		Decision Tree		**XGBoost**	
n_estimators	*max_depth*	*Accuracy*	*Log-loss*	*Accuracy*	*Log-loss*
100	2	0.732	0.549	0.727	0.575
100	6	0.756	0.508	0.761	0.543
100	10	0.832	0.396	0.832	0.483
500	2	0.735	0.549	0.743	0.536
500	6	0.757	0.507	0.780	0.462
500	10	0.834	0.396	0.870	0.346
900	2	0.733	0.549	0.743	0.533
900	6	0.756	0.507	0.792	0.437
900	10	0.833	0.396	**0.895**	**0.317**

shows the obtained confusion matrix. The confusion matrix highlights an issue on the prediction of class 0 (not churned people). This issue arises when the two classes are unbalanced. An accuracy of 0.734 and log-loss of 0.567 were obtained. The two metrics exhibit a deterioration from validation set to test set. This deterioration shows a low generalization power of the XGBoost with the parameters configuration selected.

Table 3 Confusion matrix of the XGBoost Classifier on the Test set.

	Observed class 1	Observed class 0
Predicted class 1	557	97
Predicted class 0	169	178

The ROC curve shows a good performance in terms of area under the curve, which is equal to 0.744.

5 Conclusions and future work

In this work, XGBoost is applied to the customer retention (churn) modelling problems. Churn models are appealing tools for the marketing sector. The novel classifier is compared with the Decision Tree. The two approaches were tested on a dataset related to retail sector. From the empirical study, XGBoost outperforms Decision Tree classifier in all the parameters configurations tested except when the number of trees (*n_estimators*) is set to 100.

The best XGBoost's configuration (*n_estimators* = 900 and *max_depth* = 10) was evaluated on the Test set. XGBoost confirms the good results obtained in the validation set but some issues arise. First of all, the target feature was identified considering the transactions from 22^{th} January 2018 to 2^{nd} February 2018. A sensitive

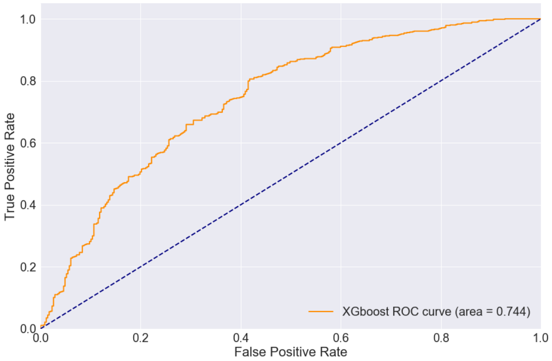

Fig. 1 ROC curve of the XGBoost classifier on the Test set.

analysis on the time window used for target feature definition should be done in oder to improve prediction capability. Additionally, XGboost should be compared with more classification approaches in order to understand the main advantages and disadvantages. A wider parameter analysis needs to be carried out to improve the generalization power. Techniques for unbalanced data should be considered to avoid misclassification problems.

Given that, XGBoost is a promising approach for customer retention modelling problems.

HPC-accelerated Approximate Bayesian Computation for Biological Science

Ritabrata Dutta

Abstract Approximate Bayesian computation (ABC) provides us a rigorous tool to perform parameter inference for models without an easily accessible likelihood function. Here we give a short introduction to ABC, focusing on applications in biological science: estimation of parameters of an epidemiological spreading process on a network and a numerical platelets deposition model. Furthermore, we introduce users to a Python suite implementing ABC algorithms, with optimal use of high performance computing (HPC) facilities.

Key words: Approximate Bayesian Computation, Biological science, ABCpy

Introduction

With the recent innovations in biological science, we are increasingly facing large datasets of varied type and more realistic but complex models of natural phenomenon. This trend has led to a scenario where we do not easily have a likelihood function which is available in closed form and thus easy to evaluate at any given point (as required by most Monte Carlo and Markov chain Monte Carlo methods). Thus, traditional likelihood based inference, as Maximum likelihood or Bayesian methodology, is not possible. Still, if from the complex model, given values of the parameters that index it, we can forward simulate pseudo-dataset, a new methodology becomes available, namely Approximate Bayesian Computation (ABC). Models that have this possibility of forward simulation are known as simulator-based models and are becoming more and more popular in diverse fields of science [Martinez et al., 2016, Turchin et al., 2013, Schaye et al., 2015]; just restricting to the biological domain we can find many examples: evolution of genomes [Marttinen

