network. The main limitation of the proposed algorithms is that they are applicable only to elliptical copula distributions, restricting the choice of possible copula families. Future research will necessarily concern the definition of a new class of algorithms suitable for non normal data without any restriction to the class of copula families.

Advances in Clustering Techniques

On the choice of an appropriate bandwidth for modal clustering

Scelta di un appropriato parametro di lisciamento per il clustering modale

Alessandro Casa, José E. Chacón and Giovanna Menardi

Abstract In *modal* clustering framework groups are regarded as the domains of attraction of the modes of probability density function underlying the data. Operationally, to obtain a partition, a nonparametric density estimate is required and kernel density estimator is commonly considered. When resorting to these methods a relevant issue regards the selection of the smoothing parameter governing the shape of the density and hence possibly the modal structure. In this work we propose a criterion to choose the bandwidth, specifically tailored for the clustering problem since based on the minimization of the distance between a partition of the data induced by the kernel estimator and the whole-space partition induced by the true density.
Abstract Nell'ambito del clustering, l'approccio modale associa i gruppi ai domini di attrazione delle mode della funzione di densità sottostante i dati. L'individuazione dei gruppi richiede una stima non parametrica della densità, spesso basata su metodi kernel. Un problema rilevante, a tale scopo, riguarda la selezione del parametro di lisciamento che governa la forma della densità e, di conseguenza, la struttura modale. In questo lavoro si propone un criterio per la selezione del parametro di lisciamento, specificamente orientato al problema del clustering non parametrico e basato sulla minimizzazione di una misura di distanza tra la partizione dei dati indotta da uno stimatore kernel e la partizione dello spazio indotta dalla vera funzione di densità.

1 Introduction

Distance-based clustering is probably the most common approach to the unsupervised problem of obtaining a partition of a set of data into a number of groups. In spite of an intuitive interpretation and conceptual simplicity, this approach lacks of a 'ground truth', thus preventing the possibility to resort to formal statistical procedures. The density-based approach to cluster analysis overcomes such drawback by providing a formal definition of cluster, based on some specific features of the probability density function assumed to underlie the data. This approach has been developed following two distinct directions. The parametric one hinges on modelling the density function by means of a mixture distribution, where clusters are associated to the mixture components. Readers can refer to [3] for a recent review. This work focuses on the nonparametric - or *modal* - formulation, which is built on the concept of clusters as the "domains of attraction" of the modes of the density underlying the data [7]. The local maxima of the density are regarded to as the archetypes of the clusters, which are represented by the sorrounding regions (see Figure 1 for an illustration). These concepts have been translated into a formal definition of cluster by [1], resorting to notions and tools borrowed from Morse theory (see [2] for an introduction). Operationally, modal clustering has been pursued by two different strands of methods, both based on a preliminary nonparametric estimate of the density. The first strand looks directly for the modes of the estimated density and associates each cluster to the set of points along the steepest ascent path towards a mode, while the second one associates the clusters to the estimated density level sets of the sample space. For a detailed review see [4].

Modal clustering is appealing for several reasons. The outlined notion of cluster is close to the intuition of groups as dense regions; consistently, clusters are not constrained to have some particular pre-determined shape and resorting to nonparametric tools allow to mantain this flexibility. Also, since clusters are the domains of attraction of the density modes, the number of clusters is an intrinsic property of the data generator mechanism and its determination is itself an integral part of the estimation procedure. Furthermore, the existence of a formalized notion of cluster, based on the features of the density, allows to define an ideal population clustering goal, and frames the clustering problem into a standard inferential context.

Despite enjoying these relevant strenghts, when resorting to the nonparametric formulation, some criticalities have to be faced, mostly related to the estimation of the density underlying the data. Firstly obtaining nonparametric density estimates is usually computationally burdensome. This issue gets worse when working in high-dimensional spaces where nonparametric estimators suffer of the "curse of dimensionality". A relevant issue is that, regardless of the specific choice of the nonparametric density estimator, the selection of a smoothing parameter is required. Choosing this parameter turns out to be crucial since an inaccurate choice could lead to a misleading resulting estimate: too large values may lead to cover interesting structures, while too small values may lead to the appearance of spurious modes. If a kernel density estimator, the most common choice in the considered framework, is employed, the selection of the smoothing parameter is based on some reference

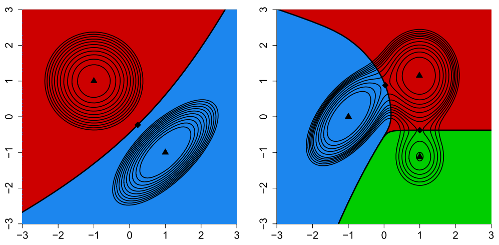

Fig. 1 Partitions induced by the modes of the density function in two examples of mixtures of bivariate normal densities.

rule or on criteria attempting to estimate properly the underlying density function. Even if these criteria have proved to produce appropriate clustering results in different situations, we believe that the clustering problem, being of a different nature with respect to the estimation of the density, would require a different rationale. In this work, a possible way to choose the optimal amount of smoothing, hinging on the specific clustering aim, is discussed. After formally defining a convenient loss function to measure the distance between data and population clustering, in the following we obtain its asymptotic expansion which, through a minimization, allows a focused selection of the smoothing parameter. Implications of this selection are finally discussed.

2 Kernel density estimation

According to the nonparametric formulation of density-based clustering the observed data $\mathscr{X} = \{x_i\}_{i=1,\dots,n}, x_i \in \mathbb{R}$, are supposed to be sampled from a random variable $\mathbb{X}$ with unknown density f. Note that, initially, we restrict our attention to the univariate case to allow a more rigorous treatment of the problem, with the intention to generalize the results to higher dimensional situations. To obtain a partition of the data adopting a nonparametric clustering perspective, regardless of its operational formulation (level set-based or mode seeking-based), an estimate $\hat{f}$ of the true density f is needed. In the rest of the paper we focus on the kernel density estimator

$$\hat{f}_h(x) = \frac{1}{nh} \sum_{i=1}^{n} K\left(\frac{x - x_i}{h}\right) , \tag{1}$$

where K is the kernel, usually a symmetric density function, and $h > 0$ is the bandwidth, controlling the smoothness of the resulting estimate. A large value for h will tend to oversmooth the density, possibly covering some revelant features, while a small value will lead to an undersmoothed estimate where spurious modes (i.e. clusters) could arise.

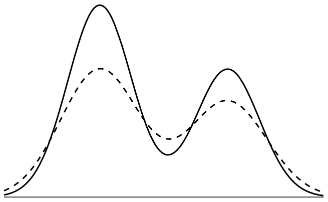

Fig. 2 Two density functions that are not close but induce exactly the same clustering.

The usual approach to select the bandwidth consists in minimizing some specific optimality criterion: the most used one is the *Mean Integrated Squared Error* (MISE)

$$MISE(h) = \mathbb{E}\int_{\mathbb{R}} \{\hat{f}_h(x) - f(x)\}^2 dx \tag{2}$$

which employs the $L2$-distance to assess the performance of the estimator. However, this expression does not have a tractable closed form and its asymptotic approximation -AMISE- is usually minimized, instead. Since both the MISE and the AMISE depend on the unknown f, different approaches to estimate them have been pursued, such as the ones based on *least square cross validation*, *biased cross validation* or *plug-in bandwidth selectors*. For a more comprehensive review and comparison see, e.g., [8].

3 The proposed selector

The selectors introduced in Section 2 are designed to choose the bandwidth so that it induces an appropriate estimate of the density. Nonetheless density estimation and clustering are two different problems with different requirements. It has been shown (e.g. [1]) that, even if two density functions are not really close, they can produce exactly the same partition of the data; see Figure 2 for an example. Furthermore, modal clustering strongly depends on some specific characteristics of the density function (the gradient for the mode seeking-based formulation and the high-density regions for the level set-based one) while, minimizing criteria such as the AMISE, an appropriate estimate is required in a global sense.

Our contribution hence finds its motivation in the lack of bandwidth selectors specifically conceived for nonparametric cluster analysis. In a similar fashion, even without specifically referring to clustering, [6] develop a plug-in type bandwidth selector that is appropriate for estimation of the highest density regions thus focusing on the modal regions, particularly relevant in the clustering formulation outlined above.

When density estimate is employed to subsequently partition the data, a more specifically tailored and appropriate performance measure than the $L2$-distance should be considered to select the amount of smoothing. Recalling [1], a natural way to quantify the performance of a data-based clustering is to consider the distance in measure between sets, where the measure has to be intended as the probability distribution with density f.

Formally, let $\mathscr{C} = \{C_1, \dots, C_r\}$ and $\mathscr{D} = \{D_1, \dots, D_r\}$ be two clusterings with the same number of groups r, their distance in measure can be measured by

$$d_1(\mathscr{C}, \mathscr{D}) = \min_{\nu \in \mathscr{P}} \sum_{i=1}^{r} \mathbb{P}(C_i \Delta D_{\nu(i)}) \, , \tag{3}$$

where $\mathscr{P}$ is the set of the permutation of $\{1, \dots, r\}$, and $C\Delta D = (C \cap D^c) \cup (C^c \cap D)$. In the following we will actually consider

$$d_P(\mathscr{C}, \mathscr{D}) = \frac{1}{2} \min_{\nu \in \mathscr{P}} \left\{ \sum_{i=1}^{r} \mathbb{P}(C_i \Delta D_{\nu(i)}) + \sum_{i=r+1}^{s} \mathbb{P}(D_{\nu(i)}) \right\} \, , \tag{4}$$

accounting for the intrinsic redundancy in (3) and for the possibility of having clustering with different number of groups. This distance can be seen as the minimal probability mass that needs to be moved to transform one clustering into the other.

Consider $\mathscr{C}_0$ as the ideal population clustering induced by the true density f and $\hat{\mathscr{C}}_n$ a data-based partition obtained from the sample $\mathscr{X}$. The idea is to quantify the quality of $\hat{\mathscr{C}}_n$ by measuring its distance in measure from $\mathscr{C}_0$. For large n, since the estimated number converges to the true number of clusters, it can be shown [1, Theorem 4.1] that (4) could be written as

$$d_P(\hat{\mathscr{C}}_n, \mathscr{C}_0) = \sum_{j=1}^{r-1} |F(\hat{m}_j) - F(m_j)| \, , \tag{5}$$

where F is the distribution function associated with f while $m_1, \dots, m_{r-1}$ and $\hat{m}_1, \dots, \hat{m}_{r-1}$ denote respectively the local minima (i.e. cluster boundaries in the univariate setting) of f and $\hat{f}$. Through two Taylor expansions, under some regularitiy conditions [1, Theorem 4.1], we obtain

$$|F(\hat{m}_j) - F(m_j)| \simeq \frac{f(m_j)}{f^{(2)}(m_j)} |\hat{f}^{(1)}(m_j)| \, , \tag{6}$$

where $f^{(j)}$ is the $j-th$ derivative of f. To obtain an asymptotic expression for (6) we have to study further the limit behavior of $\hat{f}^{(1)}(m_j)$. Considering that, if $h \to 0$ and $nh^{2r+1} \to \infty$, it is known that

$$(nh^{2r+1})^{1/2} \{\hat{f}^{(r)}(x) - K_h * f^{(r)}(x)\} \sim \mathscr{N}(0, R(K^{(r)}) f(x)) \, , \tag{7}$$

where $R(K^{(r)}) = \int_{\mathbb{R}} (K^{(r)}(x))^2 dx$ and $(h * g)(x) = \int h(x-y) g(y) dy$. For a detailed treatment of the behaviour of kernel estimators at the critical points of a density, see [5]. Studying appropriately the bias term in (7), considering $r = 1$ and focusing on the local minima (i.e. $x = m_j$) we end up obtaining the limit distribution for the quantity of interest

$$n^{2/7}\hat{f}^{(1)}(m_j) \sim \mathscr{N}\left(\frac{\beta^2 f^{(3)}(m_j)\mu_2(K)}{2}, \frac{R(K^{(1)})f(m_j)}{\beta^3}\right),$$

where $\mu_2(K) = \int_{\mathbb{R}} x^2 K(x)dx$ and $\beta = n^{1/7}h$.
Thus, considering the property of a *folded normal distribution* and after some algebra, the asymptotic *expected distance in measure* (EDM) between a data clustering $\hat{\mathscr{C}}_n$ and the ideal population clustering $\mathscr{C}_0$ is given by

$$\begin{aligned}\mathbb{E}(d_P(\hat{\mathscr{C}}_n, \mathscr{C}_0)) &= \sum_{j=1}^{r-1} \frac{f(m_j)}{f^{(2)}(m_j)} \mathbb{E}(|\hat{f}^{(1)}(m_j)|) \\ &\simeq \sum_{j=1}^{r-1} \frac{f(m_j)}{f^{(2)}(m_j)} n^{-2/7}\{2\sigma^2\phi_\sigma(\mu) + \mu[1-2\Phi_\sigma(-\mu)]\}, \qquad (8)\end{aligned}$$

where ϕ_σ and Φ_σ denote respectively the density and the distribution function of a $\mathscr{N}(0,\sigma^2)$ random variable, $\mu = \beta^2 f^{(3)}(m_j)\mu_2(K)/2$ and $\sigma^2 = R(K^{(1)})f(m_j)/\beta^3$.
The optimal bandwidth h_{d_P} for modal clustering purposes can be then obtained as $h_{d_P} = argmin_h \mathbb{E}(d_P(\hat{\mathscr{C}}_n, \mathscr{C}_0))$ by means of numerical optimization, after obtaining a suitable estimate of the unknown quantities $f(\cdot)$ and $f^{(2)}(\cdot)$ in the guise of the MISE/AMISE minimization. Another viable solution would be to work with a more manageable upper bound of (8) in order to obtain an explicit formula for the minimizer.

Further work is required to evaluate the performance of the proposed bandwidth selector as well as its comparison with some alternatives. There is much room for proceeding, and a multivariate extension of the discussed selector is needed to provide it with a concrete usability in more realistic settings.

Unsupervised clustering of Italian schools via non-parametric multilevel models

Classificazione non supervisionata delle scuole italiane per mezzo di modelli a effetti misti non parametrici

Chiara Masci, Francesca Ieva and Anna Maria Paganoni

Abstract This work proposes an EM algorithm for the estimation of non-parametric mixed-effects models (NPEM algorithm) and shows its application to the National Institute for the Educational Evaluation of Instruction and Training (INVALSI) dataset of 2013/2014, as a tool for unsupervised clustering of Italian schools. Among the main novelties, the NPEM algorithm, when applied to hierarchical data, allows the covariates to be group specific and assumes the random effects to be distributed according to a discrete distribution with an (a priori) unknown number of support points. In doing so, it induces an automatic clustering of the grouping factor at higher level of hierarchy. In the application to INVALSI data, the NPEM algorithm enables the identification of latent groups of schools that differ in their effects on student achievements.

Abstract *Questo lavoro propone un algoritmo EM per la stima di modelli a effetti misti non parametrici (algoritmo NPEM) e mostra la sua applicazione ai dati dell'Istituto Nazionale per la Valutazione del Sistema Educativo di Istruzione e di Formazione (INVALSI) 2013/2014, con l'obiettivo di fare classificazione non supervisionata delle scuole italiane. Tra i principali vantaggi, l'algoritmo NPEM, applicato a dati gerarchici, permette alle covariate di essere specifiche del gruppo e assume che gli effetti casuali seguano una distribuzione discreta, con un numero di masse non noto a priori. Questa assunzione induce un clustering automatico del fattore di raggruppamento al piú alto livello della gerarchia. Nell'applicazione ai dati INVALSI, l'algoritmo NPEM permette l'idetificazione di gruppi latenti di scuole, che differiscono nel loro effetto sul rendimento scolastico degli studenti.*

1 Introduction

Administrative educational databases are often characterized by a hierarchical structure, in which students are nested within classes, that are in turn nested within schools. Given this, mixed-effects models are increasingly used in several educational applications. Mixed-effects models include parameters associated with the entire population (fixed effects) and subject/group specific parameters (random effects). They provide both estimates for the entire population's model and for each group's one, where the random effects represent a deviation from the common dynamics of the population. In this work, we develop random effects models, for applying them to educational data, whose random effects have a different meaning: they describe the common dynamics of different clusters of subjects/groups. Indeed, the mixed-effects models that we develop provide estimates for each cluster specific model and they may be considered as an unsupervised clustering tools for hierarchical data. The difference with respect to classical parametric mixed-effects models is that the random effects, instead of being Normal distributed, follow a discrete distribution that we call P^* [16]. Most of the mixed-effects models used in the educational field are parametric linear multilevel models [6], but parametric assumptions sometimes result to be too restrictive to describe very heterogeneous populations. Moreover, when the number of measurements for group is small, predictions for random effects are strongly influenced by the parametric assumptions. For these reasons, we opt for a nonparametric (NP) framework, which allows P^* to live in an infinite dimensional space and that also provides, in a natural way, a classification tool. Hierarchical models have been already applied to educational data in the Italian literature: [1], [2], [11] and [17] apply multilevel linear models in order to disentangle the portion of variability in students' scores given to different levels such as the family, the class or the school. Differently, our algorithm aims at identifying clusters of schools that perform in similar ways and, in a second step, at characterizing these clusters in terms of similarities within/between groups [13]. To the best of our knowledge, this is one of the first times that this kind of algorithm has been applied in the educational context [7]. Our method is strictly related to the branch of literature about growth mixture models (GMM) [15], latent class analysis (LCA) [14] and finite mixture models [18], which also aim at the identification of latent subpopulations, but with the main difference that all these models need to fix a priori the number of latent subpopulations. The choice of the number of latent classes (mass points) is not trivial when the sample is very big or the knowledge about possible different trends across the individuals (groups) is limited. For this reason, our approach brings a significant value-added with respect to the existing literature. In particular, our algorithm is inspired by both the one proposed in [3] and [4] and the one proposed in [5], but with some substantial changes. Contrarily to the algorithm described in [3] and [4], we do not need to fix the number of groups a priori but the algorithm identifies it by itself, standing on given tolerance values. While referring to the algorithm in [5], we adjust it in order to consider the linear case, to allow the covariates to be group-specific and to compute the optimization of the Maximization step in closed-form. We apply this algorithm to INVALSI data of year 2013/2014, in which we consider students nested within schools. Each group is identified by a school and the aim is to cluster schools standing on their different effects on their student performance trends. In this way, it is possible to identify clusters of schools that perform in different ways, trying to find out which are the determinants of different school effects.

2 The Dataset

The INVALSI database [8] contains information about more than 6,500 Italian students attending the third year of junior secondary school in the year 2013/2014, nested within about 500 schools. At pupil's level, we have reading and mathematics INVALSI test scores at grade 8 (RS and MS) and also, reading and mathematics INVALSI test scores at grade 6, two years before, of the same students. It is well known from the literature that education is a cumulative process, where achievement in the period t exerts an effect on results of the period t + 1. These variables take values between 0 and 100. Moreover, the following information is available: gender, immigrant status, if the student is early/late-enrolled, information about the family's background and socioeconomic status of the student (ESCS). At school's level, we have variables about three different areas: (i) the school-body composition (school-average characteristics of students, such as the proportion of immigrants, early and late-enrolled students, etc); (ii) school principal's characteristics; (iii) managerial practices of the school. Two dummies are also included to distinguish (i) private schools from public ones, and (ii) "Istituti Comprensivi", which are schools that include both primary and lower-secondary schools in the same building/structure. This latest variable is relevant to understand if the "continuity" of the same educational environment affects (positively or negatively) students results. Some variables about size (number of students per class, average size of classes, number of students of the school) are also included to take size effects into account. Lastly, regarding geographical location, we include two dummies for schools located in Central and Southern Italy and the district in which the school is located; some previous literature, indeed, pointed at demonstrating that students attending the schools located in Northern Italy tend to have higher achievement scores than their counterparts in other regions, all else equal. As we have the anonymous student ID, we have also the encrypted school IDs that allow us to identify and distinguish schools.

3 Methodology

We consider the case of a non-parametric two-level model with one covariate with fixed effect, one covariate with random slope and one random intercept. The model takes the following form:

$$\begin{aligned} &\mathbf{y}_i = \beta \mathbf{x}_i + c_{0l} + c_{1l}\mathbf{z}_i + \varepsilon_i \quad i = 1,\dots,N, l = 1,\dots,M \\ &\varepsilon_i \overset{ind}{\sim} N(\mathbf{0}, \sigma^2 \mathbf{1}_n) \end{aligned} \tag{1}$$

where, in our application, N is the total number of schools; $\mathbf{y}_i$ is the n_i-dimensional vector of student achievements at grade 8 in school i; $\mathbf{x}_i$ is the n_i-dimensional vector of ESCS of students in school i; $\mathbf{z}_i$ is the n_i-dimensional vector of the same students achievements at grade 6 (two years before) in school i. We use these three variables at student level and we make this choice of random and fixed effects because we are interested in modeling the association between student achievements at grade 6 and 8, across different schools, adjusting the model for the effect of the ESCS, that, standing on the Italian literature, [2], [11], [12], results to be one of the most influential variable, with an homogeneous effect in the whole country. $\mathbf{c} \in R^2$ is the vector containing the coefficients of random effects. $\mathbf{c}$ follows a discrete distribution P^* with M support points, where M is not known a priori. P^* can then be interpreted as the mixing distribution that generates the density of the stochastic model in (1). The ML estimator $\hat{P}^*$ of P^* can be obtained following the theory of mixture likelihoods in [9] and [10], where the author proves the existence, discreteness and uniqueness of the non-parametric maximum likelihood estimator of a mixing distribution, in the case of exponential family densities.The ML estimator of the random effects distribution can be expressed as a set of points $(c_1,\dots,c_M)$, where $M \leq N$ and $c_l \in R^2$ for $l = 1,\dots,M$, and a set of weights $(w_1,\dots,w_m)$, where $\sum_{l=1}^{M} w_l = 1$ and $w_l \geq 0$ for each $l = 1,\dots,M$. Given this, we develop an algorithm for the joint estimation of σ^2, β, $(c_1,\dots,c_M)$ and $(w_1,\dots,w_M)$, that is performed through the maximization of the likelihood, mixture by the discrete distribution of the random effects,

$$L(\beta,\sigma^2,c_l,w_l|y) = \sum_{l=1}^{M} \frac{w_l}{(2\pi\sigma^2)^{\sum_{i=1}^{N} n_i}} exp\Big\{ -\frac{1}{2\sigma^2} \sum_{i=1}^{N} \sum_{j=1}^{n_i} (y_{ij} - \beta x_{ij} - c_{0l} - c_{1l} z_{ij})^2 \Big\} \tag{2}$$

with respect to σ^2, β and (c_l, w_l), for $l = 1,\dots,M$. Each school i, for $i = 1,\dots,N$ is therefore assigned to a cluster l, for $l = 1,\dots,M$. The EM algorithm is an iterative algorithm that alternates two steps: the expectation step (E step) in which we compute the conditional expectation of the likelihood function with respect to the random effects, given the observations and the parameters computed in the previous iteration; and the maximization step (M step) in which we maximize the conditional expectation of the likelihood function. Moreover, given N starting support points, during the iterations of the EM algorithm, we reduce the support of the discrete distribution standing on both two criteria: the former is that we fix a threshold D and if two points are closer than D they collapse to a unique point; the latter is that we remove points with very low weight ($w_l \leq \tilde{w}$, being $\tilde{w}$ a given threshold on weights) and that are not associated to any school. When two points $\mathbf{c}_l$ and $\mathbf{c}_k$ collapse to a unique point, because their Euclidean distance is smaller than D, we obtain a new mass point $\mathbf{c}_{l,k} = \frac{\mathbf{c}_l + \mathbf{c}_k}{2}$ with weight $w_{l,k} = w_l + w_k$. The thresholds D and $\tilde{w}$ are two complexity parameters that affect the estimation of the nonparametric distribution: the higher is D, the lower is the number of clusters. The choice of the values for D and $\tilde{w}$ depends on how much we want to be sensitive to the differences among clusters (D) and which is the minimum number of groups (schools) that we allow within each clusters ($\tilde{w}$). Anyway, different results obtained using different set of tuning parameters can be compared in terms of AIC or BIC in order to choose the best one. Notice that the number of support points M is computed by the algorithm as well and we do not have to fix it a priori. Since we do not have to specify a priori the number of support points, the NP mixed-effects model could be interpreted as an unsupervised clustering tool for longitudinal data.

4 Results

The algorithm cluster the Italian schools within 5 clusters, whose estimated parameters are shown in Table 1.

	$\hat{\beta}$	$\hat{c}_0$	$\hat{c}_1$	$\hat{w}$
Cluster 1	1.417	46.028	0.454	12.2%
Cluster 2	1.417	22.579	0.707	39.6%
Cluster 3	1.417	30.293	0.648	37.5%
Cluster 4	1.417	31.207	0.393	8.8%
Cluster 5	1.417	25.359	0.027	1.9%

Table 1 Coefficients of Eq. (1) estimated by the NPEM algorithm. Each row corresponds to a cluster l. The intercept and the coefficient of z differ across groups (c_0 and c_1 respectively), while the coefficient of x (β) is fixed. $\hat{w}$ represents the weight assigned to each cluster.

Each cluster is characterized by an intercept, a slope of the grade 6 test score variable and by the fixed coefficient of the ESCS. We identify two main clusters (Cluster 2 and Cluster 3 in Table 1), that contain about the 77% of the total population of schools, while the remaining 23% is distributed across the other three clusters. From an interpretative point of view, with respect to Cluster 2 and Cluster 3 that form the reference cluster, while Cluster 5 contains the “worse” set of Italian schools. Indeed, it is characterized by both low intercept and slope and this means that there is a kind of equality in student achievements, but with on average very low scores at grade 8, even if the results at grade 6 were on average higher. In a second step, we apply a multinomial logit model at school level, by treating the five clusters as the categorical outcome variable and all the school level characteristics as covariates, with the aim of characterizing the identified clusters by means of school level variables. It emerges that the dummy for private/public school, the percentage of disadvantaged students and the geographical area are associated to heterogeneity across groups.

An INDCLUS-type model for occasion-specific complementary partitions

Un modello INDCLUS per partizioni complementari specifiche per occasione

Laura Bocci and Donatella Vicari

Abstract This paper presents an INDCLUS-type model for partitioning the units in three-way proximity data taking into account the systematic differences among the occasions. Specifically, the proximity structure of each occasion is assumed to underlie two complementary partitions: the first, common to all occasions, defines a partitioning of a subset of units and the second, occasion-specific, defines a partitioning of the remaining units. The model is fitted in a least-squares framework and an efficient ALS algorithm is given.

Abstract *Si presenta un modello di tipo INDCLUS per partizionare le unità nel caso di dati di prossimità a tre vie tenendo conto delle differenze sistematiche esistenti tra le similarità a coppie rilevate in diverse occasioni. In particolare, si assume che la struttura di prossimità di ciascuna occasione si componga di due partizioni complementari: un sottogruppo di unità definisce dei gruppi comuni a tutte le occasioni, mentre le rimanenti unità sono allocate a dei gruppi specifici per ogni occasione. Il modello, formulato seguendo l'approccio dei minimi quadrati, è stimato utilizzando un algoritmo ALS.*

Key words: three-way proximity data, INDCLUS, clustering

1 Introduction

[1] Laura Bocci, Department of Communication and Social Sciences, Sapienza University of Rome; email: laura.bocci@uniroma1.it

Donatella Vicari, Department of Statistical Sciences, Sapienza University of Rome; email: donatella.vicari@uniroma1.it

In many research domains, there is an increasing interest in how the perception or evaluation of several units (objects or stimuli) differs across several sources or occasions such as subjects, experimental conditions, situations, scenarios or times.

Such kind of information can be arranged in three-way data represented as a cube having multiple data matrices stacked as slices along the third dimension which represents the data sources. Our concern here is three-way two-mode data, so that the frontal slices consist of square symmetric matrices $\mathbf{S}_h$ $(h = 1, \dots, H)$ of pairwise proximities of a set of *N* units coming from H occasions.

Clustering three-way data is a complex task since each proximity data matrix $\mathbf{S}_h$ generally subsumes a (more or less) different clustering of units due to the occasion heterogeneity. Therefore, a three-way clustering should represent a consensus classification of the ones obtained from each occasion, but such a consensus is actually representative only when the classifications from each frontal slice of the three-way data do not contain systematic differences.

However, since this hypothesis is often not appropriate in real situations, several methodologies for clustering three-way proximity data have been proposed both in a least-squares (Carroll and Arabie (1983), Gordon and Vichi (1998), Vichi (1999), Vicari and Vichi (2009), Giordani and Kiers (2012), Bocci and Vicari (2017)) and in a maximum likelihood approach (Basford and McLachlan (1985), Hunt and Basford (1999), Bocci, Vicari and Vichi (2006)).

Carroll and Arabie (1983) introduced the INDCLUS (INdividual Differences CLUStering) model to extract (overlapping) clusters of *N* units from a set of proximity matrices provided in H occasions which are supposed to differently weigh each group of units. Therefore, all occasions in the INDCLUS model are assumed to employ the same clustering, but with different patterns of weights indicating the effect of each cluster on the proximities.

A fuzzy variant of the INDCLUS model, called FINDCLUS, has been proposed by Giordani and Kiers (2012), where a fuzzy membership matrix, still common to all occasions, is assigned to the classification of units.

Bocci and Vicari (2017) proposed a Generalized INDCLUS model, called GINDCLUS, for clustering both units and occasions incorporating (possible) information from external variables not directly involved in the collection process of the similarities.

In the context of clustering and multidimensional scaling for three-way data, the CLUSCALE (simultaneous CLUstering and SCAL[E]ing) model (Chaturvedi and Carroll, (2006)) combines additively INDCLUS and INDSCAL (Carrol and Chang, (1970)) searching for a common both (discrete) clustering representation and continuous spatial configuration of the units.

In order to extract more information from the three-way proximities accounting for and taking advantage of the heterogeneity of the occasions, we present an INDCLUS-type model where the pairwise proximities subsume two complementary partitions of the units: one is common to all occasions while the other is occasion-specific. Therefore, we assume that a subset of the *N* units defines a partition shared by all occasions, while the remaining units are differently clustered in each occasion. The model is formalized in a least-squares framework and an appropriate ALS algorithm is given.

2 The model

In order to present our INDCLUS-type model, let's formally recall the INDCLUS model (Carroll and Arabie, (1983))

$$\mathbf{S}_h = \widetilde{\mathbf{P}}\widetilde{\mathbf{W}}_h\widetilde{\mathbf{P}}' + \tilde{c}_h\mathbf{1}_N\mathbf{1}_N' + \mathbf{E}_h, \qquad h = 1, \dots, H, \tag{1}$$

where $\widetilde{\mathbf{P}} = [\tilde{p}_{ij}]$ ($\tilde{p}_{ij} = \{0,1\}$ for $i = 1, \dots, N$ and $j = 1, \dots, J$) is a $N \times J$ binary matrix defining the clustering of N units, $\widetilde{\mathbf{W}}_h$ is a non-negative diagonal weight matrix of order J for occasion h, $\tilde{c}_h$ is a real-valued additive constant for occasion h, $\mathbf{1}_N$ denotes the column vector with N ones and $\mathbf{E}_h$ is the square matrix of errors which represents the part of $\mathbf{S}_h$ not accounted for by the model.

On the other hand, when the occasions present systematic differences, it is reasonable to think that a subset of the N units shares the same partition and weights in all occasions but for each occasion there exists a different partitioning and weighing of the remaining units. This assumption specifies a new model

$$\begin{aligned}\mathbf{S}_h = {} & (\mathbf{P} + \mathbf{M}_h)\mathbf{W}(\mathbf{P} + \mathbf{M}_h)' \\ & + \mathbf{M}_h\mathbf{R}_h(\mathbf{P} + \mathbf{M}_h)' + \mathbf{P}\mathbf{R}_h\mathbf{M}_h' + c_h\mathbf{1}_N\mathbf{1}_N' + \mathbf{E}_h, \qquad h = 1, \dots, H,\end{aligned} \tag{2}$$

where $\mathbf{P} = [p_{ij}]$ ($p_{ij} = \{0,1\}$ for $i = 1, \dots, N$ and $j = 1, \dots, J$) is an $N \times J$ binary matrix defining the common partition of N_C ($\leq N$) units in J groups, $\mathbf{M}_h = [m_{ijh}]$ ($m_{ijh} = \{0,1\}$ for $i = 1, \dots, N$ and $j = 1, \dots, J$) is an $N \times J$ binary matrix defining the partition of $N_I = N - N_C$ units in J groups for occasion h ($h = 1, \dots, H$), $\mathbf{W} = [w_{ij}]$ is a non-negative diagonal weight matrix of order J, $\mathbf{R}_h = [r_{ijh}]$ is a non-negative diagonal matrix of order J containing the *differential* weights for occasion h ($h = 1, \dots, H$).

Therefore, on one hand, we suppose that there exists a subset N_C of the N units whose pairwise proximities for each occasion subsume the same partition **P** and the same weights **W** for its clusters; on the other hand, the partition of the remaining N_I units is supposed to be different for each occasion, so that H occasion-specific complementary partition $\mathbf{M}_h$ ($h = 1, \dots, H$) can be recognised.

Within this framework, the i-th unit ($i = 1, \dots, N$) at occasion h ($h = 1, \dots, H$) is assigned to one of the J groups in either **P** or $\mathbf{M}_h$ ($h = 1, \dots, H$): if $p_{ij} = 1$ for some $j = 1, \dots, J$ then $m_{ijh} = 0$ for all $j = 1, \dots, J$, while if $p_{ij} = 0$ for all $j = 1, \dots, J$ then $m_{ij'h} = 1$ for some $j' = 1, \dots, J$.

Therefore, conditionally on occasion h, the binary membership matrices **P** and $\mathbf{M}_h$ ($h = 1, \dots, H$) specify pairs of *incomplete and complementary* partitions which together define the occasion-specific clustering structure of the N units in J groups. Note that $\mathbf{P} + \mathbf{M}_h$ ($h = 1, \dots, H$) is a membership matrix defining a *complete* occasion-specific partition where each group is the union of the corresponding groups from **P** and $\mathbf{M}_h$ ($h = 1, \dots, H$).

The J groups identified in **P** can be considered as *core* clusters in the sense that they represent the part common to all occasions, while the *complementary* partitions identified in $\mathbf{M}_h$ $(h = 1, \dots, H)$ capture the heterogeneity of the occasions.

Moreover, the H clustering structures $\mathbf{P} + \mathbf{M}_h$ $(h = 1, \dots, H)$ are weighted by two patterns of weights: **W** which is common to all occasions and $\mathbf{R}_h$ which is occasion-specific and expresses how the *complementary* partition $\mathbf{M}_h$ is *differently* weighted with respect to the *core* partition **P** in occasion *h*.

3 The algorithm

In model (2), the incomplete membership matrices **P** and $\mathbf{M}_h$ $(h = 1, \dots, H)$, the weight matrices **W** and $\mathbf{R}_h$ $(h = 1, \dots, H)$ and constants c_h $(h = 1, \dots, H)$ can be estimated by solving the following least-squares fitting problem:

$$\min F(\mathbf{P}, \mathbf{W}, \mathbf{M}_h, \mathbf{R}_h, c_h) = \sum_{h=1}^{H} \| \mathbf{S}_h - (\mathbf{P} + \mathbf{M}_h)\mathbf{W}(\mathbf{P} + \mathbf{M}_h)' - \mathbf{M}_h\mathbf{R}_h(\mathbf{P} + \mathbf{M}_h)' - \mathbf{P}\mathbf{R}_h\mathbf{M}_h' + c_h \mathbf{1}_N \mathbf{1}_N' \| \quad (3)$$

subject to

$$p_{ij} = \{0,1\} \quad (i = 1, \dots, N; j = 1, \dots, J) \text{ and } \textstyle\sum_{j=1}^{J} p_{ij} \leq 1 \quad (i = 1, \dots, N), \quad \text{(3a)}$$

$$m_{ijh} = \{0,1\} \ (i = 1, \dots, N; j = 1, \dots, J; h = 1, \dots, H) \text{ and}$$
$$\textstyle\sum_{j=1}^{J} m_{ijh} \leq 1 \quad (i = 1, \dots, N; h = 1, \dots, H), \quad \text{(3b)}$$

$$\text{if } \textstyle\sum_{j=1}^{J} p_{ij} = 1 \text{ then } \sum_{j=1}^{J} m_{ijh} = 0 \quad (i = 1, \dots, N), \quad \text{(3c)}$$

$$\text{if } \textstyle\sum_{j=1}^{J} p_{ij} = 0 \text{ then } \sum_{j=1}^{J} m_{ijh} = 1 \quad (i = 1, \dots, N), \quad \text{(3d)}$$

$$w_{jj} \geq 0 \quad (j = 1, \dots, J), \quad \text{(3e)}$$

$$r_{jjh} \geq 0 \quad (j = 1, \dots, J; h = 1, \dots, H). \quad \text{(3f)}$$

For the sake of clarity, the set of constraints (3a)-(3d) specify that in the partitions defined by **P** and $\mathbf{M}_h$ $(h = 1, \dots, H)$ each units is assigned to only one clusters in either **P** or $\mathbf{M}_h$ $(h = 1, \dots, H)$, while constraints (3e)-(3f) specify the non-negativity of the weights **W** and $\mathbf{R}_h$ $(h = 1, \dots, H)$, respectively.

Problem (3) can be solved using an appropriate coordinate descent algorithm also known as Alternating Least-Squares (ALS) algorithm, which alternates the estimation of a set of parameters when all the other are fixed.

The algorithm proposed here estimates in turn:

a) the *core* membership matrix **P** by sequentially solving assignment problems for the different rows of **P**, where each unit can possibly remain not assigned;
b) the occasion-specific membership matrix $\mathbf{M}_h$ $(h = 1, \dots, H)$ by sequentially solving h $(h = 1, \dots, H)$ assignment problems for the rows of $\mathbf{M}_h$ corresponding to the N_I units not assigned in **P**;
c) the common weight matrix **W** by solving a regression problem using nonnegative least squares (Lawson and Hanson, 1974);

d) the occasion-specific weight matrix $\mathbf{R}_h$ $(h = 1, \dots, H)$ by solving h $(h = 1, \dots, H)$ regression problems using nonnegative least squares (Lawson and Hanson, 1974);
e) the additive constant c_h $(h = 1, \dots, H)$ by successive residualizations of the three-way data matrix.

The five main steps are alternated and iterated until convergence and the best solution over different random starting classification matrices is retained to prevent from local minima.

Results from applications to real and artificial data will be presented to show the performance of the algorithm and the capability of the model to capture the heterogeneity of the occasions.

Robust Reduced k-Means and Factorial k-Means by trimming

Un approccio robusto a Reduced k-Means e Factorial k-Means

Luca Greco and Antonio Lucadamo and Pietro Amenta

Abstract In this paper we propose a robust version of Reduced and Factorial k-means, based on a trimming strategy. Reduced and Factorial k-means are data reduction techniques for simultaneous dimension reduction and clustering. The occurrence of data inadequacies can invalidate standard analyses. An appealing approach to develop robust counterparts of Reduced and Factorial k-means is given by impartial trimming. The idea is to discard a fraction of observations that are selected as the most distant from the centroids.
Abstract *In questo lavoro viene proposta una versione robusta di Reduced e Factorial k-means, basata su una procedura di trimming. Reduced e Factorial k-means sono tecniche che simultaneamente realizzano una riduzione della dimensionalitá e della numerosità, mediante analisi in componenti principali e k-means, rispettivamente. La presenza di contaminazione nei dati puó invalidare le analisi standard. Un approccio utile per sviluppare una procedura robusta alla presenza di valori anomali é rappresentato dal trimming, che si basa sull'idea di eliminare le osservazioni piú distanti dai centroidi stimati.*

1 Introduction

Reduced (De Soete and Carroll, 1994) and Factorial k-means (Vichi and Kiers, 2001) (RKM and FKM, respectively, hereafter) are data reduction techniques aimed at performing principal components and k-means clustering simultaneously. The main idea is that cluster centroids are located in a low dimensional subspace determined by the most relevant features.

Let $\mathbf{X}$ be the $n \times p$ zero centered data matrix, where n denotes the number of objects and p the number of variables, k be the number of clusters and $q < p$ the number of components, with $k \geq q+1$. We denote by $\mathbf{U}$ the $n \times k$ membership matrix whose i^{th} row has a one corresponding to the cluster assignment of the i^{th} object and zero otherwise, whereas $\mathbf{A}$ is the $p \times q$ loadings matrix and $\mathbf{Y} = \mathbf{XA}$ is the $n \times q$ scores matrix. RKM looks for centroids in a low dimensional subspace that minimize the distance of the data points from such centroids. The optimization problem connected with RKM can be expressed as

$$\min_{A,\bar{Y}} ||\mathbf{X} - \mathbf{U}\bar{\mathbf{Y}}\mathbf{A}^{\mathrm{T}}||^2 = \min_{A,\bar{Y}} \sum_{i=1}^{n} \min_{c=1,\dots,k} \sum_{j=1}^{p} \left(x_{ij} - \sum_{j'=1}^{q} \bar{y}_{cj'} a_{j'j} \right)^2 , \qquad (1)$$

where $\bar{\mathbf{Y}}$ is the $k \times q$ matrix collecting centroids $\bar{\mathbf{y}}_{\mathbf{c}} = (\bar{y}_{c1}, \dots, \bar{y}_{cq})$. In a complementary fashion, FKM finds low dimensional centroids such that the scores, rather than the original data, are closest to them, that is

$$\min_{A,\bar{Y}} ||\mathbf{XA} - \mathbf{U}\bar{\mathbf{Y}}||^2 = \min_{A,\bar{Y}} \sum_{i=1}^{n} \min_{c=1,\dots,k} \sum_{j=1}^{q} (y_{ij} - \bar{y}_{cj})^2 \ . \qquad (2)$$

Both RKM and FKM are built on conventional k-means that can be badly affected by the occurrence of contamination in the data (the reader is pointed to Farcomeni and Greco (2016) for a recent account on robustness issues in data reduction). In this paper, we aim at developing a robust counterpart of RKM and FKM stemming from trimmed k-means (Cuesta-Albertos et al, 1997). Let us assume that a fraction α of data points is prone to contamination and therefore discarded. The remaining part of clean objects is then used to solve the k-means optimization problem. Trimmed data are not assigned to any cluster and do not contribute to centroids estimation. The key feature is that trimming and estimation are performed simultaneously: this approach is usually referred as impartial trimming (Gordaliza, 1991). Here, in a similar fashion, it is suggested to introduce impartial trimming into problems (1) and (2). The interesting features of the proposed methodologies rely on the ability of the method, on the one hand, to detect the anomalous data and rightly assign the remaining ones to clusters and, on the other hand, to estimate clusters' centroids in the presence of outliers. These objectives are shown in the following illustrative examples. Since the complementary nature of the RKM and FKM models, we only consider the latter model both for simulated and real data.

Figure 1 displays the result of applying trimmed FKM (tFKM) to three simulated datasets of size 400 × 8. All the panels display the scores lying in a two dimensional subspace, where the data are assumed to be clustered. A sample of 320 genuine scores has been drawn from a mixture of three bivariate normal with standardized components and null correlation, that is we are dealing with spherical clusters. Then 80 outliers were added, that are simulated from a different random mechanism. Genuine data have been generated according to the scheme described in Timmerman et al (2010). Three different scenarios have been considered. In the top left panel, the anomalous data have been randomly generated from a bivariate normal centered at the mean of the centroids corresponding to the three original groups with a dispersion large enough to produce both inner and outer contaminations. In the top middle panel, outliers are clustered to form a well separated group from the genuine observations. In the top right panel, outliers are clustered along some linear structures. In all scenarios, we observe the capability of the proposed method both in detecting outliers and adapting to the true underlying clustering structure. On the contrary, in the first and third data configuration, the standard procedure allocates outliers in the three clusters leading to biased centroids' estimates, inflated within-group variances and lack of separation among them, whereas in the second scenario, two well separated clusters are wrongly merged together.

2 Trimmed RKM and FKM

The optimization problems connected with trimmed RKM and FKM (tRKM and tFKM, hereafter) can be expressed as follows, respectively:

$$\min_{z \in Z} \min_{A,\bar{Y}} \sum_{i=1}^{n} z_i \min_{c=1,\ldots,k} \sum_{j=1}^{p} \left(x_{ij} - \sum_{j'=1}^{q} \bar{y}_{cj'} a_{j'j} \right)^2 \tag{3}$$

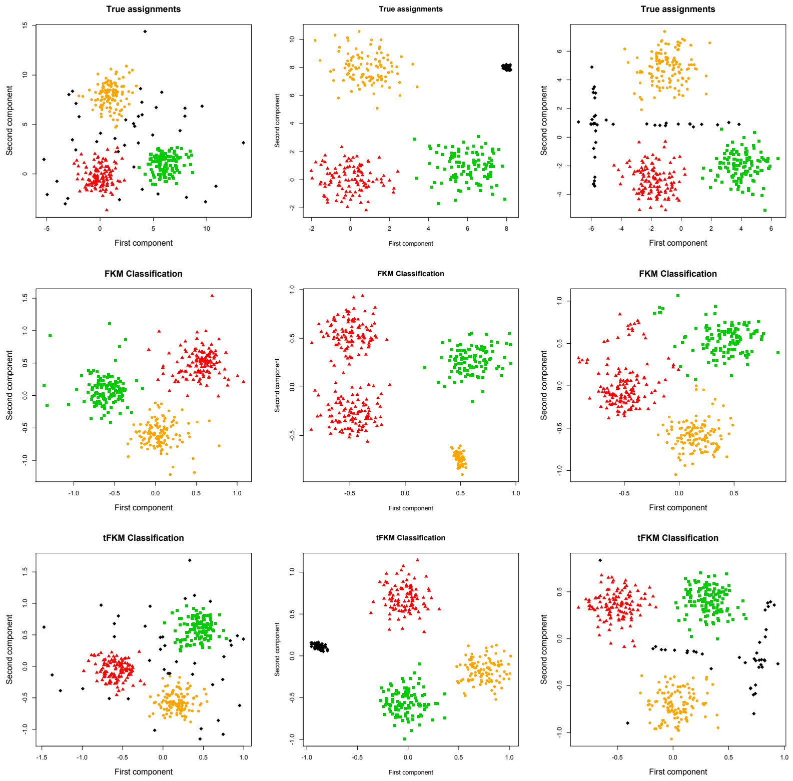
and

$$\min_{z \in Z} \min_{A,\bar{Y}} \sum_{i=1}^{n} z_i \min_{c=1,\ldots,k} \sum_{j=1}^{q} \left(y_{ij} - \bar{y}_{cj} \right)^2, \tag{4}$$

where $\mathbf{z} = (z_1, z_2, \ldots, z_n)^{\mathrm{T}}$ is a binary vector and $Z = \{z : \sum_{i=1}^{n} z_i = \lfloor (n(1-\alpha) \rfloor \}$. The objective functions (3) and (4) are such that data points for which $z_i = 0$ do not contribute to their minimization. It is worth noting that classical RKM and FKM are included in the above definitions as limiting cases when $\alpha = 0$.

Minimization of the objective functions (3) and (4) requires an iterative algorithm characterized by the introduction of concentration steps. The concentration step (Rousseeuw and Driessen, 1999; Gallegos and Ritter, 2005; Farcomeni, 2009) is meant to detect the $n\alpha$ largest distances with respect to the current closest centroid and trim the corresponding observations. Then, the loss functions in (1) or (2) are minimized based on the observations not flagged for trimming. The final $\mathbf{U}$ obtained at convergence simultaneously identifies the optimal cluster for each

Fig. 1 Three simulated data sets with true assignments (top row), classical classification from FKM (middle row), robust classification from tFKM (bottom row). The symbol ♦ is used to denote true outliers in the top row and trimmed observations in the other rows.



observation that is not trimmed and trimmed observations, which correspond to a constant row of zeros. Both algorithms have been implemented into the statistical environment `R` by combining the main features of the functions `cluspca` from package `clustrd` and `tkmeans` from package `tclust`.

3 Selecting the number of clusters, components and the trimming level

The selection of the number of clusters k can be pursued by paralleling the approach described in García-Escudero et al (2011): the strategy could be to display the objective function at convergence against the trimming level α for different choices of

k. Then, the number of clusters should be set equal to the minimum k for which there is no substantial improvement in the loss function when adding one group more.

In order to choose the number of components q, it is suggested to explore the quality of the fitted model by varying q from 1 to $(k-1)$. For instance, this task could be exploited by looking at the rate of explained robust variance or the adjusted Rand index. Then, the number of components can be augmented until there is no more significant increase in the selected criterion.

The selection of α could be based on the inspection of the G-statistic or of the generalized G-statistic introduced in Farcomeni (2009). Parameters' estimates or the objective function itself are monitored by varying α. Then, we select a trimming level above which the differences in parameters' estimates or in the objective function become negligible.

4 Macroeconomic data

This is a 20×6 data set, already analyzed in Vichi and Kiers (2001), concerning the macroeconomic performance of national economies in September 1999. Six main economic indicators, that measure the percentage change from the previous year, have been considered: gross domestic product (GDP), leading indicator (LI), unemployment rate (UR), interest rate (IR), trade balance (TB), net national savings (NNS). A classification of the countries into $k = 3$ groups is considered, that is expected to reflect the striking features of economic development and to take into account the differences in growth among them. The G-statistic leads to select $\alpha = 0.15$ (i.e. 3 trimmed observations). Figure 2 gives the classification resulting from FKM and tFKM. There are remarkable differences between the classical and the robust analysis, mainly due to the three outlying countries that have been detected. The cluster profiles and the raw score measurements for the outlying countries are given in Table 1. It can be seen that the three clusters are well separated, even if Cluster 2 and Cluster 3 are separated only w.r.t. the second component. The first component is mainly determined by NNS (positive sign), UR (positive sign) and TB (negative sign), whereas the second is dominated by GDP. The first cluster is composed by 4 countries that are characterized by the largest values on the first component, that is countries showing large values of NNS or UR and small values of TB. The second cluster is composed by 5 countries. It is characterized by the largest values on the second component, that is countries with large GDP. The third cluster is composed by 8 countries, that are those exhibiting the lowest growth in GDP. The outlying countries Sweden and Japan are easily explained. Sweden is well spotted on the left side and it actually shows the lowest NNS; Japan, on the contrary, is well detected along the first component since it exhibits the minimum growth in GDP. The explanation for Denmark is more complicated: it could be included in Cluster 3 but it shows an unexpected low growth in UR and NNS.

Fig. 2 Macroeconomic data: classification from FKM (left) and tFKM (right). Trimmed observations in the right panel are denoted by ♦.

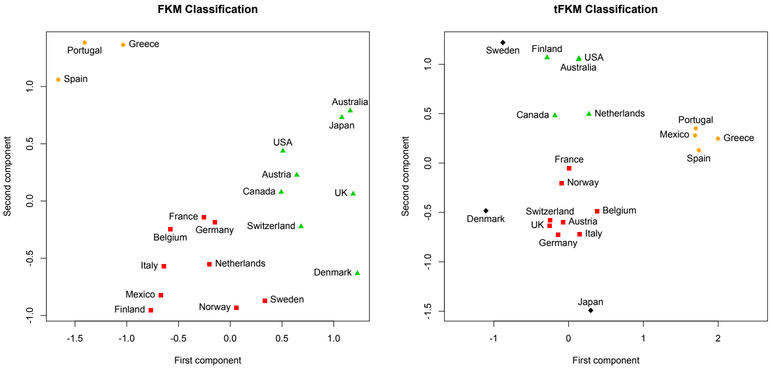


Table 1 Macroeconomic data: cluster profiles and raw scores for the outlying countries.

	Comp. 1	Comp. 2		Comp.1	Comp. 2
Cluster 1	1.782	0.252	Denmark	-1.106	-0.483
Cluster 2	0.014	0.830	Japan	0.296	-1.491
Cluster 3	-0.034	-0.500	Sweden	-0.879	1.220

Dirichlet processes, posterior similarity and graph clustering

Processo di Dirichlet, similarità a posteriori e classificazione su grafi

Stefano Tonellato

Abstract This paper proposes a clustering method based on the sequential estimation of the random partition induced by the Dirichlet process. Our approach relies on the Sequential Importance Resampling (SIR) algorithm and on the estimation of the posterior probabilities that each pair of observations are generated by the same mixture component. Such estimates do not require the identification of mixture components, and therefore are not affected by label switching. Then, a similarity matrix can be easily built, allowing for the construction of a weighted undirected graph. A random walk can be defined on such a graph, whose dynamics is closely linked to the posterior similarity. A community detection algorithm, the map equation, can then be implemented in order to achieve a clustering by minimising an information theoretic criterion.

Abstract *Si propone un metodo di classificazione basato sulla stima sequenziale della partizione indotta dal processo di Dirichlet. Il metodo si basa su un algoritmo stocastico sequenziale (SIR) e sulla probabilità a posteriori che ciascuna coppia di osservazioni sia generata da una componente della mistura. Il metodo non richiede l'identificazione delle singole componenti e non risente degli inconvenienti del label switching. Una matrice di similarità può quindi essere stimata a posteriori. Questo consente la costruzione di un grafo pesato e la definizione, su di esso, di una passeggiata aleatoria. Un algoritmo utilizzato nella classificazione di reti, chiamato map equation, che ricerca la partizione che minimizza un criterio di informazione, può quindi essere facilmente implementato.*

1 Dirichlet process mixtures and clustering

A very important class of models in Bayesian nonparametrics is based on the Dirichlet process and is known as Dirichlet process mixture [1]. In this model, the observable random variables, X_i, $i = 1, \ldots, n$, are assumed to be exchangeable and generated by the following hierarchical model:

$$\begin{aligned} X_i|\theta_i &\overset{ind}{\sim} p(\cdot|\theta_i),\ \theta_i \in \Theta \\ \theta_i|G &\overset{iid}{\sim} G \\ G &\sim DP(\alpha, G_0), \end{aligned}$$

where $DP(\alpha, G_0)$ denotes a Dirichlet process (DP) with base measure G_0 and precision parameter $\alpha > 0$. Since the DP generates almost surely discrete random measures on the parameter space Θ, ties among the parameter values have positive probability, leading to a batch of clusters of the parameter vector $\theta = [\theta_1, \ldots, \theta_n]^T$. Exploiting the Pólya urn representation of the DP, the model can be rewritten as

$$X_i|s_i, \theta^*_{s_i} \overset{iid}{\sim} p(\cdot|\theta^*_{s_i}),\ \theta^*_{s_i} \in \Theta \tag{1}$$

$$\theta^*_{s_i} \overset{iid}{\sim} G_0 \tag{2}$$

$$p(s_i = j|\mathbf{s}_{<i}) = \begin{cases} \frac{\alpha}{\alpha+i-1} & j = k \\ \frac{n_j}{\alpha+i-1} & j \in \{k-1\}, \end{cases} \tag{3}$$

$$s_i \perp \theta^*_j \qquad \forall i, j, \tag{4}$$

where $\{k\} = \{1, \ldots, k\}$, $\mathbf{s}_{<i} = \{s_j,\ j \in \{i-1\}\}$ (in the rest of the paper, the subscript $< i$ will refer to those quantities that involve all the observations $X_{i'}$ such that $i' < i$), $s_j \in \{k\}$ for $j \in \{k-1\}$, and n_j is the number of θ_i's equal to θ^*_j. In this model representation, the parameter θ can be expressed as $(\mathbf{s}, \theta^*)$, with $\mathbf{s} = \{s_i : s_i \in \{k\},\ i \in \{n\}\}$, $\theta^* = [\theta^*_1, \ldots, \theta^*_k]^T$ with $\theta^*_j \overset{iid}{\sim} G_0$, and $\theta_i = \theta^*_{s_i}$. Consequently, the marginal distribution of X_i is a mixture with k components, where k is an unknown random integer.

In the case of finite mixtures with k components, with k fixed and known, under a frequentist perspective it would be quite straightforward to cluster the data by maximising the probability of the allocation of each datum to one of the k components, conditionally on the observed sample [6]. Under a Bayesian perspective, the same results can be achieved, provided that either some identifiability constraints on the parameters are introduced, or a suitable risk function is minimised [12]. Unfortunately, under the assumptions we made, such computations are not feasible even numerically, due to the well known label switching problem [3] that persists when the number of mixture components is not known, nor finite, as in the case of Dirichlet process mixtures. Nevertheless, equations (1)–(4) are very helpful in estimating posterior pairwise similarities and building hierarchical clustering algorithms as in [7, 8]. In section 2, a sequential estimation algorithm analogous to the one in [5] is developed. In section 3, individuals are represented as nodes of a weighted undirected graph on which a random walk is built, with transition probabilities proportional to the posterior similarities. Nodes can then be classified by minimising the entropy through the map algorithm introduced in [10, 11]. The approach proposed in sections 2 and 3 has a double benefit. On one hand, the sequential estimation algorithm guarantees a fast estimation of pairwise similarities. On the other hand, the construction of the random walk on the graph mentioned above, allows us to choose the optimal partition by a minimum description length algorithm, so avoiding the subjective choice of a cut of the dendrogram usually associated to hierarchical clustering algorithms. Furthermore, as a byproduct, the entropy of any partition of the data can be computed and it is closely linked to the fitted model. This allows for a model based comparison of any pair of partitions.

2 Sampling importance resampling

Under the assumptions we introduced above, following the arguments of [5], we can write the conditional posterior distribution of s_i given $x_1,\ldots,x_i$, as

$$p(s_i = j|\mathbf{s}_{<i},\theta^*,\mathbf{x}^{(j)}_{<i},x_i) = \begin{cases} \frac{n_j}{\alpha+i-1} p(x_i|\theta^*_j,\mathbf{s}_{<i},\mathbf{x}^{(j)}_{<i}) & j \in \{k\} \\ \frac{\alpha}{\alpha+i-1} p(x_i|\theta^*_{k+1}) & j = k+1, \end{cases}$$

where $\mathbf{x}^{(j)}_{<i} = \{x_{i'} : i' < i, s_{i'} = j\}$, $j = 1,\ldots,k$, and $\mathbf{x}^{(k+1)}_{<i} = \emptyset$, since $\forall i' < i$, $s_{i'} \in \{k\}$.