Ritabrata Dutta
Institute of Computational Science, Università della Svizzera italiana, Switzerland, e-mail: duttar@usi.ch

et al., 2015], numerical model of platelet deposition [Chopard et al., 2017], demographic spread of a species [Excoffier et al., 2013] among many. Research in statistical science in the last decade or so, has illustrateted how ABC can be a tool to infer and calibrate the parameters of these models.

The fundamental rejection ABC sampling scheme iterates between three step: First a pseudo-dataset, $\boldsymbol{x}^{\text{sim}}$, is simulated from the simulator-based model $\mathscr{M}(\boldsymbol{\phi})$ for a fixed parameter value of $\boldsymbol{\phi}$. Then we compute a measure of the closeness between $\boldsymbol{x}^{\text{sim}}$ and $\boldsymbol{x}^0$, the observed dataset, using a pre-defined discrepancy measure $d(\boldsymbol{x}^{\text{sim}},\boldsymbol{x}^0)$. Finally, based on this discrepancy measure, ABC accepts the parameter value $\boldsymbol{\phi}$ when $d(\boldsymbol{x}^{\text{sim}},\boldsymbol{x}^0)$ is less than a pre-specified threshold value ε.

Following this ABC sampler, the intractable likelihood $\mathscr{L}(\boldsymbol{\phi})$ is approximated by $\mathscr{L}_{d,\varepsilon}(\boldsymbol{\phi})$ for some $\varepsilon > 0$, where

$$\mathscr{L}_{d,\varepsilon}(\boldsymbol{\phi}) \propto P(d(\boldsymbol{x}^{\text{sim}},\boldsymbol{x}^0) < \varepsilon) \tag{1}$$

and, as a consequence, the accepted parameters follow the posterior distribution of $\boldsymbol{\phi}$ conditional on $d(\boldsymbol{x}^{\text{sim}},\boldsymbol{x}^0) < \varepsilon$:

$$p_{d,\varepsilon}(\boldsymbol{\phi}|\boldsymbol{x}^0) \propto P(d(\boldsymbol{x}^{\text{sim}},\boldsymbol{x}^0) < \varepsilon)\pi(\boldsymbol{\phi}).$$

For a better approximation of the likelihood function, computationally efficient sequential ABC algorithms [Marin et al., 2012, Lenormand et al., 2013, Albert et al., 2015] decrease the value of the threshold ε adaptively while exploring the parameter space.

The crucial aspect for a good ABC approximation to the likelihood function is the choice of the summary statistics, as we define the discrepancy measure between $\boldsymbol{x}^{\text{sim}}$ and $\boldsymbol{x}^0$ through a distance between the extracted summary statistics from $\boldsymbol{x}^{\text{sim}}$ and $\boldsymbol{x}^0$. Knowledge domain driven summary statistics are normally chosen keeping in mind that we want to minimize the loss of information on $\boldsymbol{\phi}$ contained in the data through the choice of summary statistics. But one can also rely on automatic summary selection for ABC, thus removing a subjective component in this choice, as described in Fearnhead and Prangle [2012], Pudlo et al. [2015], Jiang et al. [2015] and Gutmann et al. [2017].

ABCpy

ABC provides a tool for statistical inference for simulator-based models, still, the necessity to simulate lots of pseudo-data, makes the algorithm extremely computationally expensive when data-simulation itself is costly. Further, the varied types of data sets available in different domain specific problems have hindered the applicability of ABC algorithms to many applied science domains. Recently, [Dutta et al., 2017a,d], have developed an High Performance Computing framework to efficiently parallelize different ABC algorithms which we believe will be extremely beneficial for inferential problems across different scientific domains.

ABC and HPC were first brought together in the ABC-sysbio package for the systems biology community, where sequential Monte Carlo ABC (ABC-SMC) [T. Toni, 2009] algorithm was efficiently parallelized using graphics processing units (GPUs). The goal of ABCpy was to overcome the need for users to have knowledge of parallel programming, as is required for using ABC-sysbio [Liepe et al., 2010], and also to make a software package available for scientists across domains. These objectives were partly addressed by parallelization of ABC-SMC using MPI/OpenMPI Stram et al. [2015], and by making ABC-SMC available for the astronomical community Jennings and Madigan [2016]. Regardless of these advances, a recent ABC review article Lintusaari et al. [2017] highlights the depth and breadth of available ABC algorithms, which can be optimally efficient only via parallelization in an HPC environment Kulakova et al. [2016], Chiachio et al. [2014]. These developments emphasized the need of a generalized HPC supported platform for efficient ABC algorithms, which can be parallelized on multi-processor computers or computing clusters and is accessible to a broad range of scientists.

ABCpy addressed this need for an user-friendly scientific library of ABC algorithms, which is written in Python and designed in a highly modular fashion. Existing ABC software suites are mainly domain-specific and optimized for a narrower class of problems. Modularity of ABCpy makes it intuitive to use and easy to extend. Further, it enables users to run ABC sampling schemes in parallel without too much re-factoring of existing code. ABCpy includes likelihood free inference schemes, both based on discrepancy measures and approximate likelihood, providing a complete environment to develop new ABC algorithms.

Illustrative Applications

To highlight the versatility of ABC and ABCpy in diverse applied problems, we point the interested reader to two recent research papers with biological applications in mind: a) estimation of parameters of an epidemiological spreading process on a contact network[Dutta et al., 2017c] and b) estimation of parameters of a numerical platelets deposition model [Dutta et al., 2017b].

Epidemics on a Contact Network

Infectious diseases are studied to understand their spreading mechanisms, to evaluate control strategies and to predict the risk and course of future outbreaks. Because people only interact with a small number of individuals, and because the structure of these inter- actions matters for spreading processes, the pairwise relationships between individuals in a population can be usefully represented by a network. For modeling the spread of infections on a human contact network, we consider a simple spreading process, i.e., the standard susceptible-infected (SI) process with unit infectivity on a fixed network [Zhou et al., 2006, Staples et al., 2016]. In this model, there are only two states, susceptible and infected, and this process is suitable for modeling the spread of pathogens in contact networks because a single successful exposure can be sufficient for transmission. In this process, at each time step, each infected node chooses one of its neighbors with equal probability regardless of their status (susceptible or infected), and if this neighboring node is susceptible, the node successfully infects it with probability θ. We denote this model by $\mathscr{M}_S$ and parametrize it in terms of the spreading rate θ and of the seed node (the node representing the first infected person) n_{SN}. For given values of these two parameters, $n_{\text{SN}} = n^*_{\text{SN}}$ and $\theta = \theta^*$, we can forward simulate the evolving epidemic over time using the $\mathscr{M}_S$ model as

$$\mathscr{M}_S[n^*_{\text{SN}}, \theta^*] \rightarrow \{\mathbb{N}_{\mathbb{I}}(t), t = 0, \ldots, T\}, \tag{2}$$

where $\mathbb{N}_{\mathbb{I}}(t)$ is a list of infected nodes at time t. We simulated an epidemic of a disease using the above simple contagion process in an Indian village contact network[Banerjee et al., 2013]. The network has 354 nodes and 1541 edges, representing 354 villagers and reported contacts and social relationships among them. The epidemic is simulated using $\theta^0 = 0.3$, $n^0_{\text{SN}} = 70$, and the observed dataset $\boldsymbol{x}^0$ is the infected nodes $\mathbb{N}_{\mathbb{I}}(t)$ for $t = t_0, \ldots, T$ with $t_0 = 20$ and $T = 70$. The marginal posterior distributions and the Bayes estimates of (θ, n_{SN}) are show in Figure 1. The inferred posterior distributions for the epidemics on the Indian village contact network, is concentrated around the true parameter values. The Bayes estimates are also in a very small neighborhood of the true value, specifically the estimated seed-node $(\hat{n}_{\text{SN}})$ has a shortest path distance of 1 from n^0_{SN} in both the cases.