We can marginalise the conditional posterior of s_i with respect to θ^*, obtaining

$$p(s_i = j|\mathbf{s}_{<i},\mathbf{x}^{(j)}_{<i},x_i) = \begin{cases} \frac{n_j}{\alpha+i-1} p(x_i|s_i = j,\mathbf{s}_{<i},\mathbf{x}^{(j)}_{<i}) & j \in \{k\} \\ \frac{\alpha}{\alpha+i-1} p(x_i|s_i = k+1,\mathbf{s}_{<i},\mathbf{x}_{<i}) & j = k+1, \end{cases}$$

where

$$p(x_i|s_i = j,\mathbf{s}_{<i},\mathbf{x}_{<i}) = \int_\Theta p(x_i|\theta,s_i = j,\mathbf{s}_{<i},\mathbf{x}^{(j)}_{<i}) p(\theta|s_i = j,\mathbf{s}_{<i},\mathbf{x}^{(j)}_{<i}) d\theta \tag{5}$$

and

$$p(x_i|s_i = k+1,\mathbf{s}_{<i},\mathbf{x}_{<i}) = \int_\Theta p(x_i|\theta) dG_0(\theta). \tag{6}$$

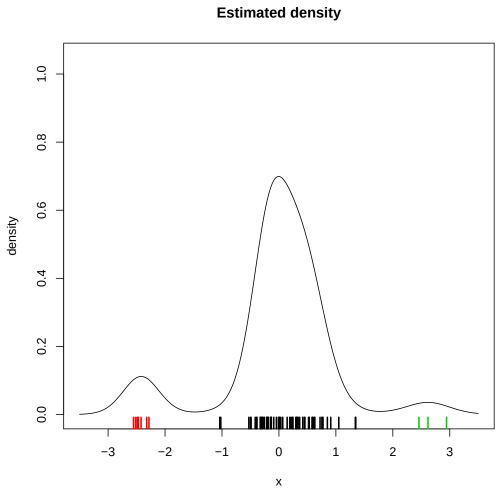
Notice that when G_0 is a conjugate prior for (1), the computation of (5) and (6) is often straightforward.

The following importance sampler has been introduced in [5].

SIR algorithm. For $i = 1,\ldots,n$, repeat steps (A) and (B)

(A) Compute

Fig. 1 Estimated posterior density function and clustering



$$g(x_i|\mathbf{s}_{<i},\mathbf{x}_{<i}) \propto \sum_{j=1}^{k+1} \frac{n_j}{\alpha+i-1} p(x_i|s_i=j,\mathbf{s}_{<i},\mathbf{x}^{(j)}_{<i}),$$

with $n_{k+1}=\alpha$.

(B) Generate s_i from the multinomial distribution with

$$p(s_i=j|\mathbf{s}_{<i},\mathbf{x}^{(j)}_{<i},x_i) \propto \frac{n_j}{\alpha+i-1} p(x_i|s_i=j,\mathbf{s}_{<i},\mathbf{x}^{(j)}_{<i}).$$

Taking R independent replicas of this algorithm we obtain $s_i^{(r)}$, $i=1,\ldots,n$, $r=1,\ldots,R$, and $\theta_j^* \sim p(\theta|\mathbf{x}^{(j)})$, with $\mathbf{x}^{(j)}=\{x_i : i \in \{n\}, s_i=j\}$, and compute the importance weights

$$w_r \propto \prod_{i=1}^{n} g(x_i|\mathbf{s}_{<i},\mathbf{x}_{<i})$$

such that $\sum_{r=1}^{R} w_r = 1$. Should the variance of the importance weights be too small, the efficiency of the sampler could be improved by resampling as follows [2]. Compute $N_{\text{eff}} = (\sum_{r=1}^{R} w_r^2)^{(-1)}$. If $N_{\text{eff}<\frac{R}{2}}$, draw R particles from the current particle set with probabilities equal to their weights, replace the old particle with the new ones and assign them constant weights $w_r = \frac{1}{R}$.

3 Pairwise similarities and community detection

Intuitively, we can state that two individuals, i and j, are similar if x_i and x_j are generated by the same mixture component, i.e. if $s_i = s_j$. Label switching prevents

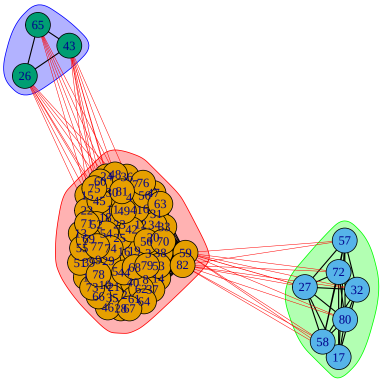


Fig. 2 The graph induced by the posterior similarity and the clusters detected by the map equation algorithm

us from identifying mixture components, but not from assessing similarities among individuals. In fact, the algorithm introduced in the previous section may help us in estimating pairwise similarities between individuals. The posterior probability that x_i and x_j are generated by the same component, i.e. the posterior probability of the event $\left\{s_i = s_j\right\}$, can be estimated as

$$\hat{p}_{ij} = \sum_{r=1}^{R} w_r I\left(s_i^{(r)}, s_j^{(r)}\right),$$

where $I(x,y) = 1$ if $x = y$ and $I(x,y) = 0$ otherwise. We can then define a similarity matrix S with ij-th element $s_{ij} = \hat{p}_{ij}$.

The matrix S can be used to build the weighted undirected graph $G = (V,E)$, where each node in the set V represents an individual in the sample, i.e. $V = \{n\}$, and the set E contains all the edges in G. Furthermore, the weight of the generic edge (i,j) is given by $w_{ij} = s_{ij}$ if $i \neq j$, and $w_{ij} = 0$ otherwise. We can then define a random walk $\mathscr{X}$ on G, with state space V. Let $d_i = \sum_{j=1}^{n} w_{ij}$, $i = 1,\ldots,n$ and $D = \mathrm{diag}(d_1,\ldots,d_n)$. We define the transition matrix of $\mathscr{X}$ as $P = D^{-1}W$. If G is connected, $\mathscr{X}$ has π as invariant distribution, with $\pi_i = \frac{d_i}{\sum_{i,j} w_{ij}}$ [4]. The random walk we have just defined represents an artificial stochastic flow such that the probability of moving from i to j is proportional to w_{ij}, i.e. to the similarity between i and j. Such a dynamics induces some high density subsets of V, i.e. subsets where the random walker spends a long time before moving to other clusters, separated by low weight edges. In such a context, community detection algorithms attempt to identify an optimal partition of V. We shall refer, in particular, to the so called map equation [10, 11] that attempts to find a partition of V such that the length of the code describing the behaviour of $\mathscr{X}$ is minimised. Let M be a partition of V. The map equation computes the entropy $L(M)$, which is strictly related to P and π. The optimal partition minimises $L(M)$. As stated in [10], "the map equation calculates the minimum description length of a random walk on the network for a two-level code that separates the important structures from the insignificant details based on the partition M".

As an example, figures 1 and 2 show the results of an application to the well known galaxy data set [9].

Bootstrap ClustGeo with spatial constraints

Bootstrap ClustGeo con vincoli spaziali

Veronica Distefano[1,2], Valentina Mameli[1], Fabio Della Marra[1,2]

Abstract The aim of this paper is to introduce a new statistical procedure for clustering spatial data when an high number of covariates is considered. In particular, this procedure is obtained by coupling the agglomerative hierarchical clustering method that ha been recently proposed for spatial data, referred as *ClustGeo* (*CG*) method , with the bootstrap technique. The proposed procedure, which we call *Bootstrap ClustGeo* (*BCG*), is developed and tested on a real dataset. The results that we achieve show that *BCG* outperforms *CG* in terms of accuracy of some cluster evaluation measures.

Abstract Il presente lavoro propone una nuova procedura di clustering per dati spaziali, che denoteremo *Bootstrap ClustGeo* (*BCG*). In particolare, questa nuova procedura coniuga il metodo di clustering agglomerativo gerarchico, recentemente proposto per dati spaziali sotto il nome di *ClustGeo* (*CG*), con il metodo bootstrap. I risultati ottenuti dimostrano una migliore performance dell'approccio *BCG* secondo un insieme di misure di valutazione di clustering.

1 Introduction

Addressing a study on sustainable development of geographical areas is becoming crucial to derive geopolitical policy. As noted by UN-GGIM (2012), "all of

[1] European Centre for Living Technology, Ca' Foscari University of Venice, Italy.
[2]Department of Environmental Sciences, Informatics and Statistics, Ca' Foscari University of Venice, Italy.

the issues impacting sustainable development can be analyzed, mapped, discussed and modeled within a geographic context. Whether collecting and analyzing satellite images or developing geopolitical policy, geography can provide the integrative framework necessary for global collaboration and consensus decision-making" [11]. In this context, the geo-spatial clustering procedures represent an important area of research in data analysis, and a growing interest in clustering spatial data is emerging in several application fields. Indeed, the geo-spatial data and accurate clustering approaches in selecting constraints and parameters can provide better and more meaningful results.
In this study, we address the problem of clustering n spatial locations into K disjoint clusters when an high number of covariates is considered. Most approaches in the literature have been developed to derive clusters containing only contiguous locations. These procedures are based on the assumption that, within each cluster, there exists a connecting path for any couple of locations [9, 10, 5, 2]. This assumption involves then a strict-spacial constraint, i.e. locations characterized by social-economic variables with very similar values, but not close to each other in space, will be likely to be grouped into different clusters. Very recently, a non-strict constrained procedure has been developed, in which the condition of spatial closeness is relaxed [4]. In [6], the authors propose a hierarchical clustering method with non-strict spatial constraints, which is referred as *ClustGeo*. The method is based on two dissimilarity matrices: a matrix with dissimilarities derived from the "covariate-space"and a matrix with the dissimilarities derived from the "non-strict constraint space". In our work, we extend the aforementioned approach proposed in [6] by developing a procedure based on the generation of multiple bootstrap clustering partitions combined by using the Hamming distance. The novel procedure is called *Bootstrap ClustGeo*.

The paper is organized as follows. In Section, 2 we review the *ClustGeo* method and we then introduce the novel procedure *Bootstrap ClustGeo*. In Section 3, we evaluate this procedure on a real and known database which includes 303 French municipalities characterized by a set of 10 socio-economic covariates.

2 Methods

In classical cluster analysis, similar observations can be grouped into clusters. There exist different types of clustering algorithms which have been developed for different structure of data to be analyzed [8, 3]. In this paper, we select the agglomerative hierarchical clustering approach for analyzing geo-spatial data. The structure of an agglomerative hierarchical clustering approach can be summerised as follows. At the initialization, each cluster contains a single observation. Then, at each step of the agglomerative process, the two clusters with the smallest distance are merged into a new one. This procedure is iterated until a single cluster containing all the observations is obtained. The results of the agglomerative algorithm are usually represented with a tree or a dendrogram.

Formally, let $\{x_i = (x_{i1}, \ldots, x_{ip})\}_{i=1,\ldots,n}$ be the set of n observations (municipalities in the dataset), each of which is described by p covariates. Let $\{w_i\}_{i=1,\ldots,n}$ be the weights associated to the i-th observation selected by the researcher. $\{w_i\}_{i=1,\ldots,n}$ can be proportional to the inverse of the total poluation of the municipality x_i. Consider $D_0 = (d_{0ij})_{i,j=1,\ldots,n}$ a $n \times n$ dissimilarity matrix associated with the n observations, where $d_{0ij} = d_0(x_i,x_j)$ is the dissimilarity measure between observations i and j, which could be Euclidean or non-Euclidean. In this paper we focus only on the non-Euclidean case. The matrix D_0 is usually referred as the dissimilarity of the "covariate-space". Consider also the $n \times n$ dissimilarity matrix $D_1 = \{(d_1(x_i,x_j))\}_{i,j=1,\ldots,n} = (d_{1ij})_{i,j=1,\ldots,n}$ containing spatial constraints between the observations, which is refereed as the dissimilarity of the "non-strict geo-spatial constraint space". In this research we consider the geographical distances as spatial constraints.

Let $\alpha \in [0,1]$ be a parameter which controls the importance of the spatial constraints in the clustering procedure. Suppose that the dataset, $X = (x_1,\ldots,x_n)^T$, is partitioned into K clusters C_k^α with $k = 1,\ldots,K$, which form the partition $\mathscr{P}_K^\alpha = (C_1^\alpha,\ldots,C_K^\alpha)$. In the agglomerative clustering process for spatial data, the distance between clusters could be determined by using the *ClustGeo* (*CG*) method as proposed in [6], which is based on the minimization of the pseudo within-cluster inertia of the partition $\mathscr{P}_K^\alpha$. The pseudo within-cluster inertia is defined as

$$W(\mathscr{P}_K^\alpha) = \sum_{k=1}^{K} I_\alpha(C_k^\alpha),$$

where

$$I_\alpha(C_k^\alpha) = (1-\alpha)\sum_{i\in C_k^\alpha}\sum_{j\in C_k^\alpha}\frac{w_i w_j}{2\mu_k^\alpha}d_{0ij}^2 + \alpha\sum_{i\in C_k^\alpha}\sum_{j\in C_k^\alpha}\frac{w_i w_j}{2\mu_k^\alpha}d_{1ij}^2,$$

with $\mu_k^\alpha = \sum_{i\in C_k^\alpha} w_i$. Starting from a given partition $\mathscr{P}_K^\alpha$, the *CG* method aggregates the two clusters with the smallest within-cluster inertia in order to obtain a new partition with $K-1$ clusters.

In order to analyze the database with an high number of covariates, in this paper we develop a novel procedure based on the *CG* method. This novel procedure is derived by generating multiple bootstrap clustering partitions with the *CG* method and combining the results by using the Hamming distance. We will refer to the new methodology as the *Bootstrap ClustGeo* (*BCG*) method. The main features of this novel methodology are described in the following.

At first, we take B bootstrap sample from the n data points x_i. Each bootstrap sample sample will be denoted by X_b, for $b = 1,\ldots,B$. For each bootstrap sample X_b, we will set the number of clusters K_b by drawing it from a discrete uniform distribution, i.e. $K_b \sim DUnif$. Then, we use the *CG* method to find a clustering partition $\mathscr{P}_{K_b}^\alpha$ of size K_b for each dataset X_b. At the end of the B bootstrap replications, we construct the incidence matrix

$$\mathscr{I}^{\alpha} = \begin{bmatrix} r_{11} & r_{12} & \dots & r_{1B} \\ \vdots & \vdots & \vdots & \vdots \\ r_{n1} & r_{n2} & \dots & r_{nB} \end{bmatrix},$$

where r_{ib} represents the index of the cluster in the partition $\mathscr{P}^{\alpha}_{K_b}$ to which x_i belongs. At last, we derive a new dissimilarity matrix

$$D^{\alpha}_{B} = (d^{\alpha}_{B}(x_i, x_j))_{i,j=1,\dots,n},$$

in which

$$d^{\alpha}_{B}(x_i, x_j) = \frac{1}{B} \sum_{b=1}^{B} \delta(r_{ib}, r_{jb}),$$

where δ is the Hamming distance. The new dissimilarity matrix D^{α}_{B} will be used to find a new clustering partition by exploiting the *CG* method.

3 Results

In this section, we compare the performances of *CG* and *BCG* methods on a real and known database. We perform a geo-spatial clustering analysis with geographical constraints in the administrative region of the Nouvelle Aquitanie, which is located in the southwest of France. The available dataset consists of n = 303 municipalities and $p = 10$ indicators, which includes social and economic indicators, as shown in Table 1. The data source of the indicators is the INSEE (*National Institute of Statistics and Economic Studies*).

The number of clusters has been estimated by visual inspection of the clustering tree generated by the *CG* algorithm when only D_0 is taken into account. The optimal value of the parameter α has been chosen by using the criterion proposed in [6]. From Table 1, we can see that the means of the vast majority of the variables within clusters 1 and 2 do not show significant differences across the two clustering methods. We can notice more relevant differences in the remaining clusters (3, 4, and 5). For example, the mean of the variable “Ratio of the agricultural area”assumes a small value (2.90) in cluster 5 by using the *CG* method with respect to the mean of the same variable (35.16) in cluster 3 with the *BCG* method.

From the results presented in Fig. 1, we can note that the clusters obtained by using the *BCG* are spatially more compact than those obtained by the *CG* method. Indeed, the municipalities located in cluster 2 for the *CG* method are grouped into a greater number of clusters than by the *BCG* method. Neither of the two methods requires any strict-contiguity assumption, as shown in Fig 1. Hence, cluster 1 contains municipalities which are not connected in space.

To assess the quality of the two clustering partitions obtained with the *CG* and the *BCG* algorithms, we consider some known evaluation measures, such as the Con-

Indicators	Method	Cluster 1	Cluster 2	Cluster 3	Cluster 4	Cluster 5

Table 1: Comparison of the CG and the BCG methods in derived clusters for Economic (E) and Social (S) indicators. In each cluster we present the mean value and the standard deviation within brackets.

nectivity, the average Silhouette, and the Dunn indices [7]. The Connectivity represents the strength of connectedness of the clusters, lies in the range between 0 and infinity and should be minimized. Both the Silhouette and the Dunn indices measure the quality of the compactness and the separation of the the clusters and should be maximized. The Silhouette value lies in the interval $[-1,1]$, and the Dunn index assumes values between 0 and infinity. As we can see from Table 2, the *BCG* algorithm outperforms the *CG* algorithm for all the indices. These results show that the novel methodology proposed is capable of exploiting the spatial constraints to achieve better clustering accuracy in comparison with the *CG*. The use of the bootstrap sampling and the Hamming distance for categorical variables permit to accurately obtain information for defining the Clustering structure. The results show the BCG to be more accurate then the CG.

Advances in Statistical Models

Regression modeling via latent predictors

Regressione basata su predittori latenti

Francesca Martella and Donatella Vicari

Abstract A proposal for multivariate regression modeling based on latent predictors (LPs) is presented. The idea of the proposed model is to predict the responses on LPs which, in turn, are built as linear combinations of disjoint groups of observed covariates. The formulation naturally allows to identify LPs that best predict the responses by jointly clustering the covariates and estimating the regression coefficients of the LPs. Clearly, in this way the LP interpretation is greatly simplified since LPs are exactly represented by a subset of covariates only. The model is formalized in a maximum likelihood framework which is intuitively appealing for comparisons with other methodologies, for allowing inference on the model parameters and for choosing the number of subsets leading to LPs. An Expectation Conditional Maximization (ECM) algorithm is proposed for parameter estimation and experiments on simulated and real data show the performance of our proposal.

Abstract *In questo lavoro si propone un nuovo modello di regressione basato su predittori latenti (PL) che, a loro volta, sono modellizzati come combinazioni lineari di gruppi disgiunti di covariate osservate. Tale formulazione permette di identificare direttamente i migliori PL che predicono le risposte attraverso: la classificazione delle covariate e la stima dei coefficienti di regressione. In questo modo l'interpretazione dei PL é notevolmente semplificata poiché i PL sono rappresentati solamente da sottoinsiemi di covariate. Il modello é formalizzato in un contesto di massima verosimiglianza e viene presentato un algoritmo Expectation Conditional Maximization (ECM) per la stima dei parametri. Esperimenti su dati simulati e reali mostrano l'utilitá e la validitá della proposta.*

1 Introduction

Considering ordinary repression modeling of several dependent variables (responses) on a large set of covariates is not always the best choice. In fact, in such a case, difficulties in interpretation of the (many) regression coefficients and the presence of multicollinearity among predictors may arise. Many strategies can be adopted in order to reduce such problems such as standard variable selection methods, penalized (or shrinkage) techniques and dimensionality reduction methods (DRMs). The latter attempt to build small set of linear combinations of the predictors, used as input to the regression model, and differ in how the linear combinations are built. See among others, principal component regression (PCR, [7]), factor analysis regression (FAR, [2]), canonical correlation regression (CCR, [5]), partial least squares regression (PLSR, [12]), [10] for the continuum regression (unified regression technique embracing OLS, PLSR and PCR), reduced rank regression (RRR, [1], [6]), redundancy analysis (RA, [11]). [13] proposed a general formulation for dimensionality reduction and coefficient estimation in multivariate linear regression, which includes many existing DRMs as specific cases. Finally, [3] proposed a new formulation to the multiblock setting of latent root regression applied to epidemiological data and [4] investigated a continuum approach between MR and PLS. [8] proposed a multivariate regression model based on the optimal partition of predictors (MRBOP). A drawback of DRMs is that they may generally suffer from a possible difficulty of interpretability of the resulting linear combinations which are often overcome through rotation methods. Here, we propose to build latent predictors (LPs) as linear combinations of disjoint groups of covariates that best predict the responses where such groups identify block-correlated covariates. Actually, we simultaneously perform clustering of the covariates and estimation of the regression coefficients of the LPs. This turns out to be a relevant gain in the interpretation of the regression analysis, since LPs are formed by disjoint groups of covariates and, therefore easily interpretable. Clearly, in this way the LP interpretation is greatly simplified since LPs are exactly represented by a subset of covariates only. An Expectation Conditional Maximization algorithm (ECM, [9]), for maximum likelihood estimation of the model parameters is described. The performance of the proposed model is confirmed by the application on simulated and real data sets. The results are encouraging and would deserve further discussion.

2 Model

Consider $\mathbf{x}_i$ be a J-dimensional data vector representing the covariates and $\mathbf{y}_i$ be a M-dimensional data vector of the responses observed on the i-th unit in a sample of size n. Without loss of generality, $\mathbf{x}_i$ and $\mathbf{y}_i$ are assumed to be centered to zero mean vector. Our proposal can be summarized by two models: the first is a regression model formalizing the relations between responses and latent predictors, while the second one represents a dimensional reduction model where the latent predictors synthesize the relations among the covariates. In formula, we have

$$\mathbf{y}_i = \mathbf{C}'\mathbf{f}_i + \mathbf{e}_i \tag{1}$$

and

$$\mathbf{f}_i = \mathbf{V}'\mathbf{W}\mathbf{x}_i + \xi_i \tag{2}$$

where $\mathbf{C}$ is the $(Q \times M)$ regression coefficient matrix, $\mathbf{f}_i$ is the Q-th dimensional LP vector, $\mathbf{e}_i$ is the M-th dimensional noise term vector, $\mathbf{V}$ is the $(J \times Q)$ binary membership matrix defining a partition of the covariates in Q non-empty groups $(Q \leq J)$, $\mathbf{W}$ is the $(J \times J)$ diagonal matrix which gives weights to the J covariates, ξ_i is the Q-th dimensional noise term vector $(i = 1, \ldots, n)$.
Moreover, we assume that the noise terms are independent and follow multivariate Normal distributions: $\mathbf{e}_i \sim \mathrm{MVN}(\mathbf{0}, \Sigma_{\mathbf{e}})$ with $\Sigma_{\mathbf{e}}$ diagonal matrix and $\xi_i \sim \mathrm{MVN}(\mathbf{0}, \mathbf{I}_Q)$. Then, we derive that $\mathbf{f}_i \sim \mathrm{MVN}(\mathbf{V}'\mathbf{W}\mathbf{x}_i, \mathbf{I}_Q)$, $\mathbf{y}_i \sim \mathrm{MVN}(\mathbf{C}'\mathbf{V}'\mathbf{W}\mathbf{x}_i, \mathbf{C}'\mathbf{C} + \Sigma_{\mathbf{e}})$ and, conditional on $\mathbf{f}_i$, results in $\mathbf{y}_i | \mathbf{f}_i \sim \mathrm{MVN}(\mathbf{C}'\mathbf{f}_i, \Sigma_{\mathbf{e}})$. Thus, the log-likelihood function $l(\Theta)$, being $\Theta = \{\mathbf{C}, \mathbf{V}, \mathbf{W}, \Sigma_{\mathbf{e}}\}$, is given by

$$\begin{aligned} l(\Theta) = &- \sum_{i=1}^{n} \left[(2\pi)^{M/2} |\mathbf{C}'\mathbf{C} + \Sigma_{\mathbf{e}}|^{1/2} \right] \\ &+ \sum_{i=1}^{n} \left\{ \frac{1}{2} \left(\mathbf{y}_i - \mathbf{C}'\mathbf{V}'\mathbf{W}\mathbf{x}_i \right)' (\mathbf{C}'\mathbf{C} + \Sigma_{\mathbf{e}})^{-1} \left(\mathbf{y}_i - \mathbf{C}'\mathbf{V}'\mathbf{W}\mathbf{x}_i \right) \right\}. \end{aligned} \tag{3}$$

Finding the maximum likelihood estimates for $\mathbf{C}, \mathbf{W}, \Sigma_{\mathbf{e}}, \mathbf{V}$ is more problematic. We propose an ECM algorithm which iteratively computes the expected value of the complete-data log-likelihood and maximizes the expected complete-data log-likelihood over one of the parameters while holding the other fixed until convergence is achieved. Similarly to the factor analysis context, we take $\mathbf{y}$ as the observed data and $\mathbf{f}$ as the missing data, by assuming, therefore, that the complete data vector consist of $\mathbf{z}_i = (\mathbf{y}_i', \mathbf{f}_i')'$ $(i = 1, \ldots, n)$. Therefore, the complete-data log-likelihood is given by:

$$\begin{aligned} \ell_C(\Theta) &= \sum_{i=1}^{n} \log\left[\phi(\mathbf{y}_i | \mathbf{f}_i, \Theta)\right] + \sum_{i=1}^{n} \log\left[\phi(\mathbf{f}_i | \Theta)\right] \\ &= \sum_{i=1}^{n} \log\left[\phi(\mathbf{y}_i | \mathbf{f}_i, \Theta)\right] + \sum_{i=1}^{n} \log\left[\phi(\mathbf{f}_i | \mathbf{W}, \mathbf{V})\right] \end{aligned} \tag{4}$$

since the distribution of $\mathbf{f}_i$ is independent of $\mathbf{C}$ and $\Sigma_{\mathbf{e}}$. The expected value of $\mathbf{f}_i$ conditional on $\mathbf{y}_i$ and the current model parameters is

$$\mathrm{E}(\mathbf{f}_i|\mathbf{y}_i,\Theta) = \mathbf{V}'\mathbf{W}\mathbf{x}_i + \beta(\mathbf{y}_i - \mathbf{C}'\mathbf{V}'\mathbf{W}\mathbf{x}_i) \tag{5}$$

and

$$\begin{aligned}\mathrm{E}(\mathbf{f}_i\mathbf{f}_i'|\mathbf{y}_i,\Theta) = {}& (\mathbf{I}_Q - \beta\mathbf{C}') + [\mathbf{V}'\mathbf{W}\mathbf{x}_i + \beta(\mathbf{y}_i - \mathbf{C}'\mathbf{V}'\mathbf{W}\mathbf{x}_i)]\\ & [\mathbf{V}'\mathbf{W}\mathbf{x}_i + \beta(\mathbf{y}_i - \mathbf{C}'\mathbf{V}'\mathbf{W}\mathbf{x}_i)]'\end{aligned} \tag{6}$$

where $\beta = \mathbf{C}(\mathbf{C}'\mathbf{C} + \Sigma_{\mathbf{e}})^{-1}$. Therefore the expected complete-data log-likelihood Q is

$$\begin{aligned}Q = K - \frac{n}{2}\log|\Sigma_{\mathbf{e}}| - \frac{1}{2}\sum_{i=1}^{n}\{&\mathbf{y}_i'\Sigma_{\mathbf{e}}^{-1}\mathbf{y}_i - 2\mathbf{y}_i'\Sigma_{\mathbf{e}}^{-1}\mathbf{C}'\mathrm{E}(\mathbf{f}_i|\mathbf{y}_i,\Theta)\\ &+ \mathrm{Tr}\left[\mathbf{C}\Sigma_{\mathbf{e}}^{-1}\mathbf{C}'\mathrm{E}(\mathbf{f}_i\mathbf{f}_i'|\mathbf{y}_i,\Theta)\right] + \mathrm{Tr}\left[\mathrm{E}(\mathbf{f}_i\mathbf{f}_i'|\mathbf{y}_i,\Theta)\right]\\ &- 2\mathrm{E}(\mathbf{f}_i|\mathbf{y}_i,\Theta)'\mathbf{B}_i\mathbf{w} + \mathrm{Tr}\left[\mathbf{w}'\mathbf{B}_i'\mathbf{B}_i\mathbf{w})\right]\}.\end{aligned} \tag{7}$$

where K is a constant, $\mathbf{w}$ is the J-dimensional vector of the diagonal elements of $\mathbf{W}$ (i.e. $\hat{\mathbf{W}} = \mathrm{diag}(\hat{\mathbf{w}})$), and $\mathbf{B}_i$ is the $(Q \times J)$ matrix having the j-th column equal to $\mathbf{v}_j x_{ij}$ with $\mathbf{v}_j$ being the j-th row of $\mathbf{V}$ $(i = 1,\ldots,n)$.
Differentiating Q with respect to each parameter in Θ and setting to zero the corresponding score functions, we obtain

$$\hat{\mathbf{C}} = \left[\sum_{i=1}^{n}\mathrm{E}(\mathbf{f}_i\mathbf{f}_i'|\mathbf{y}_i,\Theta)\right]^{-1}\left[\sum_{i=1}^{n}\mathrm{E}(\mathbf{f}_i|\mathbf{y}_i,\Theta)\mathbf{y}_i'\right], \tag{8}$$

$$\hat{\Sigma}_{\mathbf{e}} = \frac{1}{n}\mathrm{diag}\left[\sum_{i=1}^{n}\mathbf{y}_i\mathbf{y}_i' - \sum_{i=1}^{n}\mathbf{y}_i\mathrm{E}(\mathbf{f}_i|\mathbf{y}_i,\Theta)'\mathbf{C}\right], \tag{9}$$

$$\hat{\mathbf{w}} = \left[\sum_{i=1}^{n}\mathbf{B}_i'\mathbf{B}_i\right]^{-1}\left[\sum_{i=1}^{n}\mathbf{B}_i'\mathrm{E}(\mathbf{f}_i|\mathbf{y}_i,\Theta)\right]. \tag{10}$$

In order to estimate the membership matrix of the covariates $\hat{\mathbf{V}}$, we proceed as follows:

- For each covariate j and group q, compute the log-likelihood values

$$l_{jq} = l(\cdot, v_{jq} = 1|\mathbf{C}, \Sigma_{\mathbf{e}}, \mathbf{W}, \{v_{hs}\}_{h=1,\ldots,J,h\neq j;s=1,\ldots,Q,s\neq q});$$

- Fix j and compute the maximum of this set $\{l_{jq}\}$ over $q = 1,\ldots,Q$; denote this term by l_j^{max};
- Allocate the j-th covariate to the q-th group ($\hat{v}_{jq} = 1$) iff $l_{jq} = l_j^{max}$ $q = 1,\ldots,Q$.

The ECM algorithm for the proposed model therefore becomes:

- E-step: Compute the expected values $\mathrm{E}(\mathbf{f}_i|\mathbf{y}_i,\Theta)$ and $\mathrm{E}(\mathbf{f}_i\mathbf{f}_i'|\mathbf{y}_i,\Theta)$ for all data ($i = 1,\dots,n$).
- CM-steps: Maximize Q over one of the parameters Θ while holding the other fixed.

The log-likelihood function, l, is computed for the current parameter values. The two steps are repeatedly alternated until convergence, which is reached when:

$$l_{(r)} - l_{(r-1)} < \varepsilon, \qquad \varepsilon > 0 \tag{11}$$

where r is the current iteration and ε is a small tolerance value.

3 Conclusions

A new mutivariate regression model based on latent predictors is presented. The latter are built as linear combinations of disjoint groups of observed covariates which best predict the responses. In this way, we jointly cluster covariates and estimate regression coefficients of the LPs. The model is particularly appropriate in a regression context where the reduction of the number of covariates is required for interpretability reasons or multicollinearity problems. In fact, in situations where the covariates are block-correlated, the assumptions on the covariances of the error terms, which are supposed diagonal, are fulfilled and lead to a gain in terms of parsimony and interpretability. We describe an EM algorithm for estimating model parameters and we will discuss the performance of the proposed approach on both simulated and real datasets. The results are encouraging and would deserve further discussion.

Analysis of dropout in engineering BSc using logistic mixed-effect models

Analisi dell'abbandono universitario nelle lauree di primo livello di ingegneria utilizzando modelli logistici a effetti misti

Luca Fontana and Anna Maria Paganoni

Abstract The main goal of this report is to apply a logistic mixed-effect model to analyse the relationship between the success probability in getting the BSc engineering degree in Politecnico di Milano and different sets of covariates, using as grouping factor the engineering programme attended. The dataset of interest contains detailed information about more than 18,000 students enrolled in BSc from 2010 to 2013. This analysis is performed within the Student Profile for Enhancing Tutoring Engineering (SPEET) ERASMUS+ project that involves Politecnico di Milano and five other european engineering universities, aimed at opening a new perspective to university tutoring systems.

Abstract *L'obiettivo di questo report è quello di applicare un modello logistico a effetti misti per analizzare la possibile dipendenza tra la probabilità di concludere con successo la Laurea di Primo Livello in Ingegneria al Politecnico di Milano e diversi insiemi di covariate, raggruppando gli studenti per corso di studi frequentato. Il dataset utilizzato contiene informazioni dettagliate riguardo più di 18,000 studenti immatricolati tra il 2010 e il 2013. Questa analisi è parte del progetto Student Profile for Enhancing Tutoring Engineering (SPEET), una collaborazione ERASMUS+ tra il Politecnico di Milano e cinque altri atenei europei di ingegneria.*

Key words: academic data; engineering programmes; university tutoring systems; generalized linear mixed-effects model; dropout prediction.

1 Introduction

The present work is a first step of statistical analysis of academic data related to engineering students attending Bachelor of Science Degree in Politecnico di Milano. This analysis is performed within the Student Profile for Enhancing Tutoring Engineering (SPEET) ERASMUS+ project that involves Politecnico di Milano, University of Galati (Romania), Escola d'Enginyeria UAB (Spain), Instituto Politecnico de Braganca (Portugal), Opole University of Technology (Poland) and Universidad de Leon (Spain). The project novelty emerges from the potential synergy among the huge amount of academic data actually existing at the academic departments and the maturity of data science algorithms and tools to analyse and extract information from those data. SPEET project aims to process the academic data to identify different student profiles to provide them with a personal tutoring service [6]. Despite many possibilities we have chosen to start the project by analyzing the distinction between students who complete their programme and those who instead decide to abandon studies [2]. This choice is based on the fact that across all SPEET partners almost a student out of two resigns his engineering studies before obtaining the BSc degree, and this phenomenon marks Politecnico di Milano in a remarkable way. The student profiles we are referring to within the SPEET project scope are:

- *dropout*: careers permanently finished for any reason other than the achievement of the BSc degree;
- *graduate*: careers definitely closed with the achievement of academic qualification, sooner or later.

Mixed-effects models are commonly employed in the analysis of grouped or clustered data, where observations in a cluster cannot reasonably be assumed to be independent of one-another: we use a mixed model in which engineering students are nested within the programmes they are attending.

2 Dataset and Model

The dataset consists of $18,612$ careers that began from A.Y. 2010/2011 to A.Y. 2013/2014, from 19 different engineering programmes at Politecnico di Milano. Collected data include degree information, collateral information regarding the students' background (nationality, previous studies, age, ...) as well as student performance on every subject of his study plan (subject score, subject year, subject semester, ...). The variables we are including in the model are described in table 1.

We now analyze the relationship between the success probability in getting the degree and a set of explainatory variables. Our response variable is the career `status`, a two-level factor we coded as a binary variable:

- `status` $= 1$ for careers definitely closed with the achievement of academic qualification (factor level = *graduate*)

- `status` $= 0$ if the career is permanently finished for any reason other than the achievement of the BSc degree (factor level = *dropout*).

Since those careers belong to 19 different engineering programmes, the choice of a Logit Mixed-Effects Model in which students are nested within programmes is justified [1]. The influence of the programme on the linear predictor is modeled through a single random effect on the intercept. Let y_{ij} denote observation j in group i $(i = 1:19, j = 1:n_i)$. The model formulation in extended form is:

$$\begin{aligned} Y_{ij} &\sim Bernoulli(p_{ij}) \\ p_{ij} &= E[Y_{ij}|b_i] = P(y_{ij}=1|b_i) \\ logit(p_{ij}) &= \log\left(\frac{p_{ij}}{1-p_{ij}}\right) = \sum_{h=0}^{p} x_{ijh}\beta_k + b_i \\ b_i &\sim N(0,\sigma^2) \\ b_i, b_{i'} &\text{ are independent for } i \neq i' \end{aligned} \tag{1}$$

where x_{ijh} represents the values of explanatory variables for fixed effects model parameters; $\boldsymbol{\beta} = [\beta_0 \quad \beta_1 \quad \dots \quad \beta_p]^T$ is the $(p{+}1)$-dimensional vector of fixed effects and b_i is the scalar random effect on the intercept of the linear predictor for observations in group i. We can fit and analyze models of this type using the `lme4` library [3] in the open-source statistical software `R` [5].

As SPEET main goal is to analyze the data trail of the student in real time in order to know as in advance as possible which profile the student belongs to, we decided to keep the set of covariates that are available at the time of the enrollment, and three more variables that could be recorded after the first semester of the first year of study. Thus, in the fixed-effect part of the model we consider the covariates that are described in table 1.

3 Results

We decide to randomly split the dataset into training and evaluation subsets, with a ratio of 80% for training and 20% for evaluation. Not all covariates turn out to be significant. We use stepwise backward elimination to obtain a reduced model: regressors `PreviousStudies` and `Nationality` are removed from the full model through this procedure. We can make the following considerations about fixed-effect parameters estimation:

- female students outperform their male counterpart: being a men penalize the log odds by 0.311. This information suggest that female students who decide to enroll in engineering degree are more resolute in their choice.
- The relationship between the linear predictor and the age at the time of the admission is negative. Generally, the aged students may have less time to devote to studies and this may affects their performance ($\hat{\beta} = -0.201$).

Variable	**Description**	**Type of variable**
`Sex`	sex	factor (2 levels: M, F)
`Nationality`	nationality	factor (2 levels: Italian, Foreigner)
`PreviousStudies`	high school studies	factor (3 levels: Liceo Scientifico, Istituto Tecnico, Other)
`AdmissionScore`	PoliMi admission test result	real number [0,100]
`AccessToStudiesAge`	age at the beginning of the BSc studies at PoliMi	natural number
`WeightedAvgEval1.1`	weighted average (by ECTS) of the evaluations during the first semester of the first year	real number [18,30]
`AvgAttempts1.1`	average number of attempts to be evaluated for both passed and not passed exams, during the first semester of the first year	real number [0,3]
`TotalCredits1.1`	number of ECTS credits obtained by the student during the first semester of the first year	natural number

Table 1: *Set of used covariates for the GLM model* (1)

- PoliMi admission test has a positive influence on the transformed response: a unit increase in the score improves the log odds by 0.008.
- The weighted average of the evaluations in the first semester shows strong positive effect on the transformed response: this result is reasonable and realistic. A unit increase improves the log odds by 0.060.
- `AverageExamAttempts1.1` has positive effect on the response: this information may suggest that if a student do not give up and tries to complete all his exams during the first semester of the first year, even after failing more than once, he is more likely to end successfully his programme ($\hat{\beta} = 0.243$).
- The effect of regressor `TotalCreditsObtained1.1` is positive as expected: a better performance during the first semester of the first year greatly improves the success probability in getting the degree ($\hat{\beta} = 0.196$).

Parameter	**Estimate**	**P-value**
`(Intercept)`	0.664	0.2354
`Sex(male)`	-0.311	0.0002
`AdmissionScore`	0.008	0.0124
`AccessToStudiesAge`	-0.201	4.87×10^{-11}
`WeightedAverageEvaluations1.1`	0.060	$<2 \times 10^{-16}$
`AverageExamAttempts1.1`	0.243	3.49×10^{-7}
`TotalCreditsObtained1.1`	0.196	$<2 \times 10^{-16}$

Table 2: *Fixed-effect coefficient estimates and P-values of model* (1)

As next step we underline the differences among the study programmes. Figure 1 shows the estimated random effects for all 19 groups in the dataset. Many of the 95% confidence intervals for $\hat{b}_i$ do not overlap the vertical line at zero, underlining substantial differences between the programmes. For example, level *Environmental and Land Planning Engineering* has the highest positive effect on the intercept: being a student from this programme improves the log odds by 1.486. On the contrary, studying *Civil Engineering* penalizes the log odds by 1.008.

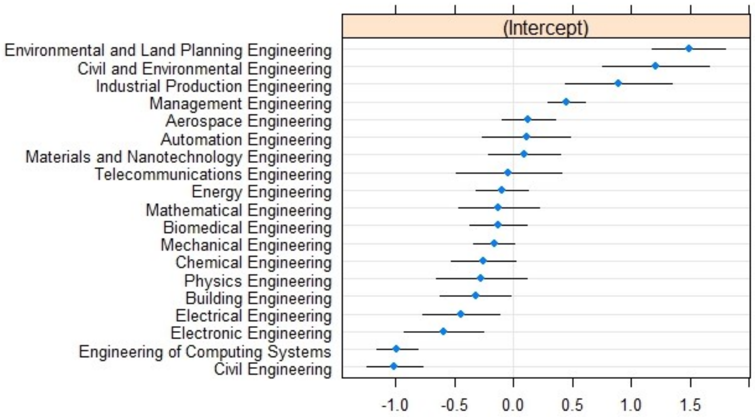

Fig. 1: *Random effect of the degree programme on the intercept in model* (1)

By using a multilevel model we can account for the interdependence of observations by partitioning the total variance into different components of variation due to the various cluster levels in the data. The intraclass correlation is equal to the percentage of variation that is found at the higher level and it is generally called the Variance Partition Coefficient [4]. Using the *latent variable approach* method the VPC is constant across all individuals and it is defined as $VPC = \frac{\sigma_b^2}{\sigma_b^2+\sigma_{lat}^2}$. Since the variance of the standard logistic distribution is $\sigma_{lat}^2 = \pi^2/3$ and the estimated variance is $\hat{\sigma}_b^2 = 0.4245$, the estimated VPC is equal to 0.1143. This means that 11.4% of variation in the response is attributed to the classification by degree type.

As last step, we use this model for classification and prediction of success probability. After fixing the optimal threshold value of $p_0 = 0.6$ using ROC curve analysis, we evaluate the predictive performance of the model by computing average classification indexes. We repeat 20 times the following procedure:

- randomly split the observations in training set (80% of the full dataset) and test set (20% of the full dataset)
- using the training set, fit the logit mixed-effect model and estimate its parameters
- estimate the success probability of observations in the test set and classify them using the optimal threshold value
- build the classification table and compute accuracy, sensitivity and specificity.

At the end of the 20 iterations we compute the average accuracy, sensitivity and specificity and their standard deviation, reported in table 3. High values of accuracy, sensitivity and specificity point to a good performance of the model. In addition, the model performance is notably robust, as highlighted by the low standard deviation of all performance indexes.

Index	Mean	Std deviation
Accuracy	0.899	0.0045
Sensitivity	0.925	0.0050
Specificity	0.850	0.0089

Table 3: *Performance indexes of a classifier based on the GLM* (1)

4 Conclusions

As far as the SPEET consortium knowledge, this is one of the first experiences of Learning Analytics at university level in Italy. Using predictive analytics we can give our educational institutes insights in future students outcomes: this predictions can be used to change particular programmes and deliver an optimal learning environment for the students.

Other further studies are being conducted within this project, proposing alternative nonparametric modeling in order to test the validity of the mixed-effect model and to analyse advantages and drawbacks of both methods. An immediate step further is extending the student profiling to other SPEET partners and compare the differences (if any) that arise at country level.

dgLARS method for relative risk regression models

Il metodo dgLARS per i modelli di regressione del rischio relativo

Luigi Augugliaro and Angelo M. Mineo

Abstract With the introduction of high-throughput technologies in clinical and epidemiological studies, the need for inferential tools that are able to deal with fat data-structures, i.e., relatively small number of observations compared to the number of features, is becoming more prominent. To solve this problem, in this paper we propose an extension of the dgLARS method to relative risk regression model. The main idea of proposed method is to use the differential geometric structure of the partial likelihood function in order to select the optimal subset of covariates.
Abstract *L'introduzione di tecnologie di screening ad elevata capacità negli studi clinici ed epidemiologici ha reso preminente il problema dello sviluppo di metodologie inferenziali applicabili ai casi in cui la numerosità campionaria è inferiore al numero di parametri. In questo lavoro proponiamo un'estensione del metodo dgLARS ai modello di regressione del rischio relativo. L'idea di fondo del metodo proposto è quella di utilizzare la struttura geometrica della partial likelihood al fine di selezionare il sottoinsieme ottimo di variabili esplicative.*

Key words: dgLARS, relative risk regression models, sparsity, survival analysis.

1 Introduction

In the study of the dependence of survival time on covariates, the Cox proportional hazards model [3] has proved to be a major tool in many clinical and epidemiological applications. However, when the number of features is large, the simple Cox

Angelo M. Mineo
Department of Economics, Business and Statistics, University of Palermo, Italy, e-mail: angelo.mineo@unipa.it

proportional breaks down. Many variable selection techniques for linear regression models have been extended to the context of survival models. They include best-subset selection, stepwise selection, asymptotic procedures based on score tests, Wald tests and other approximate chi-squared testing procedures, bootstrap procedures and Bayesian variable selection. However, the theoretical properties of these methods are generally unknown. Recently a family of penalized partial likelihood methods, such as the Lasso [11] and the smoothly clipped absolute deviation method [5] were proposed for the Cox proportional hazards model. By shrinking some regression coefficients to zero, these methods select important variables and estimate the regression model simultaneously. Whereas the Lasso estimator does not possess oracle properties, the smoothly clipped absolute deviation estimator for linear models, has better theoretical properties. However, the non-convex form of the penalty term of the latter makes its optimization challenging in practice, and the solutions may suffer from numerical instability. In this paper we propose an alternative to the penalized inference methods. We extend the differential-geometric least angle regression method (dgLARS) [1] to the case of the Cox proportional hazards model.

2 The differential geometrical structure of a relative risk regression model

In analyzing survival data, one of the most important tools is the hazard function. Formally, let T be the absolutely continuous random variable associated with the survival time and let $f(t)$ be the corresponding probability density function. The hazard function is defined as $\lambda(t) = f(t)/\{1-\int_0^t f(s)ds\}$ and specifies the instantaneous rate at which failures occur for subjects that are surviving at time t. Suppose that the hazard function $\lambda(t)$ can depend on a p-dimensional vector of covariates which can depend on time and denoted by $\boldsymbol{x}(t) = (x_1(t),\ldots,x_p(t))^\top$. The relative risk regression models [10] are based on the assumption that the vector $\boldsymbol{x}(t)$ influence the hazard function $\lambda(t)$ by the following relation $\lambda(t;\boldsymbol{x}) = \lambda_0(t)\psi(\boldsymbol{x}(t);\boldsymbol{\beta})$, where $\boldsymbol{\beta}$ is a p-dimensional vector of unknown fixed parameters, $\lambda_0(t)$ is the base hazard function at time t which is left unspecified and, finally, $\psi : \mathbb{R} \to \mathbb{R}$ is a fixed twice continuously differentiable function, called the relative risk function. The parameter space is such that $\psi(\boldsymbol{x}(t);\boldsymbol{\beta}) > 0$ for each $\boldsymbol{\beta}$; we also assume that the relative risk function is normalized, i.e., $\psi(\boldsymbol{0};\boldsymbol{\beta}) = 0$.

Suppose that n observations are available and let with t_i the ith observed failure time. Assume that we have k uncensored failure times and let us denoted by D the set of indices for which the corresponding failure time is observed. The remaining failure times are right censored. Under the assumption of independent censoring, the inference about $\boldsymbol{\beta}$ can be carried out by the following partial likelihood function

$$\mathscr{L}_p(\boldsymbol{\beta}) = \prod_{i\in D} \frac{\psi(\boldsymbol{x}_i(t_i);\boldsymbol{\beta})}{\sum_{j\in R(t_i)} \psi(\boldsymbol{x}_j(t_i);\boldsymbol{\beta})}, \tag{1}$$

where $R(t)$ denotes the risk set, i.e. the set of indices corresponding to the subjects how have not failed and are still under observation just prior to time t. In order to extend the dgLARS method to the relative risk regression model, it is useful to see the partial likelihood (1) as arising from a multinomial sampling scheme. Consider an index $i \in D$ and let $\boldsymbol{Y}_i = (Y_{ih})_{h \in R(t_i)}$ be a multinomial random variable with sample size equal to 1 and cell probabilities $\boldsymbol{\pi}_i = (\pi_{ih})_{h \in R(t_i)} \in \Pi_i$. Assuming that the random vectors $\boldsymbol{Y}_i$ are independent, the joint probability density function is an element of the set $S = \left\{\prod_{i \in D} \prod_{h \in R(t_i)} \pi_{ih}^{y_{ih}} : (\boldsymbol{\pi}_i)_{i \in D} \in \bigotimes_{i \in D} \Pi_i\right\}$. In the following of our differential geometric constructions, the set S will play the role of ambient space. Consider the following model for the conditional expected value of the random variable Y_{ih}: $E_{\boldsymbol{\beta}}(Y_{ih}) = \pi_{ih}(\boldsymbol{\beta}) = \psi(\boldsymbol{x}_h(t_i); \boldsymbol{\beta}) / \sum_{j \in R(t_i)} \psi(\boldsymbol{x}_j(t_i); \boldsymbol{\beta})$, then our model space is the set $M = \left\{\prod_{i \in D} \prod_{h \in R(t_i)} \pi_{ih}(\boldsymbol{\beta})^{y_{ih}} : (\boldsymbol{\pi}_i)_{i \in D} \in \bigotimes_{i \in D} \Pi_i\right\}$. The partial likelihood (1) is formally equivalent to the likelihood function associated with the model space M if we assume that for each $i \in D$, the observed y_{ih} is equal to one if h is equal to i and zero otherwise. Let $\ell(\boldsymbol{\beta})$ be the log-likelihood function associated to the model space M and let $\partial_m \ell(\boldsymbol{\beta}) = \partial \ell(\boldsymbol{\beta}) / \partial \beta_m$. The tangent space $T_{\boldsymbol{\beta}} M$ of M at the model point $\prod_{i \in D} \prod_{h \in R(t_i)} \pi_{ih}(\boldsymbol{\beta})^{y_{ih}}$ is defined as that linear vector space spanned by the p elements of the score vector, formally $T_{\boldsymbol{\beta}} M = span\{\partial_1 \ell(\boldsymbol{\beta}), \ldots, \partial_p \ell(\boldsymbol{\beta})\}$. Under the standard regularity conditions, it is easy to see that $T_{\boldsymbol{\beta}} M$ is the linear vector space of the random variables $v(\boldsymbol{\beta}) = \sum_{m=1}^{p} v_m \partial_m \ell(\boldsymbol{\beta})$ with zero expected value and finite variance. As a simple consequence of the chain rule we have the following identity for any tangent vector belonging to the tangent space $T_{\boldsymbol{\beta}} M$, i.e.

$$v(\boldsymbol{\beta}) = \sum_{m=1}^{p} v_m \partial_m \ell(\boldsymbol{\beta}) = \sum_{i \in D} \sum_{h \in R(t_i)} \left(\sum_{m=1}^{p} v_m \frac{\partial \pi_{ih}(\boldsymbol{\beta})}{\partial \beta_m} \right) \frac{\partial \ell(\boldsymbol{\beta})}{\partial \pi_{ih}} = \sum_{i \in D} \sum_{h \in R(t_i)} w_{ih} \frac{\partial \ell(\boldsymbol{\beta})}{\partial \pi_{ih}},$$

which shows that $T_{\boldsymbol{\beta}} M$ is a linear vector subspace of the tangent space $T_{\boldsymbol{\beta}} S$ spanned by the random variables $\partial_{ih} \ell(\boldsymbol{\beta}) = \partial \ell(\boldsymbol{\beta}) / \partial \pi_{ih}$. To define the notion of angle between two given tangent vectors belonging to $T_{\boldsymbol{\beta}} M$, say $v(\boldsymbol{\beta})$ and $w(\boldsymbol{\beta})$, we shall use the information metric [9], i.e.

$$\langle v(\boldsymbol{\beta}); w(\boldsymbol{\beta}) \rangle_{\boldsymbol{\beta}} = E_{\boldsymbol{\beta}}(v(\boldsymbol{\beta}) w(\boldsymbol{\beta})) = \boldsymbol{v}^{\top} I(\boldsymbol{\beta}) \boldsymbol{w}, \tag{2}$$

where $\boldsymbol{v} = (v_1 \ldots, v_p)^{\top}$, $\boldsymbol{w} = (w_1 \ldots, w_p)^{\top}$ and $I(\boldsymbol{\beta})$ is the Fisher information matrix evaluated at $\boldsymbol{\beta}$. As observed in [6], the matrix $I(\boldsymbol{\beta})$ used in (2) is not exactly equal to the Fisher information matrix of the relative risk regression model, however it has the appropriate asymptotic properties for the inference [8].

3 dgLARS method for relative risk regression model

dgLARS method is a sequential method developed to estimate a sparse solution curve embedded in the parameter space based on a differential geometric characterization of the Rao score test statistic obtained considering the inner product between the bases of the tangent space $T_{\boldsymbol{\beta}}M$ and the tangent residual vector $r(\boldsymbol{\beta}) = \sum_{i\in D}\sum_{h\in R(t_i)} r_{ih}(\boldsymbol{\beta})\partial_{ih}\ell(\boldsymbol{\beta}) \in T_{\boldsymbol{\beta}}S$, where $r_{ih}(\boldsymbol{\beta}) = y_{ih} - \pi_{ih}(\boldsymbol{\beta})$. As observed in [1], the mth signed Rao score test statistic satisfies the following differential geometric characterization, i.e.

$$r^u_m(\boldsymbol{\beta}) = I_{mm}^{-1/2}(\boldsymbol{\beta})\partial_m\ell(\boldsymbol{\beta}) = \cos(\rho_m(\boldsymbol{\beta}))\|r(\boldsymbol{\beta})\|_{\boldsymbol{\beta}}, \tag{3}$$

where $I_{mm}(\boldsymbol{\beta})$ is the Fisher information for β_m, $\|r(\boldsymbol{\beta})\|^2_{\boldsymbol{\beta}} = E_{\boldsymbol{\beta}}(r(\boldsymbol{\beta})^2)$ and $\cos(\rho_m(\boldsymbol{\beta}))$ is a generalization of the Euclidean notion of angle between the mth column of the design matrix and the residual vector. Characterization (3) gives us a natural way to generalize the equiangularity condition [4]: two given predictors, say the mth and nth, satisfy the generalizes equiangularity condition at the point $\boldsymbol{\beta}$ when $|r^u_m(\boldsymbol{\beta})| = |r^u_n(\boldsymbol{\beta})|$. Inside the dgLARS theory, the generalized equiangularity condition is used to identify the predictors that are included in the model.

The nonzero estimates are formally defined as follows. For any data set there is a finite sequence of transition points, say $\gamma^{(1)} \geq \ldots \geq \gamma^{(K)} \geq 0$, such that for any fixed γ between $\gamma^{(k+1)}$ and $\gamma^{(k)}$ the sub vector of the non nonzero dgLARS estimates, denoted as $\hat{\boldsymbol{\beta}}_{\hat{\mathscr{A}}}(\gamma) = (\hat{\beta}_m(\gamma))_{m\in\hat{\mathscr{A}}}$, satisfies the following conditions:

$$\begin{aligned} r^u_m\{\hat{\boldsymbol{\beta}}_{\hat{\mathscr{A}}}(\gamma)\} &= s_m\gamma, \quad m \in \hat{\mathscr{A}} \\ |r^u_n\{\hat{\boldsymbol{\beta}}_{\hat{\mathscr{A}}}(\gamma)\}| &< \gamma, \quad n \notin \hat{\mathscr{A}} \end{aligned}$$

where $s_m = \text{sign}\{\hat{\beta}_m(\gamma)\}$ and $\hat{\mathscr{A}} = \{m : \hat{\beta}_m(\gamma) \neq 0\}$, called active set, is the set of the indices of the predictors that are included in the current model, called active predictors. In any transition point, say for example $\gamma^{(k)}$, one of the following two conditions occurs:

1. there is a non active predictor, say the nth, satisfying the generalized equiangularity condition with any active predictor, i.e.,

$$|r^u_n\{\hat{\boldsymbol{\beta}}_{\hat{\mathscr{A}}}(\gamma^{(k)})\}| = |r^u_m\{\hat{\boldsymbol{\beta}}_{\hat{\mathscr{A}}}(\gamma^{(k)})\}| = \gamma^{(k)}, \tag{4}$$

   for any m in $\hat{\mathscr{A}}$, then it is included in the active set;
2. there is an active predictor, say the mth, such that

$$\text{sign}[r^u_m\{\hat{\boldsymbol{\beta}}_{\hat{\mathscr{A}}}(\gamma^{(k)})\}] \neq \text{sign}\{\hat{\beta}_m(\gamma^{(k)})\}, \tag{5}$$

   then it is removed from the active set.

Given the previous definition, the path of solutions can be constructed in the following way. Since we are working with a class of regression models without intercept term, the starting point of the dgLARS curve is the zero vector this means that, at the starting point, the p predictors are ranked using $|r^u_m(\mathbf{0})|$. Suppose that $a_1 = \arg\max_m |r^u_m(\mathbf{0})|$, then $\hat{\mathscr{A}} = \{a_1\}$, $\gamma^{(1)}$ is set equal to $|r^u_{a_1}(\mathbf{0})|$ and the first segment of the dgLARS curve is implicitly defined by the nonlinear equation $r^u_{a_1}\{\hat{\beta}_{a_1}(\gamma)\} - s_{a_1}\gamma = 0$. The proposed method traces the first segment of the dgLARS curve reducing γ until we find the transition point $\gamma^{(2)}$ corresponding to the inclusion of a new index in the active set, in other words, there exists a predictor, say the a_2th, satisfying condition (4), then a_2 is included in $\hat{\mathscr{A}}$ and the new segment of the dgLARS curve is implicitly defined by the system with nonlinear equations:

$$r^u_{a_i}\{\hat{\boldsymbol{\beta}}_{\hat{\mathscr{A}}}(\gamma)\} - s_{a_i}\gamma = 0, \quad a_i \in \hat{\mathscr{A}},$$

where $\hat{\boldsymbol{\beta}}_{\hat{\mathscr{A}}}(\gamma) = (\hat{\beta}_{a_1}(\gamma), \hat{\beta}_{a_2}(\gamma))^\top$. The second segment is computed reducing γ and solving the previous system until we find the transition point $\gamma^{(3)}$. At this point, if condition (4) occurs a new index is included in $\hat{\mathscr{A}}$ otherwise condition (5) occurs and an index is removed from $\hat{\mathscr{A}}$. In the first case the previous system is updated adding a new nonlinear equation while, in the second case, a nonlinear equation is removed. The curve is traced as previously described until parameter γ is equal to a fixed value that can be zero, if the the sample size is large enough, or a positive value if we are working in a high-dimensional setting, i.e., the number of predictors is larger than the sample size. In this way we can avoid the problems coming from the overfitting of the model. From a computational point of view, the entire dgLARS curve can be computed using the algorithms proposed in [2, 7].

4 Simulation study

In this section we compare the method introduced in Section 3 with three popular algorithms named CoxNet, CoxPath, and CoxPen. Given the fact that these methods have only been implemented only for Cox regression model, our comparison will focus on this kind of relative risk regression model. In the following of this section, dgLARS method applied to the Cox regression model is named dgCox model.

We simulated one hundred datasets from a Cox regression model where the survival times t_i $(i = 1, \dots, n)$ follow an exponential distributions with parameter $\lambda_i = \exp(\boldsymbol{\beta}^\top \boldsymbol{x}_i)$, and $\boldsymbol{x}_i$ is sampled from a p-variate normal distribution $\mathrm{N}(\mathbf{0}, \Sigma)$; the entries of Σ are fixed to $\mathrm{corr}(X_m, X_n) = \rho^{|m-n|}$ with $\rho = 0.9$. The censorship is randomly assigned to the survival times with probability $\pi \in \{0.2, 0.4\}$. To emulate an high-dimensional setting, we fixed the sample size to 50, the number of predictors to 100 and $\beta_m = 0.5$ $(m = 1, \dots, 30)$; the remaining regression coefficients are zero in order to have a sparse vector. To remove the effects coming from the information measure used to select the optimal point of each paths of solutions, we evaluated the global behaviour of the paths by using the ROC curve and the corresponding Area Under the Curve (AUC). Figure 1 shows that dgCox model is clearly the superior approach for both levels of censorship. For the same false positive rate, the true positive rate of the dgCox method is around 10% higher than the rate obtained by CoxNet, CoxPath and CoxPen.

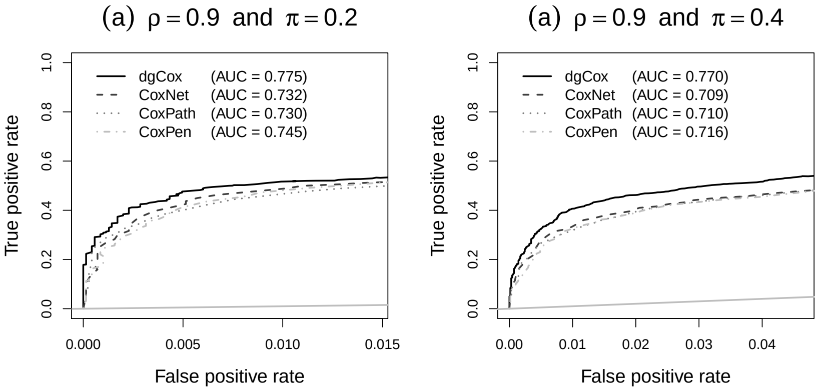

Fig. 1 Results from the simulation study; for each scenario we show the averaged ROC curve for dgCox, CoxNet, CoxPath and CoxPen algorithm. The average Area Under the Curve (AUC) is also reported. The 45-degree diagonal is also included in the plots.

A Latent Class Conjoint Analysis for analysing graduates' profiles

Un modello Latent Class Conjoint per l'analisi dei profili dei laureati

Paolo Mariani, Andrea Marletta, Lucio Masserini and Mariangela Zenga

Abstract This paper aims to stabilize the relationship between universities and companies. Lombardy companies with at least 15 employees were asked them to manifest their preferences choosing among profiles of new graduates. A Latent Class Metric Conjoint Analysis is employed to evaluate the ideal graduate's profile for a job position and to detect the existence of subgroups of companies having homogeneous preferences about such features.
Abstract *Questo lavora mira ad analizzare la relazione tra aziende ed università. Alle imprese lombarde con almeno* 15 *dipendenti è stato chiesto di esprimere le loro preferenze fra alcuni profili dei neolaureati a loro sottoposti per una possibile nuova assunzione. Un modello Latent Class Conjoint è stato utilizzato per valutare il profilo ideale fra i candidati e individuare l'esistenza di sottogruppi di imprese.*

Mariangela Zenga
University of Milano-Bicocca, e-mail: mariangela.zenga@unimib.it

and people with less work experience. Most of the times, there is no possibility for turnover, so the younger people are not able to access the labour market. In Italy, according to Istat, from 2007 over 2014, the young unemployment rate (15-24 years) increased from 20.4% over to 44.7%.

In relation to the labour market, it reveals evident how the other side of the phenomena is represented by the companies and their expectations about the possibility for a new hiring. It appears useful to carry out information from the companies' point of view obtaining a deep analysis about what they are looking for.

In a perspective of synergy between education and labour market, a possible solution is represented by ELECTUS, an acronym standing for Education-for-Labour Elicitation from Companies' Attitudes towards University Studies, a research project involving several Italian universities [3]. The ELECTUS survey was conducted in 2015 using CAWI technique using a questionnaire containing two macro-sections. In the first part the entrepreneurs are asked to choose and rank four possible profiles of new graduates for five different job vacancies. In the second part the entrepreneurs are asked about their socio-demographic features.

The candidates' profile are characterized by six attributes: *Field of Study*, *Degree Mark*, *Degree Level*, *English Knowledge*, *Relevant Work Experience*, *Willingness to Travel on Business*.

The aim of this paper is to carry out a segmentation analysis of employers' preferences for graduates' profiles evaluated as candidates in a job position by using a Latent Class Metric Conjoint Analysis [1]. In fact, it has been highlighted that the tandem approach suffers from some problems: a) different clustering methods often yield different results, in terms of number of clusters and their composition; b) in presence of highly fractionated designs, as in our study, individual-level part-worth estimates are rather unstable and then may be untrustworthy when employed in successive clustering algorithms. On the other hand, the LCMCA, unlike cluster analysis, is a model-based approach in which model parameters and subgroups (segments or latent classes) are estimated simultaneously, and segments are composed of individuals whose part-worth utilities are similar.

The paper is organized as follows. Section 2 introduces Latent Class Metric Conjoint Analysis. Section 3 presents the results of the estimated model. Finally, Section 4 is reserved to discussion and final remarks.

2 Latent Class Conjoint Analysis

In this study, a Latent Class Metric Conjoint Analysis (LCMCA) [1] is employed is carried out to evaluate which characteristics of a graduate's profile employers prefer for a potential candidate in the job position of administrative clerk. In particular, in order to detect if there exist unobserved subgroups of employers having homogeneous preferences about graduates' characteristics for this position. Latent Class Metric Conjoint Analysis is a statistical modelling technique included in the more general class of Finite Mixture Models (FMMs) [4]. Following the FMMs approach, LCMCA relaxes the single homogeneous population assumption to allow for parameter differences across G latent classes and supposes that the marginal density function of the response variable y is given by a weighted sum over the G mixture components, with weights indicating the *a-priori* probability for an observation to come from a specific component [1]:

$$f(y_{ij}|\pi, x, z, \Sigma) = \sum_{g=1}^{G} \pi_{g|z} f_g(y_{ij}|x, z, \beta_g \Sigma_g) \tag{1}$$

where y_{ij} is the vector of response variable which refers to the rating expressed by employer i to conjoint profile j; $\pi = (\pi_1, \pi_2, \ldots, \pi_{G-1})$ are $G-1$ independent mixing proportions of the mixture, such that $0 \leq \pi_g \leq 1$; x is a matrix containing the M conjoint dummy variables which defines the profiles evaluated; β_g is the vector of the estimated conjoint part-worth coefficients for subgroup g, and $\Sigma = (\Sigma_1 \Sigma_2, \ldots, \Sigma_g)$ is $J \times J$ vector of covariance matrices of the error terms estimated for each subgroup. Moreover, given that the weights depend on a set of explanatory variables, also referred to as concomitant variables, z defines the vector of variables which characterise employers. Given the metric response variable, each of the conditional distributions, f_g, is conventionally specified as a conditional multivariate normal distribution. Instead, the prior probability of group membership varies as a multinomial logistic regression model, in function of the concomitant variables, as it follows:

$$\pi_{k|z} = \frac{exp(\gamma_{0g} + z\gamma_{1g})}{\sum_{g=1}^{G} exp(\gamma_{0g} + z\gamma_{1g})} \tag{2}$$

where γ_{0g} is the intercept while γ_{1g} contains the vector of regression coefficients, quantifying the effect of the concomitant variables on the prior probability for class g. For identification purpose, usually $\gamma_{01} = 0$ and $\gamma_{11} = 0$, and designate the first category as a reference class. Moreover, the following constraints hold: $\sum_{g=1}^{G} \pi_{g|z} = 1, \pi_{g|z} > 0$. Once the estimates of all the model parameters of the mixture of probability density are obtained, the posterior probability that an observation belongs to class g, denoted with p_{ig}, can be calculated by updating the previous according to the Bayes' theorem, as follows:

$$\hat{p}_{ig} = \frac{\hat{\pi}_{g|z} \hat{f}_{ig}(y_{ij}|x, z, \beta_g \Sigma_g)}{\sum_{g=1}^{G} \hat{\pi}_{g|z} \hat{f}_{ig}(y_{ij}|x, z, \beta_g \Sigma_g)} \tag{3}$$

where $\sum_{g=1}^{G} \hat{p}_{ig} = 1$ and $0 \leq \hat{p}_{ig} \leq 1$. The posterior probabilities provide a probabilistic allocation of observations to the latent classes and can be used to classify data by assigning each employer to the class with the maximum posterior probability. Parameter estimation was carried out via Maximum Likelihood (ML) by using the Expectation-Maximization (E-M) algorithm [2], in which conjoint part-worth coefficients and class membership are obtained simultaneously. The conventional Akaike's information criterion (AIC) was used for choosing the number of latent classes.

3 Application and Results

After estimating several LCMCAs, starting from the aggregate solution, with one class ($G = 1$), to the most complex one, with five latent classes ($G = 5$), the solution with $G = 3$ seems to represent the latent structure underlying the employers' ratings quite well.

Table 1 provides the estimated regression coefficients (or part-worths) for the $G = 3$ latent classes solution. Given that categorical attributes were preventively converted into the appropriate number of dummy variables, the intercept represents the average rating of the reference profile and refers to a graduate in foreign languages, with a Master's degree, a low final grades, with a knowledge of English language, no working experience, and not willing to business trips. At a first glance, it is clear the substantial difference between the aggregate part-worth coefficients and those in each sub-model of the three-class solution. Moreover, the aggregate model is also the one with the highest value of AIC and this confirms that a single set of regression coefficients estimated for all the employers may produce misleading results. The first class is the one with the lowest average rating corresponding to the reference profile (2.56) and identifies especially Economics as the most preferred degree, whereas Law, Statistics and Engineering are also appreciated but to a lesser extent. Among the employers included in this class, it seems preferable for a candidate to have some kind of work experience, excluding the internship. On the other hand, low final grades and willing to long-term business trips produce a lower preference. The second class is the one with the higher average rating (8.25) and this indicates that the reference profile is already highly appreciated. Given such a high average score, part-worth coefficients are almost all negative. In particular, employers within such class evaluate Economics, Engineering, Mathematics and computer sciences as less important degrees. On the contrary, a Bachelor's degree and a medium final grades increase employers' preference. The third class is the one with the intermediate average rating and its value is also very similar to that of the aggregate model (4.46). Mathematics and computer sciences and Economics are the most preferred degrees. Political science is also evaluated positively but to a lesser extent. For employers in this class, a previous work experience both as a stable experience and internship experience is relevant.

The Maximum likelihood estimates of the multinomial logistic regression model allows to determine which variables affect the latent classes' membership. Among the available variables which describe the characteristics and the context of the company, only the variables 'Recruitment of staff within one year', 'Company run by a manager' and 'Company committed also in the foreign market' seem to affect class membership when using the usual 0.05 as significance level. However, considering 0.10 as significance level also the variables 'Hired personnel over the past 3 years' and 'Education of the last administrative hired: graduated' contribute to explain class membership. In particular, the probability of being in Class 2 is higher for companies which plan to recruit staff within one year ($p = 0.007$) but lower for those that hired personnel over the past 3 years ($p = 0.070$) and those which have already taken a graduated as administrative ($p = 0.076$). On the other hand, the

Table 1 Maximum likelihood estimates of part-worth coefficients for each latent class

		Latent	class	
	1	2	3	Aggregate
Intercept	2.56**	8.25**	4.46**	4.79**
Philosophy and Literature	2.60**	-1.65**	-2.20	-0.88
Education sciences	1.54*	-0.02	-0.48	0.15
Political sciences	1.21	-1.23**	1.45**	0.97
Economics	6.52**	-5.21**	2.18**	1.92**
Law	4.29**	-3.75**	-0.47	-0.25
Statistics	3.99**	-2.77**	-0.63	0.42
Engineering	3.81**	-4.74**	-2.25**	-1.16*
Mathematics and computer sciences	2.68**	-5.41**	2.92**	0.45
Psychology	2.80**	-3.66**	-2.42**	-1.61*
Bachelor's degree	-0.23	0.59**	0.47	0.49
Low final grades	-1.62**	-1.13**	-1.01**	-1.25**
Medium final grades	-0.92*	1.70**	-0.94**	-0.50
No knowledge of English language	0.49	-0.75**	-1.57**	-0.87**
Internship experience	-0.56	0.84**	1.37**	0.46
Occasional working experience	2.10**	-0.25**	0.82	0.66
Stable working experience	1.04*	-2.28**	2.36**	1.07**
Willing to short-term business travels	-0.44	-1.46**	0.85**	-0.15
Willing to long-term business travels	-1.33*	-0.88**	0.53	-0.10

probability of being in Class 3 is higher for companies which plan to recruit staff within one year ($p < 0.0001$), for companies run by a manager ($p = 0.036$) and for companies committed also in the foreign market ($p = 0.033$) but lower for those that hired personnel over the past 3 years ($p = 0.072$). It seems adequate to identify the three latent groups by their peculiar features. In particular, the first group (26.4% of the sample) is characterized by companies lead by not a managerial view, working in a service sector in prevalence in domestic market, they neither will do recruitment new staff in the next year neither hired personnel over the past three years. This group could be named *Domestic Consolidated Companies*. The best profile for the AC required by these companies results to be related to a classical view of the position: a well graduated in Economics with some kind of working experience. The second group (17.1% of the sample) is composed by big sized companies, they will recruit staff in the next year, but they did not hire personnel over the past three years. This group could be called as *Static Companies*: respect to the expected profile of new graduates they seem to prefer new graduates with a not suitable major for AC (Language) with Bachelor's degree and a medium final grade, the English knowledge and working experience are not required. In some way, they prefer new graduates who must be fully trained. The third group (56.5% of the sample) is represented by small or medium enterprises, guided by a manager and committed also in the foreign market with a willingness to recruit new staff in the next year. They can be named as *Dynamic Companies*. The new graduate profile fits the description of these firms: it has to be a student in Economics or Political Sciences major, with a higher final grade and an English knowledge suitable to communicate with foreign people. Important requirements are also working experience and willing to business trips.

4 Discussion and final remarks

Using the survey ELECTUS, a segmentation of employers' preferences for graduates' profiles for administrative clerk is carried out by using a Latent Class Metric Conjoint Analysis. In general the features of the profiles for the new graduates' job are very different for every sub-groups but all respondents agree that a low final grades at graduation is not a preferable. Certainly the characteristics of the companies could influence the preferences about graduates' characteristics: the membership of the latent groups seems in fact to be effected by peculiar factors. In fact, the *Domestic Consolidated Companies*, run by not a managerial view, working in a service sector in prevalence in domestic market, without willingness to recruit in the past and in the future, require a well graduated students in Economics with some kind of working experience for AC position. The *Static Companies*, composed by big sized companies with the willingness to recruit in the future but not in the past, prefer new graduates who must be fully trained. The *Dynamic Companies*, represented by SME lead by a manager and committed also in the foreign market with a willingness to recruit new staff in the next year, look for a new graduate in Economics or Political Sciences major, with a higher final grade and an English knowledge suitable to communicate with foreign people with working experience and willing to business trips.

A longitudinal analysis of the degree of accomplishment of anti-corruption measures by Italian municipalities: a latent Markov approach

Analisi longitudinale del grado di attuazione di misure anti-corruzione nei comuni italiani: un approccio latent Markov

Simone Del Sarto, Michela Gnaldi, Francesco Bartolucci

Abstract The recent Italian anti-corruption law has introduced a new figure, the supervisor for corruption prevention, who has to fill in an annual report about the accomplishment of anti-corruption measures within the institution he/she represents. Using data coming from such annual reports referred to a sample of Italian municipalities, a latent Markov model is fitted to investigate the evolution over time of the degree of accomplishment of anti-corruption measures. First results evidence three latent states of increasing virtuosity. Moreover, at the beginning of the study, the most of the sample belongs to the low and intermediate states of virtuosity, even if there is evidence of high probabilities to move to upper states over time.

Abstract *La recente legge anti-corruzione italiana ha introdotto una nuova figura, il responsabile per la prevenzione della corruzione, che deve predisporre una relazione annuale sull'attuazione di misure anti-corruzione in capo all'istituzione che rappresenta. Per analizzare i dati provenienti da tali relazioni annuali riferiti a un campione di comuni italiani, è stato stimato un modello latent Markov, che permette di investigare l'evoluzione temporale del grado di attuazione di misure anti-corruzione. I primi risultati evidenziano l'esistenza di tre stati latenti corrispondenti a gradi crescenti di virtuosità. Inoltre, agli inizi dello studio, la maggior parte del campione appartiene ai primi due stati (bassa e intermedia virtuosità), sebbene vi siano alte probabilità di spostarsi nel tempo in stati corrispondenti a gradi più alti di virtuosità.*

1 Introduction

The recent approaches to combat corruption have seen a shift from a penal and repressive focus to a broader preventive approach. Attention has to be paid not only on all illegal and criminal conducts, but also on any social behaviour and malpractice, even if it is not framed in a specific type of penal offence against public administration [2].

The Italian legislation has recently adopted such preventive perspective with law n. 190 of 2012, named “Provisions for the prevention and repression of corruption and lawlessness in the public administration”. It introduces two main tools to be implemented within all Italian public administrations, in order to reduce the risk of occurrence of corruptive events. The first is a three-year plan for corruption prevention (PTPC), by which each administration evaluates its own internal situation in terms of exposure levels to the risk of corruption and specifies potential organisational changes to reduce such a risk. The second is the introduction of a new figure, the supervisor for corruption prevention (RPC) that, within the public administrative unit (i.e., regions, municipalities, etc.) he/she represents, fills in an annual report about the degree of accomplishment of anti-corruption measures. This report is based on a questionnaire made available by the Italian National Anticorruption authority (ANAC). Previous works [3, 4, 5] exploited the data contained in the RPC forms for investigating the degree of accomplishment of anti-corruption measures by Italian municipalities, with the aim of ascertaining clusters of units characterised by distinctive anti-corruption behaviours, their geographical distribution, and the association between anti-corruption behaviours and some relevant covariates (e.g., the municipality size).

The objective of the present work is to extend previous findings by deepening our understanding as regards the evolution over time of anti-corruption behaviours of Italian municipalities. A statistical model suitable for the aim at issue is the Latent Markov (LM) model, whose original formulation is due to Wiggins [7]; for an up to date review, see Bartolucci et al. [1]. The LM model is tailored to the analysis of longitudinal dataset, specifically made of several response variables observed at different time occasions for each unit. It allows us to cluster the sample units in latent states as regards the underlying latent variable (degree of accomplishment of anti-corruption measures in our case) and to describe the evolution over time of the transitions among latent states.

The reminder of this work is organised as follows. Section 2 briefly describes the data used for this analysis, while the LM model is introduced in Section 3. Section 4 shows the results, while some concluding remarks are provided in Section 5.

2 The data

The data we consider are collected through the RPC forms for the years from 2014 – the year in which the anti-corruption law entered into force – to 2016. The sample is made of 213 municipalities, comprising all Italian province municipalities, all the other municipalities with at least 40,000 inhabitants and particular "advised" municipalities, as stated by ANAC act n. 71 of 2013.

The objective of the present work is to sketch the evolution over time of the Italian municipalities attitude as regard the degree of implementation of anti-corruption measures. For this reason, we focus on ten questions of the RPC form, requiring the administrations to state whether a specific anti-corruption measure has been accomplished in the reference year. The selected ten questions concern the following subjects:

1. monitoring the sustainability of all measures, general and specific, identified in the PTPC;
2. specific measures, in addition to mandatory ones;
3. computerising the flaw to fuel data publication in the "transparent administration" website section;
4. monitoring data publication processes;
5. training of employees, specifically dedicated to prevention of corruption;
6. staff turnover as a risk prevention measure;
7. checking the truthfulness of statements made by parties concerned with unfitness for office causes;
8. measures to verify the existence of incompatibility conditions;
9. prearranged procedures for issuing permits for assignments performance;
10. whistleblowing, which is a procedure for reporting the collection of misconduct by public administration employees.

Three possible answers can be provided to these items, ordered according to their virtuosity: (A) "Yes, the anti-corruption measure has been accomplished" (the most virtuous behaviour); (B) "No, the anti-corruption measure has not been accomplished because it was not expected by the PTPC" (intermediate level of virtuosity); (C) "No, the anti-corruption measure has not been accomplished but it was expected by the PTPC" (the least virtuous conduct).

3 The latent Markov model

Suppose that for every unit we observe the vector of r response variables at occasion $t = 1,\dots,T$, denoted by $\boldsymbol{Y}^{(t)} = [Y_1^{(t)},\dots,Y_r^{(t)}]^\top$. Each variable $Y_j^{(t)}$ is categorical with l_j modalities, coded from 0 to $l_j - 1$, $j = 1,\dots,r$. We assume that a latent process $\boldsymbol{U} = [U^{(1)},\dots,U^{(T)}]^\top$ affects the response variables: such a process follows a first-order Markov chain with state space $\{1,\ldots,k\}$. Local independence is assumed for the variables in each $\boldsymbol{Y}^{(t)}$, so its r components are conditionally independent given $U^{(t)}$.

The model at issue has the following parameters:

- $\phi_{jy|u}$: conditional response probability that component $Y_j^{(t)}$ assumes modality y, given latent space u, with $j=1,\ldots,r$, $t=1,\ldots,T$, $y=0,\ldots,l_j-1$ and $u=1,\ldots,k$;
- π_u: initial probabilities, with $u=1,\ldots,k$;
- $\pi_{u|\bar{u}}^{(t)}$: transition probabilities from state $\bar{u}$ to state u at time t, with $u,\bar{u}=1,\ldots,k$ and $t=2,\ldots,T$.

The model assumptions imply that

$$f_{\boldsymbol{Y}|\boldsymbol{U}}(\boldsymbol{y}|\boldsymbol{u})=\prod_{t=1}^{T}\phi_{\boldsymbol{y}^{(t)}|u^{(t)}},$$

where $\boldsymbol{Y}$ is a vector obtained by the union of the vectors $\boldsymbol{Y}^{(t)}$, $t=1,\ldots,T$ and in general $\phi_{\boldsymbol{y}|u}$ is the probability that $\boldsymbol{Y}^{(t)}$ assumes value $\boldsymbol{y}$, given latent state u. Moreover, given the local independence assumption, $\phi_{\boldsymbol{y}|u}$ can be obtained as the product of the single conditional probabilities over the r components, as follows:

$$\phi_{\boldsymbol{y}|u}=\prod_{j=1}^{r}\phi_{jy_j|u}.$$

The model parameters are estimated by maximum likelihood through an Expectation-Maximisation algorithm: see [1] for details.

4 Results

According to the Bayesian Information Criterion (BIC) [6], we find evidence of $k=3$ latent states. By inspecting the conditional response probabilities (see Table 1), it is possible to notice that such states correspond to increasing levels of corruption prevention fulfilment. The estimates of the initial probabilities are reported in Table 2(a). Hence, in 2014 (beginning of the study), the state of the most virtuous municipalities (i.e., those grouped in the third latent state) collects less than 15% of administrations, while the other two states approximately equally split the remaining units.

Regarding the transition probabilities – see Table 2(b) and 2(c) – we note that the probabilities to remain in the current state are higher than those to move to other states and such probabilities are increasing over time. However, from 2014 to 2015 units belonging to the first two states (characterised by low and intermediate virtuosity) have large probability to move to higher state, hence to increase their compliance of anti-corruption measures. In 2016 the situation seems to stabilise, since almost all the off-diagonal elements of the relative transition matrix are close to 0, expect for a share of probability (around 20-30%) to move to the third state for units belonging to the first two states.

5 Conclusions

In this work, a longitudinal analysis of the Italian municipalities compliance as regards anti-corruption measures is presented. The information contained in the annual reports of the supervisor for corruption prevention (RPC forms) are exploited with reference to a set of items about the accomplishment of anti-corruption measures. Data about a sample of more than 200 municipalities are used for the years 2014, 2015 and 2016. A latent Markov model is fitted on the data at issue, finding evidence of three states of increasing virtuosity in terms of anti-corruption behaviour. Results show that in 2014 – year of introduction of the new Italian anti-corruption law – less than 15% of the sample belongs to the group of the most virtuous municipalities, then only few administrations have accomplished measures for contrasting corruptive events. The analysis of the transition matrices reveals high probabilities to move to higher virtuosity states, even though a clear tendency to stay in the current state is observable, especially in the last year.

Modelling the effects of covariates for unbiased estimates in ecological inference methods

Analisi degli effetti delle covariate per stime non distorte nei metodi di inferenza ecologica

Venera Tomaselli, Antonio Forcina and Michela Gnaldi

Abstract After showing that the estimates provided by three main ecological inference methods are heavily biased when compared to multilevel logistic models applied to a set of real individual data, the paper argues that ecological bias can be corrected only by accounting for relevant covariates. In addition, a data generating mechanism where bias cannot even be corrected by using covariates is described.

Abstract *Dopo aver dimostrato che le stime ottenute mediante i tre principali metodi di inferenza ecologica sono fortemente distorte rispetto a quelle ottenute applicando modelli logistici multilivello, lo studio conclude che le distorsioni possono essere corrette soltanto tenendo conto di covariate pertinenti. E', inoltre, descritto un sistema di generazione di dati dove le distorsioni non possono essere corrette neppure usando covariate.*

Key words: ecological fallacy, biased estimates, covariates effects, multilevel logistic regression.

1 Ecological Fallacy and ecological inference models

Since Robinson's seminal paper [16], it is well known that the association between two variables estimated from data aggregated within territorial units, like polling stations, may be substantially biased compared to the association that would emerge

Venera Tomaselli (*corresponding author*)
Department of Political and Social Sciences, University of Catania, e-mail: tomavene@unict.it
Antonio Forcina
Department of Economics, University of Perugia, e-mail: forcinarosara@gmail.com
Michela Gnaldi
Department of Political Sciences, University of Perugia, e-mail: michela.gnaldi@unipg.it

if data recorded at the individual level were available. This phenomenon became known as the *ecological fallacy*.

Subramanian et al. [19] pointed out that, in certain contexts, the degree of association at the individual level may depend on modelling assumptions and thus may not be such an objective quantity as Robinson seemed to believe. An important implication of this result is that, when the estimates from ecological and individual level studies do not agree, additional investigation may be necessary before concluding that the ecological estimates are inappropriate.

Since the introduction of ecological regression by Goodman [8], several methods of ecological inference have been developed by King [11], [12] and coworkers [17]; their merits are debated [5], [2], [14]. Though less popular, the methods proposed by Brown and Payne [1] and Greiner and Quinn [9] may be considered as valid alternatives.

In a recent paper [6] the authors, by elaborating on the work of Wakefield [20] and Firebaugh [3], argue that, when certain assumptions are violated, the estimates produced by any method of ecological inference are going to be biased. Though bias might be corrected by modelling the effects of relevant covariates, even this may fail under certain data generating mechanisms.

2 Ecological Estimates by Multilevel Logistic Models

This paper is based on the analysis of an extensive set of individual data on voting behaviour in the Democratic Party Primary election for the candidate Mayor in the city of Palermo, Italy, in 2012. For each polling station, the data provide the joint distribution of voters classified by their decision (vote or not at the primary election) on one side and their age and sex on the other.

The estimates of ecological inference methods rely on the marginal distribution of voting decisions and that of sex, age; when individual data are available, these estimates can be compared with the actual proportions of voters within each age by sex group. In addition, by applying multilevel logistic models one can check if the propensity to vote depends on the relative size of the sex by age groups together with other covariates: when this happens it can be shown that ecological estimates are going to be biased.

The estimates of voting probabilities provided by the Goodman [8] regression model, the King [17] multinomial-Dirichlet and the modified Brown and Payne model [4] without covariates (Table 1) are substantially different from those based on individual data: for certain age groups, estimated probabilities are close to 0 while, for other age groups, they are much higher than the observed proportions.

Next we apply multilevel models [7],[10],[18] to the individual dataset with three objectives: (i) to verify whether the estimates provided by the raw proportions (used by Robinson) and those obtained from multilevel models are substantially different as in [19], (ii) to obtain an estimate of the different variance components and (iii) to detect the appropriate covariates to be used in the ecological inference models. For each polling station, voters are cross-classified by sex (M, F) and 6 age groups and, for each of these 12 categories, according to decision to vote or not. These data may be seen as 12 binomial variables nested within a polling station, with the polling stations grouped into 31 seats. For these data there are three sources of random variation:

(i) binomial within the polling stations;
(ii) among polling stations within seats with an estimated standard deviation of 0.2311;
(iii) among seats with an estimated standard deviation of 0.2547.

To investigate how the propensity to vote depends on available covariates, several different models were explored and the following highly significant covariates were selected:

- *pd*, the proportion of voters for the Democratic Party at the municipal election held a month later (3.8% on average for all the polling stations within total eligible voters);
- *idv*, the proportion of voters for the *Italia dei Valori* Party at the same municipal election (5.1% on average for all the polling stations within total eligible voters);
- *mol*, the proportion of males aged between 45 and 74 (45.0% within male eligible voters);
- *fol*, the proportion of females aged between 45 and 74 (45.4% within female eligible voters).

By the multilevel logistic models fitted separately to each age group, where the observations at the lowest level are the number of voters (classified by sex and age group) nested within the polling stations which, in turn, are nested within the seats, as potentially relevant covariates, we considered the proportions of eligible voters belonging to each age group separately for males and females, in addition to the *pd* and *idv* covariates described above. The parameter estimates of the propensity to vote based on the effects of the relevant covariates are displayed in Table 2.

Though the proportions of voters aged 45-65 and 65-75 were significant most of the times, when *pd* and *idv* were also used, some of the previous covariates appeared to no longer have a significant effect. This could be due to the fact that *pd* and *idv* are closely related to the age distribution within each polling station: when either *pd*

Table 1 Ecological inference estimates of the probability of voting by sex and age groups, without covariates.

$P(65-75)$	2.3888*	0.0000°	1.9564*	1.3247*	2.9426$^\bullet$	0.0000°
$M-F$	0.0256°	-0.0570°	0.0853$^\bullet$	0.0898$^\bullet$	0.4785$^\bullet$	0.8171$^\bullet$

F is the intercept within females; $M-F$ is the difference in intercept between males and females; $\circ$ = not significant, $\star$ = 5% significant, $*$ = 1% significant, $\bullet$ = p-value smaller than 0.001.

or *idv* increases, the proportion of eligible voters in the 18-45 age group decreases while the proportion in the age range from 45 to 75 and over increases.

The fact that in the multilevel logistic models applied to the individual data the propensity to vote depends significantly on covariates measured at the level of polling station provides an explanation for the bias present in ecological inference estimates.

However, both the King and the Brown-Payne methods allow modelling the effects of covariates on the logit of the propensity to vote. A rather disappointing (but at the same time rather intriguing) feature of the Palermo data is that both the King and the Brown and Payne model continues to provide biased estimates even if we allow the logit of the propensity to vote to depend on the same covariates which were detected as significant in the multilevel logistic models applied to the individual data.

An important result of this paper is that the failure of covariates to correct the ecological bias is not a feature specific to the Palermo data set. To support this claim we describe a plausible data generating mechanism which may have been working in the Palermo Primary election and explain why, under these conditions, modelling the effects of covariates may not correct the bias.

Let q_{as} be the probability of voting at the Primary election for an eligible voter with sex s and affiliation to centre-left parties $a = 0,\,1$. Let also v_{us} denote the proportion of eligible voters of sex s who are affiliated to the same parties in the polling station u. Then, it is easily shown that:

$$\pi_{us1} = q_{0s}(1 - v_{us}) + q_{1s}v_{us}. \tag{1}$$

There are two important features in this equation: (i) it depends on the proportion of voters affiliated to centre-left parties (which cannot be observed), rather than on the proportion of females; (ii) the dependence is linear rather than logistic. Artificial electoral data based on equation (1) were generated at random as follows:

1. for each polling station, splitting eligible voters at random between affiliated and not and then among females and males in such a way that sex and affiliation are correlated;

2. assigning plausible values to the q_{as} probabilities;
3. generating random electoral data as in a revised Brown and Payne model.

Table 3 shows the estimated proportions of females and males voters using individual data and the Brown and Payne and King OLS models. These estimates are computed on an artificial data set generated according to the procedure described above. Because it contains 16,000 polling stations with 1,000 voters each, standard errors of the raw proportions in the individual data are very small (less than 0.0005). As a consequence, any new replication should produce, essentially, the same estimates. Since the differences between estimates from ecological and individual data are substantially large, relative to the very large sample size, they are certainly due to bias and not to random variations.

Table 3 Estimated proportions of voters in the artificial data; Ind=Individual data, BP=Brown and Payne and King=King OLS.

Females			Males		
Ind	BP	King	Ind	BP	King
0.0464	0.1012	0.1015	0.0548	0.0000	0.000

3 Conclusions

The findings in this paper indicate that the only possibility to correct ecological bias is to model the effects of covariates; also Liu [14] noted that the estimates from the King's model improved substantially by including certain covariates. However, while Liu was searching among all possible covariates, the results in this paper show that only covariates strongly correlated with the marginal proportions in the explanatory variables (sex and age in our context) are relevant.

An interesting result here is that, while the extended version of an ecologic inference model with covariates does provide a very accurate fit of the total number of voters in the Primary election in each polling station, the estimated number of the same voters by sex and age groups are not much better than those obtained by the same model without covariates.

When voter's choices depend on covariates measured at the level of polling station, any method of ecological inference that does not account for this is going to provide biased estimates. But even this may fail, as in the Palermo data and in the artificial data set generated at random according to a model which assumes that voting decisions depend on party affiliation rather than sex and age.

Advances in Time Series

Filtering outliers in time series of electricity prices

Ilaria Lucrezia Amerise

Abstract In this paper, we describe a tool for detecting outliers in electricity prices. The tool primarily consists of a filtering procedure (Whittaker smoother) that removes unpredictable effects and captures long-term smooth variations. So as to identify outliers, we compare observed prices with smoothed ones. If the difference between the two exceeds a predetermined limit, the corresponding prices are considered anomalous and candidates for an appropriate statistical treatment. The new tool is compared with another method based on local regression.

Key words: Whittacker smoother, penalized least squares, price spikes.

1 Introduction

The frequent occurrence of irregular, abrupt, extreme movements or spikes in spot prices is one of the most salient characteristics of electricity markets. These spikes are of very short duration so that only a few traces of their influence is revealed at adjacent time points. It should be recognized that price peaks and/or troughs are natural characteristics of the electricity market and are very important for energy market participants. On the other hand, we do not expect that the choice of forecasting method to be conditioned by any mere irregularity in prices. The main purpose of the present study is to identify outlying spikes by using a non-parametric filter that returns a smoothed time series, which acts as benchmark against which moderate and extreme spike prices can be identified. The same pre-processing can be applied to other phenomena with fast dynamics, such as meteorological time series, stock market indices and exchange rates.

Ilaria Lucrezia Amerise
Università della Calabria, Dipartimento di Economia, Statistica e Finanza - Cosenza, Italy e-mail: ilaria.amerise@unical.it

Let us suppose that a time series of electricity prices consists of a, not-better-specified, underlying long-term pattern and of a non-observable random error

$$p_t = \widehat{p}_t + a_t, \qquad t = 1, 2, \cdots, n \tag{1}$$

where p_t is the price in €/MWh (if necessary, log-transformed) on day t, n is the length of the time series, $\widehat{p}_t$ is the baseline and the errors a_t have zero mean. The baseline $\widehat{p}_t$ aims to capture any predictable variation in electricity price behavior arising from regularities over time and it is used to interpolate or filter the observed prices. The stochastic term a_t can be interpreted as what remains of the price after the baseline has been removed. Deviations between observed and baseline prices falling outside a prefixed range will indicate aberrant prices.

To keep (1) simple and general, the description of the baseline has to be smooth, with no preconceptions about its form. Perhaps the simplest smoothing function is a straight line parallel to the time axis. The smoothness, however, is just one side of the coin. The filtered prices must also be close to the observed prices. For example, a polynomial with the number of parameters equal to the number of data points will give the exact fit. Since the two requirements of adequacy to p_t and roughness of $\widehat{p}_t$ may conflict, the choice of $\widehat{p}$ is inevitably a compromise solution.

In this paper, we discuss the penalized least squares method of smoothing a time series. The basic idea dates back at least as far as [4] and the method has been highly studied since. The paper is organized as follows. In Section 2, we present our basic method and show how a valid time series smoother can be obtained by balancing goodness of fit and lack of smoothness. Section 3 discusses the detection of outliers in hourly time series of electricity prices. The alternative method proposed by [3] is briefly outlined. The case studies in Section 3 serve to exemplify how the two methods can be used as a data preparation tool. The final section discusses our results and points out some further applications and improvements.

2 Whittacker smoother

The scope of this section is to model p_t by applying a baseline time series which best matches the original whilst being as smooth as possible. By assigning the proportion in which an increase in the goodness of fit is to be taken as counterbalancing a decrease in the smoothness, we can determine the series which best harmonizes the two requirements. The Whittacker smoother (WS) requires

$$\min_{\widehat{p}_t} Q_t\left(\widehat{p}_t\right) = L_t\left(\widehat{p}_t\right) + \lambda R_t\left(\widehat{p}_t\right) \tag{2}$$

$$L_t\left(\widehat{p}_t\right) = \sum_{t=1}^{n} \left(\widehat{p}_t - p_t\right)^2, \qquad R_t\left(\widehat{p}_t\right) = \sum_{t=m}^{n} \left[\nabla^m \widehat{p}_t\right]^2, \qquad t = 1, 2, \cdots, n \tag{3}$$

Here m is a positive integer, $\lambda > 0$ is a scalar and $\nabla = (1-B)$ is the difference operator: $\nabla\widehat{p}_t = \widehat{p}_t - \widehat{p}_{t-1}$. Note that $R_t\left(\widehat{p}_t\right)$ is null if $\widehat{p}_t$ is a polynomial of degree m.

The component L_t reflects the lack of fit, which is measured as the usual sum of squares of differences. The component R_t expresses the lack of smoothness in terms of the m-th differences of $\widehat{p}_t$. The positive constant λ controls the solution trade-off between smoothness and fidelity to p_t. If $\lambda \to 0$, then the dominant component of (2) will be the residual sum of squares and $\widehat{p}_t$ will resemble the original data points increasingly closely, no matter how irregular it may be. As the value of λ approaches ∞, the resulting baseline will approach a polynomial of degree m. Thus, an optimal relationship between the two components could and should be provided. It may be easily shown that

$$\nabla^m \widehat{p}_j = \sum_{j=i}^{n} D_{ij}\widehat{p}_j \tag{4}$$

$$D_{ij} = \begin{cases} (-1)^{m+j-i}\binom{m}{j-i} & i=1,2,\cdots,m; j=i,i+1,\cdots,i+m \\ 0 & \text{otherwise} \end{cases} \quad \text{for } 1 \le i \le n-m\,. \tag{5}$$

Thanks to this relationship, model (2) can be expressed in matrix notation

$$\mathbf{Q}(\widehat{\mathbf{p}}) = (\widehat{\mathbf{p}} - \mathbf{p})^t(\widehat{\mathbf{p}} - \mathbf{p}) + \lambda(\mathbf{D}\widehat{\mathbf{p}})^t(\mathbf{D}\widehat{\mathbf{p}})\,. \tag{6}$$

where $\mathbf{D}$ is a rectangular matrix with $(n-m)$ rows and n columns. Deriving $\mathbf{Q}(\widehat{\mathbf{p}})$ with respect to $\widehat{\mathbf{p}}$ and equating the partial derivatives to zero gives the linear system

$$\mathbf{A}\widehat{\mathbf{p}} = \mathbf{p} \quad \text{wih } \mathbf{A} = (\mathbf{I}_n + \lambda\mathbf{B}), \quad \mathbf{B} = \mathbf{D}^t\mathbf{D} \tag{7}$$

Here $\mathbf{I}_n$ is the $(n \times n)$ identity matrix and $\mathbf{A}$ is a symmetrical, positive definite matrix of order $(n \times n)$. It follows that the minimum occurs when $\widehat{\mathbf{p}} = \mathbf{A}^{-1}\mathbf{p}$.

Taking into account the considerable length of time series collected in the electricity market, the solution of (7) appears problematic. However, the difficulties are fewer than at first appear. Several authors, in fact, have devised very efficient computing software by exploiting the characteristics of the matrices involved. See [2]. It should be pointed out that any single value of λ could capture the smooth components of time series such as those encountered in the electricity market. A virtually flat baseline using a large value of λ will generate more false rejections of valid prices and a peak-rich one using a small value of λ will lead to false acceptances. According to [1], an objective value of λ can be obtained by minimizing the generalized cross-validation (GCV) score

$$\min_{\lambda} gcv(\lambda) = \frac{n^{-1}\sum_{t=1}^{n}\left[p_t - \widehat{p}_t(\lambda)\right]^2}{\left[1 - n^{-1}Tr(\mathbf{A}^{-1})\right]^2} \tag{8}$$

where Tr denotes the matrix trace. Criterion (8) is a measure of the leave-one-out mean squared prediction error. The effect of applying gcv to hourly time series is shown in Fig. 1 with different degrees of the polynomial in the smoothness component.

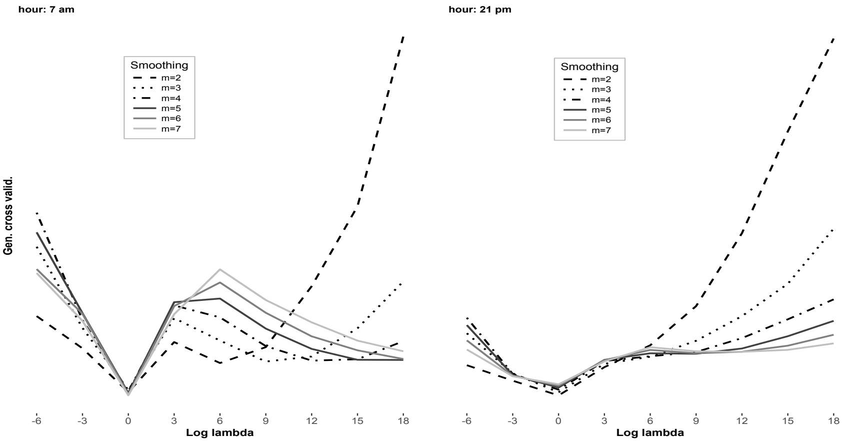

Fig. 1 Zonal electricity price in Northern Italy. Search for the best λ.

In practice, values of gcv are computed for many trial values of λ. Since no analytical solution exists, we need to resort to a numerical method to solve (8). We perform the minimization of (8) by performing a simple grid search for λ in a set of values for $log(\lambda) : 0, 10^j, j = 0, 1, \cdots, 9$. The $\hat{\lambda}$ value corresponding to the minimum of the minima will indicate the apparently most suitable Whittaker smoother for the time series under investigation. In so doing, the procedure for finding a baseline is fully automated. However, the simple fact that a procedure can be executed using a computer does not, of course, make it objective. It is not by coincidence that we said apparently because there is no guarantee that the λ corresponding to the global minimum will produce a valid smoother. Unfortunately, some heuristic calculations show that the minimizer of (8) will give a $\hat{\lambda}$ that leads to substantial under-smoothing and the resulting long-term pattern tends to have too many oscillations that often show up in the wrong places. These cast many doubts on the validity of (8).

As a final consideration, we note that the order of difference m is, to a limited extent, another parameter, other than λ, influencing the result of filtering a time series. However, in practice, the choice is confined to $m = 2$ or $m = 3$ because the curves for $m > 3$ show a similar pattern.

3 Detection of outliers

As stated in the introduction, we detect outliers on the basis of the difference between original and interpolated prices $\widehat{a}_t = p_t - \widehat{p}_t$ $t = 1,2,\cdots,n$. In this regard, it is necessary to define a lower and upper bound for the residuals $\widehat{a}_t$

$$\widehat{a}_t < Q_\beta - K\left(Q_{1-\beta} - Q_\beta\right) \quad \text{or} \quad \widehat{a}_t > Q_{1-\beta} + K\left(Q_{1-\beta} - Q_\beta\right) \quad t = 1,2,\cdots,n \quad (9)$$

where Q_β is the β-quantile and K is a positive multiplicative factor. If a residual surpasses the fences, then the corresponding price is considered an outlier. Obviously, different definitions of K and β may lead to quite different results and identification of price spikes. As an illustration of the potential merit/demerit balance of the proposed method, we compare the results of WS with those obtained by using the *tsoutliers* routine of *forecast* package in *R* software. Put briefly, *tsoutliers* is a recursive filter that decomposes the time series into seasonal, trend and irregular components, which are used to construct a reference time series based on locally weighted polynomial regression (loess). The *tsoutliers* function has the default values $\beta = 0.1$, $K = 2$. We have applied these bounds to the time series of hourly zonal electricity prices in northern Italy for the years 2013-2017. The method indicates 47 suspect spikes. The grid search proposes $\hat{\lambda} = 282'613$ and $m = 3$. To obtain the same number of outliers with the WS, we used $\beta = 0.25$ and $K = 2.714$. However, there are only 26 values in common with $tsoutliers$.

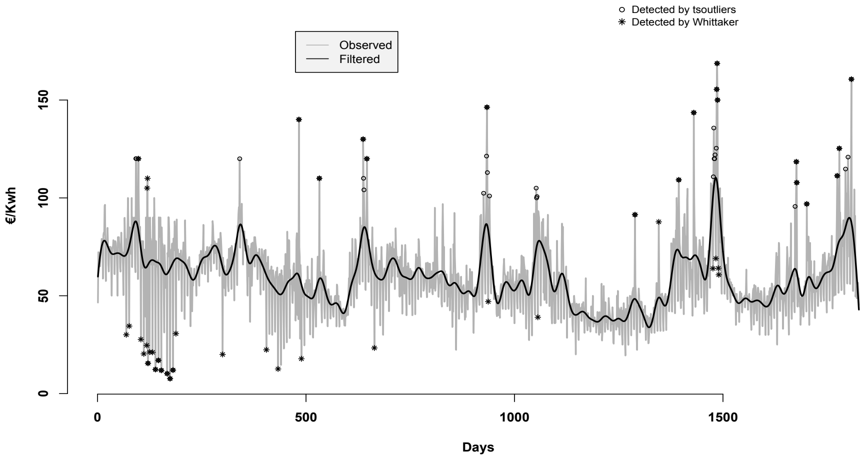

Fig. 2 Outliers detection in hourly prices, h: 10am, Zone: North, period: 2013-2017.

Once an extreme outlier has been detected and a complete time-series is required, the aberrant value may be replaced by a less unusual value. This question, however, is not discussed in the present paper.

4 Results and conclusions

In Table 1, we have collected the results obtained from the examination of $144 = 6 * 24$ time series (one of these has been used in Fig. 2). The data employed are hourly spot prices from the Italian day-ahead zonal market. The time series runs from 1am on Tuesday, 1st January 2013 to 24pm on Sunday, 31st December 2017, yielding data for each hour of the day and for each one of the six zones of the Italian market 1826 days. Table 1 shows the frequency of outliers and the three quartiles of the relative magnitude of outliers: $(p_t - \hat{p}_t)/p_t, p_t > 0$. The percentage of peaks and valleys that were marked as outliers by both methods is about 24‰ (in practice, 18 hourly outliers each month), which is less than a half of that detected by at least one of the filters. The findings in the table reveal that WS tends to be more aggressive than $tsoutliers$ because it not only locates a greater number of outliers than $tsoutliers$, but also because their relative size is smaller.

Table 1 Comparison of the Whittaker filter with the Hyndman filter.

	N	Q_1	Q_2	Q_3		N	Q_1	Q_2	Q_3
$H:$	46‰	0.110	0.318	0.496	$W:$	35‰	0.146	0.240	0.389
$H \cup W:$	56‰	0.112	0.301	0.521	$H \cap W:$	24‰	0.175	0.404	1.148

The two methods agree fairly well with each other in the case of extreme spikes, asis evident from the quartiles of $H \cap W$. Since we have little information about the real position and magnitude of the possible outliers, it is unclear which filter is more appropriate for our type of data.

In conclusion we can say that, although it is not possible to identify a single best method for outlier detection in day-ahead Italian zonal hourly electricity prices, the two procedures that we have applied provide sufficiently distinct results to allow them to be used in combination. Therefore, it seems logical to suggest that aberrant prices should be searched for among those that lie outside the fences of both methods.

Time-varying long-memory processes

Processi a memoria lunga con parametro frazionario variabile nel tempo

Luisa Bisaglia and Matteo Grigoletto

Abstract In this work we propose a new class of long-memory models with time-varying fractional parameter. In particular, the dynamics of the long-memory coefficient, d, is specified through a stochastic recurrence equation driven by the score of the predictive likelihood, as suggested by Creal *et al.* (2013) and Harvey (2013).

Key words: long-memory, GAS model, time-varying parameter

1 Introduction

Long-memory processes have proved to be useful tools in the analysis of many empirical time series. These series present the property that the autocorrelation function at large lags decreases to zero like a power function rather than exponentially, so that the correlations are not summable.

One of the most popular processes that takes into account this particular behavior of the autocorrelation function is the AutoRegressive Fractionally Integrated Moving Average process (ARFIMA(p,d,q)), independently introduced by Granger and Joyeux (1980) and Hosking (1981). This process generalizes the ARIMA(p,d,q) process by relaxing the assumption that d is an integer.

The ARFIMA(p,d,q) process, Y_t, is defined by the difference equation

$$\Phi(B)(1-B)^d(Y_t-\mu)=\Theta(B)\varepsilon_t,$$

where $\varepsilon_t \sim WN(0,\sigma^2)$, and $\Phi(\cdot)$ and $\Theta(\cdot)$ are polynomials in the backward shift operator B of degrees p and q, respectively. Furthermore, $(1-B)^d = \sum_{j=0}^{\infty}\pi_j B^j$,

with $\pi_j = \Gamma(j-d)/[\Gamma(j+1)\Gamma(-d)]$, where $\Gamma(\cdot)$ denotes the gamma function. When the roots of $\Phi(B)=0$ and $\Theta(B)=0$ lie outside the unit circle and $\mid d \mid < 0.5$, the process is stationary, causal and invertible. We will assume these conditions to be satisfied.

When $d \in (0, 0.5)$ the autocorrelation function of the process decays to zero hyperbolically at a rate $O(k^{2d-1})$, where k denotes the lag. In this case we say that the process has a long-memory behavior. When $d \in (-0.5, 0)$ the process is said to have intermediate memory.

If $p = q = 0$, the process $\{Y_t,\ t = 0, \pm 1, \ldots\}$ is called Fractionally Integrated Noise, $FI(d)$. In the following we will concentrate on $FI(d)$ processes with $d \in (-0.5, 0.5)$.

Several papers have addressed the detection of breaks in the order of fractional integration. Some of these works allowed for just one unknown breakpoint (see, for instance, Berand and Terrin, 1996; Yamaghuchi, 2011). Others treated the number of breaks as well as their timing as unknown (Ray and Tsay, 2002; Hassler and Meller, 2014). Boutahar *et al.* (2008) generalize the standard long memory modeling by assuming that the long memory parameter d is stochastic and time-varying. The authors introduce a STAR process, characterized by a logistic function, on this parameter and propose an estimation method for the model. Finally, Roueff and von Sachs (2011) take into account the time-varying feature of long-memory parameter d using the wavelets approach.

Our approach is completely different because we allow the long memory parameter d to vary at each time t. Moreover, our approach is based on the theory of Generalized Autoregressive Score (GAS) models. In particular, the peculiarity of our approach is that the dynamics of the long-memory parameter is specified through a stochastic recurrence equation driven by the score of the predictive likelihood. In this way we are able to take into account also smooth changes of the long-memory parameter.

2 GAS model

To allow for time-varying parameters, Creal *et al.* (2013) and Harvey (2013) proposed an updating equation where the innovation is given by the score of the conditional distribution of the observations (GAS models). The basic framework is the following. Consider a time series $\{y_1, \cdots, y_n\}$ with time-t observation density $p(y_t \mid \psi_t)$, where $\psi_t = (f_t, \theta)$ is the parameter vector, with f_t representing the time-varying parameter(s) and θ the remaining fixed coefficients.

In time series the likelihood function can be written via prediction errors as:

$$\mathscr{L}(y, \psi) = p(y_1; \psi_1) \prod_{t=2}^{n} p(y_t \mid y_1, \cdots, y_{t-1}; \psi_1, \cdots, \psi_t) \; .$$

Thus, the t-th contribution to the log-likelihood is:

$$l_t = \log p(y_t \mid y_1, \cdots, y_{t-1}; f_1, \cdots, f_t; \theta) = \log p(y_t \mid y_1, \cdots, y_{t-1}; f_t; \theta) \ ,$$

where we assume that $f_1, \cdots, f_t$ are known (because they are realized).

The parameter value for the next period, f_{t+1}, is determined by an autoregressive updating function that has an innovation equal to the score of l_t with respect to f_t. In particular, we can assume that:

$$f_{t+1} = \omega + \beta f_t + \alpha s_t \ ,$$

where the innovation s_t is given by

$$s_t = S_t \cdot \nabla_t \ ,$$

with

$$\nabla_t = \frac{\partial \log p(y_t \mid y_1, \cdots, y_{t-1}; f_t, \theta)}{\partial f_t} \tag{1}$$

and

$$S_t = \mathscr{I}_{t-1}^{-1} = -E_{t-1}\left[\frac{\partial^2 \log p(y_t \mid y_1, \cdots, y_{t-1}; f_t, \theta)}{\partial f_t \partial f_t'}\right]^{-1} \ . \tag{2}$$

By determining f_{t+1} in this way, we obtain a recursive algorithm for the estimation of time-varying parameters.

3 TV-FI(d) model

In this section, we extend the class of $FI(d)$ models, by allowing the long-memory parameter d to change over time. The dynamics of the time-varying coefficient d_t is specified in the GAS framework outlined above.

The $TV-FI(d)$ model is described by the following equations:

$$(1-B)^{d_t}\, y_t = \varepsilon_t \ ,$$

$$d_{t+1} = \omega + \beta d_t + \alpha s_t \ , \tag{3}$$

where $\varepsilon_t \sim iid\mathscr{N}(0, \sigma^2)$, and $s_t = S_t \nabla_t$ with S_t and ∇_t defined below.

To calculate the score of the log-likelihood it is preferable to consider the use of autoregressive representation (see, for instance, Palma, 2007):

$$(1-B)^{d_t} y_t = y_t + \sum_{j=1}^{\infty} \pi_j(d_t) y_{t-j} = \varepsilon_t \ ,$$

where

$$\pi_j(d_t) = \prod_{k=1}^{j} \frac{k-1-d_t}{k} = -\frac{d_t \Gamma(j-d_t)}{\Gamma(1-d_t)\Gamma(j+1)} = \frac{\Gamma(j-d_t)}{\Gamma(-d_t)\Gamma(j+1)} \ .$$

In practice, only a finite number n of observations is available. Therefore, we use the approximation

$$y_t = -\pi_1(d_t)y_{t-1} - \pi_2(d_t)y_{t-2} - \cdots - \pi_m(d_t)y_{t-m} + \varepsilon_t \ ,$$

with $m < n$. Then, the t-th contribution, $t = 1, \ldots, n$, to the log-likelihood is:

$$l_t(d_t, \sigma^2) = c - \log(\sigma^2) - \frac{1}{\sigma^2}\left(y_t + \sum_{j=1}^{t-1} \pi_j(d_t) y_{t-j}\right)^2$$

where c is a constant and the corresponding score of the predictive likelihood, see equation (1), becomes

$$\nabla_t = -\frac{1}{\sigma^2}\left(y_t + \sum_{j=1}^{t-1} \pi_j(d_t)y_{t-j}\right)\left(\sum_{j=1}^{t-1} \nu_j(d_t)y_{t-j}\right) \ , \tag{4}$$

where

$$\nu_j(d_t) = \frac{\partial \pi_j(d_t)}{\partial d_t} = \pi_j(d_t)\left(-\Psi(j-d_t) + \Psi(1-d_t) + \frac{1}{d_t}\right) \ , \tag{5}$$

with $\Psi(\cdot)$ representing the digamma function. Finally, we find that S_t in equation (2) is

$$S_t = \sigma^2 \cdot \left(\sum_{j=1}^{t-1} \nu_j(d_t)y_{t-j}\right)^{-2} \ .$$

4 Some Monte Carlo results

We simulated $y_1, \ldots, y_n$ from a process

$$(1-B)^{d_t} y_t = \varepsilon_t \ , \tag{6}$$

where $\varepsilon_t \sim iid\mathcal{N}(0, \sigma^2)$, and d_t is defined by

$$d_t = 0.1 + 0.3 \ \frac{t}{n} \tag{7}$$

or

$$d_t = 0.1 + 0.3 \ \Phi\left(\frac{t-n/2}{3\sqrt{n}}\right) \ , \tag{8}$$

with $\Phi(\cdot)$ indicating the standard Gaussian distribution function.