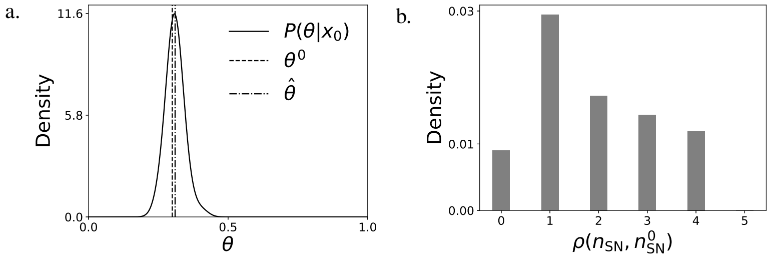

Fig. 1: **Simple contagion model on Indian village contact network.** Panel **a** shows the density of the inferred marginal posterior distribution and Bayes estimate of θ, given $\boldsymbol{x}^0$, the epidemics on the Indian village contact network. Panel **b** displays the average marginal posterior distribution at different distances from the true seed-node n^0_{SN}. The shortest path length distance between $n^0_{\text{SN}} = 70$ and $\hat{n}_{\text{SN}} = 59$ is 1.

For details on how the inference was performed via ABC and ABCpy, we direct readers to Dutta et al. [2017]. We can further extend this inferential approach to any complex spreading processes on a network, e.g. inference of parameters of complex contagion model representing a disinformation campaign on a social network is reported in Dutta et al. [2017].

Platelet Deposition Model

Chopard et al. [2015], Chopard et al. [2017] has recently developed a numerical model that quantitatively describes how platelets in a shear flow adhere and aggregate on a deposition surface. Five parameters specify the deposition process and are relevant for a biomedical understanding of the phenomena. An experimental observations can be collected from a patient, at time intervals, on the average size of the aggregation clusters, their number per mm^2, the number of platelets and the ones activated per $\mu\ell$ still in suspension. In Dutta et al. [2017b], we have demonstrated that approximate Bayesian computation (ABC) can be used to automatically explore the parameter space of this numerical model. To illustrate the performance of ABC, in Figure 2, we show the inferred posterior distribution of the parameters (adhesion rate p_{Ad}, the aggregation rates p_{Ag} and p_T, the deposition rate of albumin p_F, and the attenuation factor a_T) of the platelet deposition model. For details on the specific model and on how the inference was performed via ABC, we direct readers to Chopard et al. [2017] and Dutta et al. [2017b] correspondingly.

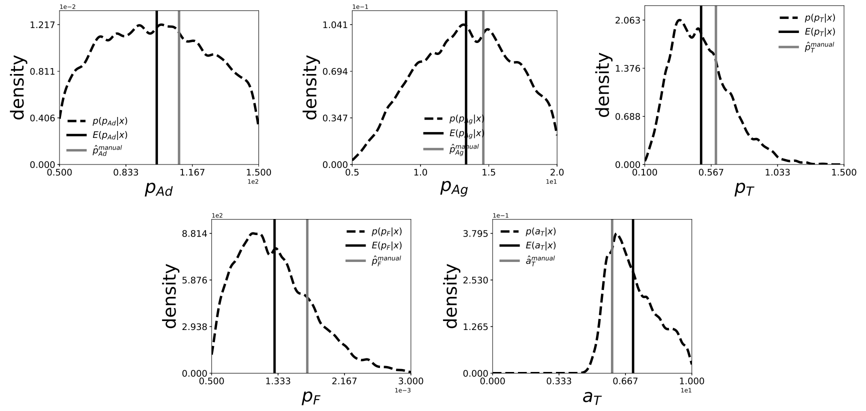

Fig. 2: Marginal posterior distribution (black-dashed) and Bayes Estimate (back-solid) of $(p_{Ad}, p_{Ag}, p_T, p_F, a_T)$ for collective data set generated from of 7 patients. The smoothed marginal distribution is created by a Gaussian-kernel density estimator on 5000 samples drawn from the posterior distribution using Simulated annealing approximate Bayesian computation [Albert et al., 2015]. The (gray-solid) line indicates the manually estimated values of the parameters as in [Chopard et al., 2017].