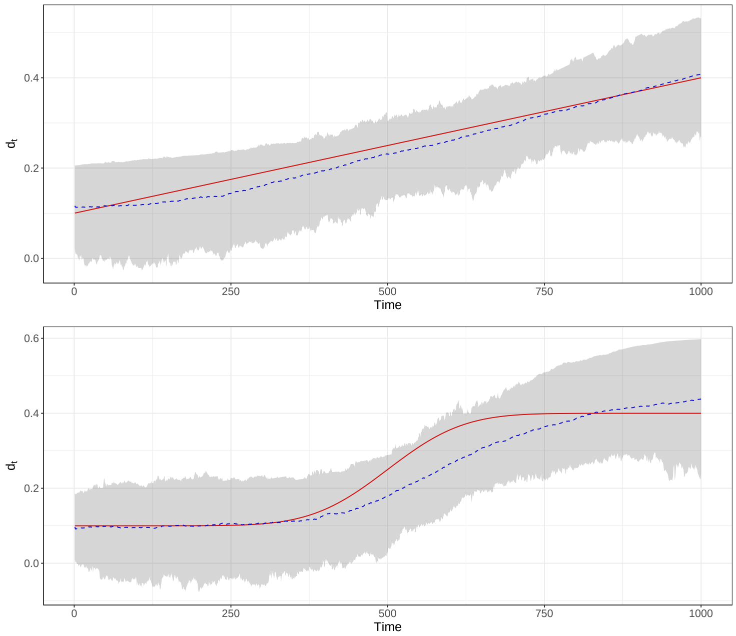

Fig. 1 Result of 200 Monte Carlo simulations, where a time variable fractional parameter (solid line) is estimated with a TV-I(d) model. The dashed line represent the average estimates, while the gray band shows the empirical 95% intervals.

The evolution of d_t was then estimated using the TV-FI(d) model introduced above. It should be noted that in GAS models the scaling defined by (2) is often replaced by S_t^γ, for some suitable γ. We found results (Creal *et al.*, 2013) to be more stable with $\gamma = 0.5$. Also, GAS models can easily be accommodated in order to include a link function $\Lambda(\cdot)$, typically with the objective to constrain the parameter of interest to vary in some region. We used

$$d_t = \Lambda(g_t) = a + (b-a)\,\frac{e^{g_t}}{1+e^{g_t}}\ ,$$

so that $d_t \in (a,b)$, while $g_t \in \mathbb{R}$. Recursion (3) is then defined in terms of g_t, with (4) and (5) easily adjusted for the reparametrization.

It should be remarked that d_0, the value of the fractional at time 0, is necessary to define the likelihood. In the following, we treat d_0 as a parameter to be estimated along with the others.

We obtained 200 Monte Carlo replications from the process defined by (6), and (7) or (8), setting $n = 1000$ and $\sigma = 2$.

For each replication, the TV-FI(d) model was estimated by maximum likelihood, setting $(a,b) = (-0.4, 0.6)$ and $\omega = 0$, while estimating $(d_0, \alpha, \beta, \sigma)$.

Simulation results are shown in Figure 1. The solid line shows the true evolution of d_t, while the dashed line is its estimate, averaged over the Monte Carlo replications. The gray band represents the empirical 95% intervals.

Chapter 1
Statistical Analysis of Markov Switching DSGE Models

Maddalena Cavicchioli

Abstract We investigate statistical properties of Markov switching Dynamic Stochastic General Equilibrium (MS DSGE) models: L^2 structure, stationarity, autocovariance function, and spectral density.

Abstract In questo lavoro si studiano le proprietà statistiche dei modelli Markov switching Dynamic Stochastic General Equilibrium (MS DSGE): L^2 struttura, stazionarietà e le funzioni di autocovarianza e di densità spettrale.

Key words: Multivariate DSGE, State-Space models, Markov chains, changes in regime, autocovariance structure, spectral density function

1.1 Introduction

Dynamic Stochastic General Equilibrium (DSGE) models have recently gained a central role for analyzing the mechanisms of propagation of economic shocks. See, for example, Fernández–Villaverde *et al.* (2007) and Giacomini (2013). However, empirical work has shown that DSGE models have failed to fit the data very well over a long period of time. In fact, the changes of parameters require the economists to re–estimate them. This observation leads to Markov switching (MS) DSGE models, that is, DSGE models in which the coefficient parameters are assumed to depend on the state of an unobserved Markov chain.

Since the influential work of Hamilton (1989, 1990), Markov switching models are widely used to capture the business cycle regime shifts typically observed in

Maddalena Cavicchioli

economic data. See also Hamilton (1994, §22), and Hamilton (2005) for more recent references. Markov switching VARMA models have been studied by many authors. For information concerning the stationarity, estimation, consistency, asymptotic variance and model selection of MS VARMA models see Hamilton (cited above), Krolzig (1997), Francq and Zakoïan (2001), Yang (2000), Zhang and Stine (2001), and Cavicchioli (2014a). See also Cavicchioli (2014b), where explicit matrix expressions for the maximum likelihood estimator of the parameters in MS VAR(CH) models have been derived. Higher-order moments and asymptotic Fisher information matrix of MS VARMA models are provided in Cavicchioli (2017a) and (2017b), respectively.

The first purpose of the present paper is to investigate the L^2–structure of the MS DSGE models. We derive stationarity conditions, compute explicitly the autocovariance function for such models, and give stable VARMA representation of them. A second goal of the paper is to propose a tractable method to derive the spectral density in a matrix closed-form of MS DSGE models. Then we illustrate some statistical properties of their spectral representation.

1.2 Stationarity of MS DSGE models

Let us consider the following Markov switching DSGE (in short, MS DSGE) model

$$\mathbf{x}_t = \mathbf{A}_{s_t}\mathbf{x}_{t-1} + \mathbf{B}_{s_t}\mathbf{w}_t \tag{1.1}$$

$$\mathbf{y}_t = \mathbf{C}_{s_t}\mathbf{x}_{t-1} + \mathbf{D}_{s_t}\mathbf{w}_t \tag{1.2}$$

where $\mathbf{x}_t$ is an $n \times 1$ vector of possibly unobserved state variables, $\mathbf{y}_t$ is the $k \times 1$ vector of observable variables, and $\mathbf{w}_t \sim \mathrm{NID}(0, \mathbf{I}_m)$ is an $m \times 1$ vector of economic shocks. The matrices $\mathbf{A}_{s_t} \in \mathbb{R}^{n\times n}$, $\mathbf{B}_{s_t} \in \mathbb{R}^{n\times m}$, $\mathbf{C}_{s_t} \in \mathbb{R}^{k\times n}$ and $\mathbf{D}_{s_t} \in \mathbb{R}^{k\times m}$ are real random matrices.

The process (s_t) is a homogeneous stationary irreducible and aperiodic Markov chain with finite state-space $\Xi = \{1, \ldots, d\}$. Let $\pi(i) = \Pr(s_t = i)$ denote the ergodic probabilities, which are positive. Let $p(i, j) = \Pr(s_t = j | s_{t-1} = i)$ be the stationary transition probabilities. Then the $d \times d$ matrix $\mathbf{P} = (p(i, j))$ is called the *transition probability matrix*. The process (s_t) is independent of $(\mathbf{w}_t)$.

In order to investigate the stationarity properties of the process $(\mathbf{y}_t)$, we use the following vectorial representation of the MS DSGE model:

$$\mathbf{z}_t = \boldsymbol{\Phi}_{s_t}\mathbf{z}_{t-1} + \boldsymbol{\Psi}_{s_t}\mathbf{w}_t \tag{1.3}$$

where

$$\mathbf{z}_t = \begin{pmatrix}\mathbf{x}_t\\ \mathbf{y}_t\end{pmatrix} \qquad \boldsymbol{\Phi}_{s_t} = \begin{pmatrix}\mathbf{A}_{s_t} & 0\\ \mathbf{C}_{s_t} & 0\end{pmatrix} \qquad \boldsymbol{\Psi}_{s_t} = \begin{pmatrix}\mathbf{B}_{s_t}\\ \mathbf{D}_{s_t}\end{pmatrix}.$$

Then $\mathbf{z}_t$ is $p \times 1$, Φ_{s_t} is $p \times p$ and Ψ_{s_t} is $p \times m$, where $p = n + k$. Let Φ_i and Ψ_i be the matrices obtained by replacing s_t by i in Φ_{s_t} and Ψ_{s_t}, for $i = 1, \dots, d$. Let us consider the following matrices:

$$\mathbb{P}_{\Phi\otimes\Phi} = \begin{pmatrix} p(1,1)\{\Phi_1 \otimes \Phi_1\} & p(2,1)\{\Phi_1 \otimes \Phi_1\} & \cdots & p(d,1)\{\Phi_1 \otimes \Phi_1\} \\ p(1,2)\{\Phi_2 \otimes \Phi_2\} & p(2,2)\{\Phi_2 \otimes \Phi_2\} & \cdots & p(d,2)\{\Phi_2 \otimes \Phi_2\} \\ \vdots & \vdots & & \vdots \\ p(1,d)\{\Phi_d \otimes \Phi_d\} & p(2,d)\{\Phi_d \otimes \Phi_d\} & \cdots & p(d,d)\{\Phi_d \otimes \Phi_d\} \end{pmatrix}$$

and

$$\Pi_{\Psi\otimes\Psi} := \begin{pmatrix} \pi(1)\{\Psi_1 \otimes \Psi_1\} \\ \pi(2)\{\Psi_2 \otimes \Psi_2\} \\ \vdots \\ \pi(d)\{\Psi_d \otimes \Psi_d\} \end{pmatrix}.$$

Then $\mathbb{P}_{\Phi\otimes\Phi}$ is $(d\,p^2) \times (d\,p^2)$ and $\Pi_{\Psi\otimes\Psi}$ is $(d\,p^2) \times m^2$. Consider the top Lyapunov exponent

$$\gamma_\Phi = \inf_{t\in\mathbb{N}}\{E\,\frac{1}{t}\,\log_e ||\,\Phi_{s_t}\,\Phi_{s_{t-1}}\cdots\Phi_{s_1}\,||\,\}. \tag{1.4}$$

Theorem 1. *If* $\gamma_\Phi < 0$*, then the process* $(\mathbf{y}_t)$ *is the unique strictly stationary solution of the* MS DSGE *model in* (1.1) *and* (1.2).

Theorem 2. *If* $\rho(\mathbb{P}_{\Phi\otimes\Phi}) < 1$*, where* $\rho(\cdot)$ *denotes the spectral radius, then the process* $(\mathbf{y}_t)$ *is the unique nonanticipative second–order stationary solution of the* MS DSGE *model in* (1.1) *and* (1.2).

1.3 Autocovariance structure and spectral analysis

Let $(\mathbf{z}_t)$ (and $(\mathbf{y}_t)$) be second-order stationary. For every h, define

$$W(h) = \Pi_{E(\mathbf{z}_t\mathbf{z}'_{t-h})} := \begin{pmatrix} \pi(1)\,E(\mathbf{z}_t\,\mathbf{z}'_{t-h}|\,s_t = 1) \\ \pi(2)\,E(\mathbf{z}_t\,\mathbf{z}'_{t-h}|\,s_t = 2) \\ \vdots \\ \pi(d)\,E(\mathbf{z}_t\,\mathbf{z}'_{t-h}|\,s_t = d) \end{pmatrix} \in \mathbb{R}^{(d\,p)\times p}.$$

For $h = 0$, we prove that

$$\operatorname{vec} W(0) = \mathbb{P}_{\Phi\otimes\Phi}\,\operatorname{vec} W(0) + \Pi_{\Psi\otimes\Psi}\,\operatorname{vec}(\mathbf{I}_m) \tag{1.5}$$

where $\mathbf{I}_m$ is the identity matrix of order m. Let $\mathbb{P}_\Phi$ be the $(d\,p) \times (d\,p)$ matrix obtained by replacing $\Phi_i \otimes \Phi_i$ by Φ_i, for $i = 1, \dots, d$, in the definition of $\mathbb{P}_{\Phi\otimes\Phi}$. For $h \geq 0$, we prove that

$$W(h) = \mathbb{P}^h_\Phi\,W(0). \tag{1.6}$$

Theorem 3. *Suppose that* $\rho(\mathbb{P}_{\Phi\otimes\Phi}) < 1$. *Then the autocovariance function of the process* $(\mathbf{y}_t)$ *defined by the* MS DSGE *model in* (1.1) *and* (1.2) *is given by*

$$\Gamma_{\mathbf{y}}(h) = \mathbf{f}(\mathbf{e}' \otimes \mathbf{I}_p)\mathbb{P}^h_{\Phi} W(0)\,\mathbf{f}'$$

for every $h \geq 0$, *where*

$$\operatorname{vec} W(0) = \left(\mathbf{I}_{dp^2} - \mathbb{P}_{\Phi\otimes\Phi}\right)^{-1} \Pi_{\Psi\otimes\Psi} \operatorname{vec}\mathbf{I}_m$$

$$\mathbf{f} = (0_{k\times n} \qquad \mathbf{I}_k) \in \mathbb{R}^{k\times p} \qquad\qquad \mathbf{e} = (1\ \cdots\ 1)' \in \mathbb{R}^d.$$

Theorem 3 allows to obtain a stable VARMA representation for any second-order stationary process $(\mathbf{y}_t)$ driven by an MS DSGE model.

Theorem 4. *Suppose that* $\rho(\mathbb{P}_{\Phi\otimes\Phi}) < 1$. *The spectral density matrix of the process* $(\mathbf{y}_t)$ *driven by the* MS DSGE *in* (1.1) *and* (1.2) *is given by*

$$\mathbf{F}_{\mathbf{y}}(\omega) = \mathbf{f}(\mathbf{e}' \otimes \mathbf{I}_p)[-\mathbf{I}_{dp} + 2Re\,Y(\omega)]W(0)\mathbf{f}'$$

where

$$Y(\omega) = (\mathbf{I}_{dp} - \mathbb{P}_{\Phi} e^{-i\omega})^{-1}$$

is a $(dp)\times(dp)$ *complex matrix and* $ReY(\omega)$ *denotes the real part of* $Y(\omega)$.

Theorems 1–4 are the main results proved in Cavicchioli (2018). Examples and numerical applications complete the mentioned paper.

Forecasting energy price volatilities and comovements with fractionally integrated MGARCH models

Previsione della volatilità e co-movimenti dei prezzi dei prodotti energetici mediante modelli MGARCH frazionalmente integrati

Malvina Marchese and Francesca Di Iorio

Abstract We investigate the use of fractionally integrated MGARCH models from a forecasting and a risk management perspective for energy prices. Our in-sample results show significant evidence of long memory decay in energy price returns volatilities, of leverage effects and of time-varying autocorrelations. The forecasting performance of the models is assessed by the SPA test, the Model Confidence Set and the Value at Risk.

Abstract *I modelli MGARCH frazionalmente integrati vengono impiegti in questo lavoro per lo previsione e la gestione del rischio nel mercato dei prodotti energetici. I risultati ottenuti mostrano la presenza di long-memory nella volatilità dei rendimenti dei prezzi, effetti di leverage e autocorrelatione variante nel tempo. La capacit previsiva di questi modelli è stata verificata mediante il test SPA, il Model Confidence Set e il Value at Risk.*

1 Introduction

The effects of oil price shocks on macroeconomic variables, the impact on the financial sector of energy prices fluctuations, the degree of integration between different energy markets, have been the main fields of a increasing studies. It seems to be a growing consensus in the literature on the use of multivariate GARCH (MGARCH) models. A main reference can be Wang and Wu (2012) that compare the forecasting performances of several univariate and bivariate GARCH-type models for spot

Malvina Marchese
Cass Business School, 106 Bunhill Row London EC1Y 8TZ, e-mail: malvina.marchese@city.ac.uk

Università di Napoli Federico II, via L. Rodinò 22 80138 Napoli, Italia e-mail: fdiiorio@unina.it

price returns of crude oil (WTI), conventional gasoline (NYH), heating oil (NYH) and jet fuel. Using several univariate loss functions, they find that the full and diagonal BEKK cannot be outperformed by any other model according to the superior predictive ability (SPA) test of Hansen (2005). Growing attention has been devoted to the problem of an accurate modelling and forecasting of energy price volatilities and correlations for portfolio construction, hedging purposes and risk management. The multivariate model used to these ends should capture all the statistical regularities of the volatility series and allow for time dependent correlations. While there is significant empirical evidence that univariate energy price volatilities display a strong degree of persistence, consistent with a long memory structure (e.g. Chang et al., 2010), it would seem that no attempt to include it in multivariate models has yet been made. More, choosing the most appropriate MGARCH specification must also entail comparison of the models' forecasting abilities and usefulness in a decision based framework. Most forecasting comparisons in the energy literature are based on univariate loss functions and univariate tests such as the Diebold-Mariano, that do not allow for joint evaluation of volatilities and correlations forecasts accuracy. Indeed a comprehensive conditional variance matrix forecasts comparison based on matrix loss functions seems to be lacking so far. This paper investigates and analyze the comovements across three major energy markets, namely crude oil (West Texas Intermediate-Cushing Oklaoma), conventional gasoline (New York Harbor) and heating oil (New York Harbor), by means of several multivariate GARCH-type models with particular attention on the fractionally integrated dynamic conditional correlation (FI-DCC) model. This multivariate GARCH models with long memory, asymmetries and dynamic correlations significantly improves the models' in sample and forecasting performance, and then the attractiveness in terms of risk monitoring of this class of models.

The aims of this papers are: (i) compare the in sample performances of several alternative multivariate GARCH models for the returns on the spot prices of the three series using standard information criteria; (ii) evaluate their forecasting accuracy using the Superior Predictive Ability (SPA) test of Hansen (2005) and the Model Confidence Set (MCS) method of Hansen, Lunde and Nason (2011); (iii) explore the efficiency gains in using the fractionally integrated DCC model for one step ahead Value at Risk prediction for short and long positions.

2 Data and models estimations

The series under investigation are the spot energy price returns of the crude oil (CO), conventional gasoline (CG) and heating oil (HO). We obtain 6401 valid daily observations from June 1st 1992 till June 12th 2017 from the Energy Information Administration (EIA) in the U.S. Department of Energy. Each series show the expected stylized facts, such as non normality and fat tails, and the Ljung and Box Q shows that the null hypothesis of no autocorrelation up to the 10th lag is rejected at 10% level of significance. The presence of long memory for the returns $\boldsymbol{r}_t$ is assessed by the significant estimation of the long-memory parameter d using the local Whittle estimator. To account for the serial correlation found in the data, we fit a VAR model to the returns vector whit 1 Lag as suggested by selection criteria. Only conventional gasoline displays time dependence in the mean equation and there are no evidences of spillover effects between the series. Post-estimation diagnostic tests for the residuals of the estimated VAR(1) model confirm the presence of strong GARCH effects, non Normality and no serial correlation up to lag 20. Based on the above evidences we fit the several multivariate GARCH specifications to the VAR(1) residuals. Denoting by $\boldsymbol{r}_t$ the vector of log- returns of n oil prices and θ a finite vector of parameters, the general form of a multivariate GARCH (MGARCH) model is: $\boldsymbol{r}_t = \boldsymbol{\mu}_t(\theta) + \boldsymbol{\varepsilon}_t$, with $\boldsymbol{\varepsilon}_t = \boldsymbol{H}_t^{1/2}(\theta)\boldsymbol{z}_t$ where $\boldsymbol{z}_t$ is an *i.i.d* zero mean random vector such that $Var(\boldsymbol{z}_t) = \boldsymbol{I}_n$, and $\boldsymbol{H}_t^{1/2}$ is a $n \times n$ positive definite matrix. The conditional mean of the process is $\boldsymbol{\mu}_t(\theta)$, the matrix $\boldsymbol{H}_t(\theta) = \boldsymbol{H}_t^{1/2}\boldsymbol{I}_n\left(\boldsymbol{H}_t^{1/2}\right)'$ is the conditional variance. The MGARCH specifications are based on different parameterizations of $\boldsymbol{H}_t$ which have been proposed to capture the dynamics of volatilities and correlations, avoiding the *curse of dimensionality* and to ensure positive definiteness of the covariance matrix. Comprehensive reviews of multivariate GARCH models can be found in Bauwens *et al* (2006) and Silvennoinen and Terasvirta (2009). The MGARCH models estimated in the paper and their main characteristics are summarized in Table 1. In this paper the model estimation is performed by Maximum Likelihood methods in one step under the assumption of joint normality of the vector of disturbances using Kevin Sheppard's MFE Toolbox for *Matlab*, release 2016a. Standardized residuals of estimated volatility models are fat tailed, so the assumption of Gaussianity of the innovations is not innocuous and reduces efficiency; however Gaussian likelihood retains consistency under misspecification of the conditional density, as long as the conditional mean and the conditional variance are correctly specified. We estimate $\hat{\theta}$ by maximizing the conditional log likelihood: $L_T(\theta) = c - \frac{1}{2}\sum_{t=1}^{T}\ln|\boldsymbol{H}_T| - \frac{1}{2}\sum_{t=1}^{T}\boldsymbol{r}_t'\boldsymbol{H}_t^{-1}\boldsymbol{r}_t$.

Full results concerning the model estimations, obtained with one-step Maximum Likelihood, are available from the authors on request. Table 2 reports the maximized log-likelihood and information criteria for all the fitted models. 'Np' is the number of estimated parameters in each model and the values in bold correspond to the best performing models. Weather the criterion is AIC or BIC, constant conditional correlation specifications are outperformed by their dynamic counterparts and symmetric specifications are outperformed by specifications including leverage effects.

3 The forecasting exercise

Evaluation of volatility forecasts is particularly challenging since volatility itself is latent and thus unobservable even ex post. In this case to compare model based forecasts with ex post realizations a statistical or an economic loss function as well as a proxy for the true unobservable conditional variance matrix have to be chosen. Proxy might lead to a different ordering of competing models that would be obtained if the true volatility were observed. To avoid a distorted outcome, the choice of an appropriate loss function is crucial. In this paper, we follow Bauwens et al. (2016) and use several loss functions, robust to noisy proxies. i.e. expected to provide the same forecasts ranking using the true conditional covariance or a conditionally unbiased proxy. Their definition is provided in Table 3 where H_{it} , for $i = 1, \dots, k$ denotes each model predicted covariance matrix for day t, $\hat{\Sigma}_t$ is the proxy of the conditional covariance matrix, ι is a vector of ones, T is the out of sample length and n is the the sample size. As a proxy for the conditional variance matrix at day t we use the matrix of the outer products of the daily mean forecast errors, $e_{T+1}e'_{T+1}$ which is a conditionally unbiased proxy. The forecasting ability of the set of proposed models is evaluated over a series of 630 out-of sample predictions. We compare the one day ahead conditional variance matrix forecasts based on the models estimated. We divide the full data set into two periods: the *in-sample period* from 02 August 2004 to 9 January 2014 (2430 observations), the *out of sample* with 510 observations from 10 January 2014 to 31 December 2015, used for forecasting evaluation. Forecasts are constructed using a fixed rolling window scheme: the estimation period is rolled forward by adding one new daily observation and dropping the most distant observation. Models parameters are re-estimated each day to obtain tomorrow volatility forecasts and the sample size employed to estimate is fixed and any dependence on the mean dynamics has been accounted for by fitting a VAR(1), so the mean forecasts do not depend on the models. This scheme satisfies the assumptions required by the MCS method and the SPA test and allows a unified treatment of nested and non-nested models. For each statistical loss function, we evaluate the significance of loss functions differences by means of the SPA and MCS.

Table 3 Loss function

Loss function		Type
Frobenius	$tr\left[\left(\hat{\Sigma}_t - H_{it}\right)'\left(\hat{\Sigma}_t - H_{it}\right)\right]$	Symmetric
Euclidean	$vech\left(\hat{\Sigma}_t - H_{it}\right)' vech\left(\hat{\Sigma}_t - H_{it}\right)$	Symmetric
MSFE	$\frac{1}{T} vec\left(\hat{\Sigma}_t - H_{it}\right)' vec\left(\hat{\Sigma}_t - H_{it}\right)'$	Symmetric
QLIKE	$\log\lvert H_t\rvert + vec\left(H_{it}^{-1}\hat{\Sigma}_t\right)' \iota$	Symmetric
Stein	$tr\left(H_{it}^{-1}\hat{\Sigma}_t\right) - \log\left\lvert H_{it}^{-1}\hat{\Sigma}_t\right\rvert - n$	Asymmetric
VDN	$tr(\hat{\Sigma}_t \log\hat{\Sigma}_t - \hat{\Sigma}_t \log H_{it} - \hat{\Sigma}_t + H_{it})$	Symmetric

We follow Hansen (2005) and obtain the p-values of the test by bootstrap. We implement a block bootstrap with block length equal to 2 and 10000 bootstrap samples. We find that the hypothesis of constant correlation is always rejected, as well as the hypothesis of short memory. The hypothesis of symmetry in the volatility dynamics is rejected in most benchmarks, and allowing for dynamic correlations significantly improves the models' forecasting accuracy. In the overall it appears that the most valid specification in this application is the fractionally integrated exponential DCC model that captures well the dynamics of the variance covariance matrix. The MCS methodology identifies a set of models with equivalent predictive ability which outperform all the other competing models at a given confidence level α with respect to a particular loss function. MCS determines the set of models that at a given confidence level have the best forecasting performance. We use a block bootstrap scheme to obtain the quantiles of the distribution. The block length bootstrap parameter is set equal to 2 and the number of bootstrap sample used is 10000. At the 90% confidence level the asymmetric BEKK and the fractionally integrated exponential DCC are included in the MCS resulting from the Euclidean, Frobenious, MSFE and VDN loss functions. The fractionally integrated DCC is included in the MCS deriving from the Euclidean, Frobenious and MSFE loss functions. The highest number of models (eight) is included for the Euclidean and Frobenious loss functions. The most striking result is the inclusion of the fractionally integrated exponential DCC model in the MCS of four loss functions supporting the hypothesis that the inclusion of long memory, asymmetries and time varying correlations significantly improve forecasting accuracy.

The possible efficiency gains of using long-memory asymmetric MGARCH models over short memory benchmarks for one-step ahead Value at Risk forecasting for equally weighted portfolios. To this end, we focus on the models' ability to predict the tail behavior of the returns rather than obtaining the 'best' volatility model.

We forecast the one day ahead Value at Risk for each of the models under comparison at 5%, 2.5% and 1% levels, and we assess their accuracy using statistical back-testing. We are concerned with both the long and short positions *VaR*. So we focus respectively on the left and right tail of the forecasted distribution of returns and we assess the models joint ability to delivery accurate VaR forecasts for both tails. To asses the accuracy of the *VaRs* obtained by the different models we test weather the failure rate implied by each model is statistically equal to the expected one. A popular back-testing procedure is based on the unconditional coverage test of Kupiec (e.g. Giot and Laurent, 2003). The test is a likelihood ratio test, built under the assumption that VaR violations are independent. Under the null, the test statistic is distributed as a χ^2-distribution with two degrees of freedom. Results for the short memory constant correlation models are homogenous for short and long VaRs, leading in all cases to rejection of the null hypothesis, regardless of the model structure. Models with dynamic conditional correlations perform much better passing all the tests with the occasional rejection for the most extreme quantiles. Models with dynamic conditional correlations and long memory adequately forecast *VaRs* at all levels. In conclusion for equally weighted portfolios, reliable *VaR* forecasts can be obtained under the assumption of conditionally normally standardized portfolio returns, by using DCC-type of models that include long range dependence and asymmetries in the individual volatilities.

As a general finding, fractionally integrated dynamic conditional correlation models display good in-sample fit. Using a fixed rolling window scheme, we assess the one-day ahead forecasting accuracy of the models with the MCS method and the SPA test using several matrix loss functions, robust to the choice of the volatility proxy. Short memory constant correlations models are always rejected in favour of long memory dynamic correlation models, and that the use of the latter significantly improves forecasts accuracy from a statistical as well as a risk management perspective.

Improved bootstrap simultaneous prediction limits

Limiti di previsione simultanei migliorati basati su procedure bootstrap

Paolo Vidoni

Abstract This paper concerns the problem of constructing joint prediction regions having coverage probability equal or close to the target nominal value. In particular, the focus is on prediction regions defined using a system of simultaneous prediction limits. These regions are not necessarily of rectangular form and each component prediction interval depends on the preceding future observations. The specification of prediction regions with well-calibrated coverage probability has been considered in [2] and [5]. In this paper we consider an asymptotically equivalent procedure, which extends to the multivariate setting the bootstrap-based approach proposed in [3]. A simple application to autoregressive time series models is presented.
Abstract *In questo lavoro si considera il problema della costruzione di regioni di previsione con probabilità di copertura uguale o prossima a quella nominale, con particolare attenzione a regioni basate su limiti di previsione simultanei. Tali regioni non hanno necessariamente una forma rettangolare e ogni intervallo componente dipende dalle osservazioni future precedenti. La specificazione di regioni ben calibrate è stata studiata in [2] e [5]. In questo contributo si presenta una procedura di calcolo asintoticamente equivalente, e di facile implementazione, che estende all'ambito multivariato la procedura bootstrap introdotta in [3]. Si propone, infine, una semplice applicazione al caso dei modelli autoregressivi per serie storiche.*

Key words: bootstrap calibration, coverage, simultaneous prediction, time series

1 Introduction and preliminaries

This paper concerns the problem of constructing multivariate prediction regions having coverage probability equal or close to the target nominal value. In partic-

ular, the focus here is on multivariate prediction regions defined using a system of simultaneous prediction limits. These regions are not necessarily of rectangular form and they can be usefully considered whenever there is a natural order in the observations, such as for time series data, since each component prediction interval turns out to be influenced by the preceding future observations. With regard to time series applications, a system of simultaneous prediction intervals could be viewed as an alternative to a sequence of marginal prediction intervals at different periods into the future, which do not properly account for the actual dynamic evolution of the interest phenomenon.

Let (Y,Z) be a continuous random vector having joint density function $f(y,z;\theta)$, with $\theta \in \Theta \subseteq \mathbf{R}^d$, $d \geq 1$, an unknown d-dimensional parameter; $Y = (Y_1,\dots,Y_n)$, $n \geq 1$, is observable, while $Z = (Z_1,\dots,Z_m)$, $m \geq 1$, denotes a future, or yet unobserved, random vector. Although prediction problems may be studied from different perspectives, the aim here is to define an α-prediction region for Z, that is a random set $R(Y,\alpha) \subset \mathbf{R}^m$, depending on the observable sample Y and on the nominal coverage probability α, such that

$$P_{Y,Z}\{Z \in R(Y,\alpha);\theta\} = E_Y[P_{Z|Y}\{Z \in R(Y,\alpha)|Y;\theta\};\theta] = \alpha, \qquad (1)$$

for every $\theta \in \Theta$ and for any fixed $\alpha \in (0,1)$. The above probability is called coverage probability and it is calculated with respect to the joint distribution of (Z,Y); moreover, the expectation is with respect to Y and $P_{Z|Y}\{\cdot;\theta\}$ is the probability distribution of Z given Y.

When there exists a transitive statistics $U = g(Y)$, it is natural to consider the conditional coverage probability such that, exactly or approximately,

$$P_{Y,Z|U}\{Z \in R(Y,\alpha)|U = u;\theta\} = E_{Y|U}[P_{Z|U}\{Z \in R(Y,\alpha)|U;\theta\}|U = u;\theta] = \alpha, \quad (2)$$

where the probability and the expectation are conditioned on $U = u$. For example, if we consider an autoregressive (AR) model of order 1, the transitive statistics is $U = Y_n$. Obviously, conditional solutions satisfying (2) also satisfy (1) and, when we can not find a transitive statistic, the conditional approach is meaningless.

The easiest way for making prediction on Z is to define a prediction region by using the estimative (plug-in) predictive distribution $P_{Z|Y}\{\cdot;\hat{\theta}\}$, where the unknown parameter θ is substituted with an asymptotically efficient estimator $\hat{\theta}$ based on Y, such that $\hat{\theta} - \theta = O_p(n^{-1/2})$; we usually consider the maximum likelihood estimator or any asymptotically equivalent alternative estimator. However, estimative α-prediction regions $R_e(Y,\alpha)$ are not entirely adequate predictive solutions, since the additional uncertainty introduced by assuming $\theta = \hat{\theta}$ is underestimated and then the (conditional) coverage probability differs from α by a term usually of order $O(n^{-1})$. This lack of accuracy can be substantial for small n and/or large m.

Here we focus on a particular estimative prediction region $R_e(Y,\alpha)$ based on the system of simultaneous prediction limits defined as quantiles of the conditional distributions of the components of vector $Z = (Z_1,\dots,Z_m)$. We assume, for simplifying the exposition, that (Y,Z) follows a first-order Markovian dependence structure (so that $U = Y_n$) and then we set

$$R_e(Y,\alpha) = \{z \in \mathbf{R}^m : z_i \leq \hat{q}_i(\alpha_i), i = 1,\ldots,m\}, \tag{3}$$

where $\hat{q}_i(\alpha_i) = q_i(\alpha_i, z_{i-1}; \hat{\theta})$, $i = 1,\ldots,m$, is the α_i-quantile of the conditional distribution of Z_i given $Z_{i-1} = z_{i-1}$, evaluated at $\theta = \hat{\theta}$, with $Z_0 = Y_n$. Finally, we assume $\prod_{i=i}^m \alpha_i = \alpha$ in order to assure that $R_e(Y,\alpha)$ is an α-prediction region, namely that $P_{Z|Y_n}\{Z \in R_e(Y,\alpha)|Y_n = y_n; \hat{\theta}\} = \alpha$. Note that the conditional prediction limit $\hat{q}_i(\alpha_i)$, for each $i = 2,\ldots,m$, is obtained recursively as a function of the previous, unknown future observation z_{i-1}.

Corcuera and Giummolè [2] find that the (conditional) coverage probability of the estimative prediction region (3) is

$$P_{Y,Z|Y_n}\{Z \in R_e(Y,\alpha)|Y_n = y_n;\theta\} = E_{Y|Y_n}\left\{\int_{-\infty}^{\hat{q}_1(\alpha_1)} \cdots \int_{-\infty}^{\hat{q}_m(\alpha_m)} f_{Z|Y_n}(z|Y_n;\theta)dz \Big| Y_n = y_n;\theta\right\}$$
$$= C_m(\alpha_1,\ldots,\alpha_m;\theta,y_n) = \alpha + Q_m(\alpha_1,\ldots,\alpha_m;\theta,y_n) + O(n^{-3/2}),$$

where $f_{Z|Y_n}(z|y_n;\theta)$ is the joint conditional density of Z given $Y_n = y_n$. Moreover, after tedious calculations, an explicit expression for the $O(n^{-1})$ coverage error term $Q_m(\alpha_1,\ldots,\alpha_m;\theta,y_n)$ is also derived.

2 Improved simultaneous prediction

In order to improve the estimative predictive approach a number of solutions have been proposed. One of these strategies (see, for example, [1] and [4]) is to define an explicit modification for the estimative prediction limits, so that the associated coverage probability turns out to be equal to the target α with a high degree of accuracy. With regard to the univariate case (namely, $m = 1$, $Z = Z_1$ and $\alpha = \alpha_1$), given the estimative α_1-prediction limit $\hat{q}_1(\alpha_1)$, it is easy to prove that the modified estimative prediction limit

$$\tilde{q}_1(\alpha_1) = \hat{q}_1(\alpha_1) - \frac{Q_1(\alpha_1;\hat{\theta},y_n)}{f_{Z_1|Y_n}(\hat{q}_1(\alpha_1)|y_n;\hat{\theta})}, \tag{4}$$

reduces the coverage error to order $o(n^{-1})$. Here, $f_{Z_1|Y_n}(z_1|y_n;\theta)$ is the conditional density function of Z_1 given $Y_n = y_n$. A potential drawback of this strategy is that the evaluation of the fundamental term $Q_1(\alpha_1;\theta,y_n)$ may require complicated asymptotic calculations. To overcome this difficulty, Ueki and Fueda [3] show that the modifying term of the improved prediction limit (4) can be equivalently expressed as $\hat{q}_1(C_1(\alpha_1;\theta,y_n)) - \hat{q}_1(\alpha_1)$ and then, to the relevant order of approximation, the modified estimative prediction limit (4) corresponds to

$$\tilde{q}_1(\alpha_1) = 2\hat{q}_1(\alpha_1) - \hat{q}_1(C_1(\alpha_1;\theta,y_n)). \tag{5}$$

Therefore, the computation is greatly simplified, since we need only the value of the coverage probability $C_1(\alpha_1;\theta,y_n) = E_{Y|Y_n}\{F_{Z_1|Y_n}(\hat{q}_1(\alpha_1)|Y_n;\theta)|Y_n = y_n;\theta\}$, with $F_{Z_1|Y_n}(z_1|y_n;\theta)$ the conditional distribution function of Z_1 given $Y_n = y_n$, which can be usually estimated using a simple parametric bootstrap procedure.

The approach based on high-order analytical corrections can be extended to the multivariate case. In particular, Corcuera and Giummolè [2] specify a system of improved prediction limits $\tilde{q}_1(\alpha_1),\ldots,\tilde{q}_m(\alpha_m)$, where $\tilde{q}_1(\alpha_1)$ is defined as in (4), whereas each $\tilde{q}_i(\alpha_i)$, $i = 2,\ldots,m$, requires a further correction term in order to account for the additional dependence introduced, among the limits, by substituting θ with the same $\hat{\theta}$. This second correction term is far more complex that the first one.

In order to simplify the calculation, using a general result presented in [5], we prove that it is possible to extend the Ueki and Fueda's procedure to the multivariate setting. More precisely, an asymptotically equivalent expression for the improved simultaneous prediction limits corresponds to

$$\tilde{q}_i(\alpha_i) = 2\hat{q}_i(\alpha_i) - \hat{q}_i(C_i(\alpha_i;\theta,y_n,z_{(i-1)})),\ i = 1,\ldots,m, \tag{6}$$

with $z_{(i-1)} = (z_1,\ldots,z_{i-1})$. For $i = 1$, $C_1(\alpha_1;\theta,y_n)$ is the coverage probability of $\hat{q}_1(\alpha_1)$ as given in (5) and, for $i = 2,\ldots,m$, we consider the conditional coverage probability of $\hat{q}_i(\alpha_i)$ given $Z_{(i-1)} = z_{(i-1)}$ defined as

$$C_i(\alpha_i;\theta,y_n,z_{(i-1)}) = \frac{E_{Y|Y_n}\left\{\frac{f_{Z_{(i-1)}|Y_n}(z_{(i-1)}|Y_n;\theta)}{f_{Z_{(i-1)}|Y_n}(z_{(i-1)}|Y_n;\hat{\theta})} F_{Z_i|Z_{i-1}}(\hat{q}_i(\alpha_i)|z_{i-1};\theta)\Big|Y_n = y_n,\theta\right\}}{E_{Y|Y_n}\left\{\frac{f_{Z_{(i-1)}|Y_n}(z_{(i-1)}|Y_n;\theta)}{f_{Z_{(i-1)}|Y_n}(z_{(i-1)}|Y_n;\hat{\theta})}\Big|Y_n = y_n,\theta\right\}}, \tag{7}$$

where $F_{Z_i|Z_{i-1}}(z_i|z_{i-1};\theta)$ is the conditional distribution function of Z_i given $Z_{i-1} = z_{i-1}$ and $f_{Z_{(i-1)}|Y_n}(z_{(i-1)}|y_n;\theta)$ is the joint conditional density of $Z_{(i-1)}$ given $Y_n = y_n$. Also the conditional coverage probability (7) can be estimated using a fairly simple bootstrap parametric approach and, since the explicit expression for the correction terms is not required, this greatly simplifies the computation of the improved limits.

3 An application to a simple autoregressive model

Let us consider a stationary AR(1) process $\{Y_j\}_{j\geq 1}$ defined as

$$Y_j = \mu + \rho\,(Y_{j-1} - \mu) + \varepsilon_j, \quad j \geq 1,$$

where $\mu \in \mathbf{R}$, $|\rho| < 1$ and $\{\varepsilon_j\}_{j\geq 1}$ is a sequence of independent normal distributed random variables with zero mean and variance $\sigma^2 > 0$. Then, using the notation introduced in Section 1, $Y = (Y_1,\ldots,Y_n)$, $Z = (Z_1,\ldots,Z_m) = (Y_{n+1},\ldots,Y_{n+m})$ and $\theta = (\theta_1,\theta_2,\theta_3) = (\mu,\rho,\sigma^2)$ is the unknown model parameter. Furthermore $\hat{\theta} =$

$(\hat{\mu}, \hat{\rho}, \hat{\sigma}^2)$ is the vector of the corresponding maximum likelihood estimators which, in this case, are explicitly known.

Since Z_i given $Z_{i-1} = z_{i-1}$, $i = 1, \ldots, m$, follows a normal distribution with mean $\mu + \rho\,(z_{i-1} - \mu)$ and variance σ^2, it is immediate to define the estimative prediction region $R_e(Y, \alpha)$ as specified by (3), with simultaneous prediction limits $\hat{q}_i(\alpha_i) = \hat{\mu} + \hat{\rho}\,(z_{i-1} - \hat{\mu}) + u_{\alpha_i}\hat{\sigma}$, $i = 1, \ldots, m$. Here, u_{α_i} is such that $\Phi(u_{\alpha_i}) = \alpha_i$, where $\Phi(\cdot)$ is the distribution function of a standard normal random variable, and $\prod_{i=1}^{m} \alpha_i = \alpha$. Using the bootstrap-based procedure outlined in Section 2, we obtain the modified simultaneous prediction limits (6), which are supposed to improve the coverage accuracy of the estimative solution.

We also consider a sequence of m marginal prediction limits, which correspond the the plug-in estimates of the α_i-quantile, for $i = 1, \ldots, m$, of the conditional distribution of Z_i given $Y_n = y_n$. Notice that the first marginal prediction limit corresponds to $\hat{q}_1(\alpha_1)$. These prediction limits are computed repeatedly one period at a time and they define a rectangular-shaped prediction region. In this case, the nominal coverage probability is not equal to $\prod_{i=1}^{m} \alpha_i = \alpha$, since the component prediction limits are not independent of each other. Furthermore, by applying a bootstrap-calibrated procedure to these marginal prediction limits, as supposed to be independent, we try to improve, also in this different situation, the coverage accuracy of the corresponding prediction region.

Table 1 presents the results of a preliminary simulation study for comparing the coverage accuracy of prediction regions based on estimative and bootstrap-calibrated simultaneous prediction limits and on estimative and bootstrap-calibrated marginal prediction limits. Conditional coverage probabilities, with nominal level $\alpha = 0.9, 0.95$, are estimated using 1,000 samples of dimension $n = 50, 100$ simulated from an AR(1) model with the last observation fixed to $y_n = 1$ and assuming $y_0 = 0$; indeed, we consider $\mu = 1$, $\sigma^2 = 1$ and (a) $\rho = 0.5$, (b) $\rho = 0.8$. The prediction regions have dimension $m = 5, 10$ and $\alpha_i = \alpha^{1/m}$, $i = 1, \ldots, m$. The bootstrap procedure is based on 1,000 conditional bootstrap samples. The results are in accordance with the theoretical findings and show that the improved bootstrap-based procedures remarkably improve on the estimative ones. The improvement is more pronounced when the dimension m of the future random vector is high with respect to n. Moreover, the bootstrap-calibrated technique seems to improve the coverage accuracy of the marginal estimative prediction limits as-well, accounting also for the dependence among the component prediction limits. This is an important point which require further attention.

Finally, we conclude this section by presenting the following Figure 1, which describes a simulated path of dimension $n = 80$ from an AR(1) Gaussian model with $y_0 = 1$, $\mu = 1$, $\sigma^2 = 1$ and $\rho = 0.5$, and a sequence of $m = 50$ future simulated observations generated from the same model. Moreover, we draw the sequence of estimative and improved simultaneous prediction intervals with level $\alpha_i = 0.9$, together with the estimative and improved marginal prediction intervals with the same nominal level. The simultaneous prediction intervals account for the actual evolution of the interest time series. Note that, using the bootstrap-based approach, the

Table 1 AR(1) Gaussian model with $\mu = 1$, $\sigma^2 = 1$ and (a) $\rho = 0.5$, (b) $\rho = 0.8$. Conditional coverage probabilities for the simultaneous (estimative and improved) and marginal (estimative and improved) prediction limits of level $\alpha = 0.9, 0.95$, with $m = 5, 10$. Estimation is based on 1,000 Monte Carlo conditional (on $y_n = 1$) samples of dimension $n = 50, 100$, with $y_0 = 0$. The bootstrap procedure is based on 1,000 conditional bootstrap samples.

Data Management

Using web scraping techniques to derive co-authorship data: insights from a case study

Utilizzo di tecniche di web scraping per derivare reti di co-authorship: evidenze da un caso studio

Domenico De Stefano, Vittorio Fuccella, Maria Prosperina Vitale, Susanna Zaccarin

Abstract The aim of the present contribution is to discuss the first results of the application of web scraping techniques to derive co-authorship data among scholars. A semi-automatic tool is adopted to retrieve metadata from a platform introduced for managing and supporting research products in Italian universities. The co-authorship relationships among Italian academic statisticians will be used as basis to analyze updated collaborations patterns in this scientific community.

Abstract *Il presente contributo riporta i primi risultati delle procedure di web scraping utilizzate per ottenere dati sulla co-autorship tra studiosi. Uno strumento semi-automatico è stato utilizzato per estrarre i metadati delle pubblicazioni da una piattaforma online introdotta per la gestione dei prodotti della ricerca delle università italiane. Le relazioni di co-authorship tra gli statistici italiani saranno utilizzate come base per individuare i patterns di collaborazione recenti.*

1 Introduction

Several bibliographic sources are available online to retrieve co-authorship relations to analyze scientific collaboration among groups of scholars. Usually, scientific collaboration studies are based on international databases (e.g. ISI-WoS or Scopus) containing high-impact publications. Whereas the interest is to describe collaboration patterns among scholars involved in a field and/or affiliated to an institution, these sources can provide a partial coverage of their scientific production. Hence, it emerges the need to integrate these results by using local bibliographic archives. In addition, the complexities related to the scraping data process from heterogeneous online sources at international and national level, often including different data format, are well-recognized (7; 8; 6). Data mining tools have been introduced for this topic highlighting the strengths and weaknesses of each of them (7).

In this scenario, scientific production of the Italian academic scholars can be retrieved from general and thematic international bibliographic archives as well as national ones (2). To describe collaboration in the national academic community, publications can be collected from individual web pages ("sito docente"), managed by the Italian Ministry of University and Research (MIUR) and the Cineca consortium. Unfortunately, the access to this database is not freely available, due to privacy policies.

The recent introduction of the Institutional Research Information System (IRIS) developed by Cineca consortium seems to furnish a unique platform in Italy for managing and supporting research in academic and research institutions. Within this system, it is available an open archive module for the repository of the research products allowing the storage, the consultation and the enhancement of these outputs. Thanks to this tool, the affiliated universities can access to a system able to communicate with the national (i.e. "sito docente" of MIUR) and international databases for the management and dissemination of scholars' scientific publications. Considering the list of institutions affiliated to the IRIS platform,[1] 65 Italian universities out of 97 [2] (in which 67 are public universities, 19 private universities and 11 private online universities) adopt the IRIS platform for publications data storage.

The aim of the present contribution is to discuss the main results of the first step of web scraping procedures, before to obtain clean data to derive co-authorship relationships among scholars. A semi-automatic tool is adopted to retrieve publication metadata from the IRIS platform with the purpose of automatically extract the data from the system in order to obtain a good coverage of the author scientific production and reducing the manual adjustments to manage errors. The derived co-authorship relationships among Italian academic statisticians, considering the publications until 2017, will be used as basis to derive updated collaborations patterns in this scientific community. The contribution offers also the possibility to compare

[2] For detail see http://www.miur.gov.it/istituzioni-universitarie-accreditate.

the results with the previous network analysis carried on the same target population with data updated to 2010 (2; 3).

The paper is organized as follows. Section 2 reports details on the population under analysis and on the web scraping procedure adopted to extract data from the IRIS system. Section 3 traces the directions of the further network analysis.

2 Web scraping techniques to extract publications of Italian statisticians

The present contribution deals with the retrieval of proper data to construct co-authorship network in Statistics starting from the IRIS online platform. In particular, we focus on the academic statisticians in Italy, that is, those scientists classified as belonging to one of the five subfields established by the governmental official classification: Statistics (Stat), Statistics for Experimental and Technological Research (Stat for E&T), Economic Statistics (Economic Stat), Demography (Demo), and Social Statistics (Social Stat). The target population is composed of the 721 statisticians who have permanent positions in Italian universities, as recorded in the MIUR database at July 2017. Table 1 reports the composition of the statisticians by Statistics subfields, gender, academic ranking and university geographic location. A comparison with the number of scholars by Statistics subfields with a permanent position in March 2010 is also given (Table 1 in De Stefano et al. 2, p. 373).

Table 1 Italian academic statisticians by Statistics subfields (%) in 2017 and (total) and 2010 comparison. Source: MIUR, March 2010 and July 2017

	All	Stat	Stat for E&T	Economic Stat	Demo	Social Stat

South	31.6	29.7	65.0	29.7	32.9	36.9
Total (July 2017)	721	421	20	145	70	65
Total (March 2010)	792	443	30	160	85	74
Relative difference 2017-2010 (%)	-9.0	-5.0	-33.3	-9.4	-17.6	-12.2

Starting from scraping data techniques, a semi-automated tool based on two main steps is used to retrieve the publication metadata of the population of Italian academic statisticians in the IRIS platform. Indeed, each author has a page from which it is possible to access to the data of his/her publications. The tool is implemented in Java. Besides Java standard libraries to download Web pages, the Tagsoup library[3] is used for parsing well-formed or even unstructured and malformed HTML. This tool is programmed with the aim of automatically extract the data from the system obtaining a good coverage of the author publications and reducing the manual adjustments to manage errors or uncertainty conditions.

The input information is a table containing references (name, surname and academic institution) of the 721 statisticians.

In the *first step*, the URL of IRIS page is retrieved for each author. It is worth noting that each institution hosts a different deployment of the system, thus each statistician is linked to the index page of the IRIS deployment of his/her institution. Then a query is launched on a specific search by author interface available on the system. The interface responds by outputting a Web page containing a list of authors indicated by name and surname, each associated with a link to the author's page. The last name of the author is used as a query string and both author's name and surname are considered to match an item in the list. In the case of a single match, the link is directly captured. In case of no match or multiple matches, the procedure returned an error. As a result of the first step, the complete database of publications records for each author is available. The author's page contains the list of publications of which the person is co-author. If an author has more than 100 publications, these are necessarily split into multiple pages. Each publication in the list is associated to a link to a new page containing the details of the publication (title, authors, venue, year of publication and various identifiers –URL, DOI, ISI codes WoS and Scopus and so on).

In the *second step*, the proposed web scraping procedure retrieved and followed the links of each author publication in order to download these metadata. In a few cases, it will be necessary to manually retrieve the link to the author's publication pages to check the aforementioned errors and to integrate the retrieved metadata for the authors not found by the tool. The complete database of publication records for each author derived at step 2 reports information for the entire population of statisticians. It could contain many duplications in presence of publications co-authored by statisticians affiliated to different institutions. Indeed, in each IRIS system the same publication can be reported with a different format. To manage this issue, it is therefore necessary a further phase of record linkage, in which the records corresponding to the same publication are automatically reconciled. Where available, the correspondence of any of the aforementioned authors' identifiers allowed a sure identification of the match. In case of lack of unique identifiers, the records can be reconciled using information related to the title, list of authors and year of publication, following the procedure described in Fuccella et al. (3).

The aforementioned procedure allowed us to obtain a good coverage of the target population of authors in the first data extraction phase from IRIS platform. The metadata of the publications of around 80% of all statisticians is available from the

[3] For details see https://hackage.haskell.org/package/tagsoup.

extraction made in April 2018. After a manual check to integrate the retrieved metadata, we improved the coverage rate for all subfields (Table 2). This result seems almost in line with the authors' coverage obtained by using three different archives (Table 2 in De Stefano et al. 2, p. 374).

The tool returned zero publications for some authors, especially belonging to the Statistics and Economic Stat subfields. These errors are mainly due to the absence of the IRIS platform in some institutions (mainly private and online universities) and limitations to its access (i.e., a password is required to access to the system). Errors happened also when the author search returned more than one match.

Table 2 Statisticians found before and after manual check and descriptive statistics of the retrieved publications by Statistics subfields

	Authors			Publications				
	Found	Manual check	% found	Min.	Max.	Median	Average	Dev.ST.
All	555	82	88.3	1	333	50.0	56.4	38.0
Stat	319	54	88.6	1	292	49.0	54.9	34.6
Stat for E&T	18	2	100.0	8	126	46.0	55.5	34.1
Economic Stat	110	11	83.4	2	196	42.0	45.2	29.1
Demo	55	8	90.0	12	314	55.0	68.2	48.6
Social Stat	53	7	92.3	8	333	68.5	75.6	50.1

Focusing on the retrieved bibliographic data, several issues affect the data quality. First, the IRIS platform content is different and independent for each university and there is no automatic procedure that allows to match the same publication co-authored by authors enrolled in different institutions. Therefore for each co-authored publication, a number of duplication of this product equal to the number of the co-authors hired by different universities can be found. Second, the imputation of some crucial fields for the network construction –e.g. the name of the external authors– is up to the individual researcher and for this reason it can happen that same author names can be typed in several ways.

Both product and author name duplications should be addressed before the co-authorship network construction by adapting to this context the procedure proposed in Fuccella et al. (3).

3 Final remarks and future lines of research

The availability of the IRIS archive is certainly a promising tool but a lot of issues must be managed during the data collection process from this source. The unavailability of IRIS platform in some universities, the private access to the IRIS system in some cases, the different publication data format, and the presence of more than one record found for the same author are examples of errors obtained after the extraction of information. In addition, record linkage and author disambiguation processes need to be taken into account to obtain co-authorship data among scholars affiliated in different universities.

After the data cleaning to reconcile publication records, the detection of duplicates and the recognition of internal and external authors of the same publications, the co-authorship networks will be derived. In line with the findings discussed in the previous contributions, the advancements of the current study will be devoted to two main directions of analysis. First, the interest is in discovering clusters of scholars through community detection algorithms, comparing results from two well-known community detection algorithms (4; 1), and a new proposed method based on an adaptation of modal clustering procedure (5). Second, the stability of research groups and of collaboration behaviors will be analyzed in order to capture the effect of research assessment exercises, introduced in Italy to evaluate researchers and their scientific production.

Dealing with Data Evolution and Data Integration: An approach using Rarefaction

Luca Del Core, Eugenio Montini, Clelia Di Serio, Andrea Calabria

Abstract Heterogeneity and unreliability of data negatively influence the effectiveness and reproducibility of the results in all fields involving sampling techniques. Heterogeneity is mainly due to technological advances which imply improvements in measurements resolution. Unreliability or under-representativeness in data may be due to machine/software or human variances/errors, or other unidentifiable external factors. In the era of big data, technological evolution, and continuous data integration, scientists are increasingly facing with the problems of how to (1) identify and filter-out unreliable data, and (2) harmonize samples gauged with different platforms improved over time. This work is aimed at developing a new statistical framework to address both issues, showing results in real case scenarios.

Key words: Heterogeneity, Rarefaction, Filtering, Abundance Models, Species Pooling, Generalized Nonlinear Models, Hurlbert-Heck Model, Entropy, Integration Sites, Gene Therapy.

Motivation and background

Nowadays, with the advent of high throughput technologies, new statistical challenges are aimed at combining large heterogeneous datasets produced under different platforms having different efficiency, reliability and resolution. This is the case of biomedical data, where the follow-ups of a clinical cohort of patients under treatment may last over several decades and the monitoring of patient health-care must benefit by the biotechnological improvements continuously consolidated. Therefore, new statistical methods are required to understand how to consider, within a unique framework, time series that are observed over a long period, and how to distinguish whether the increased number of events is attributable to the change in technology rather than to the disease change itself. Thus, it is crucial to obtain reliable and harmonized time-course data, addressing the problems of (1) the identification and filtering of unreliable data, and (2) how to scale heterogeneous integrated data to obtain consistent results in the application domain. This work is proposed as a first step towards a mathematical/statistical solution of both problems.

Material and Methods

The filtering problem is addressed through the expected richness estimation via the Hurlbert-Heck (HH) curve[1, 2] and the Species Pooling (SP) methods[3, 4, 5] for an estimation of the unseen species. The base statistical methods have been previously applied in ecological and population-based studies. We exploited the Generalized Nonlinear Model (GNM) as an estimator of the HH curve properly rescaled. Then, using an empirical approach, we identified a minimum threshold for the richness over the whole cohort of data to filter out under-representative observations. To address the problem of data integration for reproducible results over continuous technological improvements and the scaling problem, we used a Rarefaction Method[1, 2].Both methodologies have been applied in biomedical science using molecular data (retroviral vector integration sites, IS) of Gene Therapy (GT) clinical trials, a good case study for the presence of heterogeneous data. The filtering technique is used basing on the richness in distinct number of ISs. The rarefaction approach allowed improving data integration of IS by rescaling data in order to obtain rarefied population measures (such as entropy indexes[6, 7]) that are more robust and homogeneous than the un-scaled ones, thus potentially improving the assessment of safety and long term efficacy of the treatment. A discussion of results is finally presented.

Results

Filtering Unreliable Data

Dealing with biological and molecular data, such as IS in GT studies, means dealing with high variability in data collection and sampling, due to the high variability of the available biological material (for example the different amount of DNA used in each test). Thus, the number of retrieved IS from each patient at different time points (IS_s Richness) may vary. Therefore, we have to evaluate the level of richness for each sample and filter-out those samples with an insufficient level of IS richness. To overcome this problem, the percentage $S_{\%}$ of richness in IS_s observed over the total can be defined as the ratio between the observed richness S and an estimator of the whole theoretical richness $\hat{S}_{tot}$, namely $S_{\%} = S/\hat{S}_{tot}$. The theoretical richness $\hat{S}_{tot}$ can be estimated in different ways, depending on the chosen Sampling Pooling (SP) technique[3, 4, 5]. In this work, the SP estimator is chosen based on the best Ranked Abundance Distribution (RAD)[8, 9] together with a p-leave out cross validation. Namely, if the general lognormal (gln) curve is chosen as the best AIC_c[10] RAD model among the candidates[1], or if, according to a χ^2 Goodness of Fit test, the gln distribution can be used in place of the optimal one, then the Preston estimator $\hat{S}^{tot}_{Preston}$[3] is used. Otherwise the performance of Chao and ACE estimators is compared[11] via a uniform leave-$p = .3$-out cross validation: the whole sample is considered as the sampling universe with a known total richness S_{obs} and the $[0,1]$-bounded quantity[2]

$$A^{est}_{absolute} = \min\{S_{obs}, \hat{S}_{est}\}/\max\{S_{obs}, \hat{S}_{est}\}$$

is used to compare the performance of the two non-parametric estimators. The more the accuracy of the estimator, the greater $A^{est}_{absolute}$ is: therefore, the estimator $best = argmin_{est}\{A^{est}_{absolute}\}$ is chosen if the gln distribution is rejected as RAD model. Also, in order to assess the accuracy of the species pooling estimator chosen among the candidates, during the $nFld = 100$ p-leave-out cross simulations, three additional accuracy indexes are calculated and compared with $A^{best}_{absolute}$. These are defined as

$$A_{effective} = 1 - |.7 - S^{0.7}_{obs}/\hat{S}^{0.7}_{tot}| \qquad A_{relative} = 1 - |S^{0.7}_{obs}/\hat{S}^{0.7}_{tot} - S^{1}_{obs}/\hat{S}^{1}_{tot}|$$

$$A_{cumulative} = \min\{\hat{S}^{0.7}_{tot}, \hat{S}^{1}_{tot}\}/\max\{\hat{S}^{0.7}_{tot}, \hat{S}^{1}_{tot}\}$$

where $S^{0.7}_{obs}$, $\hat{S}^{0.7}_{tot}$, S^{1}_{obs}, $\hat{S}^{1}_{tot}$ are the observed and estimated (using the chosen estimator) total richness in the 70% fold and in the whole sample respectively. By definition, they are $[0,1]$ bounded and the more the accuracy, the greater they are. As an

[1] Geometric Series, MacArthur's Broken Stick, Zipf-Mandelbrodt, Zipf, General lognormal are the candidate RAD models in the case study. All these distributions are fitted with the Maximum Likelihood Estimation (MLE) technique.