The proposed approach can be applied patient per patient, in a systematic way, without the bias of a human operator. In addition, the approach is computationally fast enough to provide results in an acceptable time for contributing to a new medical diagnosis, by giving data that no other known method can provide.

Conclusion

We would like to stress here the fact that ABC inference scheme provides not only a point estimate of the parameters of interest but also their entire (approximated) posterior distribution thus allowing for uncertainty quantification: the higher the variability of the posterior distribution the higher the uncertainty inherent in the inferential scheme. Via the ABC approximated posterior one can then construct credible intervals and perform hypothesis testing. Furthermore ABC allows to compare possible alternative models by simply adding, to the three steps Rejection ABC scheme illustrated above, an additional initial layer where first a model index is sampled from the model prior distribution and then, once a model has been selected a regular ABC scheme within that model is performed. For details on ABC model selection via random forest approach see Pudlo et al. [2015].

PC Algorithm for Gaussian Copula Data

L'algoritmo PC per dati generati da copula gaussiana

Vincenzina Vitale and Paola Vicard

Abstract The PC algorithm is the most popular algorithm used to infer the structure of a Bayesian network directly from data. For Gaussian distributions, it infers the network structure using conditional independence tests based on Pearson correlation coefficients. Here, we propose two modified versions of PC, the R-vine PC and D-vine PC algorithms, suitable for elliptical copula data. The correlation matrix is inferred by means of the estimated structure and parameters of a regular vine. Simulation results are provided, showing the very good performance of the proposed algorithms with respect to their main competitors.

Abstract *L'algoritmo PC è l'algoritmo piu diffuso per l'apprendimento della struttura di una rete bayesiana direttamente dai dati. Quando i dati sono gaussiani, esso apprende la struttura della rete per mezzo di test di indipendenza condizionata basati sui coefficienti di correlazione di Pearson. In questo lavoro, proponiamo due versioni modificate del PC, gli algoritmi R-vine PC e D-vine PC, validi per dati generati da copule ellittiche. La matrice di correlazione è calcolata sulla base della struttura e dei parametri stimati di un regular vine. Vengono forniti i risultati delle simulazioni che mostrano l'ottima performance degli algoritmi qui proposti rispetto ai loro principali competitor.*

Key words: Structural learning, Bayesian networks, R-vines, Gaussian copulae, PC algorithm.

1 Introduction

A Bayesian network (BN,[6]) is a multivariate statistical model satisfying sets of (conditional) independence statements encoded in a *Directed Acyclic graph* (DAG). Each node in the graph represents a random variable while the edges between the nodes represent probabilistic dependencies among the corresponding variables. If there is an arrow from X_i to X_j, X_j is said *child* of X_i and X_i is said *parent* of X_j. The set of parents of X_j in the graph G is denoted by $pa(X_j)$. In a BN each node is associated with a conditional distribution given its parents and the joint distribution can be factorized according to the DAG structure as:

$$p(X_1 \dots X_p) = \prod_{j=1}^{p} p(X_j | pa(X_j)) \tag{1}$$

BN structure can be elicited by the expert knowledge or learnt directly from data by means of structural learning techniques [16]. Among the *constraint-based* algorithms, the most known is the PC algorithm [18]: it estimates the Markov equivalence class of a DAG performing three main steps: i) *skeleton*[1] *identification* by recursively testing marginal and conditional independencies using Pearson correlation coefficients, for a fixed significance level α; ii) v-*structures identification*: an unshielded triple $i - k - j$, such that the pairs i and k and j and k are connected while i and j is not, is oriented as $i \rightarrow k \leftarrow j$ if k is not in the separation sets of nodes X_i and X_j; iii) *orientation of some of the remaining edges* without producing additional *v*-structures and/or directed cycles.

In the BN framework, when the analysed variables are continuous, joint normality[2] is assumed. Unfortunately, in many applied context the normality assumption may not be reasonable. In such cases, copula modeling has become very popular and, recently, there is a growing literature where the theory of copulae and Bayesian networks are combined [10, 14, 8, 15, 11, 2]. Here, a modified version of the PC algorithm suitable for Gaussian and Student t copula distributions is proposed. In particular, we work in the theoretical framework of pair-copula constructions with reference to the subclass of regular vines [4, 12]. From the estimated structure and parameters of a regular vine, we infer the corresponding marginal correlation matrix valid under the assumption that data are drawn from a Gaussian copula family. The correlation coefficients are then used as sufficient statistics in the conditional independence tests implemented in the PC algorithm. Simulations are carried out in order to evaluate the performance of the proposed algorithms and to compare them with the PC and the Rank PC (RPC) algorithms. RPC has been recently introduced by [15] to overcome the normality assumption limitation and can be used for Gaussian copula data.

[1] The skeleton of a DAG is the undirected graph obtained replacing arrows with undirected edges.

[2] In the mixed continous and discrete case, the conditional Gaussian distribution is assumed.

The paper is organized as follows. In Section 2 pair copula construction and regular vines are introduced; in Section 3 the new algorithms are illustrated and simulation results are shown and discussed.

2 Pair copula construction and regular vines

Let F be a n-dimensional distribution function of the random vector $\mathbf{X} = (X_1, \cdots X_n)$ with univariate marginals $F_1 \ldots F_n$. A $n-variate\ copula$ is a multivariate cumulative distribution function (cdf) $C : [0,1]^n \to [0,1]$ with $n \in N$ and uniformly distributed marginals $U(0,1)$ on the interval $[0,1]$. By Sklar theorem [17], every cdf F with marginals $F_1 \ldots F_n$ can be written as:

$$F(\mathbf{x}) = C(F_1(x_1), \ldots, F_n(x_n)) \tag{2}$$

for some appropriate n-dimensional copula C. By copulas, multivariate distribution modeling is split into univariate marginals and dependence structure modeling. While for bidimensional case there is an exaustive literature on bivariate copula families, their extension to multivariate case is not straightforward[3]. In [3, 4] and [14] the decomposition of the multivariate copulae into the product of bivariate ones, known in literature as *pair-copula construction* (PCC), is proposed. Each pair-copula can be selected independently from the others allowing for a great flexibility in dependence modeling. Since in higher dimensions the number of possible pair-copulae constructions grows up significantly, in [3, 4] a graphical representation (called *regular vine*) to organize them, is introduced.

Generally speaking, a regular vine (R-vine) is a sequence of trees whose edges correspond to bivariate copulae; see [14] for a formal definition. A n-dimensional R-vine is a set of $n-1$ trees such that the first tree comprises n nodes, identifying $n-1$ pairs of variables and $n-1$ corresponding edges. Each subsequent tree is derived so that all the edges of tree i turn into nodes of the tree $i+1$; furthermore, two edges in T_i, becoming nodes in T_{i+1}, are joined by an edge in T_{i+1} only if these edges share a common node in T_i. The graphical structures of R-vines allow the specification of all bivariate copulae of the pair copula construction. In particular, each edge corresponds to a bivariate copula density. The copulae defined in the first tree are unconditional copulae while the others are all conditional [4]. The importance of these results arises from the fact that all bivariate copulae can belong to different families and their parameters can be specified independently from each other. Many applications concern a special case of R-vines, the Drawable vines (D-vines), see [1]. D-vines only need the ordering definition of their first tree sequence to completely

[3] Standard multivariate copulae such as Gaussian or Student t lack the flexibility of accurately modeling the dependence structure in higher dimensions.

[4] The copulae of the second tree have only one node as conditioning set, the third two nodes and so on.

identify the structure. Differently, R-vines suffer from the fact that many possible tree sequences can be specified.

Three separate steps have to be done to specify the vine structure and distribution:

1. selecting the structure with all its trees;
2. selecting the appropriate bivariate copula family for each of the $n(n-1)/2$ pair copulae associated with the vine structure;
3. estimating the parameters for each bivariate copula identified at the previous step.

Since the number of possible R-vines on n variables increases exponentially with n, a sequential method has been proposed by [7] and implemented in the `VineCopula R` package. Among the possible copula types, the independence copula can also be chosen by means of a preliminary independence test based on Kendall's tau [9]. The concept of independence copula is strictly connected to that of conditional independence: it allows to reduce the number of parameters to be estimated. In [5] the truncated R-vines, for which independence is assumed for the k last trees, is proposed. More recently, [11] have deeply analysed the truncation procedure showing the relationship between the truncated R-vines and the decomposable graphs.