[2] $\hat{S}_{est}$ is the estimation of the total richness S_{obs} obtained using the the estimator $est \in \{Chao, ACE\}$ using the 70-random subsample.

example, these indexes are calculated in the case study, together with $A^{est}_{absolute}$, and the results are shown in Fig.1(a). Furthermore, in order to check robustness with respect to little variations, the model selection and inference are performed on a fixed number *nRnd* of binomial randomizations of the original data.

Therefore, a set of $S_{\%}$'s is collected among all the samples, and a minimum threshold for this quantity is identified to filter out under-representative observations. Without any ground-truth available, we used an empirical approach in which the shape of the $S_{\%}$'s empirical cumulative distribution (eCDF) is analyzed, and we selected as threshold (if existing) the main concave/convex inflection point over the eCDF curve[3], which could be interpreted as a signal of multimodal distribution. Then, a Generalized Pareto Distribution (GPD) is fitted on the excesses above that threshold (POT method[13]) and a QQ-plot between the empirical and GPD quantiles could provide feedbacks on the quality of the fitting such that an higher quality corresponds to a better overlap of the curve to the main diagonal. This method was applied in our case study and the results are shown in Fig.1(b,c).

Another interesting question to deal with is the saturation problem: finding the total abundance Ab_{tot} needed to reach a certain percentage level p of richness, say the 90%. For this reason, the Hurlbert-Heck (HH) rarefaction curve[1, 2] $E(S)$ is calculated, over a properly chosen grid of rarefaction levels of total abundance, as a pointwise estimation of the expected richness associated with each rarefaction level. Then a family of generalized nonlinear models defined by a log-linear mixture regression function $E(Y) = g^{-1}(\alpha log(X) + \beta X)$ and binomial distribution for the response variable with *probit*, *logit*, *cloglog* as candidate link functions g are applied on the percentage ratio $S^{\%} = E(S)/\hat{S}_{tot}$ over Ab_{tot}, and the one with the maximum R^2 index is chosen. Also, in order to calculate the total abundance $Ab^{p\%}_{tot}$ associated with a certain percentage level p of richness, the regression function was inverted via the numerical resolution of the Lambert function $W(z)e^{W(z)}, z \in \mathbb{C}$. In Fig.1(d) a graphical representation of the percentage HH curve and its regression estimator are shown for one sample of the case study.

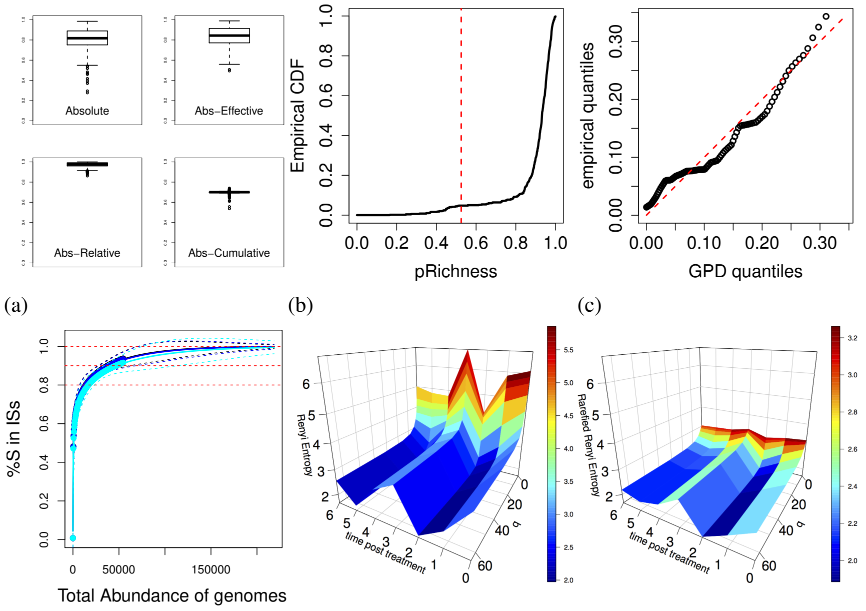
Scaling of the Heterogeneous Data

Another problem regarding the IS_s data being analyzed in the case study concerns the reliability of data interpretation due to the different orders of magnitude in total abundance Ab_{tot}, and indeed in richness S_{obs}, of IS_s reached in each sample mainly due to the variation in resolution of the gauge instruments adopted during time.

Therefore, in order to compare any measure of safety obtained in each sample (e.g. an entropy index), the whole cohort of data should be first rescaled to the same magnitude level of total abundance. In this work, the minimum total abundance level $Ab_{raremax} = \min_{samples} Ab_{tot}$ among the samples is used as rarefaction level.

[3] The eCDF inflection points are found via the Extremum Distance Estimator (EDE) algorithm [12].

Then, a rarefaction technique[2], which essentially consists in random subsampling with proportional abundances $p_i = Ab_i/Ab_{tot}$ as probability weights with Ab_i the abundance of the i-th species in the original sample, is applied in order to generate a rarefied version of that sample. This results in a more homogeneous pool of samples which can be used for entropy measures comparison during time of therapy. As an example, the Renyi Entropy Spectre (RES)[7] is calculated on the IS_s data of the case study, before and after rarefaction. The results are shown in Fig.1(e,f).



(a) (b) (c)

(d) (e) (f)

Fig. 1: (**a**) From top-left, the boxplot of the Absolute, Effective, Relative and Cumulative accuracy indexes are shown respectively. (**b**) The empirical CDF associated with the collected sample of $S^{\%}$. The vertical red highlighted line represents the threshold $S^{\%}_{thr}$ estimated via the EDE algorithm. (**c**) The scatterplot between the empirical quantiles associated with the excesses below that threshold and the GPD quantiles fitted on the same quantities. (**d**) The Hurlbert-Heck curve rescaled by the sampling pooling species estimators $S^{tot}_{Preston}$, S^{tot}_{Chao}, S^{tot}_{ACE} are drawn in black, blue and cyan. The observed and predicted ratio $S^{\%} = S_{obs}/S^{tot}$ are respectively represented by the thick and thin lines. The 80%, 90% and 100% richness thresholds are also shown as red dotted lines. This figure is related to a single sample. (**e**) The Renyi Entropy Spectre is shown during time of therapy on the heterogeneous (un-rarefied) and (**f**) homogeneous (rarefied) samples respectively.

Discussion and Conclusion

As a result of the filtering method, some of the correlations expected to be biologically relevant (e.g. between DNA nanograms DNA_{ng} and total abundance Ab_{tot} in IS_s) slightly increased, suggesting to further characterize the discarded samples.

Moreover, the comparison between the non-rarefied and rarefied entropy curves shows the positive effect in data harmonization by reducing the fluctuations in results due to change in sampling technology. These findings shed lights on reliability and reproducibility in continuous data integration over improvements in technological changes, critical challenges in the era of big data and improvements in high-throughput technologies. Species diversity could also be better addressed using the Renyi Entropy Spectre, where the effect of most abundant clones is visible at higher levels of q.

In conclusion, this work provided new methods to address the data integration and rescaling from technological sources continuously evolving and the problem of filtering unreliable data. Both problems approach the reproducibility of results in science even over time, and data accuracy and reliability.

Monitoring event attendance using a combination of traditional and advanced surveying tools

Monitoraggio della partecipazione agli eventi tramite la combinazione di strumenti tradizionali e nuove tecnologie

Mauro Ferrante, Amit Birenboim, Anna Maria Milito, Stefano De Cantis

Abstract This paper will describe the research stages and tools used for monitoring participants' attendance at the European Researchers' Night, held in Palermo in September 2017. A combination of traditional survey instruments and new technologies was effected in order to analyse participants' behaviour during the event. The results derived from these different data sources were also integrated and analysed in order to evaluate the success of the event from social and economic points of view. Data relating to participants' mobility during the event will be described and clusters of participants proposed, based on their mobility behaviour.

Abstract *Il presente articolo descrive le fasi della ricerca e gli strumenti utilizzati per lo studio del comportamento dei visitatori alla Notte Europea dei Ricercatori, svoltasi a Palermo nel Settembre 2017. Viene proposta l'integrazione di strumenti di rilevazione tradizionali con l'utilizzo di nuove tecnologie per lo studio del comportamento dei visitatori durante l'evento. I dati derivanti dall'integrazione di più fonti informative sono stati analizzati al fine di valutare il successo dell'iniziativa dal punto di vista economico e sociale. Vengono inoltre descritti i dati relativi alla mobilità dei vistatori e vengono proposti dei cluster di partecipanti sulla base del loro comportamento in termini di mobilità.*

1 Introduction

The monitoring and measurement of participant attendance at events is particularly relevant for a number of reasons. Beyond providing information to organisers and sponsors regarding the popularity of an event, it is a fundamental prerequisite for measuring the economic, social and environmental impacts of events [1]. Given these premises, the aim of this work is to describe the various research stages, the survey instruments used, and the main results of a survey performed during the European Researchers' Night, held in Palermo in September 2017. An integration of traditional survey instruments and new technologies was implemented, the aim of which was to collect information regarding the event attendance. Data relating to the participants' profile and their behaviour during the event were collected and analysed in order to characterize participants' behaviour, motivation, and satisfaction during the event. The results are of relevance for both sponsors and organisers alike for planning and management similar initiatives in the future.

2 Data and Methods

On the occasion of the second edition of the *Sharper* European Researchers' Night project, a research team from the University of Palermo planned a survey during the event, the aim of which was to monitor and evaluate participants attendance, behaviour and satisfaction at the event. This event is supported by the European Commission as a part of the Marie Skłodowska- Curie actions and funded by the Horizon 2020 programme, a stated aim of which is to boost the careers of researchers. The survey made use of an integration of several survey tools, including: i) an infra-red beam counter; ii) a questionnaire distributed at the beginning of the event (the *opening questionnaire*); iii) a smartphone App 'Sensometer'; iv) GPS devices and v) a questionnaire distributed at the close of the event (the *closing questionnaire*).

There was no charge to enter the event. In order to measure the number of participants attending the event, an infra-red beam counter was placed in the main entrance of the Botanical Garden, the main venue, to count the total number of those entering and exiting during the event. This information were used to monitor the smooth running of the event and to obtain ex-post information useful for sampling purposes. The opening questionnaire was administered to a sample of participants and aimed at collecting information regarding participants' profile, motivation and expectations. This sample was selected according to a pseudo-systematic procedure, with a sampling interval of 1 every 20 participants joining the event. It was requested that every sampled participant download and use a smartphone app 'Sensometer'. The app collected information on participants' mobility during the event and it enabled pictures of the most 'liked' aspects of the event to be sent to the research team. A sub-sample of participants also received a GPS device which collected more accurate information on participants' mobility during the event. In order to easily recognize each sampled unit at the end of the visit, a numbered badge was provided to each participant. At the end of the visit, every sampled participant was asked to return the GPS device (where given), and to answer a closing questionnaire. The aim of the latter was to: collect post-visit information relating to satisfaction of the visit, the intention to revisit, the intention to recommend the event to friends and relatives, and a question relating to the willingness to pay for similar events in the future. Finally, the impact of the event on the participants' opinion of the University of Palermo was evaluated by means of pre-visit and a post-visit questions. In order to analyse the results, the data obtained from the various survey instruments used (two questionnaires, the smartphone app, and GPS devices) and data quality evaluation were merged. The GPS trajectories of participants were compared and participant clusters were created which were based on the similarities of their trajectories. A Dynamic Time Warping (DTW) algorithm was used to measure the distance among trajectories. This is an algorithm for measuring distance between two temporal sequences, and it was applied to obtain a distance between GPS tracking [4]. The major advantage of DTW over Euclidean distance is its ability to take into account the stretching and compression of sequences. As a result, this method produces a distance-like metric, which is independent of the velocity of the two temporal sequences. The DTW algorithm remaps the time indexes of two series X and Y to produce series of the same length T, which are termed warping curves $\phi(k) = (\phi_x(k), \phi_y(k))$ with $k = (1, \dots, T)$. The monotonicity of the warping curve is usually imposed as a constraint in order to preserve time ordering. The DTW distance can, therefore, be defined as the minimum Euclidean distance between each warping curve:

$$DTW = min_{\phi} \sum_{k=1}^{T} d(\phi_x(k), \phi_y(k))$$

However, when comparing alignments between time series of different lengths, it is usually appropriate to manage an average per-step distance along the warping curve. Therefore, the DTW distance is divided by the number of steps of the warping curve T [3]. Having obtained the distance matrix among the trajectories, in order to segment participants in relation to their behaviour, an average linkage hierarchical clustering was implemented [2]. More peculiarly, an agglomerative approach was used by initially assigning each observation to its own cluster, then by computing the similarity between each cluster and recursively joining the two most similar.

3 Results

The fact that there was one entrance to the event (Fig. 1a) facilitated the use of an infra-red beam counter, which counted the number of participants attending the event: a total of 1,815 entrances and 1,819 exits were recorded throughout the period 18:30 to 00:00. Regrettably, the device malfunctioned for 16.4 minutes, representing 5% of the total time recorded (332 minutes). By considering the difference between numbers of exits and entrances, it is possible to determine the number of people attending the event over time. The number of people attending the event in a 10 minute time interval is reported in Fig. 1b. A peak of attendance was observed at around 22:00, and, at 23:00 (the time when the event officially closes), more than 400 people were still present until midnight when the event closed its doors. Table 1 reports the descriptive statistics for the main variables, which were collected from the opening and closing questionnaires. The majority of participants were young, well-educated and residing in Palermo. Approximately 20% of participants interviewed were returnees with a relatively high share of participants (62%) agreeing to download the mobile app. The majority of participants expressed a high degree of satisfaction with the event, many of whom felt they could recommend the event to friends and relatives. A positive impact of the event on the opinion of the University of Palermo was observed, with 44.1% of participants interviewed declaring an improvement in their opinion after the event.

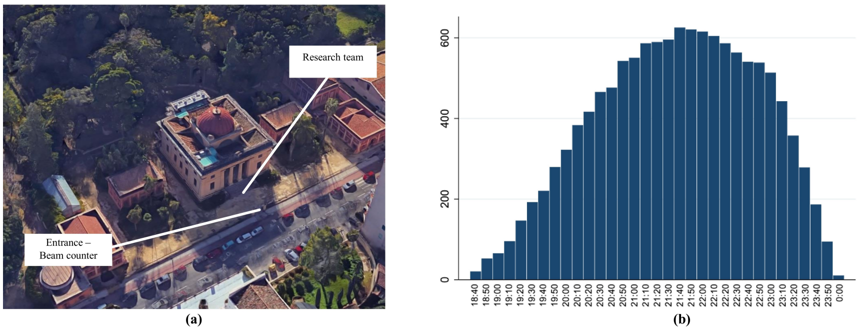

Fig. 1 Event site and survey setting (a), and number of people attending the event at 10 minutes time interval (b)

In terms of participants' behaviour at the event, a comparison of the results obtained from the mobile app and GPS devices demonstrated clearly better performances for the latter compared to the former. Indeed, the low quality of the data collected with smartphone app (missed observations, many observations with the same coordinates, irregular data collection time interval, etc.) led the authors of this paper only to analyse GPS tracking, albeit from a limited number of participants (approximately 20). After the pre-processing of GPS tracking data, the degree of similarities between each pair of trajectories was measured with the DTW algorithm. The implementation of hierarchical clustering and visual examinations of clusters of trajectories, led us to choose four clusters. Patterns of participants' mobility belonging to each cluster are reported in Fig. 2, in which the height of each polygon is proportional to the average time spent in each cell, and the colour is related to the number of participants in each cell. Differences among the identified mobility cluster patterns may be highlighted. Cluster 4 comprises those participants who had did not remain for long at the event. They made short stops at the various event sites, with little or no deviation from the circular area around the main building in the Botanical Garden. These participants spent about 1 hour at the event, and their trajectories were on average 1.7 kilometres length. Participants belonging to cluster 3 remained the longest at the event (about 2 hours) and walked the most (2.7 kilometres). The height of these polygons highlights the many stops made at several sites in the event. Similar considerations can be made for clusters 1 and 2, although their trajectories differ among each other.

Table 1 Opening and ending questionnaires: descriptive statistics (n=101).

Variable	**Categories**	%	**Variable**	**Categories**	%
Gender	Male	32.0	Took part to last year's night?	Yes	20.8

	Master or Ph.D.	7.9	Willingness to recommend	Yes	97.8
				Don't know	2.2

4 Conclusion

Events are often used strategically to contribute to the economic development of a region. The monitoring of events is particularly useful when evaluating their cultural, social, economic and environmental impact. Furthermore, it is helpful for event managers to obtain information relating to where, when and how activities take place, and the degree of satisfaction of these experiences. The monitoring of participants' space-time behaviour can, therefore, be said to be critical to supply management. Consequently, the development and implementation of new data collection tools and methods is particularly relevant for the sustainable management

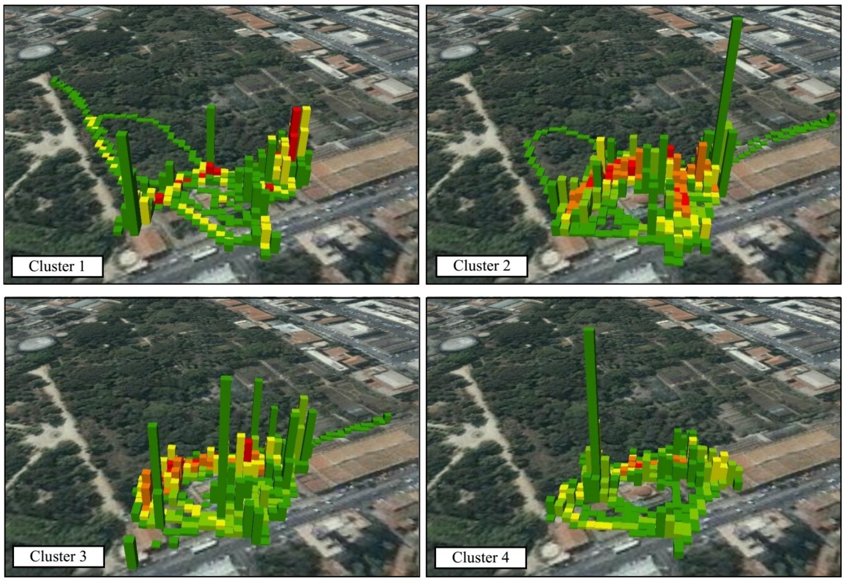

Fig. 2 Patterns of trajectories of clusters of participants

of events. The empirical application presented in this paper highlights the potential deriving from new data collection tools (e.g. GPS devices, electronic counters, etc.) for monitoring and analysing event attendance. The single entry-exit point allowed for the implementation of the presented survey strategy, a discussion on potential solutions in open events, in terms of sampling strategies and counting procedures, represents a clear research line. Moreover, an analysis of participants' characteristics as potential determinants of their behaviour at events represents an important topic for future research. An improved knowledge of participants' behaviour at events may be useful for the implementation of event management policy.

Indefinite Topological Kernels

Kernel Topologici Non Definiti

Tullia Padellini and Pierpaolo Brutti

Abstract Topological Data Analysis (TDA) is a recent and growing branch of statistics devoted to the study of the shape of the data. Motivated by the complexity of the object summarizing the topology of data, we introduce a new topological kernel that allows to extend the TDA toolbox to supervised learning. Exploiting the geodesic structure of the space of Persistence Diagrams, we define a geodesic kernel for Persistence Diagrams, we characterize it, and we show with an application that, despite not being positive semi–definite, it can be successfully used in regression tasks.
Abstract Topological Data Analysis (TDA) è una branca della statistica volta allo studio della "forma" dei dati. Data la complessità delle summaries topologiche, introduciamo una nuova famiglia di kernels per estendere TDA a problemi di apprendimento supervisionato. Sfruttando la geodesica dello spazio delle summaries topologiche, in questo lavoro definiamo un kernel geodesico, lo caratterizziamo e mostriamo con un applicazione le sue performance in un problema di regressione.

Key words: Topological Data Analysis, Kernel Methods, Indefinite Kernels

1 Introduction to Topological Data Analysis (TDA)

Topological Data Analysis TDA is a new area of research in statistics consisting of techniques aimed at recovering the topological structure of data [1, 3]. The interest in the topological structure of data stems from the immediate interpretation of the characterization provided by topological invariants: 0-dimensional features represent connected components, 1-dimensional features represent loops, 2-dimensional are voids and so on. These are all quantity of interest in statistical analysis, as for

Tullia Padellini, Pierpaolo Brutti
Sapienza Universit di Roma, Piazzale Aldo Moro, 5, 00185 Roma,
e-mail: {tullia.padellini, pierpaolo brutti}@uniroma1.it

example connected components correspond to clusters [2] and loops represent periodic structures [7].

If data come in the form of point–cloud $\mathbb{X}_n = \{X_1, \dots, X_n\}$, however, it is not possible to compute such invariants directly. A point–cloud $\mathbb{X}_n$, in fact, has a trivial topological structure, as it is composed of as many connected components as there are observations and no higher dimensional features. `TDA` provides a framework for estimating the topological structure of $\mathbb{X}_n$ by enriching it, encoding data into a filtration. The most common way to do so is to grow each observation point X_i into a ball

$$B(X_i, \varepsilon) = \{x \,|\, d_{\mathbb{X}}(x, X_i) \leq \varepsilon\},$$

of fixed radius ε.

As the resolution ε changes, the topological structure of the *cover*

$$\mathbb{X}_n^{\varepsilon} = \bigcup_{i=1}^{n} B(X_i, \varepsilon),$$

changes as well. When ε is very small, $\mathbb{X}_n^{\varepsilon}$ is topologically equivalent to $\mathbb{X}_n$; as ε grows, however, balls of the cover start to intersect, "giving birth" to loops, voids and other topologically interesting structures. At some point, when connected components merge, loops are filled and so on, these structures start to "die". Eventually when ε reaches the diameter of the data $\mathbb{X}_n$, $\mathbb{X}_n^{\varepsilon}$ is topologically equivalent to a point ball, and again retains no information. The "lifetime" of the generic i-th feature can be represented by a "birth–time" b_i representing the first value ε for which the i-th feature appears in the data, and a "death–time" d_i corresponding to when the feature disappear, i.e. the first value ε for which $\mathbb{X}_n^{\varepsilon}$ does not retain the i-th feature anymore. Birth and death times for all the features in the cover are then summarized in the *Persistence Diagram* $D = \{(b_i, d_i), i = 1, \dots m\}$.

Points that are close to the diagonal have a "short life", in the sense that the features they represent appear and disappear almost immediately and hence may be neglected; on the other hand the "longer" a feature lives, the more important it is in characterizing the structure of $\mathbb{X}_n$.

The space of Persistence Diagram $\mathscr{D}$ is a metric space when endowed with the Wasserstein distance.

Definition 1 (Wasserstein Distance between Persistence Diagrams). Given a metric d, called *ground distance*, the Wasserstein distance between two persistence diagrams D and D' is defined as

$$W_{d,p}(D, D') = \left[\inf_{\gamma} \sum_{x \in D} d\big(x, \gamma(x)\big)^p\right]^{\frac{1}{p}},$$

where the infimum is taken over all bijections $\gamma : D \mapsto D'$.

Depending on the choice of the ground distance d, Definition 1 defines a family of metrics; we focus on the L^2–norm, especially in the case $p = 2$, for which [10] proved that $W_{L^2,2}$ is a geodesic on the space of persistence diagrams.

1.1 Geodesic Topological Kernels

As most statistical learning tools are defined for inner product spaces, the metric structure of the space of persistence diagrams may be limiting, we thus turn to a kernel approach. Roughly speaking a kernel K on a space $\mathscr{M}$ is a symmetric binary function $K : \mathscr{M} \times \mathscr{M} \mapsto \mathbb{R}^+$ which represent a measure of similarity between two elements of $\mathscr{M}$. As every kernel is associated to an inner product space [9], we can use them to implicitely define an inner product space in which it is possible to perform most statistical tasks, from classification to testing, through regression.

Previous attempts in this direction (such as [8]) built kernels on persistence diagrams by considering each point of the diagram individually, thus loosing the structure of the object. In order to consider the diagram as a whole, we propose a kernel which, being based on the Wasserstein distance, preserves information about how points in the diagram are related to each others.

One popular family of kernels for a geodesic metric space $(\mathbb{X}, d)$ is the *exponential kernel*

$$k(x,y) = \exp\left\{d(x,y)^p/h\right\} \qquad p,h > 0$$

where $h > 0$ is the bandwidth parameter; for $p = 1$ this is the Laplacian kernel and for $p = 2$ this is the Gaussian kernel. It is straightforward to use this class to define a *Topological kernel* to be used for statistical learning.

Definition 2 (Geodesic Topological Kernel). Let $\mathscr{D}$ be the space of persistence diagrams, and let $h > 0$, then the Geodesic Gaussian Topological (GGT) kernel $K_{\text{GG}} : \mathscr{D} \times \mathscr{D} \mapsto \mathbb{R}^+$ is defined as

$$K_{\text{GG}}(D,D') = \exp\left\{\frac{1}{h} W_{L^2,2}(D,D')^2\right\} \qquad \forall D,D' \in \mathscr{D}.$$

Analogously, the Geodesic Laplacian Topological Kernel (GLT), K_{GL} is defined as:

$$K_{\text{GL}}(D,D') = \exp\left\{\frac{1}{h} W_{L^2,2}(D,D')\right\} \qquad \forall D,D' \in \mathscr{D}.$$

As opposed to their euclidean counterparts, the Geodesic Laplacian and Gaussian kernels are not necessarily positive definite; as shown in [4], in fact, a Geodesic Gaussian kernel on a metric space is positive definite only if the space is flat, but this is not the case for the space of Persistence Diagram, which has been proved to be curved [10].

2 Application - Fullerenes

Buckyballs fullerenes are spherical pure carbon molecules whose main trait is that atoms' linkage can form either pentagons or hexagons. We will show that our topological kernel can be exploited to predict the Total Strain Energy (measured in Ev) of a molecule from the shape of the molecule, as our Topological Kernel allows us to use Persistence Diagrams as covariates. given a sample $\{X_1,\ldots,X_n\}$ of Fullerenes we model their Total Strain Energy, Y as a function of their Persistence Diagrams $\{D_1,\ldots,D_n\}$:

$$Y_i = m(D_i) + \varepsilon_i$$

where ε_i is the usual 0–mean random error. As in standard nonparametric regression, we can estimate the regression function $m(\cdot)$ with the Nadaraya–Watson estimator[5], which does not require a positive definite kernel.

Moreover, in order to take into account the group structure naturally induced by the isomers, we also considered a model with a fixed group intercept, i.e:

$$Y_{ij} = \alpha_j + m(D_{ij}) + \varepsilon_{ij},$$

where D_{ij} denotes the persistence diagram of the $i^{\mathtt{th}}$ isomer of the $j^{\mathtt{th}}$ molecule. We fit the resulting partially linear model using Robinson's trimmed estimator, as detailed in [6]. We fit the models using data from $n = 535$ molecules of 10 different types of Fullerenes. For each molecule, the data (freely available at http://www.nanotube.msu.edu/fullerene/fullerene-isomers.html consists of the coordinates of the atoms taken from Yoshida's Fullerene Library and then re–optimized with a Dreiding–like forcefield. We focus on features of dimension 1, which recover the structure of the molecule; as we can see from Figure 1, loops in the diagrams are, in fact, clearly clustered around two centers, which represent the pentagons and the hexagons formed by the carbon atoms. Interestingly enough, the Wasserstein distance and, hence, both the geodesic kernels, fully recover the class structure induced by the isomers, as we can see in Figure 3.

	Geodesic Gaussian Kernel	Geodesic Laplacian Kernel
Nonparametric regression	339.89	342.14
Semiparametric regression	1049.02	331.04

Table 1 Residual Sum of Squares.

After choosing the bandwidth h via Leave–One–Out cross validation, we compare the different models in terms of Residual Sum of Squares (RSS). As we can see from Table 1, the two kernels yield similar results when used in a fully nonparametric estimator, while the Laplacian kernel performs better when adding the group intercept to the model. This can be understood by looking at the kernel matrices (Figure 3); the Gaussian Kernel has a sharper block structure than the Laplace Kernel, which makes it better at discriminating the 10 molecule classes. However, when

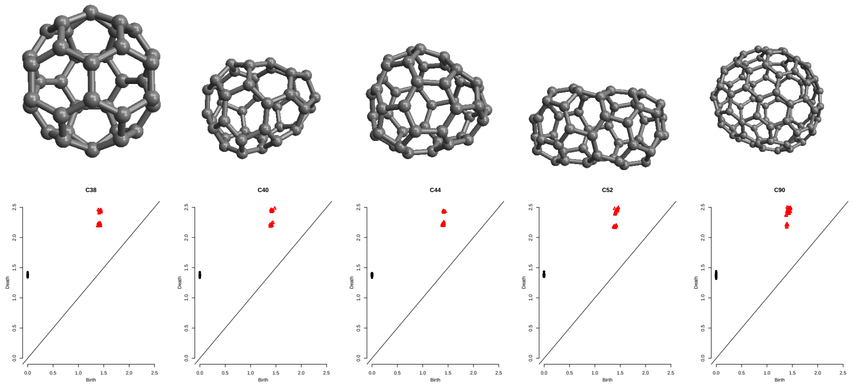

Fig. 1 Topological configurations of some fullerenes (top) and corresponding persistence diagrams (bottom). From left to right: C38(C2v), C40(C1), C44(C1), C52(C2), C90(C1).

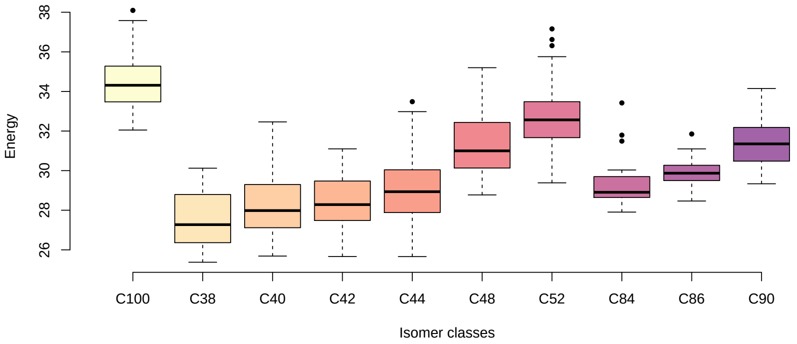

Fig. 2 Energies for the 10 different classes of isomers. It is worth noticing that Fullerenes with higher numbers of atoms do not necessarily have higher energy.

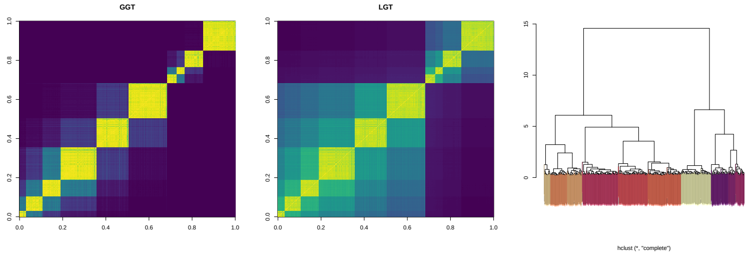

Fig. 3 Kernel Matrix for the Geodesic Gaussian Kernel (left), Geodesic Laplacian Kernel (center), Hierarchical Clustering built from the Wasserstein distance with complete linkage (right). Colors represent the different isomer classes as shown in Figure 2.

the group structure is taken into account by the model itself, this clustered structure leads to worse prediction.

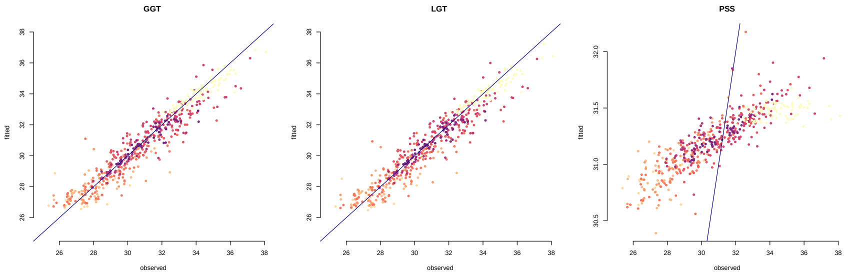

Fig. 4 Observed vs fitted plot for the fully nonparametric model fitted with the Geodesic Gaussian (left), Geodesic Laplacian (center) and the Persistence Scale Space kernel (right). Colors represent the different isomer classes as shown in Figure 2.

Finally, we compare the performance of our geodesic kernels with the Persistence Scale Space kernel K_{PSS}; as we can clearly see from the fitted-vs-observed plots in Figure 4, the positive definiteness of the PSS kernel does not result in more accurate prediction, as both K_{GG} and K_{LG} outperform it.

Data Integration in Social Sciences: the earnings intergenerational mobility problem

Integrazione di dati nelle Scienze Sociali: il problema della mobilità intergenerazionale dei redditi

Veronica Ballerini, Francesco Bloise, Dario Briscolini and Michele Raitano

Abstract Merging operations on two or more datasets has become an usual need for Statistical Institutes in the last few decades. Nowadays social sciences offer the opportunity of a new application of data integration techniques. In this short paper we deal with the problem related to the estimation of the intergenerational earnings elasticity when proper datasets are not available. We compare the classical Two Samples Two Stages Least Squares with "Record Linkage" and "Matching" procedures.
Abstract *Abstract in Italian* La fusione di due o più dataset è ormai da qualche decennio una necessità per gli Istituti di Statistica. Oggi le scienze sociali offrono un'opportunità di nuova applicazione delle tecniche di integrazione di dati. In questo lavoro verrà trattato il problema legato alla stima dell'elasticità intergenerazionale del reddito quando datasets adeguati non sono disponibili. In particolare verrà confrontato l'approccio del Two Samples Two Stages Least Squares con le procedure di Record Linkage e Matching.

1 Introduction

Empirical studies on economic mobility are usually intended to evaluate to what extent economic opportunities of children are associated with those of their parents, by estimating the so called intergenerational income elasticity (IGE) . This measure of mobility is the estimated coefficient of an OLS regression in which the dependent variable Y is the logarithm of permanent earnings (or incomes) of children and the regressor X is the logarithm of permanents earnings of parents. Unfortunately, data which allow to link earnings of sons and their fathers when the two generations were aged approximately the same are barely available in many countries. This the reason why scholars exploit another methodological approach which is called two-samples-two-stages least squares (TSTSLS) (see Björklund and Jäntti [1]). According to this methodology, it is possible to estimate IGEs by exploiting a sample of sons who report some socio-economic characteristics of their fathers and an independent sample of pseudo-fathers i.e. generic individuals taken in the pasts with approximately the same age of actual fathers. The problem of TSTSLS is that it may be biased. In this short paper we propose two different approaches to this issue, “Record Linkage” and Matching”. The paper is organized as follows. The second section describes the formal statistical framework; the third reviews the TSTSLS methodology; the fourth and the fifth illustrate our alternatives to the classical approach. Finally we show an application on a real dataset.

2 The basic statistical framework

Let us suppose we have two data sets, say F_1 of size $N_1 \times (h+1)$ and F_2 of size $N_2 \times (h+p)$. Records in each data set consist of several variables which may be observed together with a potential amount of measurement error. Let us denote the observed variables in F_1 by $(Y, Z_{*1}, Z_{*2}, \ldots, Z_{*h})$, whereas the observed variables in F_2 are $(X_1, X_2, \ldots, X_p, Z_{*1}, Z_{*2}, \ldots, Z_{*h})$. Also suppose that one is interested in performing a linear regression analysis of Y on $X_1, X_2, \ldots, X_p$ restricted to those pairs of records which are declared matches after a record linkage or a matching analysis based on variables $(Z_{*1}, \ldots, Z_{*h})$. The goal of the “merging procedures” is to detect all the pairs of units (j, j'), with $j \in F_1$ and $j' \in F_2$, such that j and j' actually refer to the same unit or j' is the unit in F_2 mostly similar to j .

3 The classical approach

The TSTSLS consists of two sequential steps. In the first stage, earnings of pseudo fathers are regressed on socio-economic characteristics in the main sample according to the following regression:

$$X_{j'} = \alpha + \theta_1 Z^{pf}_{j'*} + v_{j'} \tag{1}$$

where $X_{j'}$ are earnings of pseudo-father j', $Z^{pf}_{j'*}$ is a vector of the socio-economic characteristics of j', α is the intercept and $v_{j'}$ is the usual disturbance. The estimated coefficient $\hat{\theta}_1$ is then used to predict missing fathers earnings by merging the two samples according to child-reported characteristics of actual fathers. The intergenerational earnings (or income) elasticity β is thus estimated in the second stage:

$$Y_j = \alpha + \beta \hat{X}_j + \varepsilon_j \tag{2}$$

where Y_j is the logarithm of son j earnings and $\hat{X}_j = \hat{\theta}_1 Z^{f}_{j*}$ is the prediction of the logarithm of his father earnings (see Jerrim et al. [6]). The more the socio-economic characteristics perform well at predicting fathers economic status, the less estimated elasticities will be biased. More specifically, when one tries to impute fathers economic status, he is likely to make some errors in measuring their income. This reduces estimated elasticities under the assumption of classical measurement error. Moreover, if the set of socio-economic characteristics is not able to capture other characteristics of individuals which are positively correlated across generations, then the elasticity will be again downward biased.

4 Record Linkage

The issues raised in the previous section suggest the necessity of alternative strategies and perspectives. One of this possibilities is represented by direct modeling of the linkage uncertainty. In contrast to heuristic methods of data integration the introduction of a probabilistic model on the linkage step allows to evaluate the quality of the results. Moreover it may represent a more natural and realistic way to deal with the absence of joint information on the variables of interest.

Regression with linked data is well documented in Lahiri and Larsen [7]. Tancredi and Liseo [9] have proposed a Bayesian approach for Record Linkage (see also Briscolini et al. [2]). Let $\tilde{z}_{ijl}$ be the true latent value for field l of record j in data set Z_i and let $\tilde{Z}_i$ $(i = 1, 2)$ be the corresponding unobserved data matrix. Assume the "hit and miss' model by Copas and Hilton [3]:

$$p(Z_1, Z_2 | \tilde{Z}_1, \tilde{Z}_2, v) = \prod_{ijl} p(z_{ijl} | \tilde{z}_{ijl}, v_l) = \prod_{ijl} \left[v_l I(z_{ijl} = \tilde{z}_{ijl}) + (1 - v_l) \xi(z_{ijl}) \right] \tag{3}$$

The above expression is a mixture of two components: the former is degenerate at the true value while the latter can be any distribution whose support is the set of all possible values of the variable Z_{*l}, with $l = 1, 2, ..., h$.

As in Tancredi and Liseo [9], let C be a $N_1 \times N_2$ matrix whose unknown entries are either 0 or 1, where $C_{jj'} = 1$ represents a match, $C_{jj'} = 0$ denotes a non-match.

Assume that each data set does not contain replications. Also, assume that the joint distribution of $\tilde{Z}_1$ and $\tilde{Z}_2$ depends on C and on a probability vector θ which describes the distribution of the true values of Z_1 and Z_2. In detail, assume that

$$p(\tilde{Z}_1,\tilde{Z}_2|C,\theta) = \prod_{j:C_{jj'}=0,\forall j'} p(\tilde{z}_{1j}|\theta) \prod_{j':C_{jj'}=0,\forall j} p(\tilde{z}_{2j'}|\theta) \prod_{jj':C_{jj'}=1} p(\tilde{z}_{1j},\tilde{z}_{2j'}|\theta) \quad (4)$$

where $p(\tilde{z}_{ij}|\theta)$ and $p(\tilde{z}_{1j},\tilde{z}_{2j'}|\theta)$ are specific probability distributions depending on θ. The record linkage model has to be combined with the regression model in order to estimate the IGE. To complete the model, a prior distribution must be elicited for the matrix C, ν, θ and the regression parameters. The posterior distribution is not available in closed form: MCMC samples are required.

5 Statistical Matching

A valid alternative to the record linkage procedures described above is statistical matching. Although this integration technique may seem similar to record linkage, they address two different problems. On the one hand, contrarily to record linkage, matching procedures deal with observed units that are not overlapping. On the other hand, statistical matching does not take into account the possibility of measurement errors. To the aim of this work, we only focus on the so called micro approach of statistical matching (see D'Orazio [4]), i.e. the approach whose purpose is the generation of a synthetic dataset with complete information on both the variables observed only in one of the files and those observed in common. In practice, through the micro approach we are able to match records according to the related key variables. We assume that the samples belonging to the different files are generated from the same unknown distribution $f(Y,X,Z)$. In this framework, an example of statistical matching method belonging to the micro approach is the Distance Hot Deck (among others, see Rodgers [8]). In the two samples case, the first step consists in assigning to one of the files the role of recipient, i.e. the file that receives information from the so called donor. Secondly, for each record in the recipient file we measure the distance d among the h matching variables of each record in the donor; the pairs of records with the minimum distance become matches. In other words, (j,j'), $j \in F_1$,$j' \in F_2$, is a match if:

$$d_{(jj')} = \min_{j'} |z_{1jl} - z_{2j'l}|, \; j = 1,...,N_1, j' = 1,...,N_2, l = 1,...,h \quad (5)$$

This is valid in the case of continuous matching variables. Ordinal categorical might be associated to continuous variables, yet considering a proper weighting system, accordingly to the meaning and the role of the variable. Instead, distances between non ordinal may be computed assigning 1 if the value of the key variable of the recipient is equal to that of the donor, and 0 otherwise. At the end of the procedure, we obtain a complete dataset. According to the times each record in the donor file can be used as donor, we distinguish the methods of unconstrained (more than once) and constrained (only once) distance hot deck, whose main advantage is to maintain the marginal distribution of the imputed variable.

6 The application

We use the dataset AD-SILC that has been built merging the cross sectional 2005 wave of IT-SILC (the Italian component of the Eu-SILC) with the administrative records - collected by the Italian National Social Security Institute (INPS) - about working episodes and earnings of all individuals interviewed in IT-SILC 2005 since the beginning of their career. To our aims, IT-SILC 2005 includes a specific section about intergenerational mobility where many aspects of family background of the respondents are recorded. Sons, selected in the period 1970-1974, are followed since age 35 up to 39 in the period 2005-2013. Pseudo-fathers are selected in the period 1980-1988 and followed since age 40 up to 44: they were born in the period 1940-1944. Earnings of both generations are averaged. According to the notation introduced in section 2, let F_1 and F_2 be the matrices of records of the younger and the older generation respectively. The sizes of the files are $1509 \times (1+5)$ and $17245 \times (1+5)$ respectively. For each individual belonging to F_1, his full wage (Y), and a set $Z = (Z_{*1}, Z_{*2}, ..., Z_{*5})$[1] of characteristics about his father are recorded. Yet for each individual of F_2, his full wage (X) is recorded along with 5 personal characteristics - the same of Z.

$$F_1 = \begin{pmatrix} Y_1 & Z_{*1,1} & \cdots & Z_{*1,5} \\ \vdots & \vdots & \ddots & \vdots \\ Y_{1509} & Z_{*1509,1} & \cdots & Z_{*1509,5} \end{pmatrix}, F_2 = \begin{pmatrix} X_1 & Z_{*1,1} & \cdots & Z_{*1,5} \\ \vdots & \vdots & \ddots & \vdots \\ X_{17245} & Z_{*17245,1} & \cdots & Z_{*17245,5} \end{pmatrix}.$$

Z_{*1} is used as blocking variable in record linkage steps and, similarly, as donor class in matching procedure (as suggested by D'Orazio [5]). In the latter we assign to Z_{*4} a double role, given its structure: it is first a stratification variable and then it has been used to compute distances. Firstly, the ISCO-08 macro classification of occupation categories is used to create a blocking variable that assumes 9 values. Secondly, through Z_{*4} we compute distances within the macro categories. Z_{*2}, Z_{*3} and Z_{*5} are matching variables.

7 Discussion

As we expected, the estimates obtained through the standard approach are not the same as those provided by the data integration techniques (table 1). Differently from

[1] Z_{*1}: region of residence (ISTAT codification), Z_{*2}: year of birth, Z_{*3}: level of education (ISCED classification), Z_{*4}: occupation category (according to ISCO-08 classification), Z_{*5}: dummy assuming value 1 if the individual is self employed and 0 otherwise.

Table 1 Comparison of different estimators of the regression coefficient IGE

Method	**Point Estimate**	**Standard deviation**
TSTSLS	0.499	0.055
Record Linkage	0.272	0.040
Matching	0.256	0.023

the proposed methods, TSTSLS does not preserve the whole variability of X; the regression coefficient may be overestimated. Since X is only a proxy of the true fathers' income, further analyses including the measurement error seem opportune.

Certainly, record linkage allows to better account for linkage uncertainty with respect to the TSTSLS. Furthermore, it deals with measurement error in the matching variables; this is relevant since sons could have misreported some key information about their fathers. From this point of view, record linkage should be preferred also to statistical matching. On the other hand, as already said in section 5, matching procedures apply to non-overlapping samples. With this respect, statistical matching seems to be more appropriate than linkage procedures. Nevertheless, improving the information provided by the matching variables increases the efficiency of data integration techniques.

An innovative approach for the GDPR compliance in Big Data era

Un approccio innovativo per la conformità al regolamento GDPR nell'era dei Big Data

M. Giacalone, C. Cusatelli, F. Fanari, V. Santarcangelo, D.C. Sinitò[1]

Abstract The present work shows a preliminary overview of the Big Data Analytics scenario, introducing the related privacy issues considered by the new General Data Protection Regulation, better known by its acronym GDPR. The work then introduces an innovative index to assess the compliance of a company with this regulation on the protection of personal data, in terms of privacy by design and privacy by default.

Abstract *Il presente lavoro mostra una preventiva panoramica in merito allo scenario del Big Data Analytics, introducendo le relative problematiche di privacy considerate dal nuovo Regolamento Generale sulla Protezione dei Dati, meglio noto con l'acronimo inglese GDPR. Il lavoro introduce quindi un innovativo indice per valutare la conformità di un'azienda a tale regolamento sulla tutela dei dati personali, in termini di privacy by design e privacy by default.*

Key words: GDPR, privacy, Big Data

1 Introduction

We live the historical moment of the Big Data boom, but even more often we realize that those who use this phrase do not really know its meaning: to understand well what Big Data is, we need to understand the deep meaning of the expression and how its influence can be noticed in everyday life. It is important to start by saying that the same phrase "Big Data" is somewhat misleading as it suggests the enormous amount of data available today in different sectors and, automatically, leads to the conclusion that Big Data revolution means opportunities to have so much information available

[1] Massimiliano Giacalone, Department of Economics and Statistics, University of Naples "Federico II"; massimiliano.giacalone@unina.it

Diego Carmine Sinitò, iInformatica S.r.l.s., disinito@iinformatica.it

for business. This conclusion is only partially true, because there are sectors where data, although in large quantities, are not always available to everyone and, above all, are not always shared.

If Information Technology (IT) represents for Big Data the point from which to start with the necessary tools such as cloud computing, search algorithms, etc., on the other hand Big Data are necessary and useful in the most disparate business sectors as automotive, medicine, astronomy, biology, pharmaceutical chemistry, finance, gaming, commerce.

In the public sphere, there are many other types of Big Data applications:

- the deployment of police forces where and when the offenses are more likely to occur;
- the study of associations between air quality and health;
- genomic analysis to improve the resistance to drought of rice crops;
- the creation of models to analyze data coming from living beings in the biological sciences.

2 General Data Protection Regulation

As a consequence, the need arises to regulate the use of Big Data with the help of European legislation: the EU 679/2016 General Data Protection Regulation (GDPR) was born from this need, and the aim of this work is to provide an overview of the new legislation and to introduce a new index to measure GDPR compliance (Corrales M. et al, 2017). The GDPR, approved by the European Parliament in April 2016, will enter into force on May 25, 2018. The goal is to harmonize the laws on the confidentiality of information and privacy of all European countries and keep safe the sensitive user data processed by companies, and to limit uses according to the principles of (Anisetti et al., 2018):

- lawfulness, correctness and transparency: data must be processed in such ways;
- limitation of purposes: they must be determined, explicit and legitimate, then clearly identified;
- data minimization: data must be adequate, relevant and limited;
- accuracy: the data must be updated;
- restriction of storage: data must be kept for a limited period of time to achieve the purposes;
- integrity and confidentiality: adequate security of personal data must be guaranteed.

The GDPR, replacing the regulations of the individual European countries that differ from one another, represents an important step forward in terms of standardizing European policies and data protection at the continental level (Torra V., 2017). What changes is the extension of the jurisdiction to all companies that process personal data of subjects residing in the European Union, regardless of the geographical location of the company or the place where the data are managed and processed. Non-European companies that process data of European citizens will also have to appoint an EU representative (Terry N., 2017). It is essential that European companies identify immediately how to adapt to the new legislation, thus avoiding being unprepared to face what is considered the most significant change in the history of data protection over the last 20 years.

It is necessary that companies immediately review their internal processes, placing user privacy as a primary element to guarantee priority and precedence. It is also necessary for companies to strengthen internal corporate communication through specific training programs so that anyone in a position that implies access to personal data of users correctly knows the extent to which they can carry out their profession. The concept of "privacy by design", a fundamental point on which the GDPR is concentrated (D'Acquisto, G., & Naldi, M., 2017) establishes that the data protection measures must be planned with the relative supporting IT applications starting from the planning of the business processes. This implies that only the data that are really indispensable for the performance of one's professional duties are processed and that access to information is limited only to those who have to carry out the processing. Another important point of the legislation concerns the "Breach Notification": data breach notifications are mandatory where the violation can put at risk the rights and freedoms of individuals. The notification must be made within 72 hours from the time the violation is verified and the customers are required to be informed "without undue delay".

The changes that the GDPR will bring are not only linked to the relationship between companies and users, but also concern the internal structure of the company: the new legislation will give greater prominence to the IT team and the company CIOs, making their tasks, nevertheless many managers still consider the GDPR as a waste of money and time, not understanding the importance of data protection today. (Mittal S. & Sharma P., 2017). With the GDPR, the figure of the Data Protection Officer (DPO) is established within the company with the task of monitoring the internal processes of the structure and acting as a consultant: the controllers of the monitoring and data processing activities are still required to notify their activities to local Data Protection Advisors (DPAs) which, for example within multinationals, can be a real bureaucratic nightmare, since each Member State has different notification requirements (Bertino, E., & Ferrari, E., 2018). With the introduction of the DPO, appointed on the basis of professional quality, expert in the field of law and data protection practices and equipped with the appropriate resources, the control of internal data management processes will be simplified.

The new legislation pays particular attention, in addition to what has already been said, to the requests for consent made to the subjects (Cohen M., 2017): the GDPR wants the requests to be submitted to the user in an "intelligible and easily accessible" manner, so that it is immediately clear what is the purpose of data processing. The companies will also have to guarantee users the right to delete personal data (Right to be forgotten), the possibility to request information about their treatment and to obtain a free copy in electronic format. The new regulation will be the cause of severe sanctions for companies that do not respect it, with fines of up to 4% of the total annual turnover or € 20 million, whichever is the greater of the two. But the consequences will not be only economic: failure to comply with the new rules will also have repercussions on the reputation and image of the company, which will not be considered as attentive to the privacy of users and their sensitive data.

The GDPR has shed light on the issues of Data Protection (McDermott Y., 2017), a theme that, also due to the latest cyber attacks, requires ever more attention. It is well known that the threats against IT security and data protection are not going to decrease: just think of the recent attack of the WannaCry ransomware that hit more than 150 countries between Europe and Asia causing serious damage all over the world. Such a serious attack makes us understand the skills of today's hackers, always in search of flaws and inadequacies in IT systems, which must also be protected with the help of specialists in the sector. (Beckett P., 2017)

By taking advantage of effective security solutions, companies can protect themselves completely, thus guaranteeing their users that their data is always safe and that there is no risk of it being lost.

3 Innovative approach to GDPR compliance

To this end, it is essential to set up an IT infrastructure capable of analyzing the corporate GDPR compliance by analyzing in real time the various factors that feed the system. In particular, the system must be able to consider whether the activities of privacy by design and privacy by default are actually respected in the company. By privacy by design we mean that the company in planning a new service will have to ask itself if in this new service personal data will be processed, and if these data are ordinary or particular (sensitive): in this second case it will be necessary to express how these data will be protected. It is therefore necessary, from planning, to make all assessments concerning personal data if they are processed, the so called Data Protection Impact Assessment (DPIA).

For particular data we mean:

- patrimonial data, those related to income tax returns and other taxes and duties, etc.;
- any personal data that could potentially harm the dignity of the person or affect his natural right to privacy without legal reason.

On the other hand, the principle of privacy by default establishes that by default companies should only process personal data to the extent necessary and sufficient for the intended purposes and for the period strictly necessary for such purposes. It is therefore necessary to design the data processing system, ensuring that the collected data are not excessive. However, the UE 2016/679 does not present quantitative metrics to implement compliance about privacy by design and privacy by default. Then, it is very difficult to evaluate objectively if there is compliance on an infrastructure, and it lends itself to a heuristic implementation. Our approach introduces a possible methodology to evaluate the conformance about GDPR considering a metric to calculate privacy by design and by default considering the IT infrastructure of the company.

The risk level related to the GDPR of a business can therefore be defined as the following index:

GDPR_risk = risk_by_design + risk_by_default

If for convenience we indicate the two aforementioned addends with *rbds* and *rbdf*,

rbds = n_new/n_DPIA

where: *n_new* represents the number of services / products / processes that treat personal data activated by the business under study, *n_DPIA* represents the number of impact assessments on data protection.

A value close to 1 of *rbds* shows a high risk by design value.

Considering i the i-th asset, we can define rbdf with the following approach:

$$rbdf = \sum\left(\frac{c(i)}{BC(i) + DR(i)}\right) + VASS + PTEST$$

where the risk by default is given by various contributions: the first is related to asset management and is given by the sum of the impact of the individual assets (i), considering the ratio between the complexity (c_i) of the asset (i) and the value given by the presence of Business Continuity (BC_i) and Disaster Recovery (DR_i) for the considered asset (i), each contributes a value of 1; the incidence of the single asset (i) is thus mapped: in the case of low complexity such as desktop operating computers without specific data, the incidence of the asset is 0, in the case of medium complexity (data storage server) is equal to 1, in the case of high complexity (server for economic transactions) it is 2; the value of vulnerability assessment (*VASS*) is given by 0 in the case of established security measures (e.g. IPS, IDS), and penetration testing (*PTEST*) is dimensioned on the scale from 1 to 10 according to the Common Vulnerability Scoring System (CVSS).

A value of GDPR_risk below 10 is low (high compliance), 10 to 50 is medium (intermediate compliance), over 50 is high (no compliance).

This index is the basis of the GDPR_COMPLIANCE software developed by the young Sicilian company IINFORMATICA S.R.L.S. (first and unique innovative SME company of Trapani), free of charge for educational and academic purposes, that is a very useful tool to evaluate the GDPR compliance of one’s system.

The following example represents the calculation of the *GDPR_risk* in an Italian SME with 2 locations (P1, P2) related to administration (which do not manage data locally on the machine), 1 data server (S1), 1 accounting server (S2) and 1 server for Disaster Recovery (S3). There is no backup of the 2 stations, but 1 backup of the data server and the accounting server are provided. 5 personal data treatment processes/services have been introduced with implementation of 5 DPIA. The data server and the accounting server process business data, but also special data (e.g. payroll), therefore fall within the average semantic category (average value equal to 1). There is an IPS device which then performs activities to guarantee a good Vulnerability Assessment (risk value 0), and a CVSS score equal to 1 has been found.

The value of the *risk_by_design* is given by 5/5 = 1.

The value of the *risk_by_default* is given by the following calculation:

$$rbdf = r(P1) + r(P2) + r\left(\frac{S_1}{S_3}\right) + r\left(\frac{S_2}{S_3}\right) + VASS + PTEST$$

$$rbdf = 0 + 0 + \left(\frac{1}{1}\right) + \left(\frac{1}{1}\right) + 0 + 1 = 3$$

GDPR_risk = *risk_by_design* + *risk_by_default* = 4.

The company has a low level of risk.

This index would be further reduced in the case of adoption of ISO 27001:2013 (information security management system) and ISO 22301:2012 (business continuity).

4 Conclusions

As far as data are really in unspeakable amounts, the real revolution referred to Big Data is the ability to use all this information to process, analyze and find objective evidence on different themes: the Big Data revolution refers precisely to what can be done with this amount of information, that is, to the algorithms capable of dealing with so many variables in a short time and with few computational resources. Until recently, to analyze a mountain of data that today we would call Small or Medium Data, a scientist would have taken a long time and would have used extremely expensive mainframe computers. Today, with a simple algorithm, the same information can be processed within a few hours, perhaps using a simple laptop to access the analysis platform. This presupposes new capacities to connect information to each other to provide a visual approach to data, suggesting patterns and models of interpretation so far unimaginable.

Developments in Graphical Models

An extension of the glasso estimator to multivariate censored data

Un'estensione dello stimatore glasso per dati censurati multivariati

Antonino Abbruzzo and Luigi Augugliaro and Angelo M. Mineo

Sommario Glasso is one of the most used estimators for inferring genetic networks. Despite its diffusion, there are several fields in applied research where the limits of detection of modern measurement technologies make the use of this estimator theoretically unfounded, even when the assumption of a multivariate Gaussian distribution is satisfied. In this paper we propose an extension to censored data.
Sommario *Lo stimatore glasso è uno degli stimatori più diffusi per fare inferenza sulle reti generiche. Nonostante la sua diffusione, vi sono molti campi della ricerca applicata dove i limiti di misurazione dei moderni strumenti di misurazione rendono teoricamente infondato l'utilizzo di questo stimatore, anche quando l'assunzione sulla distribuzione gaussiana multivariata è soddisfatta. In questo lavoro, proponiamo un'estensione dello stimatore glasso ai dati censurati.*

Key words: Censored data, Gaussian graphical model, glasso estimator.