3 The R-vine and D-vine PC algorithms: simulations and results

Here, we take advantage of the use and properties of regular vines to estimate the BN dependence structure under the assumption of data coming from a Gaussian copula distribution. More precisely, we infer the R-vine (and D-vine) structure together with its copula parameters in order to extract the corresponding marginal correlation matrix. Note that the copula family is limited to Gaussian or Student t case for which the correlation coefficients can be estimated. The last step consists in using the marginal correlation coefficients as sufficient statistics for Pearson correlation tests implemented in the classical version of the PC algorithm. According to these definitions and purposes, we propose four algorithms: the R-vine PC algorithm, the D-vine PC algorithm and their truncated versions respectively. They work along the following four steps:

1. transforming data in pseudo-observations;
2. fitting a R-vine (or D-vine) to the transformed data based on the AIC criterion and the maximum likelihood estimation of copula parameters;
3. inferring the marginal correlation matrix from the estimated R-vine (or D-vine);
4. running the PC algorithm providing, in input, the estimated marginal correlation matrix of the previous step.

All functions used in the first three steps are implemented in the `VineCopula R` package. Regarding the D-vine, the `TSP R` package has been used to determine the order of the nodes of its first tree. The fourth step functions are implemented in the `pcalg R` package.

We argue that the two non truncated algorithms allow the specification of the independence copula as proposed by [9][5]. The procedure of truncation applied in this work follows the approach of [5]. To choose the optimal truncation level, a R function has been written in order to recursively perform the likelihood ratio based test between different levels.

Two random DAGs, one not decomposable and the other decomposable, with sparsity parameter $s = 0.4$ and $s = 0.3$ respectively, are simulated according to the procedure ensuring faithfulness [13]. 250 datasets are drawn from each DAG following a Gaussian copula distribution, fixing $n = 500$ and $\alpha = 0.01$. The *structural Hamming distance* (SHD, [19]) has been computed in order to evaluate the different performances of the algorithms.

Table 1 Simulation results by algorithms

Graph (n=500)	Algorithm	SHD (mean)	SHD(Median)	SHD (s.d.)	SHD (IQR)
Decomposable graph	PC	8,29	8	1,62	2
	RPC	6,43	6	1,14	1
	R-vine PC	6,14	6	1,24	2
	Truncated R-vine PC	6,38	6	1,05	1
	D-vine PC	6,23	6	1,21	2
	Truncated D-vine PC	6,56	6	1,34	1
Non decomposable graph	PC	5,87	6	2,02	2
	RPC	3,69	3	2,35	4
	R-vine PC	2,04	1	1,66	2
	Truncated R-vine PC	2,36	2	1,71	2
	D-vine PC	2,88	3	1,92	3
	Truncated D-vine PC	4,07	4	2,51	4

The simulation results, shown in Tab. 1, are very promising. As expected, under the assumption of Gaussian copula data, the performance of the PC algorithm, in terms of mean value, is worse than all the others. For a non decomposable graph, the performance of R-vine PC algorithm, followed by that of its truncated version is extremely good. The mean value of the errors is the smallest, about 2; if its median value is taken into account, it is equal to 1. As far as variability is concerned, its standard deviation is also very small. With the exception of the truncated D-vine PC algorithm, the proposed algorithms outperform their competitors.

For data generated from a decomposable graph, the differences in performance with respect to the PC algorithm are still evident. The distance between our proposals and the RPC algorithm is less remarkable. The R-vine and D-vine PC algorithms show the smallest mean values but larger variability. The truncated R-vine PC algorithm seems to balance these two aspects. Simulation results clearly show that the undirected graph R-vine is able to capture the underlying dependence structure of data. It considerably increases the capability of the PC to detect the best fitting

[5] The hypothesis test for the independence of pseudo-observations u_1 and u_2 is performed before bivariate copula selection. The independence copula is chosen for a (conditional) pair if the null hypothesis of independence cannot be rejected.