1 Introduction

An important aim in genomics is to understand interactions among genes, characterized by the regulation and synthesis of proteins under internal and external signals. These relationships can be represented by a genetic network, i.e., a graph where

Antonino Abbruzzo
Department of Economics, Business and Statistics, University of Palermo, Italy, e-mail: antonino.abbruzzo@unipa.it

Luigi Augugliaro
Department of Economics, Business and Statistics, University of Palermo, Italy, e-mail: luigi.augugliaro@unipa.it

Angelo M. Mineo
Department of Economics, Business and Statistics, University of Palermo, Italy, e-mail: angelo.mineo@unipa.it

nodes represent genes and edges describe the interactions among them. Gaussian graphical models [3] have been widely used for reconstructing a genetic network from expression data. The reason of such diffusion relies on the statistical properties of the multivariate Gaussian distribution which allow the topological structure of a network to be related with the non-zero elements of the concentration matrix, i.e., the inverse of the covariance matrix. Thus, the problem of network inference can be recast as the problem of estimating a concentration matrix. The glasso estimator [8] is a popular method for estimating a sparse concentration matrix, based on the idea of adding an ℓ_1-penalty function to the likelihood function of the multivariate Gaussian distribution.

Despite the widespread literature on the glasso estimator, there is a great number of fields in applied research where modern measurement technologies make the use of this graphical model theoretically unfounded, even when the assumption of a multivariate Gaussian distribution is satisfied. A first example of this is Reverse Transcription quantitative Polymerase Chain Reaction (RT-qPCR), a popular technology for gene expression profiling. This technique relies on fluorescence-based detection of amplicon DNA and allows the kinetics of PCR amplification to be monitored in real time, making it possible to quantify nucleic acids with extraordinary ease and precision. The analysis of the raw RT-qPCR profiles is based on the cycle-threshold, defined as the fractional cycle number in the log-linear region of PCR amplification in which the reaction reaches fixed amounts of amplicon DNA. If a target is not expressed or the amplification step fails, the threshold is not reached after the maximum number of cycles (limit of detection) and the corresponding cycle-threshold is undetermined. For this reason, the resulting data is naturally right-censored data. In this paper we propose an extension of the glasso estimator that takes into account the censoring mechanism of the data explicitly.

2 The censored glasso estimator

Let $\boldsymbol{X} = (X_1,\ldots,X_p)^\top$ be a p-dimensional random vector. Graphical models allow to represent the set of conditional independencies among these random variables by a graph $\mathscr{G} = \{\mathscr{V},\mathscr{E}\}$, where $\mathscr{V}$ is the set of nodes associated to $\boldsymbol{X}$ and $\mathscr{E} \subseteq \mathscr{V} \times \mathscr{V}$ is the set of ordered pairs, called edges, representing the conditional dependencies among the p random variables [3]. The Gaussian graphical model is a member of this class of models based on the assumption that $\boldsymbol{X}$ follows a multivariate Gaussian distribution with expected value $\boldsymbol{\mu} = (\mu_1,\ldots,\mu_p)^\top$ and covariance matrix $\Sigma = (\sigma_{hk})$. Denoting with $\Theta = (\theta_{hk})$ the concentration matrix, i.e., the inverse of the covariance matrix, the density function of $\boldsymbol{X}$ can be written as follows

$$\phi(\boldsymbol{x};\boldsymbol{\mu},\Theta) = (2\pi)^{-p/2}|\Theta|^{1/2}\exp\{-1/2(\boldsymbol{x}-\boldsymbol{\mu})^\top\Theta(\boldsymbol{x}-\boldsymbol{\mu})\}. \tag{1}$$

As shown in [3], the off-diagonal elements of the concentration matrix are the parametric tools relating the pairwise Markov property to the factorization of the density

(1). Formally, two random variables, say X_h and X_k, are conditionally independent given all the remaining variables if and only if θ_{hk} is equal to zero. This result provides a simple way to relate the topological structure of the graph $\mathscr{G}$ to the pairwise Markov property, i.e., the undirected edge (h,k) is an element of the edge set $\mathscr{E}$ if and only if $\theta_{hk} \neq 0$, consequently the graph specifying the factorization of the density (1) is also called concentration graph.

Let $\boldsymbol{X}$ be a (partially) latent random vector with density function (1). In order to include the censoring mechanism inside our framework, let us denote by $\boldsymbol{l} = (l_1,\ldots,l_p)^\top$ and $\boldsymbol{u} = (u_1,\ldots,u_p)^\top$, with $l_h < u_h$ for $h = 1,\ldots,p$, the vectors of known left and right censoring values. Thus, X_h is observed only if it is inside the interval $[l_h,u_h]$ otherwise it is censored from below if $X_h < l_h$ or censored from above if $X_h > u_h$. Under this setting, a rigorous definition of the joint distribution of the observed data can be obtained using the approach for missing data with nonignorable mechanism [4]. This requires the specification of the distribution of a p-dimensional random vector, denoted by $R(\boldsymbol{X};\boldsymbol{l},\boldsymbol{u})$, used to encode the censoring patterns. Formally, the hth element of $R(\boldsymbol{X};\boldsymbol{l},\boldsymbol{u})$ is defined as $R(X_h;l_h,u_h) = I(X_h > u_h) - I(X_h < l_h)$, where $I(\cdot)$ denotes the indicator function. By construction $R(\boldsymbol{X};\boldsymbol{l},\boldsymbol{u})$ is a discrete random vector with support the set $\{-1,0,1\}^p$ and probability function $\Pr\{R(\boldsymbol{X};\boldsymbol{l},\boldsymbol{u}) = \boldsymbol{r}\} = \int_{D_{\boldsymbol{r}}} \phi(\boldsymbol{x};\boldsymbol{\mu},\Theta)d\boldsymbol{x}$, where $D_{\boldsymbol{r}} = \{\boldsymbol{x} \in \mathbb{R}^p : R(\boldsymbol{x};\boldsymbol{l},\boldsymbol{u}) = \boldsymbol{r}\}$.

Given a censoring pattern, we can simplify our notation by partitioning the set $\mathscr{I} = \{1,\ldots,p\}$ into the sets $o = \{h \in \mathscr{I} : r_h = 0\}, c^- = \{h \in \mathscr{I} : r_h = -1\}$ and $c^+ = \{h \in \mathscr{I} : r_h = +1\}$ and, in the following of this paper, we shall use the convention that a vector indexed by a set of indices denotes the corresponding subvector. For example, the subvector of observed elements in $\boldsymbol{x}$ is denoted by $\boldsymbol{x}_o = (x_h)_{h\in o}$ and, consequently, the observed data is the vector $(\boldsymbol{x}_o^\top, \boldsymbol{r}^\top)^\top$. The joint probability distribution of the observed data, denoted by $\varphi(\boldsymbol{x}_o,\boldsymbol{r};\boldsymbol{\mu},\Theta)$, is obtained by integrating $\boldsymbol{X}_{c^+}$ and $\boldsymbol{X}_{c^-}$ out of the joint distribution of $\boldsymbol{X}$ and $R(\boldsymbol{X};\boldsymbol{l},\boldsymbol{u})$, which can be written as the product of the density function (1) and the conditional distribution of $R(\boldsymbol{X};\boldsymbol{l},\boldsymbol{u})$ given $\boldsymbol{X} = \boldsymbol{x}$. Formally

$$\varphi(\boldsymbol{x}_o,\boldsymbol{r};\boldsymbol{\mu},\Theta) = \int \phi(\boldsymbol{x}_o,\boldsymbol{x}_{c^-},\boldsymbol{x}_{c^+};\boldsymbol{\mu},\Theta)\Pr\{R(\boldsymbol{X};\boldsymbol{l},\boldsymbol{u}) = \boldsymbol{r} \mid \boldsymbol{X} = \boldsymbol{x}\}d\boldsymbol{x}_{c^-}d\boldsymbol{x}_{c^+}. \quad (2)$$

Density (2) can be simplified by observing that $\Pr\{R(\boldsymbol{X};\boldsymbol{l},\boldsymbol{u}) = \boldsymbol{r} \mid \boldsymbol{X} = \boldsymbol{x}\}$ is equal to one if the censoring pattern encoded in $\boldsymbol{r}$ is equal to the pattern observed in $\boldsymbol{x}$, otherwise it is equal to zero, i.e.,

$$\Pr\{R(\boldsymbol{X};\boldsymbol{l},\boldsymbol{u}) = \boldsymbol{r} \mid \boldsymbol{X} = \boldsymbol{x}\} = I(\boldsymbol{x}_{c^-} < \boldsymbol{l}_{c^-})I(\boldsymbol{l}_o \leq \boldsymbol{x}_o \leq \boldsymbol{u}_o)I(\boldsymbol{u}_{c^+} < \boldsymbol{x}_{c^+}),$$

where the inequalities in the previous expressions are intended elementwise. From this, $\varphi(\boldsymbol{x}_o,\boldsymbol{r};\boldsymbol{\mu},\Theta)$ can be rewritten as

$$\varphi(\boldsymbol{x}_o,\boldsymbol{r};\boldsymbol{\mu},\Theta) = \int_{\boldsymbol{u}_{c^+}}^{+\infty}\int_{-\infty}^{\boldsymbol{l}_{c^-}} \phi(\boldsymbol{x}_o,\boldsymbol{x}_{c^-},x_{c^+};\boldsymbol{\mu},\Theta)d\boldsymbol{x}_{c^-}d\boldsymbol{x}_{c^+}I(\boldsymbol{l}_o \leq \boldsymbol{x}_o \leq \boldsymbol{u}_o)$$

$$= \int_{D_c} \phi(\boldsymbol{x}_o, \boldsymbol{x}_c; \boldsymbol{\mu}, \Theta) d\boldsymbol{x}_c I(\boldsymbol{l}_o \leq \boldsymbol{x}_o \leq \boldsymbol{u}_o), \tag{3}$$

where $D_c = (-\infty, \boldsymbol{l}_{c^-}) \times (\boldsymbol{u}_{c^+}, +\infty)$ and $c = c^- \cup c^+$. Suppose we have a sample of size n; in order to simplify our notation the set of indices of the variables observed in the ith observation is denoted by $o_i = \{h \in \mathscr{I} : r_{ih} = 0\}$, while $c_i^- = \{h \in \mathscr{I} : r_{ih} = -1\}$ and $c_i^+ = \{h \in \mathscr{I} : r_{ih} = +1\}$ denote the sets of indices associated to the left and right-censored data, respectively. Denoting by $\boldsymbol{r}_i$ the realization of the random vector $R(\boldsymbol{X}_i; \boldsymbol{l}, \boldsymbol{u})$, the ith observed data is the vector $(\boldsymbol{x}_{io_i}^\top, \boldsymbol{r}_i^\top)^\top$. Using the density function (3), the observed log-likelihood function can be written as

$$\ell(\boldsymbol{\mu}, \Theta) = \sum_{i=1}^{n} \log \int_{D_{c_i}} \phi(\boldsymbol{x}_{io_i}, \boldsymbol{x}_{ic_i}; \boldsymbol{\mu}, \Theta) d\boldsymbol{x}_{ic_i} = \sum_{i=1}^{n} \log \varphi(\boldsymbol{x}_{io_i}, \boldsymbol{r}_i; \boldsymbol{\mu}, \Theta), \tag{4}$$

where $D_{c_i} = (-\infty, \boldsymbol{l}_{c_i^-}) \times (\boldsymbol{u}_{c_i^+}, +\infty)$ and $c_i = c_i^- \cup c_i^+$. Although inference about the parameters of this model can be carried out via the maximum likelihood method, the application of this inferential procedure to real datasets is limited for three main reasons. Firstly, the number of measured variables is often larger than the sample size and this implies the non-existence of the maximum likelihood estimator even when the dataset is fully observed. Secondly, even when the sample size is large enough, the maximum likelihood estimator will exhibit a very high variance [5, 7]. Thirdly, empirical evidence suggests that gene networks or more general biochemical networks are not fully connected [2]. In terms of Gaussian graphical models this evidence translates in the assumption that Θ has a sparse structure, i.e., only few θ_{hk} are different from zero, which is not obtained by a direct (or indirect) maximization of the observed log-likelihood function (4).

All that considered, we propose to estimate the parameters of the Gaussian graphical model by generalizing the approach proposed in [8], i.e., by maximizing a new objective function defined by adding a lasso-type penalty function to the observed log-likelihood (4). The resulting estimator, called censored glasso (cglasso), is formally defined as

$$\{\hat{\boldsymbol{\mu}}^\rho, \widehat{\Theta}^\rho\} = \arg\max_{\boldsymbol{\mu}, \Theta \succ 0} \frac{1}{n} \sum_{i=1}^{n} \log \varphi(\boldsymbol{x}_{io_i}, \boldsymbol{r}_i; \boldsymbol{\mu}, \Theta) - \rho \sum_{h \neq k} |\theta_{hk}|. \tag{5}$$

Like in the standard glasso estimator, the non-negative tuning parameter ρ is used to control the amount of sparsity in the estimated concentration matrix $\widehat{\Theta}^\rho = (\hat{\theta}_{hk}^\rho)$ and, consequently, in the corresponding estimated concentration graph $\widehat{\mathscr{G}}^\rho = \{\mathscr{V}, \widehat{\mathscr{E}}^\rho\}$, where $\widehat{\mathscr{E}}^\rho = \{(h,k) : \hat{\theta}_{hk}^\rho \neq 0\}$. When ρ is large enough, some $\hat{\theta}_{hk}^\rho$ are shrunken to zero resulting in the removal of the corresponding link in $\widehat{\mathscr{G}}^\rho$; on the other hand, when ρ is equal to zero and the sample size is large enough the estimator $\widehat{\Theta}^\rho$ coincides with the maximum likelihood estimator of the concentration matrix, which implies a fully connected estimated concentration graph.

Tabella 1 Results of the simulation study: for each measure used to evaluate the behaviour of the considered methods we report average values and standard deviation between parentheses

Model	$\min_\rho \text{MSE}(\hat{\boldsymbol{\mu}}^\rho)$		$\min_\rho \text{MSE}(\widehat{\Theta}^\rho)$			AUC

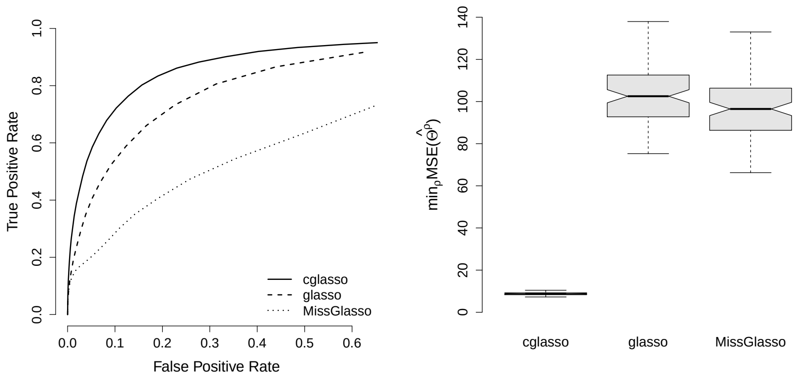
3 Simulation study

By a simulation study, we compare our proposed estimator with MissGlasso [6], which performs ℓ_1-penalised estimation under the assumption that the censored data are missing at random, and with the glasso estimator [1], where the empirical covariance matrix is calculated by imputing the missing values with the limit of detection. These estimators are evaluated in terms of both recovering the structure of the true concentration graph and the mean squared error.

Our study is based on a multivariate Gaussian distribution with $p = 50$ and sparse concentration matrix simulated by a random structure, i.e., the probability of observing a link between two nodes is 0.05. To simulate a censored sample we use the following procedure: we set the mean $\boldsymbol{\mu}$ in such a way that $\mu_h = 40$ for the H censored variables, i.e. $\Pr\{R(X_h; -\infty, 40) = +1\} = 0.50$, while for the remaining variables μ_h is sampled from a uniform distribution on the interval $[10; 35]$. The quantity H is used to evaluate the effects of the number of censored variables on the behaviour of the considered estimators. In particular, we consider $H \in \{25, 35\}$. At this point, we simulate a sample from the latent p-variate Gaussian distribution and treat all values greater than 40 as censored. We use the previous procedure to simulate 100 samples and in each simulation we compute the coefficients path using cglasso, MissGlasso and glasso. Each path is computed using an equally spaced sequence of 30 ρ-values. Table 1 reports the summary statistics $\min_\rho \text{MSE}(\hat{\boldsymbol{\mu}}^\rho)$, $\min_\rho \text{MSE}(\widehat{\Theta}^\rho)$ and the Area Under the Curve (AUC) for network discovery.

The results on the AUC suggest that cglasso can be used as an efficient tool for recovering the structure of the true concentration matrix. The distribution of the minimum value of the mean squared errors shows that, not only our estimator is able to recover the structure of the graph but also outperforms the competitors in terms of both estimation of $\boldsymbol{\mu}$ and Θ. We did not report $\min_\rho \text{MSE}(\hat{\boldsymbol{\mu}}^\rho)$ for glasso since this method does not allow to estimate the parameter $\boldsymbol{\mu}$. Figure 1 shows a graphical representation of the results obtained with $H = 25$.



(a) (b)

Figura 1 Results of the simulation study with $H = 25$. Panel (a) shows the ROC curves; Panel (b) shows the box-plots of the behaviour of quantity $\min_\rho \mathrm{MSE}(\widehat{\Theta}^\rho)$ for the considered estimators.

4 Conclusions

In this paper, we have proposed an extension of the glasso estimator to multivariate censored data. An extensive simulation study showed that the proposed estimator overcomes the existing estimators both in terms of parameter estimation and of network recovery.

Bayesian Estimation of Graphical Log-Linear Marginal Models

Stima Bayesiana di Modelli Grafici Log-Lineari Marginali

Claudia Tarantola, Ioannis Ntzoufras and Monia Lupparelli

Abstract Bayesian methods for graphical log-linear marginal models have not been developed as much as traditional frequentist approaches. The likelihood function cannot be analytically expressed in terms of the marginal log-linear interactions, but only in terms of cell counts or probabilities. No conjugate analysis is feasible, and MCMC methods are needed. We present a fully automatic and efficient MCMC strategy for quantitative learning, based on the DAG representation of the model. While the prior is expressed in terms of the marginal log-linear interactions, the proposal is on the probability parameter space. In order to obtain an efficient algorithm, we use as proposal values draws from a Gibbs sampling on the probability parameters.

Abstract *I metodi bayesiani per l'analisi di modelli grafici log-lineari marginali non sono stati sviluppati allo stesso modo di quelli frequentisti. La funzione di verosimiglianza non può essere espressa analiticamente attraverso i parametri log-lineari marginali, ma solamente in termini di frequenze o probabilità di cella. Non è possibile effettuare analisi coniugata, rendendo necessario l'utilizzo di metodi MCMC. Presentiamo una strategia MCMC per l'apprendimento quantitivo, completamente automatica ed efficiente, basata sulla rappresentazione del modello in termini di DAG. Mentre la prior è espressa in termini dei parametri marginali log-lineari, la proposal è sullo spazio delle probabilità. Al fine di ottenere un algoritmo efficiente, usiamo come proposal i valori ottenuti applicando un campionamento di Gibbs sullo spazio delle probabilità.*

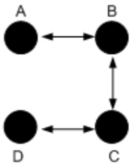
1 Introduction

Statistical models defined by imposing restrictions on marginal distributions of contingency tables have received considerable attention in economics and social sciences; for a thorough review see [2]. In particular standard log-linear models have been extended by [1] to allow the analysis of marginal distributions in contingency tables. This wider class of models is known as the class of marginal log-linear models. In these models, the log-linear interactions are estimated using the frequencies of appropriate marginal contingency tables, and are expressed in terms of marginal log-odds ratios. Following [1], the parameter vector λ of the marginal log-linear interactions can be obtained as

$$\lambda = C \log\big(M \mathrm{vec}(p)\big), \tag{1}$$

where $\mathrm{vec}(p)$ is the vector of joint probabilities, C is a contrast matrix and M specifies from which marginal each element of λ is calculated. A standard log-linear model is obtained from (1) setting M equal to the identity matrix and C to the inverse of the design matrix. Marginal log-linear models have been used by [4] to provide a parameterisation for discrete graphical models of marginal independence. A graphical log-linear marginal model is defined by zero constraints on specific log-linear interactions. It can be represented by a bi-directed graph like the one in Figure 1, where a missing edge indicates that the corresponding variables are marginally independent; for the related notation and terminology see [3] and [4] .

Fig. 1 A bi-directed graph



Despite the increasing interest in the literature for graphical log-linear marginal models, Bayesian analysis has not been developed as much as traditional methods. The main reasons are the following. Graphical log-linear marginal models belong to curved exponential families that are difficult to handle from a Bayesian perspective. Posterior distributions cannot be directly obtained, and MCMC methods are needed. The likelihood cannot be analytically expressed as a function of the marginal log-linear interactions, but only in terms of cell counts or probabilities. Hence, an iterative procedure should be implemented to calculate the cell probabilities, and consequently the model likelihood. Another important point is that, in order to have a well-defined model of marginal independence, we need to construct an algorithm which generates parameter values that lead to a joint probability distribution with compatible marginals.

A possibility is to follow the approach presented in [5], where a Gibbs sampler based on a probability parameterisation of the model is presented. Even if using this approach one can obtain as a by-product the distribution of the log-linear interactions, if the focus is on marginal log-odds a prior should be directly specified for these parameters. Additionally, and more importantly, if any prior information exists for log-odds then we need to work directly using the log-linear parameterisation. For instance, symmetry constraints, vanishing high-order associations or further prior information about the joint and marginal distributions can be easily specified by setting linear constraints on marginal log-linear interactions, instead of non-linear multiplicative constraints on the probability space. For the previous reasons, in [6] a novel MCMC strategy (the probability based sampler) is introduced. In the probability based sampler the prior is expressed in terms of the marginal log-linear interactions, while the proposal is defined on the probability parameter space. Efficient proposal values are obtained via the conditional conjugate approach of [5]. The corresponding proposal density on the marginal log-linear interactions is obtained by implementing standard theory about functions of random variables. For more details on the methodology and the obtained results, see the extended version of this work ([6]).

2 Probability Based independence Sampler

Following the notation of [5], we can divide the class of graphical log-linear marginal models in two major categories: homogeneous and non-homogeneous models. Both type of models are shown to be compatible, in terms of independencies, with a certain DAG representation (augmented DAG). Nevertheless, while homogeneous models can be generated via a DAG with the same vertex set, for non-homogeneous ones it is necessary to include some additional latent variables. The advantage of the augmented DAG representation is that the joint probability over the augmented variable space (including both observed and latent variables) can be written using the standard DAG factorisation. We parameterise the augmented DAG via a set Π of marginal and conditional probability parameters on which, following [5], we implement a conjugate analysis based on products of Dirichlet distributions. Once a suitable prior is assigned on the marginal log-linear interaction parameters, a Metropolis-Hastings algorithm can be used to obtain a sample from the posterior distribution. For $t = 1,\dots,T$, we repeat the following steps

1. propose Π' from $q(\Pi'|\Pi^{(t)})$, where $\Pi^{(t)}$ is the value of Π at t iteration;
2. from Π' calculate via marginalisation the proposed joint probabilities p' for the observed table;
3. from p', calculate λ' using (1) and then obtain the corresponding non-zero elements $\overrightarrow{\lambda}'$;
4. set $\xi' = \Pi'_{\xi}$; where Π'_{ξ} is a pre-specified subset of Π' of dimension $\dim(\Pi) - \dim(\overrightarrow{\lambda})$;
5. accept the proposed move with probability $\alpha = \min(1, A)$

$$A = \frac{f(n|\Pi')f(\overrightarrow{\lambda}')q(\Pi^{(t)}|\Pi')}{f(n|\Pi^{(t)})f(\overrightarrow{\lambda}^{(t)})q(\Pi'|\Pi^{(t)})} \times \text{abs}\left(\frac{\mathscr{J}\left(\Pi^{(t)}, \overrightarrow{\lambda}^{(t)}, \xi^{(t)}\right)}{\mathscr{J}\left(\Pi', \overrightarrow{\lambda}', \xi'\right)}\right), \qquad (2)$$

where abs$(\cdot)$ stands for the absolute value, and $\mathscr{J} = \mathscr{J}(\Pi, \overrightarrow{\lambda}, \xi)$ is the determinant of the jacobian matrix of the transformation $\Pi = g(\overrightarrow{\lambda}, \xi)$. The construction of the Jacobian matrix is facilitated by the augmented DAG representation of the model. Note that the ratio $f(\xi')/f(\xi^{(t)})$ cancels out from the acceptance rate since we set $f(\xi_t) = I_{\{0<\xi_t<1\}}$.

6. If the move is accepted, we set $\Pi^{(t+1)} = \Pi'$, $\xi^{(t+1)} = \xi'$, and $\overrightarrow{\lambda}^{(t+1)} = \overrightarrow{\lambda}'$ otherwise we set $\Pi^{(t+1)} = \Pi^{(t)}$ and $\overrightarrow{\lambda}^{(t+1)} = \overrightarrow{\lambda}^{(t)}$.

In order to obtain a high acceptance rate it is crucial the choice of the proposal density $q(\Pi'|\Pi^{(t)})$. As discussed in [6], an efficient proposal is $q(\Pi'|\Pi^{(t)}) = f_q\left(\Pi'|n^{\mathscr{A}}\right)f\left(n^{\mathscr{A}}|\Pi^{(t)}, n\right)$, where $n^{\mathscr{A}}$ is an augmented table. Exploiting the conditional conjugate approach of [5] we consider as a "prior" $f_q(\Pi)$ a product of Dirichlet distributions obtaining a conjugate "posterior" distribution $f_q(\Pi'|n'^{\mathscr{A}})$. The acceptance rate in (2) becomes equal to

$$A = \frac{f\left(n^{\mathscr{A}(t)}|\Pi'\right)f\left(\lambda'\right)f_q\left(\Pi^{(t)}|n^{\mathscr{A}(t)}\right)}{f\left(n'^{\mathscr{A}}|\Pi^{(t)}\right)f\left(\lambda^{(t)}\right)f_q\left(\Pi'|n'^{\mathscr{A}}\right)} \times \text{abs}\left(\frac{\mathscr{J}\left(\Pi^{(t)}, \lambda^{(t)}, \xi^{(t)}\right)}{\mathscr{J}\left(\Pi', \lambda', \xi'\right)}\right).$$

In the following, we will refer to this approach as the *probability-based independence sampler* (PBIS). Although PBIS simplifies the MCMC scheme, the parameter space is still considerably extended by considering the augmented frequency table $n^{\mathscr{A}}$. This algorithm can be further simplified by using as proposal a random permutation of the MCMC output obtained applying the Gibbs sampling of [5]. The acceptance rate becomes

$$A = \frac{f(\lambda')f_q(\Pi^{(t)})}{f(\lambda^{(t)})f_q(\Pi')} \times \text{abs}\left(\frac{\mathscr{J}\left(\Pi^{(t)}, \lambda^{(t)}, \xi^{(t)}\right)}{\mathscr{J}\left(\Pi', \lambda', \xi'\right)}\right).$$

This sampler is named the *prior-adjustment* algorithm (PAA) due to its characteristic to correct for the differences between the prior distributions used under the two parameterisations.

3 Simulation study

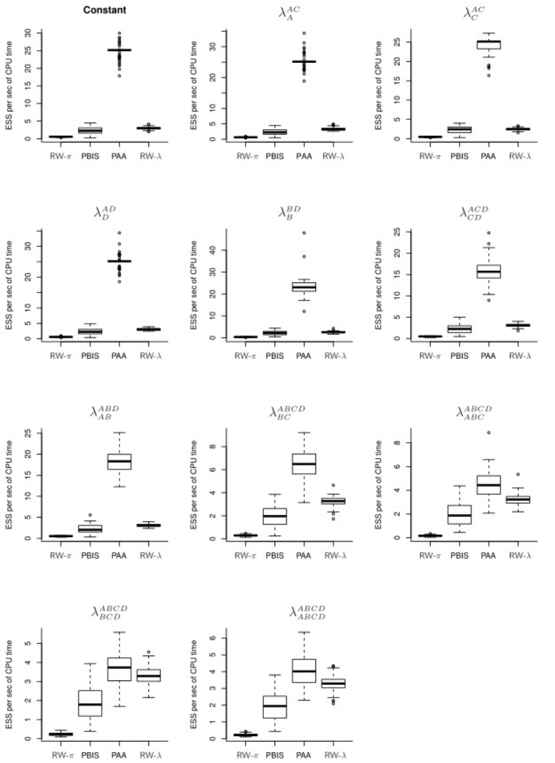
We evaluate the performance of the algorithms presented in Section 2 via a simulation study. We generated 100 samples from the marginal association model represented by the bi-directed graph of Figure 1, and true log-linear interactions given in Table 1. In addition to the algorithms described in Section 2, for comparative purposes, we consider random walks on marginal log-linear interactions λ and on logits of probability parameters π (RW-λ and RW-π respectively). We compare the examined methods in terms of Effective Sample Size (ESS) and Monte Carlo Error (MCE).

Table 1 True Effect Values Used for the Simulation Study

Marginal	Active interactions	Zero interactions
AC	$\lambda_{\emptyset}^{AC} = -1.40, \lambda_{A}^{AC}(2) = -0.15, \lambda_{C}^{AC}(2) = 0.10,$	$\lambda_{AC}^{AC} = 0$
AD	$\lambda_{B}^{AD}(2) = 0.12,$	$\lambda_{BD}^{BD}(2,2) = 0$
BD	$\lambda_{D}^{BD}(2) = -0.09,$	$\lambda_{AD}^{AD}(2,2) = 0$
ACD	$\lambda_{CD}^{ACD}(2,2) = 0.20,$	$\lambda_{ACD}^{ACD}(2,2,2) = 0$
ABD	$\lambda_{AB}^{ABD}(2,2) = -0.15,$	$\lambda_{ABD}^{ABD}(2,2,2) = 0$
ABCD	$\lambda_{BC}^{ABCD}(2,2) = -0.30, \lambda_{ABC}^{ABCD}(2,2,2) = 0.15,$ $\lambda_{BCD}^{ABCD}(2,2,2) = -0.10, \lambda_{ABCD}^{ABCD}(2,2,2) = 0.07.$	

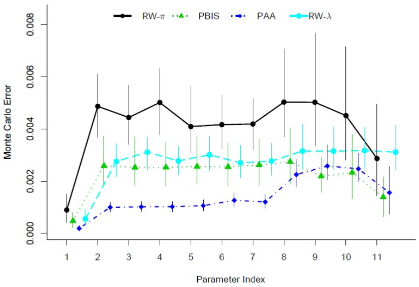
In Figure 2 we report the distribution of the ESS per second of CPU time. PAA is clearly the most efficient among the four methods under consideration.

Fig. 2 ESS per second of CPU time



In Figure 3, for all methods and all marginal log-linear interactions, we represent the time adjusted MCEs for the posterior means. In the graph we represent the 95% error bars of the average time adjusted MCEs for the posterior means. We notice that PAA performs better than all competing methods, since the corresponding MCEs are lower for almost all interactions.

Fig. 3 MCEs for posterior Mean adjusted for CPU time for the simulation study



For a more detailed analysis and a real data application, see Section 5 of [6].

4 Concluding remarks

In this paper we have presented a novel Bayesian methodology for quantitative learning for graphical log-linear marginal models. The main advantages of this approach are the following. It allows us to incorporate in the model prior information on the marginal log-linear interactions. It leads to an efficient and fully automatic setup, and no time consuming and troublesome tuning of MCMC parameters is needed. The authors are planning to extend the method to accommodate fully automatic selection, comparison and model averaging.

Statistical matching by Bayesian Networks
L'uso delle reti Bayesiane nello Statistical Matching

Daniela Marella and Paola Vicard and Vincenzina Vitale

Abstract The goal of statistical matching is the estimation of the joint distribution of variables not jointly observed in a sample survey but separately available from independent sample surveys. The lack of joint information on the variables of interest leads to uncertainty about the data generating model. In this paper we propose the use of Bayesian networks to deal with the statistical matching problem since they admit a recursive factorization of a joint distribution useful for evaluating the statistical matching uncertainty in the multivariate context.

Abstract Lo scopo dello statistical matching è stimare una distribuzione congiunta di variabili osservate separatamente in due campioni indipendenti. La mancanza di osservazioni congiunte sulle variabili di interesse causa incertezza sul modello che ha generato i dati: l'informazione campionaria non è in grado di discriminare tra un insieme di modelli plausibili. In questo lavoro il problema dello statistical matching è analizzato utilizzando le reti Bayesiane che consentono non solo di descrivere la struttura di dipendenza in distribuzioni multivariate ma ammettono una fattorizzazione della distribuzione congiunta utile ai fini della valutazione dell'incertezza.

1 Introduction

Statistical matching aims at combining information obtained from different non-overlapping sample surveys, referred to the same target population. The main target is in constructing a complete synthetic data set where all the variables of interest are jointly observed, see [3].

Formally, let (X,Y,Z) be a random variable (rv) with joint discrete distribution P. Without loss of generality, let $X = (X_1,\dots,X_H)$, $Y = (Y_1,\dots,Y_K)$ and $Z = (Z_1,\dots,Z_T)$ be vectors of rvs of dimension H, K, T, respectively. Furthermore, let A and B be two independent samples of n_A and n_B independent and identically distributed records from (X,Y,Z). Assume that (X,Y) are observed in sample A while (X,Z) are observed in sample B. The main goal of statistical matching consists in estimating the joint distribution of (X,Y,Z) from the samples A and B. Such a distribution is not identifiable due to the lack of joint information on Z and Y given X.

In order to overcome this problem, the following approaches have been considered. The first approach uses techniques based on the conditional independence assumption between Y and Z given X (henceforth CIA assumption) see, e.g., [9]. The second approach uses techniques based on external auxiliary information regarding the statistical relationship between Y and Z , e.g. an additional file C where (X,Y,Z) are jointly observed is available, as in [12].

However, it is possible that neither case is appropriate, then the third group of techniques addresses the so called *identification problem*. The lack of joint information on the variables of interest is the cause of uncertainty about the model of (X,Y,Z). In other terms, the sample information provided by A and B is actually unable to discriminate among a set of plausible models for (X,Y,Z). For instance, in a parametric setting and for $K = T = 1$ the estimation problem cannot be "pointwise", only ranges of values containing all the pointwise estimates obtainable by each model compatible with the available sample information can be detected. Such intervals are uncertainty intervals. Uncertainty in statistical matching is analyzed in [8],[11], [4],[1] and [2].

In this paper we propose the use of Bayesian networks (BNs) to deal with statistical matching in the identification problem framework for multivariate categorical data. The first attempt in such direction is in [5] where the CIA is assumed.

The use of BNs is motivated by the following advantages: (i) BNs are widely used to describe dependencies among variables in multivariate distributions; (ii) BNs admit convenient recursive factorizations of their joint probability useful for the uncertainty evaluation in a multivariate context.

The paper is organized as follows. In section 2 the concept of uncertainty in statistical matching when BNs are used is discussed.

2 Uncertainty in Statistical Matching using graphical models

BNs are multivariate statistical models satisfying sets of conditional independence statements contained in a directed acyclic graph (DAG), see [10]. The network consists of two components: the DAG where each node corresponds to a random variable, while edges represent direct dependencies; the set of all parameters in the network. For instance, with regard to the random vector $X = (X_1,\dots,X_H)$, a BN encodes the joint probability distribution of X by specifying: (i) the set of conditional independence statements by means of a DAG and (ii) the set of conditional probability distributions associated to the nodes of the graph. The joint probability distribution can be factorized according to the DAG as follows

$$P(X_1,\dots,X_H) = \prod_{h=1}^{H} P\left(X_h|\text{pa}(X_h)\right)$$

where $P\left(X_h|\text{pa}(X_h)\right)$ is the probability distribution associated to node X_h given its parents $\text{pa}(X_h)$, $h = 1,\dots,H$. Given two nodes $X_{h'}$ and X_h, linked by an arrow pointing from to $X_{h'}$ to X_h, $X_{h'}$ is said parent of X_h, and X_h is said child of $X_{h'}$. We say that two vertices X_h and $X_{h'}$ are adjacent if there is an edge connecting them. Let $fa(X_h) = X_h \bigcup pa(X_h)$ then the clan of X_h is defined as $clan(X_h) = fa(X_h \bigcup ch(X_h))$ where $ch(X_h)$ is the set of all children of X_h.

The non identifiability of a statistical model for (X,Y,Z) implies that both the DAG and its parameters can not be estimated from the available sample information. Two kinds of uncertainty can be distinguished: 1) uncertainty regarding the DAG, that is the dependence structure between the variables of interest; 2) uncertainty regarding the network parameters, given the DAG, *i.e.* the joint probability factorization.

2.1 Uncertainty in the dependence structure

Let P be the joint probability distribution of (X,Y,Z) associated to the DAG $G_{XYZ} = (V,E)$ consisting of a set of vertices V and a set E of directed edges between pairs of nodes. Let us denote by $G_{XY} = (V_{XY},E_{XY})$ and $G_{XZ} = (V_{XZ},E_{XZ})$ the DAGs estimated on sample A and B, respectively. As in [5] G_{XY} and G_{XZ} are estimated subject to the condition that the association structure of the common variables X is fixed. In particular, the DAG G_X is estimated on the overall sample $A \bigcup B$. Given G_X, we proceed to estimate the association structure between (X,Y) and (X,Z) on the basis of sample data in A and B, respectively.

As far as P is concerned, unless special assumptions are made, one can only say that it lies in the class of all joint probability distributions for (X,Y,Z) satisfying the estimate collapsibility over Y and Z, respectively. Formally, we say that the joint probability distribution P is *estimate collapsible* over Z_t if

$$\widehat{P}(X,Y,Z\backslash\{Z_t\}) = \widehat{P}_{G_{XYZ\backslash\{Z_t\}}}(X,Y,Z\backslash\{Z_t\}). \tag{1}$$

That is, the estimate $\widehat{P}(X,Y,Z\backslash\{Z_t\})$ of $P(X,Y,Z\backslash\{Z_t\})$ obtained by marginalizing the maximum likelihood estimate (MLE) of $\widehat{P}(X,Y,Z)$ under the original DAG model (G_{XYZ},P) coincides with the MLE under the DAG model $(G_{XYZ\backslash\{Z_t\}})$, see [7]. Estimate collapsibility over a set Z is defined similarly. In terms of graphs a concept equivalent to estimate collapsibility is the c-removability. A vertex Z_t is c-removable from G_{XYZ} if any two vertices in $clan(Z_t)$ are adjacent, except when both vertices belong to $pa(Z_t)$. Further, the set $Z = (Z_1,\dots,Z_T)$ is sequentially c-removable if all vertices in Z can be ordered so that they can be c-removed according to that ordering. An analogous condition is required for the estimate collapsibility over Y. The class of plausible joint distributions for (X,Y,Z) can be described as follows

$$\mathscr{P}_{XYZ} = \{P : \widehat{P}(X,Y) = \widehat{P}_{G_{XY}}(X,Y), \widehat{P}(X,Z) = \widehat{P}_{G_{XZ}}(X,Z)\} \tag{2}$$

or equivalently by using the graph of the model structure, the class can also be defined as the class of plausible DAGs G_{XYZ} where the variables Z and Y are removable, respectively. Formally

$$\mathscr{G}_{XYZ} = \{G_{XYZ} : Z \quad is \quad removable, \quad Y \quad is \quad removable\} \tag{3}$$

The most favorable case, that for instance happens under CIA, occurs when the class (2) is composed by a single joint probability distribution defined as $P(X,Y,Z) = P(X)P(Y|X)P(Z|X)$. In an equivalent manner, this means that the class (3) collapses into a single graph given by $G^{CIA}_{XYZ} = G_{XY} \bigcup G_{XZ}$ where Y and Z are d-separated by the set X. Note that such a network always belongs to the class (3). Under the CIA, both the dependence structure and the BN parameters are estimable from the sample data.

Clearly, when the CIA does not hold, in order to choose a plausible DAG from the class $\mathscr{G}_{XYZ}$, it is important to have extra-sample information on the dependence structure. This is generally available or can be elicited by experts. As stressed in [6], *qualitative dependencies among variables can often be asserted with confidence, whereas numerical assessments are subject to a great deal of hesitacy*. For example, for $K = T = 1$ an expert may willingly state that the variable Y is related to variable Z, however he/she would not provide a numeric quantification of this relationships.

2.2 Uncertainty in the parameter estimation

Suppose that a DAG G^*_{XYZ} has been selected from the class $\mathscr{G}_{XYZ}$. Let P^* the joint probability distribution associated to G^*_{XYZ}. According to G^*_{XYZ} the distribution P^* can be factorized into local probability distributions some of which can be estimated from the available sample information while other not. In the case of categorical variables, uncertainty is dealt with in [4] where parameters uncertainty is estimated according to the maximum likelihood principle. The parameter estimate maximizing the likelihood function is not unique and the set of maximum likelihood estimates is called likelihood ridge.

Assume that, X_h, Y_k and Z_t are discrete rvs with I, J and L categories, respectively and that their joint distribution is multinomial with vector parameter $\theta^* = \{\theta^*_{ijl}\}$, for $i = 1,\ldots,I$, $j = 1,\ldots,J$, and $l = 1,\ldots,L$. Suppose that from the factorization of P^*, the unique parameter that can not be estimated is the joint probability $P(X_h,Y_k,Z_t)$. Analogously to (2), as far as θ^* is concerned, one can only say that it lies in the following set:

$$\Theta^* = \{\theta^* : \sum_l \theta^*_{ijl} = \widehat{\theta}_{ij.}, \sum_j \theta^*_{i.l} = \widehat{\theta}_{i.l}, \theta^*_{ijl} \geq 0, \sum_{ijl} \theta^*_{ijl} = 1\} \tag{4}$$

where

$$\widehat{\theta}_{ij.} = \frac{n^A_{ij.}}{n^A_{i..}} \frac{n^A_{i..} + n^B_{i..}}{n_A + n_B}, \quad \widehat{\theta}_{i.l} = \frac{n^A_{i.l}}{n^A_{i..}} \frac{n^A_{i..} + n^B_{i..}}{n_A + n_B} \tag{5}$$

are the marginal distribution ML estimates of (X_h,Y_k) and (X_h,Z_t) from samples A and B, respectively. The maximum of the observed likelihood in θ^*_{ijl} is not unique, all the distributions in the likelihood ridge are equally informative, given the data. For details, see [4].

In order to exclude some parameter vectors in Θ^* it is important to introduce constraints characterizing the phenomenon under study. These constraints can be defined in terms of structural zero ($\theta^*_{ijl} = 0$ for some (i,j,l)) and inequality constraints between pairs of distribution parameters ($\theta^*_{ijl} < \theta^*_{i'j'l'}$ for some $(i,j,l),(i',j',l')$). Their introduction is useful for reducing the overall parameter uncertainty. Clearly, the amount of reduction depends on the informativeness of the imposed constraints. The problem of the likelihood function maximization when constraints are imposed may be solved through a modified EM algorithm, see [13].

Example Suppose that an expert can elicit the association structure between the variables of interest (X_1,Y_1,Y_2,Z_1,Z_2). The BN is reported in Figure 1. Note that, $Y = (Y_1,Y_2)$ is sequentially c-removable according to the ordering (Y_1,Y_2), and $Z = (Z_1,Z_2)$ is sequentially c-removable according to the ordering (Z_1,Z_2).

The joint distribution P can be factorized according to the graph as follows

$$P(X,Y,Z) = P(Z_1)P(X_1|Z_1)P(Y_1|X_1)P(Z_2|X_1,Z_1)P(Y_2|X_1,Z_1,Z_2) \tag{6}$$

The parameter $P(Y_2|X_1,Z_1,Z_2)$ can not be estimated from the sample available information in A and B. Nevertheless, such a distribution can be estimated following the approach described in Section 2.2 using an iterative procedure starting by $P(Z_1,Y_2|X_1)$ and ending with $P(Y_2,Z_2|X_1,Z_1)$.

Clearly, the larger is the number of directed edges between the components of Y and Z, the larger is the number of uncertain parameters needed to be estimated in the factorization of the joint distribution P^*.

Sparse Nonparametric Dynamic Graphical Models

Un modello Grafico non parametrico, dinamico e sparso

Fabrizio Poggioni, Mauro Bernardi, Lea Petrella

Abstract We propose a Sparse Nonparametric Dynamic Graphical Model for financial application. We base our model on multiple CAViaR quantile regression models, and we address the issue of the quantile crossing for this type of semi-parametric models. We show how to jointly estimate the multiple quantile levels by exploiting the conditions on the parameters and setting the estimation as a linear constrained optimization problem. We employ the defined non-crossing Multiple CAViaR model as non-parametric estimation of the marginal distributions to get a sparse dynamic graphical model .

Abstract *Proponiamo un modello grafico non parametrico e dinamico per applicazioni finanziarie. Stimiamo modelli di regressione quantilica multipla di tipo CAViaR, ed affrontiamo il tema del non crossing pe modelli semi parametrici. Mostriamo come stimare congiuntamente i diversi livelli garantendo la propriet di non crossing e come usare questi come stime di distribuzioni marginali per ottenere un modello grafico che risulti sparso e dinamico.*

dependency and conditional dependence ratios of a set of random variables. In financial applications the Graphical model tool allows the advantage of being able to describe complex structures in a simple way. Following the crises of the last decade, it has been very successful as a tool to describe systemic risk as systems of connections in financial markets. Quantile Regression is another very widespread tool in literature used to analyze dependency in financial markets, see for example [1]. We propose in this work an application of graphical models in which we model the time conditional CDF with dynamic quantile regression. Estimating multiple quantile regression involves numerical problems, such as the so called non-crossing problem of the estimated quantiles and the consequent violation of one of the basic principles of the inverse distributions functions: the monotone property. Even if quantile crossing problem is a finite sample problem and should be negligible when the sample size is sufficiently large and the model is correctly specified, for a large number of estimated quantities and perhaps with non-linear specifications of the model quantile crossing may remain a relevant issue. A vast literature exists about the quantile crossing problem: [7] address the quantile-crossing problem using a support vector regression approach for nonparametric models; [4] propose a method for non parametric models in which they use an initial estimate of the conditional distribution function in a first step and solve the problem of inversion and monotonization simultaneously; [9] propose a stepwise method for estimating multiple quantile regression functions without crossing for linear and kernel quantile regression models; [3] propose a method to address the non-crossing problem by rearranging the original estimated non-monotone curve into a monotone rearranged curve; [2] propose a constrained version of quantile regression to avoid the crossing problem for both linear and nonparametric quantile curves. We focus our analysis on the so called semi-parametric Quantile Regression models, specifically on the Conditional Autoregressive Value at. Risk (CAViaR) Quantile Regression model specification introduced by [5], and its multi quantile extension. The existing methods for the non crossing that are applicable to semi-parametric regression models often force the estimate procedure to be step by step, thus less efficient than a joint estimation, and, mostly, these methods do not guarantee that the estimated parameters belong to a ”non crossing” parametric space. We believe that in the case of a regression model for which we have parametrical assumption, the quantile crossing issue can be dealt with more efficiently, moreover we find that ignoring the parametric conditions related to the non-crossing property can lead to serious estimation errors.

2 Non-Crossing MQ-CAViaR as a constrained problem

We show in this chapter how to include the non crossing conditions in the estimation problem as linear constraints to the regression parameters. For the assumptions necessary for the correct specification and estimation of the models we refer to [8]. We consider here a *Symmetric Caviar* specification for two different quantile levels:

$$q_{t_i,\tau_A} = w_A + \phi_A q_{t_{i-1},\tau_A} + \gamma_A |x_0|, \tag{1}$$

$$q_{t_i,\tau_B} = w_B + \phi_B q_{t_{i-1},\tau_B} + \gamma_B |x_0|. \tag{2}$$

Let $\tau_A > \tau_B$, the non crossing condition would be, trivially, $q_{t_i,\tau_A} > q_{t_i,\tau_B}$, $i = 1,2,...,T$. Putting directly this condition as a constraint would not be efficient, contrariwise we consider the assumption made on the stochastic process X_t in order to find necessary conditions on the parameters that satisfy the non crossing issue. Let consider the time series y_t with $t = 1,\dots,T$ and a grid of p different quantile levels, the estimation problem is:

$$\begin{array}{l} \min\limits_{\omega,\gamma,\phi} \sum_{j=1}^{p} \sum_{t=1}^{T} w_{t,\tau_j}(y_t - q_{t,\tau_j}) \\ \text{s.t.} \\ \quad \gamma_{\tau_j} \le \gamma_{\tau_{j+1}}, \quad \forall j \\ \quad \phi_{\tau_j} \ge \phi_{\tau_{j+1}}, \quad j < j^* \\ \quad \phi_{\tau_j} \ge 0, \quad \forall j \end{array} \tag{3}$$

where w_{t,τ_j} is the check function for the quantile level τ_j at time t, $\tau \in [0,1]$ levels are sorted so that $\tau_j < \tau_{j+1}$, and j^* corresponds to τ^*, the quantile level where the autoregressive terms reach their possible minimum ϕ^*. It is necessary to specify that not all the conditions are included in the constraints of the estimation problem, it remains a necessary condition: $w_A(\sum_{1=0}^{n-1}\phi_A^i) - w_B(\sum_{1=0}^{n-1}\phi_B^i) + (\phi_A^n A_0 - \phi_B^n B_0) > 0$, where n is the number of the observations. This last condition can be written more simply, however ensuring this relationship for each integer n means adding a non linear constrain to the estimation problem. Following the tests carried out we choose to proceed this way: we first solve the previous linear constrained problem, then we check if the estimated parameters also meet the non included conditions. If they don't, we estimate the fully constrained problem. Most of the time we did not need to repeat the estimation, thus we believe this way can be more efficient instead of solving the fully constrained problem. It is worth noting that in the "not fully constrained" problem we don't check if our estimated quantiles exhibit crossing to verify the requirement of monotonicity for CDF, whose absence would be just a necessary condition for the monotonicity requirement, instead we check the estimated parameters whose conditions are necessary and sufficient for the non-crossing (monotonicity) requirements. Indeed, forcing the non crossing condition with the constraints $q_{t_i,\tau_A} > q_{t_i,\tau_B}$, or adjusting the estimates that exhibits crossing in this sense, does not guarantee that the non-crossing conditions are satisfied. In the case in which a model with a complex parametric structure is used, for which the non crossing conditions are not exactly known we recommend using simulations of the estimated model to ensure that no crossing occurs instead of just checking that the estimates does not exhibits crossings.

3 The Graphical model: a Sparse Gaussian Copula VAR

A *Graphical Model* exploits the graph theory as well as the statical theory to describe the dependency and conditional dependence ratios of a set of random variables. Nowadays the literature about Graphical Models is huge ,a wide but not exhaustive overview on the subject is [6]. Beyond the obvious advantages of being able to graphically represent dependency structures, we must be able to say something about the dependency and the conditional dependence of random variables. Formally, if X; Y; Z are continuous random variables which admit a joint distribution, we say that X is conditionally independent of Y given Z , and write $X \perp Y|Z \iff f_{XY|Z}(x,y|z) = f_{X|Z}(x|z)f_{Y|Z}(y|z)$. A graph $G = (V,E)$ is a *conditional independence graph* if it respects this property. In order to exploit the property of conditioned independence we will use the Gaussian copula tool as a graphical model (Gaussian Graphical Model). The Copula approach allows to model multivariate associations and dependencies separately from the univariate marginal distributions of the observed variables. The theorem by [10] shows that every multivariate distribution can be represented in terms of a copula function, which *couples* the univariate marginal distributions, i.e. $F(Y_1,\dots,Y_d) = C(F_1(Y_1),\dots,F_d(Y_d))$. In order to exploit the property of conditioned independence we will use the Gaussian copula tool as a graphical model (Gaussian Graphical Model), the we assume the copula function to be: $C(Y_1,\dots,Y_d) = \Phi_d(\Phi^{-1}(F_1(Y_1)),\dots,\Phi^{-1}(F_d(Y_d)))$, where Φ^{-1} is the univariate standard Gaussian quantile function, and Φ_d is an n-variate Gaussian CDF with mean 0_p and covariance matrix P. Moreover , in the light of the complex relationships that link financial returns we want to describe the conditional dependence of the random variables *between* and *within* time. We choose a VAR specification for the multivariate Gaussian Copula-regression model, thus the structure of the model is of the type: $Y = XB + E$. Where Y denotes the $n \times q$ random response matrix X represents a $n \times k$ regression coefficient matrix containing lagged values of Y, B is the $k \times q$ regression matrix and E is the $n \times k$ error terms matrix. Under Gaussian assumption the multivariate series E is assumed to be distributed as a $N(0,\Sigma)$. As it is known, the estimation of multivariate regression matrices can lead to numerical problems especially for high number of marginals. We employ here the MRCE (multivariate regression with covariance estimation) methodology proposed by [11] which consists in a joint estimation of the parameters in B and in Σ, adding two penalties to the negative log-likelihood function g to obtain sparse estimates for both the matrices. The penalty is of the Lasso type, the penalized estimation problem for $(\hat{B},\hat{\Omega})$ is:

$$\min_{\Omega,\Pi}\{g(B,\Omega) + \lambda_1 \sum_{j' \neq j} |\omega_{j',j}| + \lambda_2 \sum_{j=1}^{p}\sum_{i=1}^{q} |\phi_{j,k}|\} \tag{4}$$

where $\lambda_1 \geq 0, \lambda_2 \geq 0$ are the tuning parameters, $\omega_{j',j}$ are entries of Ω^{-1} and $\phi_{j,k}$ are entries of B. The problem in 4 is not convex, but solving for either Ω or P with the other fixed is a convex problem. Then [11] proposed a cyclical-coordinate descent algorithm for an efficient computation, the authors also implemented an R-package for *MRCE* methodology called MRCE. The MRCE methodology allows us to get sparse estimates of the parameters of a Copula VAR model, this will improve the interpretability of the results and the stability of the predictions.

4 Empirical application

We collected 4000 daily observation of 24 USA banking institutions. We consider a grid of 103 quantile levels $\tau = 0.0001, 0.001, 0.01, 0.02, \ldots, 0.98, 0.99, 0.999, 0.9999$ and for these levels we estimate a symmetric Non Crossing-CAViaR model for each series by solving the constrained problem and checking the non crossing parametric condition as explained in section 2. Then we can use the estimated multiple conditional quantile to get the estimation $\hat{F}(y_t)$ for $t = 1, \ldots, T$. To get the estimate $\hat{F}(y_t)$ we can proceed directly using the 103 estimated quantile at time t to get the estimated probability $\hat{u}_t = \hat{F}(y_t)$ by linear interpolation. Alternatively we can try to get more precision by estimating $\hat{F}(y_t)$ with a smoothing spline.

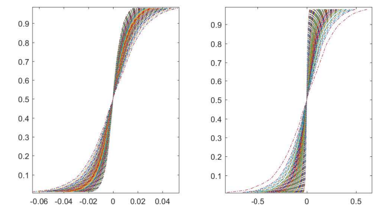

Fig. 1 Some of the time conditional density functions estimated on 103 quantile levels. A period of low volatility in the left graph,a period of high volatility in the right.

Once obtained the series $u_{i,t} = F_{i,t}^{-1}(Y_{i,t})$ with $t = 1, \ldots, 4000$ and $p = 1, \ldots, 24$, we can proceed with the estimation of the parameters of the Copula-VAR function employing the MRCE algorithm to get sparse estimates. We choose a Lag-2 VAR specification and we use the cross validation for the chose of the LASSO shrinking parameters λ_1 and λ_2. Fig. 1 shows some of the estimated cumulative marginal distribution, in Fig.2 the estimated Sparse Graphical model.

5 Conlusions and Discussion

We have identified the parametric space that ensures the non crossing condition for some of the models belonging to the CAViaR specification: this allow the possibility of jointly estimating a considerable number of semi parametric quantile regression models and use them to get non parametric estimation of the marginals for a Copula model. Despite the advantages of knowing the exact parametric space that ensure non-crossing, depending on the parametric assumption of the Multiple Quantile re-

gression model the constraints to the estimation problem can make the computational part very hard, it would be useful to find algorithms that can efficiently satisfy these conditions. Finally, it is possible to enrich the analysis by adding in the specifications of the models some additional exogenous variable, maintaining the property of non-crossing. The Multivariate part can also be extended by adding exogenous variables, in this case maintaining the same proposed estimation method.

Non-communicable diseases, socio-economic status, lifestyle and well-being in Italy: An additive Bayesian network model

Malattie croniche, status socio-economico, stile di vita e benessere: un approccio basato sui Modelli di Rete Bayesiani additivi

Laura Maniscalco and Domenica Matranga

Abstract The aim of the paper is to investigate the statistical association, on a sample of Italian subjects, extracted by Survey of Health, Ageing and Retirement in Europe (SHARE) dataset, between chronic diseases (occurrence or number of chronic diseases) and socio-economic and behavioural determinants (lifestyle indicators, QoL indicators, cognitive functioning variables). To this aim, additive Bayesian network (ABN) analysis was used. The resulting ABN model shows that better-educated individuals have better health outcomes, age is direct and gender is an indirect determinant of the number of chronic diseases. Furthermore, self-perceived health is associated with lower number of chronic diseases, lower physical limitations and higher quality of life and these indicators can be considered within a unitary vision to represent well-being of elderly people, as they share a similar distribution by gender and age.

Abstract *Lo scopo dello studio è stato quello di verificare, con dati su un campine italiano, l'associazione statistica tra la malattia cronica ed i determinanti che rigurdano lo status socio-economico, gli indicatori dello stile di vita e della qualità di vita e la funzione cognitiva. Per raggiungere lo scopo posto, sono stati usati i modelli di rete Bayesiani additivi. Il modello ABN scelto mostra che gli individui più istruiti hanno una migliore salute, tenendo costante le altre esplicative, l'età è un fattore determinante diretto e il sesso è un fattore determinante indiretto del numero di malattie croniche. Inoltre, la salute percepita è associata a un minor numero di malattie croniche, a minori limitazioni fisiche e ad una migliore qualità di vita, questi indicatori possono essere considerati nel loro insieme perché rappresentano il benessere degli anziani e condividono una distribuzione simile per genere ed età.*

1 Introduction

In Italy, the main non-communicable diseases (NCDs) all together account for heavy disease burden, due to the increasing population aging. Data from the Italian National Institute of Statistics in 2015 show that the mortality rate for cardiovascular diseases is 512 per 100000 people, while mortality for other diseases is lower but still worrying (294 per 100000 for cancer, 137 per 100000 for chronic respiratory diseases and 82 per 100000 for mental disorders). The WHO NCD global surveillance strategy is based on a multidimensional view of NCD determinants, including physiological and lifestyle influences and environmental and social factors. People with low socioeconomic status (SES) have less access to NCD care and treatment, are less aware of correct lifestyles to hamper the onset of NCDs and to prevent advanced-stage disease and complications. Some studies show that poor living conditions and primary education are associated with physical inactivity [7] and that there is an inverse social gradient for the feminine obesity [4]. Other studies show the positive impact of education on the consumption of healthy nutrients and on the reduction of individual body-mass index [3]. The majority of chronic diseases affects the overall health of patients by limiting their well-being, the functional status, productivity and health-related quality of life. The main limitation of psychosocial well-being regards the minor involvement in social activities that implicates a reduction of positive reinforcement [5]. A classical approach to investigate the statistical association between chronic diseases (presence or not of chronic diseases) and covariates of interest (SES variables, lifestyle indicators, QoL indicators, cognitive functioning variables) is based on generalized linear models, which make a net classification of variables into covariates and the response. In a multifactorial complex disease system, such that one of NCDs, it should be desirable to analyze the associations between all covariates with all variables being potentially dependent, using Additive Bayesian Networks (ABN) [10]. In order to explain this interrelationship, a data-driven approach using Additive Bayesian Network was applied to find the most probable structure.

2 Material and Methods

2.1 The sample

For the purpose of our study, it was analysed the Survey of Health, Ageing and Retirement in Europe (SHARE) dataset. This dataset is a multidisciplinary and cross-national panel database of micro data on health, socio-economic status and social and family networks on 27 European countries and Israel. In particular, for this analysis we focused on Italian data. The dataset contains, 5288 observations and 17 variables, after having removed missing values. Categorical variables with multiple categories have been transformed into binary, in order to analyze the data with the ABN methodology.

2.1.1 Dataset structure

The variables under study are: gender with two categories "Male " and "Female ", age of the respondent, years of education (yedu), marital status (mstat) with categories "Married" and "Not Married", household total net income (thinc), household net worth (hnetw), current job status (cjs), with categories "Labor force"and "Not labor force", Body Mass Index (BMI) of the respondent, smoking (esmoked), with categories "Yes" and "No", physical inactivity (phinact), with categories "Yes" and "No", number of chronic disease (chronic), US version of self-perceived health (sphus), with categories "Less than good" and "More or equal than good", global activity limitation (gali), a binary variables with categories "Limited" and "Not Limited", score of verbal fluency test (fluency), score regarding "first trial ten words list learning" test (cf008tot), score regarding "delayed trial ten words list learning" test (cf016tot), quality of life in older ages (casp), ranging between 0 to 12. Fluency, cf008tot and cf016tot measure subjective and objective aspects of the respondent's cognitive function, like memory and verbal fluency.

2.2 Statistical methods

Descriptive statistics were carried out. Continuous variables were summarized with mean, median and standard deviation. Categorical variables were analysed with frequencies distributions. Additive Bayesian network (ABN) analysis was used to identify factors associated with the non-communicable disease. Bayesian networks (BNs) belong to the family of probabilistic graphical models (GMs). These models represent a set of variables and their conditional dependencies through a directed acyclic graph (DAG). They are enabled to represent the joint probability distribution (JDP) over a set of random variables. The structure of a DAG is represented by a set of nodes that represent random variables and a set of edges visualized by arrows between nodes that are direct dependencies among variables. Additive Bayesian networks (ABN) are a special type of BN models, where the parameters instead to be based on contingency table, are based on generalized linear model (GLM). Each node in the DAG is the equivalent to the response variable in a GLM. To all DAG was imposed a uniform prior to allow a full data-driven approach. The identification of the best DAG was doing with an exact search method and the identification of the best DAG was based on the marginal log-likelihood. The marginal log-likelihood represents the goodness of fit metric in Bayesian modeling and it includes an implicit penalty for model complexity. The first step to identify the best DAG consists in increasing the maximum number of parents allowed per node (that are the number of allowed covariates in each model) until the goodness of fit remained constant. The model selection procedure started from one to twelve possible parents per node. The best DAG was identified, with eleven maximum number of possible parents per node. The second step regards the model adjustment for over-fitting, that usually is doing when the sample is small and there are many variables. In this step before to generate dataset with MCMC simulation it useful check if the area under the curve of the posterior density integrates to one. In the third step, the marginal posterior log odds ratio was estimated for each parameter from the integration of the posterior distribution with respect to the set of parameters. The maximum likelihood estimates were obtained by the joint posterior distribution. Since ABN methodology allows to evaluate the association between all variables, an arc between two variables in the final ABN model indicates a “direct” relationship, whereas an “indirect” relationship is defined as a relationship between two variables through an intermediate variable. Data were analyzed with R software (version 3.3.2), and the ABN methodology was implemented with “abn” package [11].

3 Results

The exploratory data analysis revealed that there is a strong correlation between cf008tot and cf016tot (p=0.72) and a negative correlation between age and cf008tot (r=-0.39), a positive correlation between chronic and age (r=0.35) and between years of education and cf008tot. All other quantitative variables show a correlation < 0.33. By exploring the scatter-plot of the marginal log-likelihood, the optimal number of parents allowed was found to be six. The optimal DAG (see Fig. 1), showed that the number of chronic disease showed a direct association with BMI (coeff= 0.13), years of education (coeff= -0.073) and age (coeff= 0.12) and an indirect association with gender (coeff= 0.26). Very interestingly, gender is a direct determinant of smoking status. Relating to self-perceived health, the DAG shows direct associations with chronic diseases (coeff= -0.52), cognitive function indicator (cf008 coeff=0.07, cf016tot coeff= 0.29 and fluency coeff=0.04), global activity limitations (coeff= 1.99), quality of life (coeff= 0.12) and with socio-behavioural determinants (marital status coeff=-0.36, working status coeff= -0.65 and physical inactivity coeff= -0.63).

4 Discussion

Additive Bayesian networks analysis of the Share dataset confirms the multidimensional approach of NCD determinants which is suggested by WHO [8]. According to this framework, all determinants are distributed along four successive causation levels, going from physiological influences to social structure, passing through lifestyle and environmental influences. Among physiological and lifestyle influences, our study found out BMI as direct and smoking as indirect determinant of the number of chronic diseases in line with other literature [2, 6]. Within the social structure, another important finding was the role of education and age as direct determinants and of gender as indirect determinant of the number of chronic diseases. Better-educated individuals obtain better health outcomes from a fixed set of inputs because they have the abilities and information to make better choices for their lifestyles. Education indirectly facilitates individual development and interpersonal relationships, enabling people to pursue personal and professional success, which has a positive impact on health [1]. Another finding of our study is that better self-perceived health is associated with lower number of chronic diseases, lower physical limitations and higher quality of life. All these indicators can be considered within a unitary vision to represent well-being of elderly people, as they share a similar distribution by gender and age. In fact, a higher proportion of males yield positive

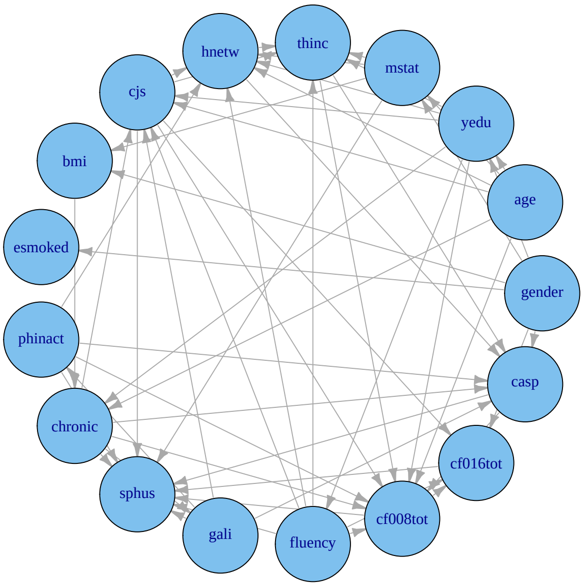

Fig. 1 Optimal ABN model, in terms of marginal likelihood, with a maximum number of six parents per node

outcomes on psychological distress, self-rated health, life satisfaction and chronic diseases and a slightly higher percentage of females display better outcomes regarding their quality of life and BMI. Furthermore, a higher level of well-being appeared to be prevalent among elderly people embedded more frequently in social activity participation [9]. One strength of our study relates to the statistical method used. Additive Bayesian networks supply a general framework to understand the multiple association process that can emerge from the complex interrelationship among health indicators, socio-economic and behavioural determinants. Moreover, through prior elicitation, it should be possible to embed all available information about the statistical association among them. Finally, the data-driven approach could help us to formulate new research hypotheses and to design and construct subsequent theoretical models.

Using Almost-Dynamic Bayesian Networks to Represent Uncertainty in Complex Epidemiological Models: a Proposal

Utilizzo di una Rete Bayesiana Quasi-Dinamica per Rappresentare l'Incertezza in Modelli Epidemiologici Complessi: una Proposta

Sabina Marchetti

Sommario We introduce a dynamic model to deal with uncertainty in complex epidemiological processes. Our proposal is based on the Dynamic Bayesian Networks formalism, where each node is associated a random variable, whose value specifies the state of an individual from a given population.
Sommario *Si introduce un modello dinamico per gestire l'incertezza nei processi epidemiologici complessi. Key words: SIR Model, Dynamic Bayesian Network, Propagation of Uncertainty

1 Introduction

Deterministic epidemiological models for the propagation of an infectious disease on a given population were first introduced by Kermack and McKendrick [5]. We propose a graphical implementation of a simple SIR model, to account for uncertainty in the propagation process. This is carried out via repeated simulations from what we call an *almost-dynamic* Bayesian network, whose pattern of mutual conditional relevances evolves with time.
Basic concepts on the SIR model and Dynamic Bayesian Networks are introduced in Sec. 2.1 and 2.2, respectively. Our proposal is sketched in Sec. 2.3. Some results, remarks and possible extensions are discussed in Sec. 3.

2 Methods

2.1 Deterministic Epidemiological Models

Infectious disease models are based on ordinary differential equations (ODEs). Each equation is associated with a single layer of the population, that is thus partitioned into homogeneous compartments. As an example, consider the well-known SIR model [5], where a given population is constituted by three mutually exclusive and exhaustive components: susceptible (S), infectious (I) and recovered (R), to some infectious disease. At any time t, $t \geq 0$, people in S may acquire the disease, according to rate $\lambda(t)$, and enter compartment I, where they spend γ^{-1} units of time on average, before they move to R; see Fig. 1. The rate $\lambda(t)$ is called *force of infection* and is often defined as

$$\lambda(t) = \tau c \frac{I(t)}{N(t)}, \tag{1}$$

where $c > 0$ is the average number of contacts per individual per unit of time, E.g. per day, resulting in an infection according to $\tau \in [0,1]$, *transmissibility* parameter, and $I(t)/N(t)$ is the proportion of infectious individuals in the population, also called the *infection prevalence*, at t. If the population is stratified into k homogeneous classes, that specify different behavior among components, $\lambda(t) \in \mathbb{R}^k$ is derived from the product of τ and contact matrix $C \in \mathbb{R}^{k \times k}$, multiplied by vector $I_k(t)/N_k(t) \in \mathbb{R}^k$, whose elements correspond to the proportion of infectious individuals in each class.

γ is called *recovery rate*. ODEs describe the flows across compartments. At each time step, $S(t), I(t)$ and $R(t)$ report the number of individuals in each homogeneous component of the population, assumed constant, i.e. $\frac{\partial S(t)}{\partial t} + \frac{\partial I(t)}{\partial t} + \frac{\partial R(t)}{\partial t} = 0$, for all $t \geq 0$. No demographic dynamics (births, deaths, ageing of the population, etc.) are considered by a simple SIR model, whose flow diagram is depicted in Fig. 1. Also, by definition individuals are assumed to acquire lifelong immunity to the disease considered, once recovered. Thanks to its simple parametrization, the SIR model was applied in a number of works, E.g., [4]. Particularly, the related set of assumptions it applies to short-termed diseases, where dynamics strictly related to the population may be neglected, as well as total or partial waning of the immunity conferred by an infection.

When an infectious individual is introduced in a fully susceptible population, the number of secondary cases she produces in a unit of time is called *basic reproduction number* [5], denoted as R_0. It may be easily proved that in an SIR model, it corresponds to $R_0 = \tau c \gamma^{-1}$ (see, E.g., [1]).

Uncertainty and sensitivity analysis of deterministic epidemiological models is usually performed following what we call a *second-order* approach: each parameter value is varied within some range according to some distribution of uncertainty, either singularly or simultaneously. Stochastic approaches were also proposed, dating back to the Reed-Frost model, in 1928 (see [2] for a survey), to deal with uncertainty in such propagation processes. In Sec. 2.3, we propose a dynamic network model, that accounts for uncertainty

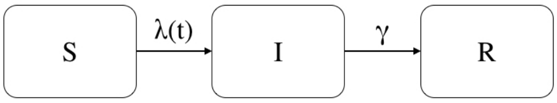

Figura 1 Flow diagram of a simple SIR model.

both in the parameters and in the pattern of contacts of any individual from the population. This way, while homogeneity of each compartment results in the parametrization of a collection of conditional probability tables, corresponding to transition matrices, the topology of the network increases (or decreases) risks at each time step. Our proposal is based on a graphical dynamic implementation of an SIR model. Our proposal is alternative to both existing epidemiological stochastic approaches, as it accounts for individual risks, and to the so-called *individual based* modeling [3], whose assumptions differ from those of an SIR.

2.2 Probabilistic Graphical Models

Probabilistic graphical models (PGMs) are used to represent the joint probability distribution of a (large) collection of random variables $\mathbf{V} = \{X_0, \dots, X_n\}$, by a graph. Bold letters are used to denote sets of random variables. PGMs exploit conditional independence assumptions among pairs of random variables (in a one-to-one correspondence with the nodes of the graph) to reduce inferential complexity.

Nodes are connected by arcs ($-$) in an undirected graph, while edges ($\rightarrow$) are used to induce an ordering among the elements of $\mathbf{V}$ in a directed graph. We write $Adj(X)$ to denote the set of nodes *adjacent* to X in any graph, irrespective of their direction. Let X and Y be any two adjacent nodes in a directed graph, if there is an outgoing edge from X into Y, X is called a *parent* of Y, whereas Y is a *child* of X. $Pa(X)$ and $Ch(X)$ denote, respectively, the parents and children set of node $X \in \mathbf{V}$. Arcs are denoted as $((X,Y))$, while edges read (X,Y); i.e. let E be the set of links in the graph, $((X,Y)) \in E$ implies $X \in Adj(Y)$ and $Y \in Adj(X)$, while $(X,Y) \in E$ implies $X \in Pa(Y)$, $Y \in Ch(X)$, for any pair $X,Y \in \mathbf{V}$. Also, let $d_X = |Pa(X)|$ denote the in-degree of node X, i.e. cardinality of its parents set.

Bayesian networks are PGMs whose graphical component is an acyclic directed graph $\mathscr{G} = (\mathbf{V}, E)$. A Bayesian network is specified by the pair $(\mathscr{G}, P)$, where P is a strictly positive joint probability mass function over $\mathbf{V}$. By the Markov condition, for a given ordering in $\mathbf{V}$, each node is independent of its non-descendants in the graph, given its parents. It follows P may be equivalently represented by a collection of $n+1$ conditional probability tables (CPTs), whose columns correspond to distinct configurations of the parents of a node.

Dynamic Bayesian Networks (DBNs, [6]) are sequences of Bayesian networks, whose structure and/or parametrization change with time. In a DBN, conditioning always extends to each node's previous state, and possibly its parents'. As a result, the joint PMF at time t corresponds:

$$P(X_0^{t+1} = x_0^{t+1}, \dots, X_n^{t+1} = x_n^{t+1}) = \prod_{i=0}^{n} P\left(X^{t+1} = x_i^{t+1} | X^t = x_i^t, Pa^{t+1}(X_i) = pa^{t+1}(X_i), Pa^t(X_i) = pa^t(X_i)\right) \tag{2}$$

where each configuration $(X_0^t = x_0^t, \dots, X_n^t = x_n^t)$ belongs to product sample space $\Omega_{\mathbf{V}} = \times_{i='}^{n} \Omega_{X_i}$, and $Pa^t(X_i) = pa^t(X_i) \in \times_{X_j \in Pa^t(X_i)} \Omega_{X_j}$ is consistent with the first, $t \geq 0$. For a given event $\mathbf{x}^t \in \Omega_{X \in \mathbf{X}}$, we write $P(\mathbf{X}^t = \mathbf{x}^t) = P(\mathbf{x}^t)$ to simplify notation.

In graph theory, a population may be described by a network, whose nodes correspond to units, i.e. individuals, whereas in PGMs, nodes are random variables. In next section, we will introduce a simplified DBN whose nodes represent individuals. Each node X is associated a three-valued random variable, whose states, x_S, x_I and x_R, indicate her location in an SIR model.

2.3 Dynamic Probabilistic Modeling of an SIR Model

Let $\mathscr{B}^t = (\mathscr{G}^t, P^t)$ denote a graphical model at any time $t \geq 0$. In our formalism the graphical component is partially directed: with time, arcs may be changed into edges, and *vice versa*. Although conditioning ought to consider the whole adjacency set of each node, say X, as for undirected networks, relevance is restricted to those in $Pa(X) \subseteq Adj(X)$. Hence, at each t, $\mathscr{G}^t$ may be intended as an acyclic directed graph.

$\mathscr{G}^t = (\mathbf{V}, E^t)$, represents the pattern of contacts among units of a population. The graph may either be a given social network, or be randomly generated according to some known contact matrix C. Let $\mathbf{V}$ be the set of $(n+1)$ nodes (individuals in the network); as already mentioned, each random variable X_i takes values in $\Omega_{X_i} = \{x_{i,S}, x_{i,I}, x_{i,R}\}$, $i = 0, \ldots, n$. State $x_{i,j}$ indicates X_i belongs to compartment j of an SIR structure, $j = S, I, R$. Also, each X_i is assigned label t_i, initialized as $t_i = -\infty$.

In our model, parameters of the model do not vary with time. Yet, if X_i takes value $x_{i,I} \in \Omega_{X_i}$, all incoming arcs are converted into $Ch^t(X_i)$[1] and t_j is updated to t. Let $d_{j,t} = |Pa^t(X_j)|$ be the *infectious-indegree* of node X_j, conditioning involves the subset of adjacent nodes of X_j in $Pa^t(X_j)$, and its corresponding state at $(t-1)$, for any $t \geq 1$.
Based on Eq. (1), we derive the individual FOI $\lambda_{j,t} = \tau d_{j,t-1}$, $j = 0, \ldots, n, t \geq 0$. At each t, $P(X^t | X^{t-1}, Pa^t(X)) = \{P(x^t | x^{t-1}, pa^t(X)) : x^t, x^{t-1} \in \Omega_X, pa^t \in \Omega_{Pa^t(X)}\}$. The CPT of node X_j at t is specified in Table 1, that may be as well intended as a transition matrix, whose columns sum to one.

In details, the first column of the CPT represents the infection process, i.e. people moving from S to I in an SIR model. We assume the infectious-indegree of any node X_j serves as a proxy of the product $cI(t)/N(t)$ from Eq. (1). By definition, *zero-case* $(X = x_I)$, i.e. a single infectious individual in a fully susceptible population, is expected to produce $|Ch^0(X)|$ primary infections, at most. We define the basic reproduction number associated to $\mathscr{B} = \cup_{t=0}^{\infty} \mathscr{B}^t$ as follows:

$$R_0^{\mathscr{B}} = \min\left(|Ch^0(X)|, |Ch^0(X)|\tau\gamma^{-1}\right) \geq 0\,. \tag{3}$$

Let $\tau = 1$, if recovery is fast, i.e. γ is large, $R_0^{\mathscr{B}}$ will likely overestimate the number of secondary cases.

	$x_{j,S}^{t-1}; Pa^t(X_j)$	$x_{j,I}^{t-1}; Pa^t(X_j)$	$x_{j,R}^{t-1}; Pa^t(X_j)$
$x_{j,S}^t; t_j$	$e^{-\lambda_{j,t}}$	0	0
$x_{j,I}^t; t_j$	$1 - e^{-\lambda_{j,t}}$	$e^{-\gamma(t-t_j+\varepsilon)}$	0
$x_{j,R}^t; t_j$	0	$1 - e^{-\gamma(t-t_j+\varepsilon)}$	1

Tabella 1 CPT of node X_j, at time t in an SIR-Bayesian network. $\varepsilon \geq 0$, in our application (see Fig. 2) we set $\varepsilon = 1$.

3 Results and Discussion

As a toy example, we applied our proposal to a population of $(n+1) = 20$ individuals, whose pattern of contacts is depicted in Fig. 2(top-panel). The propagation schema was produced over $M = 1000$ simulations of the model with $\tau = 0.45$ and $\gamma = 0.60$. At each m, introduction of a randomly selected infectious zero-

[1] Arcs only are converted into outgoing edges: if X_i has already incoming edges, those are unchanged.

cases produced on average 3.56 secondary cases.[2] We compared our results with the corresponding SIR model; epidemic curves (and empirical quantile values of uncertainty) are depicted in Fig. 2(top-panel).

Let us state some general remarks. As a first, we stress recovery of some node X_i, at $t \geq 1$, acts as a blocking mechanism, flooring $P(x^t_{j,I}|X^{t-1}, Pa^t(X_j) = \{X_i\}, t_j = \infty)$ to zero.[3] Detection of paths originating from the zero-case, say X_0, that are likely to be blocked by recovery of a single node (or few of them) allows prior identification of critical subjects. Those subjects may be targeted by prevention strategies, tackling a minimal subset approach. Graphical tools may be used to detect *blocked* from *active* paths [7] for the propagation of a disease, such as the Bayes Ball algorithm [8].

In this direction, we argue a general evaluation of the topology of the network would critical in this sense. E.g., for a fixed transmissibility, a sparse graph will be more exposed to the blocking mechanisms mentioned above, compared to a denser one. Also, identification of *cliques*, i.e. maximally connected sets of nodes, may constitute valuable knowledge to policy planning.

As a second remark, repeated sampling allows to evaluate uncertainty in the overall propagation process. Several sampling procedures were proposed in the literature of DBNs, see, E.g., [6]. A efficient naive approach would simply take the so-called *maximum a posteriori* (MAP) configurations from $\Omega_{\mathbf{V}}$, at each time step, to update E^t.

Additionally, other than $R_0^{\mathscr{B}}$, measures on the disease propagation process may be derived from repeated iterations, as well as analytically. Among others, incidence and sero-prevalence of a disease [1]. Again, MAP configurations may be considered as average values prior to simulating.

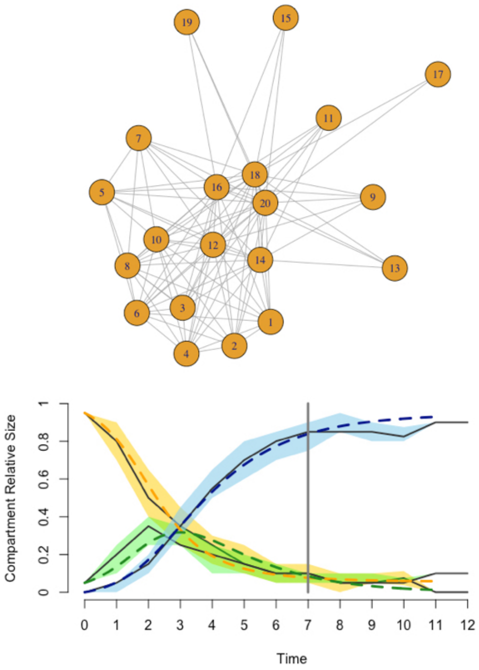

Figura 2 Top-panel: Network generated at random, with $|\mathbf{V}| = 20$, average in-degree 10 and $d = 19$. Bottom-panel: Epidemic curves resulting from $M = 1000$ simulations on the network above, $|\mathbf{V}| = 20$, $\tau = 0.45$, $\gamma = 0.60$. At every simulation, a node is selected at random as zero-case. Epidemic curves describe the relative size of compartments S (yellow), I (green) and R (light blue). Quantile bands and median are compared with the curves resulting from the SIR network, with $c = 0.20$; dashed lines orange, dark green and blue correspond, respectively to compartments S, I and R.

[2] We expected $R_0^{\mathscr{B}} \in [1.33, 10]$, by Eq. (3).

[3] Since $d_{j,t} = 0$.

As a further point, a straightforward extension might assume contacts are characterized by different strengths $w_{i,j} \in [0,1]$, such that $w_{i,j} \to 0$ indicates a almost *vacuos* contacts between nodes X_i and X_j, for any $t \geq 0$. Then, a more general definition of infectious-indegree may be introduced:

$$d_{j,t} = \sum_{X_i \in Pa^t(X_j)} w_{i,j} \mathbb{I}_{X_i^t = x_{i,I}^t} .$$

Finally, suppose we are interested in modeling an SIRS model, where recovered individuals move back to compartment S according to some rate $\phi \geq 0$, that is after ϕ^{-1} units of time in average. It suffices to replace the third column of Table 1 with $\left[e^{-\phi}, 0, 1-e^{-\phi}\right]^T$.

4 Conclusions and Future Work

We proposed an almost-Dynamic Bayesian Network to efficiently deal with uncertainty in the propagation process of a given infectious disease in an SIR model. Particularly, our proposal models uncertainty in the propagation process by i) probabilistic modeling of the transitions across compartments (analogously to a stochastic SIR model), ii) accounting for the dynamic topology of the network (like any individual-based model). We stress our proposal is aimed to provide an intuition of the methodology: extension to models with several layers of complexity is straightforward, the increased complexity being restricted to the preliminary compilation process, i.e. to its parametrization, without affecting the inferential complexity. Future work will consider applications in this direction.

Future research will also consider a thorough approach to uncertainty, by incorporating uncertainty in the parameters, E.g. by means of auxiliary root nodes, to further extend stochastic epidemiological modeling based.

How to improve the Quality Assurance System of the Universities: a study based on compositional analysis

Bertaccini B., Gallo M., Simonacci V., and Menini T.

Abstract The National Agency for the Evaluation of Universities and Research (ANVUR) has for some decades defined the criteria for systematically evaluating student satisfaction. The analysis of these data presents various difficulties both in terms of data collection and analysis. The aim of this work is to propose Candecomp/Parafac for a compositional analysis, which is able to capture the multidimensional aspects of the phenomenon taking into account its ordinal nature and the temporal characteristics of data collection.
Abstract L'Agenzia nazionale per la valutazione delle università della ricerca (ANVUR) definisce da qualche decade i criteri per valutare in modo sistematico la soddisfazione degli studenti. L'analisi di tali dati presenta diverse difficoltia in termini di raccolta dati che di analisi. Scopo del presente lavoro è proporre il Candecomp/Parafac per un'analisi composizionale, il quale, rispettando le caratteristiche temporali della raccolta dei dati e la natura ordinale degli stessi, è in grado di cogliere gli aspetti multidimensionali del fenomeno.

Key words: compositional data, log-ratios, quality, student satisfaction.

1 Introduction

Since the adoption of Law No. 370/99 in 1999, universities are directly responsible for the system of students' opinion polling on the educational modules undertaken. The main goal is to handle the information collected in a synthetic, efficient and effective way in order to obtain an actual review of the didactical organization and a general improvement of the courses offered by the university. The National Agency for the Evaluation of Universities and Research (ANVUR), established in 2006, defines the criteria to systematically assess student satisfaction on the educational activities as part of the Quality Assurance System of the Universities. Student surveys on the educational training provided, become a necessary step for the accreditation of Universities and single courses of study.

In student satisfaction analysis it is important to keep in mind that the rating expressed by each student does not only reflect the quality of service but also her/his perception, personal experiences, inclinations and socio-cultural background. Each student uses a subjective scale which influences his evaluation of the attributes of education. To address this issue a ratio-based approach such as compositional data analysis can be useful. In order to be coherent, the analysis of this kind of data should also take into account the variability of its many observable attributes, which are generally collected with multiple item questionnaires. Consequently, when student satisfaction is observed across the academic years the use of multilinear techniques as Candecomp/Parafac (CP) is advisable.

Proceeding from these considerations, a compositional analysis by CP is proposed to evaluate student satisfaction. Thus, a short review of the method proposed is given in Sect 2, while in Sect 3 the case study is presented.

2 Compositional analysis: short review

Compositional data were extensively studied in the 1980s by Aitchison, for more details see (1). The turning point of this methodology was the possibility to adopt a transformation in a log-scale to move from a constrained space, defined simplex, to the real unconstrained euclidean space. This important finding contributed towards the use of compositional data in several disciplines. In recent years, a further development of the theoretical framework (namely the principle of working in coordinates (2)) laid the basis for a practical use of compositional data in additional fields of studies as evaluation of academic educational quality (5).
Following (4) for three-way data, where on the first way there are I students, on the second way there are J aspects (variables) and on the third way there are K academic years, the starting three-way array $\underline{\mathbf{V}}$ $(I \times J \times K)$ is transformed in a new array $\underline{\mathbf{Z}}$. Here the frontal slices are obtained as $\mathbf{Z}_k = \mathbf{L}_k \mathbf{P}_J^{\perp}$, where $\mathbf{L}_k$ is the k-th frontal slice of the array $\underline{\mathbf{L}}$ with generic element $log(\dot{v}_{ijk})$. In addition, $\mathbf{P}_J^{\perp} = \left(\mathbf{I} - \mathbf{1}^T\mathbf{1}/J\right)$ represents the idempotent row centering matrix where $\mathbf{I}$ is an identity matrix of order J and $\mathbf{1}$ is a J dimensional vector of 1s. A three-way analysis can now be performed

on $\underline{\mathbf{Z}}$ where the generic row vector $\mathbf{z}_{ik}$ is a centered log-ratio (*clr*) defined as:

$$\mathbf{z}_{ik} = clr\left(\dot{\mathbf{v}}_{ik}\right) = \left[\log\frac{\dot{v}_{i1k}}{g(\dot{\mathbf{v}}_{ik})}, \ldots, \log\frac{\dot{v}_{iJk}}{g(\dot{\mathbf{v}}_{ik})}\right] \text{ with } g(\dot{\mathbf{v}}_{ik}) = \sqrt[J]{\prod_{j=1}^{J} \dot{v}_{ijk}} \quad (1)$$

As for principal component analysis on two-way arrays, the use of *clr*-coefficients allows for a direct application of the CP model on the array $\underline{\mathbf{Z}}$ without further concerns. We thus obtain the three loading matrices $\mathbf{A}$ $(I \times F)$, $\mathbf{B}$ $(J \times F)$, and $\mathbf{C}$ $(K \times F)$, where F is the number of components extracted. This decomposition can be written as follows:

$$\mathbf{Z}_I = \mathbf{A}(\mathbf{C} \odot \mathbf{B})^T + \mathbf{R}_I \quad (2)$$

$\mathbf{Z}_I$ $(I \times JK)$ and $\mathbf{R}_I$ $(I \times JK)$ identify the array of *clr*-coordinates and the array of residuals respectively, unfolded with respect to the first mode. In other words they are the horizontal concatenation of the $k = 1, \ldots, K$ matrices $\mathbf{Z}_k$ and $\mathbf{R}_k$ of dimension $(I \times J)$, i.e. frontal slices. The symbol $\odot$ identifies the Khatri-Rao product. The parameters contained in the three loading matrices are often estimated in a least squares sense by use of the Alternating Least Squares algorithm, an iterative procedure for which the objective function is:

$$\min_{\mathbf{A},\mathbf{B},\mathbf{C}} = \|\mathbf{Z}_I - \mathbf{A}(\mathbf{C} \odot \mathbf{B})^T\|^2 \quad (3)$$

where $\|\cdot\|$ is the Frobenius norm.

Of course, the CP results are expressed in $clr-$coordinates, thus it is important to keep in mind that they need to be translated back into compositional terms for proper interpretation, see (3) and (6) for more details.

3 Case study

Following the ANVUR criteria, the University of Florence monitors the students' opinions on teaching quality through questionnaires. Questionnaires have the same item structure, however, some items are excluded for students who did not attend courses. In any case, they were electronically administered for each teaching and all responses were kept anonymous. Only data collected from 2012 to 2017 were considered.

In general several univariate statistics are used to analyze the data and they are available at https://valmon.disia.unifi.it/sisvaldidat/unifi. In this work a CP analysis of the compositional structure is proposed in order to investigate the logconstrasts between the different characteristics of service. Proceeding in the fashion provides several advantages compared to others statistical methods: 1) it exposes the preference structure between items and allows to properly visualize it by means of *ad hoc* graphical tools and interpretational rules; 2) it always guarantees a coherent outcome whether the questionnaire is really measuring a specific construct or not; 3) the results are the same even if the number of items considered should change (subcompositional coherence). The full case study will be discussed at conference.

Evaluation of students' performance at lower secondary education. An empirical analysis using TIMSS and PISA data.

L'impatto della scuola secondaria di I grado sul rendimento degli studenti. Un'analisi empirica con l'impiego dei dati TIMSS e PISA.

G. Graziosi, T. Agasisti, K. De Witte and F. Pauli

Abstract The present paper aims to investigate the net impact of lower secondary education on the level of literacy in mathematics, using the international assessment of educational systems provided by TIMSS in 2007 and PISA in 2012, across OECD countries and partners. We apply a pseudo–panel approach, linking PISA achievements of 15-year-old students in 2012 with those of the same cohort in the 2007 edition of TIMSS, since *the same generation* of students is taken into account. From this perspective, we are able to assess the cumulative effects of education of students at 4th grade in 2007 on performance at 9th grade in 2012.

Abstract *Il presente lavoro ha lo scopo di individuare l'impatto della scuola secondaria di I grado sul rendimento degli studenti, misurati dalle rilevazioni internazionali TIMSS e PISA, nei paesi appartenenti all'OCSE. L'analisi si basa sulla costruzione di uno pseudo–panel in cui i risultati forniti da PISA nel 2012 vengono collegati ai dati TIMSS raccolti nel 2007, poiché la stessa coorte di studenti è stata sottoposta alle rilevazioni. Da questo punto di vista, siamo in grado di valutare l'effetto cumulativo dei cicli di istruzione, dalla scuola primaria (4 grado di istruzione) alla scuola secondaria di secondo grado (9 grado di istruzione).*

1 Introduction

Lower secondary school is a key stage of the educational path since it gives the best opportunity to strengthen basic skills and to protect students against the risk of lack of competences and educational failure in the transition between primary and upper secondary school. Preteen students go through a complex shift in their social, physical and intellectual development, as they leave childhood behind and prepare for adult responsibilities. These years are a critical point for maturation as children's roles in school and society change [4].

The present paper aims to investigate the net impact of lower secondary education on the level of literacy in mathematics, using the international assessment of educational systems provided by TIMSS[1] in 2007 and PISA[2] in 2012, across OECD countries and partners[3].

2 Methodology

We apply a pseudo–panel approach [3], linking PISA achievements of 15-year-old students in 2012 with those of the same cohort in the 2007 edition of TIMSS, since *the same generation* of students is taken into account. From this perspective, we are able to assess the cumulative effects of education of students at 4th grade in 2007 on their performance at 9th grade in 2012.

Following [1], we employ a two-step procedure:

1. For each subject i, we first estimate the impact of time-invariant observables[4] of 4th-graders, $Z_i^{(4)}$, on the performances of students' in 2007 by a linear model

$$y_{i,2007}^{(4)} = \gamma^T Z_i^{(4)} + \varepsilon_{i,2007} \tag{1}$$

where $y_{i,2007}^{(4)}$ is the score obtained by student i in TIMSS at 4th-grade and γ^T denotes the vector of coefficients attached to the time-invariant individual characteristics at grade 4.

In order to predict the test scores at grade 4 for the 9th-graders in 2012, we substitute the appropriate Z_i values for the time-invariant variables of 9th-graders, K_i, employing the vector of coefficient estimated using TIMSS data

[1] Trends in International Mathematics and Science Study

[2] Programme for International Student Assessment

[3] We collected data from the following countries: Australia, Austria, Czech Republic, Denmark, England, Germany, Hong Kong, Hungary, Italy, Japan, Kazakhstan, Latvia, Lithuania, Netherlands, Norway, New Zealand, Qatar, Slovakia, Russia, Scotland, Singapore, Sweden, Taiwan, Tunisia, United States

[4] I.e., gender, year of birth, family composition and specific items to catch the socioeconomic status of students.

$$\hat{y}^{*}_{i,2007} = \hat{\gamma}^{T} K_i^{(9)} \tag{2}$$

2. We include the predicted score at 4th grade as a proxy of the entry-level of students in secondary schools, with the aim to understand how sociodemographic characteristics affect students achievement at the beginning of upper secondary school. Therefore, we employ a model where we control for the learning gaps by the end of grade 4, including time-variant characteristics, $\hat{\gamma}^{T} K_i^{(9)}$, with time-invariant observables.

$$y^{(9)}_{i,2012} = \alpha \hat{y}^{*}_{i} + \gamma^{T} K_i^{(9)} + \beta^{T} X_i^{(9)} + u_i \tag{3}$$

where $y^{(9)}_{i,2012}$ is the score obtained by student i in PISA at 9th-grade.

Preliminary results for Italy

To verify our approach, we first run the analysis for Italy, since the recent research conducted by [2], shows that the performance of the Italian lower secondary schools is quite worrying. Further, this gap is difficult to fill at the secondary schools level, especially for students enrolled in vocational high school, and this mechanism could be responsible for disparities in both educational prospective and results of students.

Table 1 reports the time-invariant factors observed in both dataset. Unfortunately, TIMSS data at grade 4 does not include information on the educational level of parents, therefore we use the number of books at home and three specific country's item as a proxy of the indicator of sociocultural background of students', since there is a strong association among these covariates and the parents' educational attainment.

Constant	445.230^{***} (8.588)	429.51^{***} (14.500)
# Observations	4,470	4,470
R-squared	0.062	0.378

*** $p < .001$; ** $p < .01$; *$p < .05$

Table 2 reports the estimates of time-invariant observables, $\hat{\gamma}^T$, on test scores at grade 4 (Model 1). As a robustness check we repeat the estimation including time-vaying individual variables (e.g., the self-perception of ability of students' and the percentage of students' with disadvantaged socioeconomic background), the area of residence and school fixed effects (Model 2). We find that parameters do not change significantly and the R-squared improves considerably. In order to predict the entry level of students in 2012 we only include in equation (2) the significant coefficients estimated in Model 1.

Table 3 shows the estimates of the test scores' determinants at 9th-grade, accounting for the entry level of students in secondary schools, personal and sociodemographic characteristics of students. The number of observations drops from $31,073$ to $20,320$ due to missing values. The indicators of sociocultural background is at the center of our investigation on the influence of family on achievement and educational choices. Thus, we consider the education attainment of parents as a proxy of the amount and quality of family inputs and we find that the lower educational level of parents negatively affects the performance of students. According to the relevant literature, the type of high school impacts on the achievements of students: vocations schools negatively influence students' performance, while lyceum positive affects students' results. We also include the PISA index of Economic, Social and Cultural Status (ESCS) of students finding that better status corresponds to higher performance. The analysis takes into account the confidence of students towards mathematics, measured throughout the mathematics anxiety index where

*** $p < .001$; ** $p < .01$; *$p < .05$

higher difficulty corresponds to higher level of anxiety, that negatively affects the results of students. Moreover, the information on disciplinary climate in the classroom, based on five items, reveals that students better learn in disciplined contexts. Finally, we consider the impact of the Italian regions where students are enrolled on their performance. We observe high variability among Italian regions, in line with both national and international assessments: students attending schools located in the northern Italian regions outperform their peers enrolled in the South.

Conclusions

Gender gap: the observed gap at 9th grade has been actually generated during the lower secondary school, with respect to what we observed at 4th grade.
Achievements of immigrant: foreign-origin students lag behind Italian native students, and the gap increases from primary to secondary schools.
Family background: students with a disadvantaged background (i.e., parents with at most lower secondary education completed) score lower than their peers with higher educated parents.
The impact of the high school: students attending vocational institutes show lower performance, while the Lyceum increase the results of students. This results confirms that students' achievements are extremely diversified across types of secondary schools (Bratti et al., 2007).
Economic, social and cultural status of students (ESCS): students with a higher ESCS outperform their peers with lower ESCS.
Students' attitude towards mathematics: the anxiety towards mathematics negatively affects the performance of students.
Disciplinary climate in the classroom: students enrolled in quiet classrooms achieve better performance.
Italian Regions: the analysis highlights the variability existing among Italian regions, when the results of students are considered. According to both the National and International assessments, students in the North of Italy outperform their peers from the South.

Testing for the Presence of Scale Drift: An Example

Verifica della Presenza di Scale Drift: un Esempio

Michela Battauz

Abstract The comparability of the scores is a fundamental requirement in testing programs that involve several administrations over time. Differences in test difficulty can be adjusted by employing equating procedures. However, various sources of systematic error can lead to scale drift. Recently, a statistical test for the detection of scale drift under the item response theory framework was proposed. The test is based on the comparison of the equating coefficients that convert the item parameters to the scale of the base form. After briefly explaining the methodology, this paper presents an application to TIMSS achievement data.

Abstract *La comparabilità dei punteggi è un requisito fondamentale nei programmi di valutazione attraverso test somministrati ripetutamente nel tempo. Le differenze nella difficoltà dei test si possono correggere impiegando procedure di equating. Tuttavia, diverse fonti di errore sistematico possono portare a scale drift. Recentemente, è stato proposto un test statistico per rilevare lo scale drift nel contesto della item response theory. Il test si basa sulla comparazione dei coefficienti di equating che convertono i parametri degli item nella scala di riferimento. Dopo una breve spiegazione della metodologia, questo articolo presenta un'applicazione ai dati TIMSS sull'apprendimento.*

Key words: equating, item response theory, scale stability

1 Introduction

Students' achievement level can be monitored on the basis of large scale testing programs. The fundamental requirement to guarantee a fair evaluation is the comparability of the achievement levels over different administrations. Certainly, the

Michela Battauz
University of Udine - Department of Economics and Statistics, via Tomandini 30/A 33100 Udine (Italy), e-mail: michela.battauz@uniud.it

row scores (as for example the number of correct responses) are not directly comparable because they depend on the difficulty of the test form, which can be different across the administrations. Equating is a statistical process that adjusts for differences in difficulty of the forms of a test. The literature proposes various equating methods [8], and this paper focuses on the Item Response Theory (IRT) approach. However, various sources of variability can lead to scale drift [7], causing the scores to be not comparable. A statistical test for the detection of scale drift is proposed in [3]. In this paper, the methodology is briefly explained and illustrated through an application to TIMSS achievement data.

2 Models and Methods

The 2-Parameter Logistic (2PL) model is an IRT model for dichotomous responses. The probability of a correct response to item j is modeled as a function of the ability level, θ, and the item parameters a_j and b_j

$$P(a_j, b_j | \theta) = \frac{\exp\{a_j(\theta - b_j)\}}{1 + \exp\{a_j(\theta - b_j)\}}. \tag{1}$$

The 1-Parameter Logistic (1PL) model is special case that results when the discrimination parameters a_j are equal to one (for a broad review of IRT models see [14]). These models are typically estimated using the marginal maximum likelihood method [4], which assumes a standard normal distribution for θ. For this reason, when the parameters of the model are estimated separately for different groups of subjects, the item parameter estimates are expressed on different measurement scales. The item parameters can be converted from the scale of Form $g-1$ to the scale of Form g using the following equations

$$a_{jg} = \frac{a_{j,g-1}}{A_{g-1,g}}, \qquad b_{jg} = A_{g-1,g}\, b_{j,g-1} + B_{g-1,g}, \tag{2}$$

where $A_{g-1,g}$ and $B_{g-1,g}$ are two unknown constants called equating coefficients. The literature proposes various methods for the estimation of the equating coefficients between two forms with some common items [8]. When two forms can be linked through a chain of forms, it is possible to compute the chain equating coefficients [1]

$$A_p = \prod_{g=2}^{l} A_{g-1,g}, \qquad B_p = \sum_{g=2}^{l} B_{g-1,g}\, A_{g,\dots,l}\,, \tag{3}$$

where $p = \{1, \dots, l\}$ is the path from Form 1 to Form l, and $A_{g,\dots,l} = \prod_{h=g+1}^{l} A_{h-1,h}$ is the coefficient that links Form g to Form l. Each path that links two forms yields a different scale conversion. The differences are due to sampling variability or to systematic error. Since the latter can lead to scale drift, the detection of differences in the scale conversion that can not be attributed to random error, indicates the presence of scale drift. The proposal for the detection of scale drift in [3] is a test with null hypothesis

$$H_0 : \begin{pmatrix} A_1 \\ B_1 \end{pmatrix} = \cdots = \begin{pmatrix} A_p \\ B_p \end{pmatrix} = \cdots = \begin{pmatrix} A_P \\ B_P \end{pmatrix} \tag{4}$$

and as test statistics

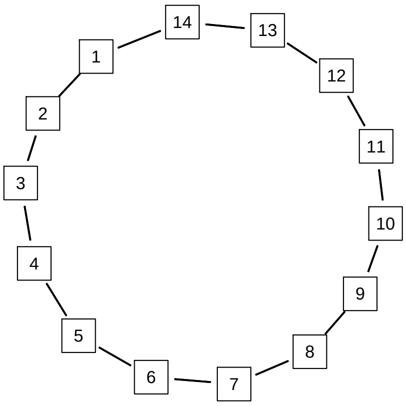
$$W = (\mathbf{C}\hat{\beta})^\top (\mathbf{C}\Sigma\mathbf{C}^\top)^{-1}\mathbf{C}\hat{\beta}, \tag{5}$$

where $\hat{\beta} = (\hat{A}_1, \ldots, \hat{A}_P, \hat{B}_1, \ldots, \hat{B}_P)^\top$, Σ is the covariance matrix of $\hat{\beta}$, $\mathbf{C}$ is a block diagonal matrix composed of two blocks both equal to $(\mathbf{1}_{P-1}, -\mathbf{I}_{P-1})$, $\mathbf{1}_{P-1}$ denotes a vector of ones with dimension $P-1$, and $\mathbf{I}_{P-1}$ denotes the identity matrix with dimension $P-1$. The covariance matrix can be computed using the delta method, considering that the equating coefficients are a function of the item parameter estimates in different administrations. Under the null hypothesis, the test statistic follows asymptotically a Chi-square distribution with $2 \times (P-1)$ degrees of freedom.

3 An Example

To illustrate the application of the procedure we used data collected for TIMSS 2011, considering achievement data in Mathematics of students at the fourth grade in Italy. Students were administered one of 14 forms (booklets). These forms present items in common as shown in Figure 1. Only dichotomous items were considered for this analysis. The total number of examinees is 3992, distributed quite uniformly between the different forms. The number of items for each form ranges between 20 and 27, while the number of common items ranges between 8 and 14.

Fig. 1 Linkage plan of the example.



The 2PL model was fit to the data of each form separately. All analyses were performed using the R statistical software [13]. The mirt package [5] was used for the estimation of the IRT models, while the equateIRT [2] package was used for the estimation of the equating coefficients.

The direct equating coefficients between forms with common items were computed using the Haebara method, and the chain equating coefficients to convert the item parameters from the scale of Form 8 to the scale of Form 1 are reported in Table 1. The two paths that connect these forms present quite different equating coefficients. Anyway, the test, also reported in the table, indicates that the differences are not statistically significant at the 0.05 level.

Table 1 Estimates of chain equating coefficients (standard errors) and scale drift test.

Path	A_p	B_p
$p = \{8, 7, 6, 5, 4, 3, 2, 1\}$	1.57 (0.36)	-0.43 (0.24)
$p = \{8, 9, 10, 11, 12, 13, 14, 1\}$	0.89 (0.19)	0.02 (0.16)
$W = 4.73$, df = 2, p-value = 0.094		

4 Discussion and Conclusions

The proposal of this paper constitutes a novel approach in the literature concerned with the detection of scale drift. While traditional methods compare the scores resulting from different administrations [9, 10, 11, 12], the approach followed here is based on the comparison of the equating coefficients. This new approach permits to formulate a statistical test for the detection of scale drift, thus allowing to take into account the presence of random error.

If the test indicates that the scale conversions deriving from different paths are different, it is then necessary to investigate which items are responsible of the drift. This can be performed using tests for the detection of differential item functioning between pairs of forms [6]. After removing these items, the test for the detection of scale drift can be performed again to verify if the scale conversions can be considered equal.

The evaluation of Formative Tutoring at the University of Padova*

La valutazione del tutorato formativo all'Università di Padova

Renata Clerici, Lorenza Da Re, Anna Giraldo, Silvia Meggiolaro

Abstract The Programme of Formative Tutoring, an integrated tutoring model to contrast drop-out and empower university students, has been experimented in Academic Year 2016-2017 in eight First Cycle Degree Courses at the University of Padova. A propensity score matching procedure has been used to build a suitable control group to evaluate the effectiveness of the tutoring. The data used to match students comes from university administrative archives and from the questionnaire submitted to all freshmen. Results show that students that attended the tutoring activities during their first year of university performed better in term of university outcomes and number of credits achieved. Results are slightly different according to the area (scientific or humanities) of the Degree Course.

Abstract *Il Programma di Tutorato Formativo, un modello di tutorato integrato per contrastare il drop-out e favorire l'empowerment gli studenti universitari, è stato sperimentato nell'Anno Accademico 2016-2017 in otto corsi di laurea triennale dell'Università di Padova. Per valutare l'efficacia del tutorato è stato costruito un appropriato gruppo di controllo utilizzando il propensity score matching. I dati utilizzati per abbinare gli studenti provengono da archivi amministrativi universitari e dal questionario compilato da tutte le matricole. I risultati mostrano che gli studenti che hanno frequentato le attività di tutorato durante il loro primo anno di università hanno conseguito risultati migliori in termini di esiti universitari e numero di crediti raggiunti. I risultati sono leggermente diversi a seconda dell'area (scientifica o umanistica) del corso.*

Key words: effectiveness, university outcomes, propensity score matching

1 The Formative Tutoring

The Programme of Formative Tutoring (Da Re et al. 2017), an integrated tutoring model to contrast drop-out and empower university students, has been extensively experimented in Academic Year 2016-2017 in eight First Cycle Degree Courses at the University of Padova. The considered Degree Courses belong to two macro scientific-didactic areas: Scientific and Humanities.

The Formative Tutoring (FT) has been offered to all first year students of the eight Degree Courses, about 1770 students (1135 in the Scientific area and 635 in the Humanities area). The program has been promoted in different forms to all students: flyers and posters were distributed in places frequented by the students during the period of completion of the enrolment procedures, e-mail was sent to all the enrolled students, presentation has been made during the days of welcome to the freshmen and during the lectures of the first semester.

The Program has foreseen some training and informative meetings divided in:

- Service tutoring: the University Student Services have met the students orienting them to the use of their resources and proposals;
- Tutoring and Peer tutoring: the students, divided into small groups, worked on transversal skills (the method and the study skills, the participation in university life, the knowledge of the academic context, the reflection about their academic and professional expectations, the ability to evaluate and self evaluate, the development of problem solving strategies, the ability to work in a group, the ability to make informed choices, etc.), with the support and coordination of a professor of the Degree Course (Academic Tutor) or of a student in the years following the first (Student Tutor). The total number of meetings for Degree Course ranged from a minimum of 10 to a maximum of 16 meetings.

The implementation of the activities of the FT, designed and prepared with the active collaboration of the Student Tutors, depends on the different scientific didactic contexts, the internal organization of each Degree Courses and its specific needs.

2 Participation to the Formative tutoring

Formative tutoring was offered to all 1770 freshman, but the actual participation was on a voluntary basis. About 42% of the students (750 students out of 1770) have been involved at least for one meeting in the FT. The students who have attended it regularly (at least one third of the activities) have been 218, around 12%, with some differences between the two macro scientific-didactic areas. From now on, we will call these students “the participants”.

Administrative data and data from a questionnaire given to all students at the moment of enrolment, can shed some light on the characteristics of the participants. A logistic regression model has been estimate to study the variables that affect participation to the FT (see Table 1).

The first result is that characteristics of the students that affect participation are different for the two macro areas, indicating different profiles of participants. Regarding the Scientific macro area, participants are characterized by having obtained higher marks at the final high school exam and have used more information sources to choose the degree course. Also practical aspects matters: students temporarily transferred in Padova have a greater propensity to participate regularly with respects to commuters. Also for the Humanities macro area a high mark at the final exam of high school increases participation, but differently from the Scientific macro area coming from a Technical Institute has a negative effect on participation. The most important factor affecting participation is the declared intention of the students to dedicate time to the study and to attend the lessons.

Table 1: *Logistic regression to model the participation to the Formative tutoring vs. non participation*

Variables	*Scientific macro area*	*Humanities macro area*
Secondary school final score	0.028***	0.04**
Enrolment after leaving secondary school (ref: Not immediately after)		
Immediately after	0.461	0.378
Secondary school (ref: High school)		
Polytechnic		-0.656**
Vocational school		-0.168
Degree course (ref: Sciences)		
Engineering	0.133	
Place of residence (ref: Live-in students)		
Commuting students	-0.731***	
Resident students	-0.924**	
Number of sources used to get information to choose the Degree Course	0.410***	
Friends as source of information to choose the Degree Course	-0.928***	
Declared intentions of attendance and commitment in the first year (ref: maxima)		
Substantial attendance and commitment		-0.823**
Low attendance but substantial commitment		-2.71***
Low attendance and commitment		-2.379***
Minimum attendance and commitment		-1.749***

*** p<0.01; ** p <0.05

In general, for both areas, there is no effect on the probability to participate of variables regarding the socio-cultural characteristics of the students' family of origin and variable related to the intentions to work during the Degree Course.

3 Evaluation of the Formative tutoring

To evaluate the effectiveness of the FT we would like to compare university outcomes of participants and non participants to the FT. But since in the previous section we have seen that participants and non participants are different in term of observed characteristics, the differences in outcomes, if any, could be attributed not to the FT but to the differences between the two groups of students. Considering the FT as a treatment (Rubin 1974, Martini and Sisti, 2009) we need to find a group of non treated students, the non-participants, comparable to the treated, the participants.

3.1 Method and results

To a build a comparable comparison group we use a matching procedure. The rationale is that each treated unit will be matched to a comparison with the same observed characteristics. In this way differences between the groups of treated and non treated with regards to university outcomes, could be attributed only to the treatment (the FT). To apply matching the underlining assumption is that all the reasons why people participate to FT are known and observed via the variables considered, in other word it's satisfied the independence of individual characteristics with respect to the presence or absence of treatment. Given that the variables considered (listed below) range from socio-economic characteristics to variables related to study motivation, we may think the unobservable part of the selection process has a negligible effect. The assumption that could be debatable is the existence of a single version of the treatment since each Degree Course organise the FT according to their needs (see section 1). Nevertheless we can considerer the FT as a whole, since the set of intervention are designed and performed with the same goals and only slightly adapted to the single context.

As regard the application of the methodology, given the high number of variable affecting the participation to the FT an exact matching in not feasible. A propensity score matching is then performed (Rosembaum and Rubin, 1983, Thoemmes and Kim 2011). The propensity score, the probability to participate to the FT conditional to a number of observed variables, has been estimated on participant and non participant with a logistic regression. The data used to match students comes from university administrative archives and from the questionnaire submitted to all freshmen. In particular, the variables used for estimating the propensity score are: gender, age, type of high school and final grade, enrolment immediately after graduation or not, score obtained in the university admission test, Degree Course, cultural and professional level of the family of origin, working status, commuting, motivation for university choice.

A nearest neighbour propensity score matching on participants and non-participants, separately for the two macro areas, has been performed. The analysis of the histograms of the estimated propensity score for participant and non participant shown a quite good common support.

The outcome variables are the distribution of university outcomes (drop-out, course change, regular students and delay) and the number of credits attained at the end of the first year. The results are shown in Tables 2 and 3.

Table 2: *Scientific macro area: university outcome on matched participants and non-participants*

Outcome	*Non-participants*	*Participants*
Drop-out	19.2	7.4
Change of Degree Course	14.9	4.3
Regular Student	55.3	74.5
Delay in the study	10.6	13.8
Number of credits	30.4*	40.7*

* Difference between the two groups significantly different from zero

Table 3: *Humanities macro area: university outcome on matched participants and non-participants*

Outcome	*Non-participants*	*Participants*
Drop-out	17.8	8.9
Change of Degree Course	5.4	3.6
Regular Student	67.9	87.5
Delay in the study	8.9	0.0
Number of credits	38.6*	60.2*

* Difference between the two groups significantly different from zero

Results show that students that attended the tutoring activities during their first year of university performed better in term of university outcomes and number of credits achieved. Results are slightly different according to the macro area (Scientific or Humanities) of the Degree Course.

For the Scientific macro area one the most relevant effect is on the outcomes: the participants have much lower rates of drop-out and change of Degree Course and a higher percentage of regularity of the studies (74.5% vs 55.3). The effect on the number of credits is present but in comparison with the other macro area it is lower (+10.3 credits). For the Humanities macro area the most relevant effect is on performance: the participants achieved a significant higher number of credits (+21.6). The differences in outcomes between participants and non- participants are, compared to the Scientific macro area lower, although still of interest.

Benefits of the Erasmus mobility experience: a discrete latent variable analysis

Benefici dell'esperienza Erasmus: un'analisi a variabili latenti discrete

Silvia Bacci, Valeria Caviezel and Anna Maria Falzoni

Abstract Internationalization of higher education has become a priority in the European education policy. For this reason, research in this area is expanding with the aim of understanding motivations and potential benefits of international mobility. In such a context, an online survey addressed to about 1,600 students with Erasmus mobility experiences was conducted by the University of Bergamo (IT). Two latent traits, that is, the impact of the Erasmus experience on the student's abilities and the student's satisfaction for this experience, are analyzed through a two-dimensional latent class Item Response Theory model under a concomitant variable approach. The twofold issue concerning the choice of the optimal number of latent classes as well as the selection of significant covariates is specially addressed.

Abstract *L'internazionalizzazione della formazione universitaria rappresenta una priorità della politica europea dell'istruzione. Per questo motivo, la ricerca in questo ambito è in espansione, al fine di comprendere le motivazioni e i potenziali benefici della mobilità internazionale. L'Università di Bergamo ha condotto un'indagine online rivolta a circa 1,600 studenti con esperienza di studio all'estero. Due variabili latenti, cioè l'impatto dell'esperienza Erasmus sulle abilità degli studenti e il grado di soddisfazione per l'esperienza vissuta, sono oggetto di analisi tramite un modello Item Response Theory bidimensionale a classi latenti con approccio di variabili concomitanti. Particolare attenzione è posta al duplice problema della scelta del numero di classi latenti e della selezione delle covariate significative.*

Key words: Concomitant variable approach, Credit mobility, Graded Response Model, Item Response Theory, Latent class model

1 Introduction

Internationalization of higher education has become a priority in the European education policy. According to the strategic objectives of Europe 2020, "*EU average of at least 20% of higher education graduates should have had a period of higher education-related study or training abroad, representing a minimum of 15 ECTS credits or lasting a minimum of three months*" (EU Council of Ministers of Education, November 29, 2011). Since it began in 1987/1988, the world's most successful student mobility programme, the Erasmus programme, has provided over three million European students with the opportunity to go abroad and study at a higher education institution or train in a company [5].

In the last years, a number of studies has analysed motivations and potential benefits of international mobility. Research findings seem to show that studying abroad positively affect students personality development and improve their language competencies and soft skills (such as problem-solving and decision-making skills). Relatedly, mobility students seem to have better labour market prospects, in particular abroad ([3], [4]).

To analyse students' motivations and the fullfilment of expectations regarding the study international experience, we asked 1,576 students, enrolled in the University of Bergamo with a credit mobility experience during the a.y. from 2008/09 to 2014/15, to answer a questionnaire. Administrative information at enrolment (e.g., age, gender, field of study, etc.) is also available for each student.

In this contribution we focus on two main aspects related to the Erasmus experience: the impact of the Erasmus experience on the student's skills and the student's fulfilling the expectations for this experience. Both these elements represent latent variables, which are measured through a set of polytmously-scored items. Our aim consists in measuring these latent variables, providing evidence of one or more problematic items. Moreover, we intend to detect individual characteristics that significantly explain the level of latent variables. For these aims, we formulate a bidimensional Latent Class Item Response Theory (LC-IRT) model ([1], [2]) with a concomitant variable approach [6].

2 Erasmus mobility data: description

To assess the international experience of the students of the University of Bergamo an ad hoc questionnaire was prepared, which was organised in three sections: Decision to study abroad, International experience and Coming back. Student's individual characteristics were also collected, such as gender, parents' level of education, parents' employment status, previous international experiences of him/herself or family, student's current employment status. The survey involved all the 1,576 students, which spent one/two semesters abroad for an Erasmus or Extra EU program from a.y. 2008/09 to a.y. 2014/15; the response rate was 48.6% (766 students).

The sample includes students from all the five fields of study of the University of Bergamo: Foreign Languages (45.7%), Economics (28.6%), Human and Social Sciences (13%), Engineering (9.6%), and Law (3.1%). They are enrolled in a bachelor degree (64%), a master degree (33.8%) and in a five-years degree of study (2.2%). As far as international experience is concerned, about half of the students spent the fall semester abroad (48.2%) and the 20.4% of students the spring semester; for just less than a third of students (31.4%) the experience lasted for the whole academic year. The preferred destination was Spain (28.1%), followed by Germany (17.7%), United Kingdom (15.8%), and France (13.7%); other European countries were overall chosen by the 18.7% of students, whereas the Extra-UE destinations were USA (2.7%), China (2.1%) and Australia (1.2%).

3 The statistical model

Given a set of J ordered polytomous items for the measurement of some latent traits about the Erasmus experience of n students, let $\boldsymbol{\Theta} = (\Theta_1, \Theta_2, \dots, \Theta_s)'$ be the vector of latent variables that drive the response process and let $\boldsymbol{\theta} = (\theta_1, \dots, \theta_s)'$ denote one of its possible realizations. Vector $\boldsymbol{\Theta}$ is assumed to have a discrete distribution with k support points, denoted by $\boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_k$, and mass probabilities (or weights) $\pi_{i1}, \dots, \pi_{ik}$ $(i = 1, \dots, n)$. From an interpretative point of view, each support point detects a group (latent class) of individuals that share a common level of the latent traits, whereas the corresponding mass probability denotes the probability of belonging to each latent class according to the individual characteristics.The mass probabilities are assumed to depend on a set of p individual characteristics $\mathbf{X}_i = (X_{i1}, \dots, X_{ip})'$ $(i = 1, \dots, n)$, that is, $\pi_{iu} = p(\boldsymbol{\Theta} = \boldsymbol{\xi}_u | \mathbf{X}_i = \mathbf{x}_i)$ $(u = 1, \dots, k)$, through a multinomial logit model

$$\log \frac{\pi_{iu}}{\pi_{i1}} = \delta_{0u} + \mathbf{x}_i' \boldsymbol{\delta}_{1u}, \quad i = 1, \dots, n;\ u = 2, \dots, k,$$

where δ_{0u} and $\boldsymbol{\delta}_{1u}$ denote, respectively, the class-specific intercept term and the class-specific vector of regression coefficients.

As concerns the response process, the probability that student i $(i = 1, \dots, n)$ answers category y $(y = 1, \dots, l_j - 1)$ to item j $(j = 1, \dots, J)$ is modelled through a multidimensional Latent Class Graded Response Model (LC-GRM; see [1] and [2] and references therein for details on the model specification and the estimation):

$$\log \frac{p(Y_{ij} \geq y | \boldsymbol{\Theta} = \boldsymbol{\theta})}{p(Y_{ij} < y | \boldsymbol{\Theta} = \boldsymbol{\theta})} = \gamma_j \sum_{d=1}^{s} (z_{jd} \theta_d - \beta_{jy}), j = 1, \dots, J;\ y = 1, \dots, l_j - 1,$$

with z_{jd} dummy variable equal to 1 if item j measures latent trait θ_d and 0 otherwise, and γ_j and β_{jy} item discriminating and difficulty parameters, respectively, having the usual interpretation as in the item response theory context.

The manifest distribution of $\mathbf{Y}_i = (Y_{i1}, \dots, Y_{iJ})'$ follows as

$$p(\mathbf{Y}_i = \mathbf{y}_i) = \sum_{u=1}^{k} p(\mathbf{Y}_i = \mathbf{y}_i | \boldsymbol{\Theta} = \boldsymbol{\theta}_u)\pi_{iu}$$

where, in virtue of the local independence assumption,

$$p(\mathbf{Y}_i = \mathbf{y}_i | \boldsymbol{\Theta} = \boldsymbol{\theta}_u) = \prod_{j=1}^{J} p(Y_{ij} = y | \boldsymbol{\Theta} = \boldsymbol{\theta}).$$

In what follow we assume $s = 2$, indicating with Θ_1 the impact of the Erasmus experience on the student's skills and with Θ_2 the fulfilling the expectations of the Erasmus experience. In addition, we consider $J = 12$ items with three ordered response categories ($l_j = 0, 1, 2$) denoting increasing levels of positive impact or satisfaction; Θ_1 is measured by 7 items and Θ_2 by the remaining 5 items.

A relevant aspect with the model at issue and, more in general, with the class of multidimensional LC-IRT models, to which the LC-GRM belongs, is represented by the choice of the number k of latent classes. The main stream of the literature agrees on using the Bayesian Information Criterion (BIC) to select the value of k. In practice, a common approach consists in estimating the model for increasing values of k, being constant all the other elements of the model, and selecting that value of k corresponding to the minimum BIC. However, it has also to be taken into account that, in the presence of several covariates, the likelihood of the model and the value of BIC are affected by the selection process of covariates. In other words, if one or more covariates are eliminated from the model because of their not significance, the sequence of BIC values would be likely different with consequences on the optimal k. In addition, strategy based on the minimization of BIC index often leads to numerous and small latent classes that are not simple to interpret.

To solve the two above problems, we here propose an iterative procedure consisting in the following steps:

Step 1: estimate the multidimensional LC-GRM without covariates and for increasing values of k until the first increasing BIC is obtained. Select that value of k corresponding to the first relative decrease of BIC smaller than a given (small) threshold α, say $\alpha = 0.01$;

Step 2: given k selected at Step 1, estimate the multidimensional LC-GRM with all the plausible covariates of interest. If all the covariates are significant at a given level (e.g., 5%) stop, otherwise go on with the next step;

Step 3: estimate the multidimensional LC-GRM with covariates selected at Step 2 and for increasing values of k until the first increasing BIC is obtained. Select the value of k as in Step 1. If all the covariates are significant stop, otherwise repeat Step 3.

The procedure finishes when there are not any more changes in the value of k and in the set of significant covariates.

4 Application to Erasmus mobility data: main results

According to the iterative procedure described above, we selected a LC-GRM with $k = 3$ components. As shown in Table 1, class 1 collects students that benefited just a little from the international experience (average weight equal to 21.0%), whereas students with significant advantage from this type of experience belong to class 3 (average weight equal to 33.1%). The remaining part of students (45.9%) is allocated in class 2, showing intermediate levels on both the latent variables.

Table 1 Estimates of support points $\hat{\xi}_{ud}$ and averages of weights $\hat{\pi}_{iu}$ $(d = 1,2;\ u = 1,2,3)$

Latent variable d	Class $u = 1$	Class $u = 2$	Class $u = 3$
Impact on skills (Θ_1, $d = 1$)	-0.951	-0.092	1.043
Satisfaction (Θ_2, $d = 2$)	-0.956	-0.084	1.039
Avg. weights	0.210	0.459	0.331

In Table 2 the distribution of the statistically significant covariates is shown. Covariates related to motivations to study abroad allow us for a clear characterisation of the three classes: improving own *curriculum studiorum* (CV), improving foreign language competencies, studying the culture of a foreign country, curiosity about new challenges, and to enhance future employability characterise class 2 and, mainly, class 3, according to an increasing trend. Instead, the impact on the latent class membership of the use of interactive teaching methods is less clear. It is worth to be noted that the host country as well as many other individual characteristics are not enclosed in the subset of significant covariates.

To conclude, Table 3 shows the item parameter estimates. The most problematic aspects related to the impact of international experience are represented by the learning ability and by the motivation to study: in both cases, the difficulty parameters $\hat{\beta}_{j1}$ and $\hat{\beta}_{j2}$ $(j = 2,7)$ are definitely greater with respect to the other items; on the opposite, the adaptability $(j = 5)$ is not a problem at all. As far as the fulfilling of the expectations, the benefits of the international experience for the Italian labour market $(j = 8)$ is perceived as the most critical aspect, whereas the students' expectations in terms of personality development $(j = 10)$ are usually completely satisfied.

Table 2 Distribution of students in the latent classes, for each significant covariate (proportions)

Covariate	Class $u = 1$	Class $u = 2$	Class $u = 3$
Motivations			
Improve CV	0.349	0.453	0.640
Improve foreign language skills	0.671	0.897	0.955
Improve host country knowledge	0.221	0.441	0.702
Curiosity about new challenges	0.732	0.915	0.955
Enhance future employability	0.121	0.306	0.566
Use of interactive teaching methods			
less than in Italy	0.013	0.006	0.025
the same as in Italy	0.182	0.062	0.091
more than in Italy	0.805	0.932	0.884

Table 3 Estimates of item difficulty parameters $\hat{\beta}_{jy}$ and item discriminating parameters $\hat{\gamma}_j$ ($j = 1,\dots,12; y = 1,2$)

Item	$\hat{\beta}_{j1}$	$\hat{\beta}_{j2}$	$\hat{\gamma}_j$
Communication skills ($j = 1$)	0.000	3.497	1.000
Learning ability ($j = 2$)	2.533	6.074	0.789
Foreign language skills ($j = 3$)	-0.757	2.864	1.005
Team working skills ($j = 4$)	0.946	5.012	0.646
Adaptability ($j = 5$)	-1.402	2.365	0.928
Problem solving skills ($j = 6$)	0.254	4.211	0.830
Motivation to study ($j = 7$)	2.704	6.612	0.541
Enhance future employability in Italy ($j = 8$)	0.000	2.196	1.000
Enhance future employability abroad ($j = 9$)	-0.514	1.404	1.518
Personality development ($j = 10$)	-1.256	-0.118	3.325
Foreign language skills ($j = 11$)	-0.633	0.303	3.770
Ability to interact with foreign people ($j = 12$)	-0.530	0.419	3.672

University choice and the attractiveness of the study area. Insights from an analysis based on generalized mixed-effect models

Silvia Columbu, Mariano Porcu and Isabella Sulis

Abstract In this work we investigate upon the determinants of students' choices to attend bachelor degree studies outside the region of residence using information provided by the Italian National Student Archive (NSA) on a cohort of students enrolled for the first time at the university in a.y. 2014/15. The aim of the analysis is twofold: (i) to suggest value-added measures of university reputation and (ii) to assess and split the role played by the field of study in determining the power to attract students from other regions. To do this, a three-level logistic regression model to deal with cross-classified units has been adopted for modelling the probability that freshmen in a given university are mover students (instead that stayer) as a function of their socio-demographic characteristics, territorial area information and other sources of heterogeneity which concern both the field of specialization and the university reputation.

Abstract In questo lavoro, considerando i dati dell'Anagrafe Nazionale Studenti (ANS) per la coorte di immatricolati nell'a.a. 2014/15, si studiano i fattori che spingono gli studenti italiani a lasciare la propria regione di residenza per intraprendere gli studi universitari. L'analisi riportata si pone due obiettivi principali: (i) suggerire delle misure di valore aggiunto della reputazione delle università e (ii) individuare l'influenza dell'indirizzo di studi nella capacità di attrarre studenti da altre regioni. Si considera un modello di regressione logistica a tre livelli, che parametrizza una struttura cross-classified, per modellizzare la probabilità che uno studente al primo anno sia fuori sede in funzione delle sue caratteristiche socio-demografiche, delle informazioni territoriali, e di altre fonti di eterogeneità relative all'area di specializzazione scelta e alla reputazione dell'università.

Key words: multilevel models, value-added, student mobility, university reputation

1 Introduction

In the last years there has been an increasing request to evaluate the effectiveness of the tertiary education institutions; these evaluations have been used to support and enhance universities and curricula which satisfy specific quality standards. The development of the assessment policies in tertiary education has determined a huge contraction of curricula supplied in many universities and a redefinition of the shape of the educational offer. Among the indicators used by the government to determine the share of the yearly public financial provisions transferred to public universities are considered, also, the job placement of graduates and the universities' capability to attract students from other territories. However, students' mobility choices are related to students' socio-economic conditions and to the economic peculiarities of both the geographical areas of students' provenance and the place where the universities are located, as well as to the university reputation and effectiveness [6] [2] [8]. Recent empirical studies on student mobility in Italy, highlight the presence of a North-South divide in the way university students make their choices [7][8]. Specifically, the distribution of university students, with respect to the region where they reside (origin) and the region where they attend the university studies (destination), shows that about 1 out of 4 freshmen students in Italy move from the South to the North or Center regions, while very few move from North-Center to South.

Many authors have addressed phenomenon of intra-and international students mobility. In an economic perspective, Dotti et al. (2013) [6] state that the migration of students in Italy can be seen as a reaction to low employment rates in the provinces of origin, and is directed mainly to the provinces with better job opportunities. D'Agostino *et al.* (2016) [5] discuss the geographical dimension of students mobility in the Italian case. Enea (2016) [7] analyses the student Italian mobility case in the transition from 1st level degree to master, highlighting that students with the best educational background have the high risk to move to another university for their master studies and that, among these, about 75% chooses a northern University. Suhonen (2014) [11] proves that in the Finnish university system the distance effect is highly conditioned to the choice of specific fields of study. The geographical dimension has also been investigated by Cattaneo et al (2016) [3], who focus on the role played by transport accessibility in determining students' choices and prove that the easiness to move is a factor of attractiveness of Italian universities. There is evidence that the migration phenomenon can be linked to the quality of university research and teaching in the Italian context ([4][2](2016) [10]). In an international framework, Beine et al. (2014) [1] identified that there exists a network effect, that contributes to spread the reputation of a university and attract new students. Giambona, Porcu & Sulis (2016) [8] highlight that the determinants of students' flows among geographical areas seem more related to the opportunities offered by the destination areas than to the characteristics of their universities in terms of facilities and services.

Moving from this framework, we define *mover* those students who enroll in universities that are not located in the region where they reside and *stayer* those who come from the same region. Since the raw rate of *movers* enrolled in a university does not allow to determine which differences in university attractiveness are related to students' characteristics and/or socio-economic background of the territorial areas of the universities and which differences are related to the vocation of the universities in terms of their education offering and/or to better education opportunities and higher level of competencies, we advance a micro analysis of the determinants of students' university choices.

The aim of the analysis is to assess and split the roles played by the field of study and by the university in determining the power to attract students from other regions. To do this, a three-level logistic regression model has been adopted for modelling the probability that freshmen in a given university are *mover* students (instead that *stayer*) as a function of their socio-demographic characteristics, territorial area information and other sources of heterogeneity of the universities; this last one concern both the field of specialization and the university reputation.

2 Data description

We use the data from Italian National Students Administrative Archive (*NSA*) provided by the Ministry of Education and Research (*MIUR*) from a cohort of students' enrolled for the first time, at a public or private university located in the national territory, in the a.y. 2014/15. We consider only records of students enrolled in traditional Bachelor or in Single-Cycle (Bachelors+Masters) Degree Programs, excluding those related to e-learning degree programs (i.e. the 10 Italian universities that offer only e-learning degree programs) or to foreign students. The analysis has been bounded to 229,813 observations, belonging to 80 (61 public and 29 private) universities that provide traditional tertiary education programs in Italy. The *NSA* collects information on students' socio-demographic characteristics, information on previous studies , university curricula (i.e. degree program and university where they enroll) and proficiency in the university studies. According to their place of origin, students are classified in 106 provinces and 20 regions. Only 99 out of 106 provinces host at least one university.

In Italy, we observe at least one university per region, thus we could advance the hypothesis that all students considered in the analysis are *free movers* [8]; namely, they all had the opportunity to attend their university studies in the region where they reside but decided to move to another. Overall, 56496 *mover* students have been identified among the subset of 229,813 students. Descriptive statistics clearly show that the propensity to be a *mover* varies across universities, the kind of degree program attended, the macro-area and the region of origin and destination. The research combines personal details on students, provided by the *NSA*, with socio-economic indicators of the provinces where the universities are located, provided by the Italian National Institute of Statistics (*ISTAT*), and other information on degree programs and universities effectiveness and reputation, provided by the surveys on Graduates' Profile and Graduates' Employment condition (carried out by the *AlmaLaurea Consortium*). Therefore, the following covariates have been considered to study the determinants of students' mobility choices: a) gender (GENDER), age at enrollment (AGE), the region of residence (REGION) and the information related to high school background- such as final grade obtained at the end of high school (GRADE) and the kind of high school attained (HIGHSCHOOL) - at student level; b) at province level the youth unemployment rate (25-34 years old) (YUNEMPLOYMENT) and a normalized indicator of gross value added per capita (NGVA) have bee used to contextualize differences in the socio-economic conditions between students' provinces of residence; moreover, the information on the number of different degree programs (NCOURSES) supplied by the universities located in the province of residence has been used as a proxy of the dimension of the tertiary education supply; c) at degree program level, (DPL) the information on graduates' rate of employment one year after graduation (EmployAfterGrad-DPL), on their average wage (WageAfterGrad-DPL) and on their self-reported perception on several aspects of the universities studies (Satisfaction -DPL), have been considered to contextualize differences in degree programs effectiveness and reputation. The information on the percentage of students with both parents graduated (GradParents -DPL) has been adopted to take into account the heterogeneity of socio-economic conditions of students belonging to different degree programs. Finally (d) at the university level the same indicators used at degree program level and described at point (c) (EmployAfterGrad-UL; Satisfaction -UL; GradParents- UL) have been adopted to contextualize differences in the characteristics of the universities. The macro-area where the university is located has been used to assess the effect of geographical components.

3 Modeling approach

Let us indicate with Y_{ijg} an indicator variable which assumes value 1 if student i ($i = 1,\dots,n$) from degree program j ($j = 1,\dots,J$) of the university g ($g = 1,\dots,G$) resides in the region where the university is located (is a *mover*) and 0 if she/he resides in the same region (is a *stayer*). The probability to be a mover is modeled using a logistic function as follows

$$logit[\gamma_{ijg}] = \tau + \boldsymbol{X}_{ijg}^T\beta + \boldsymbol{Z}_j^T\gamma + \boldsymbol{U}_g^T\delta + \theta_j + \boldsymbol{\lambda}_g^T\boldsymbol{v}_g \qquad (1)$$

where $\gamma_{ijg} = \pi_{ijg}$ and $\mathbf{X}_{ijg}$ is a vector of individual covariates (Level-1), $\mathbf{Z}_j$ is a vector of covariates at degree program level j (Level-2), and $\mathbf{U}_g$ is a vector of covariates at university level (Level-3). $\boldsymbol{\theta}_j \sim N(0,\sigma_\theta^2)$ is a random term shared by observations related to the same degree program, whereas $\boldsymbol{v}_g \sim MVN(0,\Sigma_v)$ enables to account for heteroskedasticity between universities due to geographical components (e.g between macro-area propensity to attract students). The presence of both random components enables to split the between university variability from the between degree program variability in the propensity to attract students. $\boldsymbol{\lambda}_g$ is a vector which enables to identify the macro-area where the university is located (e.g considering three geographical macro areas, $\boldsymbol{\lambda}_g$ for student i assumes value 1 only for the macro-area where the university is located). The expected posterior predictions of the random terms ($\hat{\theta}_j$ and $\hat{v}_g$) enable to make inference about degree programs (i.e. degree program-university combination) and universities attractiveness. The cross-classified model described on (1) (where students are clustered in degree programs (Level-2) that belong to different universities (Level-3)) has been made hierarchical by considering at Level-2 degree program-university combinations. Thus, the variability in the propensity to attract students is split in two components: the between-university variability and the between-degree program within-university variability, allowing the divergences in $\hat{\theta}_{jg}$ to capture the gap in the attractiveness of degree program j belonging to the university g from the overall university attractiveness parameter $\hat{v}_g$. The model has been estimated with the runmlwin routine which calls MLwiN scripts from Stata by adopting Monte Carlo Markov Chain algorithm (Leckie & Charlton (2013)) [9].

4 Model Results

A model building strategy has been carried out to select relevant predictors at each level of analysis. Starting from the null model, relevant assumptions for the definition of the model structure have been tested. The main findings suggest that the variance of the random terms across geographical areas is homoskedastic. Thus the random component $\boldsymbol{v}_g$ has been considered univariate. Results depicted in Table 1 show that `AGE` and `HIGHSCHOOL` attended influence the probability to be a *mover*. Namely, it is higher for older students who attended a classical or scientific lyceum and come from southern regions (with the exception of Aosta Valley) such as Basilicata, Calabria, and Apulia, while it is lower for younger students who attended a professional school and come from northern and center regions such as Emilia Romagna, Tuscany and Lombardy. *Movers* come mainly from provinces with disadvantage economic conditions, as it is shown by the coefficient of both socio-economic indicators `YUNEMPLOYMENT` and `NGVA` addressed to depict the socio-economic framework. The dimension of the tertiary education supply in the origin provinces does not seem to be a detterent to students' propensity to move. Looking at the geographical macro-areas where the universities are located, we can observe that *movers* prefer to study in universities of the north or center of Italy. The employment rate one year after the graduation in a given university seems to be a pull factor of mobility. The characteristics of the degree program highlight that the propensity to be a *mover* is higher in the degree programs attended by students coming from more educated families (`GradParents -DPL`), and lower in those where the perceived student satisfaction towards the university studies is higher (`Satisfaction-DPL`). The variances of the random terms show that about 70% of the variability in the propensity to be a *mover* is explained at University level, whereas differences between degree programs within each university, even if significant, have a lower effect ($\sigma_v^2 = 2.84$ vs $\sigma_\theta^2 = 0.335$).

The climate funds for energy sustainability: a counterfactual analysis

I Fondi per il clima a sostegno della sostenibilita' energetica: una analisi di impatto

Alfonso Carfora and Giuseppe Scandurra

Abstract In this paper we analyze the effectiveness of climate funds to combat climate change and promote mitigation and adaptation policies. We analyse the funds received by the recipient through a counterfactual analysis. The results show that the policy contributed to the decreasing of greenhouse gas emissions and promoted the change in generation energy systems supporting the replacement of fossil sources with renewable sources.
Abstract Si vuole analizzare l'efficacia dei fondi per il clima nella lotta al cambiamento climatico e per la promozione di politiche di mitigazione e adattamento. Sono analizzati i fondi ricevuti dai Paesi beneficiari attraverso un'analisi controfattuale. I risultati mostrano che questa politica ha contribuito alla riduzione delle emissioni di gas serra ed ha promosso il cambiamento nei sistemi di generazione elettrica favorendo la sostituzione delle fonti fossili con fonti rinnovabili.

Key words: climate finance, propensity score matching

1 Introduction

During the 15th Conference of the Parties (COP15) held in December 2009 in Copenhagen, developed countries pledged to provide new and additional resources to combat climate change, approaching USD 30 billion for the 2010-2012 period, with balanced allocation between mitigation and adaptation

strategies. This collective commitment is known as fast-start finance and prefigures the institution of Green Climate Fund (GCF) established by the 194 countries that are members of the United Nations Framework Convention on Climate Change (UNFCCC) in 2010, to support a paradigm shift in the global response to climate change. Through the GCF mechanism, donor governments distribute funds to recipient developing countries to finance low-emissions and climate-resilient projects and programs in these countries. As they are proliferating, the challenges of coordinating funds and the monitoring of recipient countries emissions became an important matter to assess their effectiveness. In this paper, we want to evaluate the impact of the climate funds distributed by donor countries on environmental and economic factors analyzing the flow of funds among countries and conducting a counterfactual analysis. To achieve our aims, we employ propensity score matching (PSM) analysis on a large dataset of 149 countries.PSM is a statistical method which make the construction of a probabilistic match among units that have participated in a treatment (treated) and units that have not participated (untreated), utilizing characteristics that are common to both groups [1]. The remainder of the paper is organized as follows: Section 2 describes the data. Section 3 reports the empirical results while in Section 4 we discuss the results. Finally Section 5 offers some concluding remarks.

2 Data

To assess the impact of fast-start finance, we use the AidData Research Release 2.1 database that is based on the Credit Report System database, managed by the OECD's Development Assistance Committee (DAC).We consider the funds for energy generation and supply by renewable sources and the flows of funds targeted at biosphere protection using a dataset of 149 countries. It considers the totality of countries eligible to receive funds according to the OECD's Official Development Assistance (ODA) list. Dataset includes countries that have received funds in 2010 (treated –- 83 countries) and those that did not receive funds (untreated –- 66 countries). Explanatory variables can be grouped as target and control indicators.
Among the target variables, we include i) the share of renewable energy in the total energy generated (shren), ii) GDP per capita (gdp), iii) CO_2 per capita emissions (CO_2) and iv) the share of fossil energy in the total energy generated (shfoss).

In the group of control variables, we consider those typically indicated by the previous literature [2] as key factors that drive countries toward increasing generation from renewable energy sources: electricity consumption, the oil supply, energy intensity, the female population and the population growth rate.

3 Empirical Results

The coefficients of the propensity score probit model are reported in Table 1.

Table 1 Coefficients and goodness of fit statistics of the probit propensity score model

Variables	Coefficients
Intercept	1.5527
Electricity Consumption	0.3752^a
Oil Supply	-0.0003^c
Energy Intensity	-0.4111^c
Female	0.0207
Population Growth	0.8419^b
Electricity Consumption Squared	0.0225
Population Growth Squared	-0.2019^b
Loglikelhood	-73.7389
Pseudo R^2	0.3185

Significance: ^{a} 0.01; ^{b} 0.05; ^{c} 0.1

Climate funds are more attractive for countries characterized by increasing population growth rates, even though at decreasing marginal rate (because the second order coefficient is negative), and high levels of energy consumption. There is no empirical evidence that climate funds are attractive to countries where the female population composition is higher, probably because in the developing countries the women feeling for environmental issues are less consolidated. By contrast, oil-exporting countries and those that are more oriented toward the use of traditional energy sources (high energy intensity) prove to be more resistant to these types of policies in support of renewable energy generation because they imply structural changes in their industrial structures and economic systems that are generally well-developed. The results of the probit model confirm several consolidated issues and they represent an important starting point for the next step of the work, which concentrates on the analysis of impact of the funds on countries that have obtained them. Moreover, the matching performed using the fitted values of the model (the propensity scores) ensures that the similarities between matched countries are respected: the average values of the control variables of the untreated countries are not significantly different from those of the countries to which they have been matched (Table 2 column 2). The matching is obtained using the nearest neighbor (1) algorithm that provides a one-to-one matching setting the caliper threshold equal ton 0.25 [3].

Table 2 Tests of balance: similarities of means of the control variables before and after matching

4 Discussion

The treatment effect on treated (ATT) represents a comparison between the observed values and the expected values of the target variables for the treated countries if they had not participated in the treatment. Countries that have received funds, in fact, are similar, in terms of the control variables, to the countries that have not received funds to which they have been matched. However, they are different in terms of the target variables, and the basic hypothesis is that this difference is due to the treatment. Table 3 reports the values of the estimated ATT.

Table 3 Average treatment effects on treated

Variables	ATT
Shren	0.1872^b
Shfoss	-0.1670^c
CO_2	-2.8205^b
GDP	$1,344.3^b$

Significance: ^{a} 0.01; ^{b} 0.05; ^{c} 0.1

In terms of CO_2 emissions , without the funds, there would have been no differences between treated countries and their similar matched countries. Instead, the significant reduction of about 2.8 metric tons in the CO_2 per capita emissions of treated countries is a result that is in line with the global climate finance architecture. This result suggests that climate finance mechanisms, in fact, are useful to enhance the efforts to reduce emissions. Focusing on per capita GDP, we observe another difference between treated and untreated countries. On average, the GDP of countries that have received funds increases approximately 1,340 USD with respect to that of the counterfactual part. This result confirms those of several recent studies on the positive effects of climate financing on the economies of developing countries [4] with renewable energy being a crucial component for the economic growth of developing countries [5]. Observing the estimation results, we note that treated countries have, on average, a share of energy produced by renewable sources (shren) that is significantly higher with respect to their similar untreated countries by approximately 19%. Complementarity, the share of energy produced by fossil fuel (shfoss) is significantly lower, on average, by approximately 17% with respect to the counterfactual part of countries. This important result suggests that climate finance can help countries increase investments in RES generation and can substitute for fossil power generation. Moreover, this result indicates that the climate funds help to change the electricity basket generation, increasing the share of RES generation in place of fossil fuel generation .

5 Conclusion

The results obtained in this paper provide clear indications on the effectiveness of climate funds in promoting the green growth. The results show that funds have been devoted to enhance energy efficiency and sustainability: the recipient countries, in fact, reduced their GHG emissions respect to their similar counterparts. The factors that explain this empirical result are the positive consequence of the policies implemented in the last years in which the need to reach the targets imposed by the climate finance leaded them toward an increasing attention for environmental issues. Moreover, the results show a decrease in the shares of electricity generated by fossil fuels and an increase in RES generation. In particular in these countries, we observe that the decrease of the generation of energy by fossil sources is balanced by the increase of the generation of RES. The increase in GDP per capita occurs in the recipient countries, with respect to the counterfactual part. Climate funds can be considered helpful instruments to promote the path towards a sustainable energy system, based on a high share of RES generation, for developing countries. In order to ensure the efficient funding allocation, policy makers have to regularly monitor the achieved results of financed projects. Our results could support the Ad Hoc Working Group on the Paris Agreement (APA) in monitoring the progresses made to reach the goals of the climate funds. Moreover, the findings provide a starting point to plan environmental policies to be undertaken in preparation to the full implementation of the Paris Agreement. The analysis carried out shows that the beneficiary countries have increased the share of electricity from renewable sources and have reduced the share of electricity from fossil ones, finding it more useful and advantageous to replace them with renewable ones. However, funding should be better targeted.

Exploratory GIS Analysis via Spatially Weighted Regression Trees

Analisi esplorativa di dati GIS mediante alberi di regressione pesati spazialmente

Carmela Iorio, Giuseppe Pandolfo, Michele Staiano, and Roberta Siciliano

Abstract The challenging goal of the *Moving Towards Adaptive Governance in Complexity: Informing Nexus Security* (MAGIC) project is to quantitatively enlighten the nexus among energy, food, water and land use toward informed governance inside EU aimed at long term environmental feasibility, economic viability and social desirability. Within the framework of recursive partitioning algorithms by tree-based methods, this paper provides an application on a real Geographic Information System (GIS) dataset regarding the irrigation communities in Almeria, Spain. We propose to build an explorative regression tree – spatially weighted – aiming at classifying the specific consumption of water (per hectare) of the farming communities based on either water management areas and different mix of sources for irrigation water (surface, groundwater, waste water, desalination).

Abstract *Il progetto Moving Towards Adaptive Governance in Complexity: Informing Nexus Security (MAGIC) mira ad illustrare quantitativamente il nesso tra consumi di energia, cibo ed acqua e l'uso del suolo nell'Unione Europea, con lo scopo di sostenerne i processi decisionali orientati alla compatibilità ambientale, fattibilità economica e desiderabilità sociale di lungo periodo. Nel presente lavoro è descritta un'applicazione a dati reali, raccolti in un sistema informativo geografico (GIS) relativo alle comunità irrigue dell'Almeria, inquadrata nell'ottica dei metodi*

di partizione ricorsiva su alberi. La proposta consiste nella costruzione di un albero di regressione esplorativo opportunamente pesato, per classificare il consumo specifico di acqua (per ettaro di superficie irrigua) nelle diverse comunit agricole della regione in base alle aree di appartenenza ed al differente mix di fonti.

Key words: Regression trees, Supervised statistical learning, Spatial methods

1 Motivation

The MAGIC project aims at suitably tackling the nexus among energy, food and water to assess the sustainability as a complex predicate. It features a novel perspective rooted in bioeconomics toward the accounting of technical and environmental resources required to assure the living standards of our societies. In order to inform and steer the processes of decision and policy making inside UE, quantitative contents of narratives about the various theme related to the project – water, energy, food accounts along with labour and land use entanglement, their nexus and scenarios for innovations in the current state of affairs – are to be produced by means of a rigorous and transparent approach to official data, specific domain knowledge and agreed models. Therefore, statistical learning is envisioned as a key tool to lift data to information and up to knowledge, as needed to cope with the complex predicament of sustainability.

Among a set of pilot case studies approached during the first year of the project, some real datasets were exploited as test bench for the fruitful interaction of domain experts and statisticians.

2 A short introduction to exploratory regression trees

Classification And Regression Trees (CART) developed by [1] is a milestone in the evolution and spreading of the tree-based methodology. Recursive partitioning tree procedures adopt a supervised approach: the response variable (of numerical or categorical type) drives the learning process on the basis of a set of predictors (of numerical or categorical type). For this reason CART methodology can be viewed as precursor of supervised statistical learning introduced by [10] and outlined by [5] . Tree-based methods have been proposed for both prediction and exploratory purposes. In the exploratory context, binary segmentation can be understood as a recursive partitioning of objects into two subgroups due to some splitting variables derived from available predictors such to obtain internally homogeneous and externally heterogeneous subgroups with respect to a target or response variable [6]. The final result is a binary tree visualizing the dependence relationship between the response variable and the predictors.

In regression trees, the splitting criterion at each non terminal node can be to maximize the decrease of impurity of the response variable within the two sub-nodes, where the impurity is a measure of variation for numerical responses. Nodes are declared to be terminal on the basis of a stopping rule. Terminal nodes include disjoint and homogeneous subgroups of objects, defining a partition of the starting group of objects at the root node with respect to the response variable. The tree with only one split at the root node is called stump. It describes the best partition of the objects into just two subgroups such to minimize the internal variation of the target variable within the two nodes. The quality of any tree can be measured by an overall impurity measure of the tree. In regression trees, this is calculated by the sum of the variation measures of the target variable within its terminal nodes. Typically, the overall impurity of any tree is compared with respect to the impurity at the root node: the ratio of the two quantities provides a relative cost reduction measure named deviance. By definition of splitting criterion, the deviance reduces as the number of terminal nodes or tree size increases. For a more detailed literature study one can refer to [7, 8, 9, 3, 2] and to the references therein.

3 A Real Problem

The analysis has been performed on a data set collected in 2013 and related to the all the irrigation communities in Almeria which are grouped geographically by 18 water management areas and technically by 38 distinct water sources patterns. Raw GIS data matrix consists of 376 instances, designated as irrigation communities. As the entire population is surveyed, the analysis is only exploratory, not confirmatory nor predictive. Exploratory trees belong to data mining methods where also visualization helps the analyst to better understand the phenomena [4]. We built an exploratory regression tree spatially weighted aiming at classifying the specific consumption of water per hectare of the irrigation communities base on either water management area (coded as in Table 1), and sources of water used (surface, groundwater, waste water, desalination), grouped in 8 different profiles described in Table 2. An expanded regression tree with the purest terminal nodes, accordingly to an initial stopping rule, has 48 leaves. Since this structure is rather complex to be interpreted, a simpler structure of the regression tree can be identified. One can fix

Table 1: Water Management Area (WMA) codes

remaining profiles (reused and desalted)	8

a certain threshold value for the overall impurity, then select among the sub-trees not exceeding the fixed threshold value the one with minimum number of leaves. Specifically, Fig. 1 shows that the deviance reduction is marginal for the trees with more than 9 leaves. Consequently, we chose the regression tree with 9 terminal nodes as final tree. We named it "intermediate regression tree" and its representation is displayed in Fig. 2. The labels set in Fig. 2 at any internal node indicate the splitting variables with those categories inducing the objects to the left sub-node; at the leaves of the tree are reported the mean values of the target variable (cubic meters of water consumed in one year per hectar of farming surface). Fig. 2 points out that the mean response values increase from the left-hand side to the right-hand side. This clearly conveys to the domain expert the information that the irrigation communities belonging to the leftmost leaves consume less water per hectare than those belonging to the rightmost terminal nodes. By watching the mean fitted values of the rightmost terminal leaves it can state that the WMA belonging to both Campo de Nijar and Poniente are the more water intensive consumption areas. Specifically, the irrigation communities belonging to Poniente has the highest mean value of water use per hectare. The simplest result of analysis reduces the tree to a stump with the only splitting rule due to WMA. Thus, the stump partitions the irrigation communities into two regions of predictor space. The resulting partition singles out the most water intensive management areas. On the right-hand side, there are the management areas with lower values of water consumed per hectare (mean value equals to 3377); on the left-hand side, there are the remaining management areas, Campo de Njar and Poniente, with higher values of water consumed per hectare (mean value equals to 6199). Thus, the stump reveals that the most important factor associated with water consumption per hectare is due the water management areas. Fig. 3 displays a geographic visualization of the stump (the map was produced elaborating the R output by open source GIS software Q-GIS and includes a satellite imagery title obtained by BING).

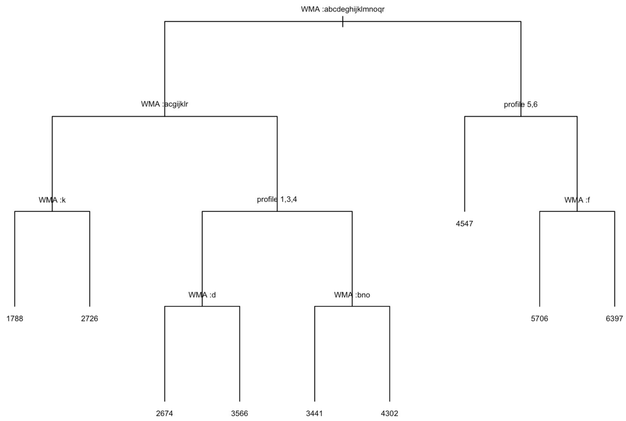

Fig. 2: The intermediate regression tree for Almeria data set.

4 Final remarks

In the framework of MAGIC project, this paper was designed to deal with a real problem of statistical analysis. We analyzed the water consumption by irrigation communities in Almeria. The regression tree is a device simple to be presented and understood; nevertheless, it required a careful tailoring of the standard approach (being the observations to be spatially weighted) and a trade off between easiness and richness of the representation should be agreed in order to choose the number of leaves. The "intermediate regression tree" enables to highlight some key features in the data set. Indeed, the leaves resulted ordered from left to right hand side of the tree with increasing levels of average water consumption per hectare: this classification is a good starting point for deepening the analysis. The water consumption per hectare in some management areas is quite more spread than in some others; this clearly depend on the types of crops and cropping methods along with the irrigation means and water sources, so grafting current data to other information could offer a

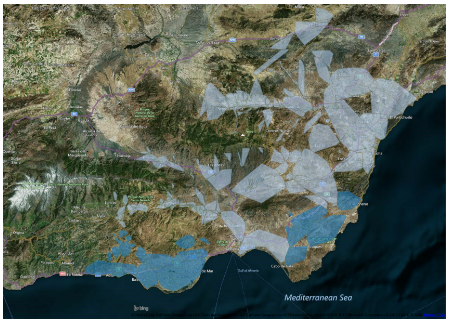

Fig. 3: GIS visualization of the STUMP (the blue areas mark the WMAs with higher consumption of water per hectare Campo de Nijar and Poniente compared to the gray ones).

better insight. The role of profiles of sources varies in different sets of water management areas, so we could technically say that the two predictors interact: this is the clue for a further investigation. A richer GIS approach to the problem could be beneficial for the analysis, so collecting more layers of data and comparing spatially any pattern could strenghten the knowledge discovery process.

A functional regression control chart for profile monitoring

Carta di controllo mediante regressione funzionale per il monitoraggio di profili

Fabio Centofanti, Antonio Lepore, Alessandra Menafoglio, Biagio Palumbo and Simone Vantini

Abstract In many applications, profile monitoring techniques are needed when the quality characteristic under control can be modeled as a function. Moreover, measures of other functional covariates are often available together with the functional quality characteristic. To combine the information coming from all the measures attainable, a new functional control chart is proposed for profile monitoring. It relies on the residuals of a function-on-function linear regression of the quality characteristic on the functional covariates. The effectiveness of the proposed monitoring scheme is illustrated on a real-case study about the monitoring of CO_2 emissions from a Ro-Pax ship owned by the shipping company *Grimaldi Group*.

Abstract *In molte applicazioni è necessario utilizzare metodi di controllo statistico di processo a caratteristiche di qualità modellabili come funzioni. Inoltre, è spesso possibile integrare nello schema di monitoraggio anche la disponibilità di osservazioni di covariate funzionali ad esse correlate. In questo lavoro, viene presentata una carta di controllo funzionale basata sui residui di un modello di regressione lineare funzionale della caratteristica di qualità sulle covariate ad essa associate. Le potenzialità dell'approccio proposto, vengono illustrate mediante un caso studio sul monitoraggio delle emissioni di CO_2 di una nave da carico e passeggeri.*

1 Introduction

New statistical process control (SPC) methods have to be developed in order to handle complex data, whose collection and storage is nowadays facilitated by modern data acquisition technologies. In many practical situations the quality characteristic of the process can be modelled as a function defined on a compact domain. Data of such kind are the foundation of a rapidly expanding area of statistics referred to as *functional data analysis* (FDA [14, 4]). SPC methods that allow monitoring and controlling such processes are better known as *profile monitoring* techniques [12].

Measures of functional covariates are often available together with the functional quality characteristic. In this communication we build a novel control charts scheme [11] which fully exploit the additional information content of those functional covariates to improve the profile monitoring of the quality characteristic. The proposed chart is referred to as *functional regression control chart* (FRCC) and provides an extension of the *regression* (or *cause-selecting*) *control chart*, which arises in the multivariate context [10, 7, 8, 16, 15]. The effectiveness of the proposed control chart is demonstrated by means of a real-case study dealing with monitoring CO_2 emissions and identifying (negative) shifts after a specific energy efficiency initiative (EEI) that has been performed on a Ro-pax ship owned by the shipping company *Grimaldi Group*.

2 The proposed control chart

Let $Y(t)$ represent the functional quality characteristic (hereinafter referred to as *response variable* or simply *response*) and $\boldsymbol{X}(t) = (X_1(t), \dots, X_p(t))^\top$ be the functional covariates (hereinafter referred to as *predictor variables* or simply *predictors*) with $t \in \mathscr{S}$, a compact set in $\mathbb{R}$, which are assumed to be elements of $L_2(\mathscr{S})$ (the Hilbert space of square integrable functions defined on the closed interval $\mathscr{S}$). In this setting, we model the predictors as influencing the response according to the following multivariate functional linear regression model

$$Y^Z(t) = \int_{\mathscr{S}} (\boldsymbol{\beta}(s,t))^\top \boldsymbol{X}^Z(s)\,ds + \varepsilon(t), \tag{1}$$

with $Y^Z(t)$ and $\boldsymbol{X}^Z(t) = \left(X_1^Z(t), \dots, X_p^Z(t)\right)^\top$ the point-wise standardized response and predictor variables and $\boldsymbol{\beta}(s,t) = (\beta_1(s,t), \dots, \beta_p(s,t))^\top$ the vector of the regression functional parameters. Given n iid observations $(Y_i(t), \boldsymbol{X}_i(t))$, $i = 1, \dots, n$ (i.e., Phase I dataset), an estimator $\hat{\boldsymbol{\beta}}(s,t)$ of the coefficent vector $\boldsymbol{\beta}(s,t)$ is obtained by considering the truncated versions of the univariate and multivariate Karhunen-Loève's basis expansions [6] of $Y^Z(t)$ and $\boldsymbol{X}^Z(t)$, respectively. The rationale behind the FRCC is monitoring the functional residual

$$e(t) = Y^Z(t) - \hat{Y}^Z(t), \tag{2}$$

where

$$\hat{Y}^{Z}(t)=\int_{\mathscr{S}}\left(\hat{\boldsymbol{\beta}}(s,t)\right)^{\top}\boldsymbol{X}^{Z}(s)\,ds \tag{3}$$

is the prediction of $Y^{Z}(t)$ given $\boldsymbol{X}^{Z}(t)$ based on the linear model (1). For this purpose, we use the approach adopted in [5, 17, 13] where the residuals are decomposed via principal component analysis and the corresponding coefficients are monitored by means of the Hotelling's T^2 and the squared prediction error (SPE) control charts. However, other expansion techniques can be used as well. The control limits of the T^2 and SPE control charts are calculated as the percentiles of their empirical distributions obtained from the Phase I sample based on an overall Type I error α. This phase, along with the estimation of the sample version of Equation (1), will be referred to as Phase I.

For a new observation $(\boldsymbol{X}^{*}(t), Y^{*}(t))$, the residual and the associated T^2 and SPE statistics can be calculated. An alarm is issued if at least one of the latter two statistics violates the control limits (Phase II).

3 A real-case study

In this section an application to a real-case study of the FRCC is illustrated. In particular, real data are collected from a Ro-Pax ship owned by the Italian shipping company *Grimaldi Group* from December 2014 to October 2017. The *CO_2 emissions* per each voyage are considered as the response variable, whereas, the *sailing time*, the *speed over ground* and the *longitudinal* and *transverse wind components* are assumed as the predictors (further information on the variables can be found in [1, 3, 9]).

During February 2016 a specific EEI was performed that plausibly produced a negative shift in the response mean [3]. In light of this, observations collected before the considered EEI are used as the Phase I sample, whereas the remaining observations pertain to the Phase II. The overall Type I error α is set to 0.0027, as commonly done to set three-sigma limits on classical Shewhart control charts. To evaluate the FRCC performance, two competitor profile monitoring schemes proposed in [2] and [13], respectively, are considered as well. The first consists of monitoring the scores along the first principal components of the response by means of the Hotelling's T^2 and SPE control charts (hereinafter referred to as as RESP control chart). The second competitor is the index-based (INBA) control charting, which monitors the area under the response curve.

The performance of the considered control charts are evaluated by means of the *average run length* (ARL) [11] after the EEI, given that the in-control ARL is equal to $1/\alpha = 370$. The estimated ARLs, denoted with $\widehat{\text{ARLs}}$, are reported in Table 1. They clearly point out that the proposed control chart outperforms the competitors. Indeed, the $\widehat{\text{ARL}}$ achieved by the proposed FRCC is markedly lower than those of the RESP and INBA control charts.

Table 1 $\widehat{ARL}$s for the FRCC, RESP control chart and INBA control chart

	$\widehat{ARL}$
FRCC	18.60
RESP	34.09
INBA	50

4 Conclusion

A regression control chart is proposed to monitor a functional quality characteristic when observations of other functional covariates are available. It consists of monitoring the functional residuals coming from a function-on-function linear regression of the response, instead of the response. An application of the proposed control chart to a real-case study aiming to monitor the CO_2 emissions of a Ro-pax ship demonstrates that it outperforms two other popular alternatives proposed in the literature in identifying a shift on the response. However, further investigations should be done to asses the FRCC performance over different scenarios.

Understanding pro-environmental travel behaviours in Western Europe

Analisi delle scelte di trasporto pro-ambientali nell'Europa Occidentale

Gennaro Punzo, Rosalia Castellano, and Demetrio Panarello[1]

Abstract This study aims at understanding, from a gender perspective, the reasons behind citizens' choice of using public transport, and whether this choice is driven by pro-environmental behaviour. Using Eurobarometer data (2013), we perform ordered logistic regressions comparatively for Germany, Italy and the Netherlands. Financial, political and environmental factors are shown to have significant roles in shaping travel behaviours, with interesting gender and cross-country differences.

Abstract *Questo studio esplora, in una prospettiva di genere, i fattori che indirizzano i cittadini alla preferenza del trasporto pubblico, con l'intento di indagare se tale scelta sia anche dettata da atteggiamenti pro-ambientali. L'analisi è eseguita su dati Eurobarometro (2013) in un'ottica di comparazione internazionale tra Germania, Italia e Olanda. I modelli di regressione logistica ordinale consentono una valutazione del ruolo che le componenti finanziarie, politiche e ambientali svolgono nella definizione dei comportamenti di viaggio, evidenziando tratti distintivi per genere e Paese.*

1 Introduction

Dealing with personal transportation is one of the major environmental challenges in current years when the car is the leading travel mode. In Europe, car use growth accelerated sharply during the last decades [1], until exceeding 80% of inland

[1] Gennaro Punzo and Demetrio Panarello, University of Naples Parthenope, Department of Economic and Legal Studies, email: gennaro.punzo@uniparthenope.it; demetrio.panarello@uniparthenope.it

Rosalia Castellano, University of Naples Parthenope, Department of Management and Quantitative Studies, email: lia.castellano@uniparthenope.it

passenger transport at the beginning of the 2000s. Since then, the share of passenger transport by car was within the range 83% to 83.7% up to 2015 – against 7.7% for trains and 9.2% for motor coaches, buses and trolley buses (Eurostat database) – and it is expected to keep its dominant position in the future.

Traffic that is not properly managed generates serious consequences for human health and large scale social and environmental problems with detrimental effects on climate changes, as well as negative emotional reactions because of noise and pollution in urban areas [5,7]. This is why many world's countries are making significant efforts to develop pro-environmental behaviours (PEBs) associated with transportation to meet the environmental challenge in the path to sustainability – e.g., Kyoto Protocol (1997), White Paper "European Transport Policy" (2001).

A widespread literature investigates the complexity of PEBs at the individual and social level by multiple perspectives. All these conceptual models, together with the recent approaches on cultural participation and civic virtue [6], have proved to be complementary as a way of providing policy makers with solid grounds to better recognise socio-economic behaviours and to design interventions for environmental sustainability [8]. Specific travel behaviours, which are usually distinctly gender-related, should constitute as small a burden on the environment as possible. For example, measures aimed at taming the car (i.e., by providing safe and inexpensive alternatives to private motor vehicles such as walking, cycling, and public transport) could be viable ways to create more sustainable transport systems [1,7].

By considering the choice of transport mode as a pro-environmental proxy of sustainability [1,8], this paper performs a comparative investigation in three Western European countries (Germany, Italy and the Netherlands) of the reasons behind citizens' choice of using public transport (PT) rather than private transportation modes, and whether this choice is driven by sustainable behaviour. Indeed, all these countries are leaders in sustainable mobility in some respects (see [4]). The research hypothesis assumes that the impact of the variety of objective and subjective factors on the use of public service differ across countries, whereby the differentials among countries should also be analysed from a gender perspective.

2 Methodology and data

One of the main elements of novelty of this work is that it links research on the driving forces of PT usage across countries to the assessment of PEBs from a gender perspective. Methodologically, we estimate ordered logistic regressions by country and gender on a set of covariates, which are grouped into three dimensions (travel mode choice, own financial perception, politics and environment) supposed to influence the frequency of use of PT (y_i, manifest variable), controlling for a range of personal socio-demographic characteristics.

An underlying decisional process – based on a comparison among the utilities of different travel modes, leading to the choice of using PT – is expected. Therefore, a continuous unobservable propensity (y_i^*, latent variable) would cross thresholds (τ) that differentiate adjacent levels of the observed ordered y_i's. It follows that a cumulative model for the ordered logit model is equivalent to a system composed of a set of thresholds τ_m and a linear regression model for an underlying continuous response. The latent variable, which represents the relative advantage of using PT, is supposed to be linearly related to the observed x's through the structural model:

$$y_i^* = x_i\beta + \varepsilon_i \qquad (1)$$

where β is the vector of coefficients and ε_i is the error term with mean zero and standard deviation $\pi/\sqrt{3}$.

The manifest ordinal variable (y_i), which measures PT use frequency through a 7-point Likert scale, is related to y_i^* according to the following model:

$$y_i = m \quad if \quad \tau_{m-1} \le y_i^* < \tau_m \qquad for \quad m = 1 \quad to \quad J \qquad (2)$$

where m identifies the seven levels (J=7) of the manifest variable (*never*, *less than twice a month*, *two/three times a month*, *about once a week*, *two/three times a week*, *once a day*, *several times a day*) and τ the estimated thresholds on a latent variable used to differentiate the levels of PT usage.

The probability that the individual i will select the alternative m is:

$$p_{im} = P(y_i = m|x_i) = F(\tau_m - x_i\beta) - F(\tau_{m-1} - x_i\beta) \qquad (3)$$

where F is the logistic cumulative density function (c.d.f.).

We use Eurobarometer data on the attitudes of Europeans towards urban mobility [3]. This survey, carried out in the EU-28 between May and June 2013, consisted in conducting face-to-face interviews in people's homes to look at their transport habits, experiences, opinions and expectations. In all three countries, it is possible to drive with supervision at age 17, and without supervision at 18. This is why we include only individuals aged 18 and above (until 79), as the use of PT before that age is driven by necessity rather than personal choice[1].

3 Main results and discussion

Tables 1 and 2 show our main results for men and women, respectively[2]. A brief focus on the outcomes from each country follows.

Table 1: Ordered logit estimation – Men (2013)

Variables	***Coefficients***		
	Germany	***Italy***	***Netherlands***
Socio-demographic			
Marital status (1: *married*)	-0.200	-0.356	-0.467^{*}
Age at completion of education (1: *<16 years*)	-0.340	-0.367	-0.987^{**}
Age (1: *61-79 years*)	-0.472^{**}	-0.801^{***}	-0.631^{***}
Job level (1: *professional/manager*)	-0.206	0.326	0.273

[1] The total number of observations is 3,329. Specifically, there are 1,391 individuals from Germany, 1,001 from Italy and 937 from the Netherlands. Post-stratification weights, based on a comparison for each sample with the respective universe, are properly accounted for.

[2] Standard errors are not included for sake of brevity; though, they are available upon request.

Results show that the variety of factors have different roles in shaping travel behaviours in the three countries and for each gender; nevertheless, a cross-national analysis of sex differences in PEBs may be drawn.

A high education level has a positive effect on PT usage for Dutch people; in Italy, women who are well-educated and have got a high-level job are about to use PT with a greater intensity than women either with a low education and low-level job, students or unemployed. This states the key role of education in environmental matters: well-educated people are, in general, more aware and concerned and, thus, more willing to engage in concrete environmental protection actions. Due to the lower availability of childcare services in Italy, which leads to major challenges in urban travelling [2], Italian women with kids appear less prone to use PT. Living in a big city has a positive influence on the probability of PT usage, as populous urban areas are usually characterised by shorter distances and more developed PT infrastructures. In each country, elderly male citizens are less likely to use PT than their younger counterparts, showing to be more addicted to private vehicles than the new generations, and confirming that the rate of people using multiple modes of transportation, rather than just the car, declines in later life stages.

Men, in general, appear to be more prone to active and multimodal transport compared to women, especially combining bike and PT use. Among women, Dutch are the only ones combining PT use and cycling in daily life, apparently due to a stronger bicycle culture and better cycling facilities in the country. Using pedestrian paths on a daily basis also seems to be positively related to PT use. Frequent car users, on the other hand, are less likely to use PT. These outcomes confirm that public and active transport can be integrated, while a car-based mobility style does not give room for other means of transportation.

Italians with a high socioeconomic status, proxied by home ownership and perceived household financial situation, are less likely to travel by PT if women, and more likely if men, maybe because women are usually travelling shorter distances to work than men, which does not make PT an attractive (e.g., fast, cheap) alternative to the car. People who own a personal car, as expected, are less likely to use PT, but not in the Netherlands, which appears to be more open to alternative transportation modes compared to the other countries.

Dutch people who evaluate road congestion as an important urban problem act differently depending on their gender: while men who do so are significantly less likely to use PT services, women are more likely to use them. It looks like Dutch women care about urban problems more and try to solve them with their behaviour. This is furtherly explained by the fact that Dutch men considering air pollution a relevant urban problem are less likely to use PT as a sustainable solution. Dutch men who are concerned about travel costs, though, are more likely to move by PT. Even if costs are indeed a sensitive issue for mobility, only German male PT users seem to mind about ticket prices. Most PT users demand for a higher PT quality, tending to favour the development of policies that improve conditions for the transport modes they habitually use. In Italy, men who think that enhanced cycling facilities could be appropriate measures to improve urban travelling apparently use PT services with a lower frequency than men who do not, showing not to have a multimodal lifestyle. German and Italian women thinking that urban traffic responsibility is a matter of citizens themselves are more likely to use PT, and the same applies to Dutch men, showing concern for the quality of urban environment and trying to make it better.

All these outcomes indicate that policies aimed at designing pro-environmental transport systems need to be adapted based on local context and gender.

Family & Economic issues

Measuring Economic Uncertainty: Longitudinal Evidence Using a Latent Transition Model

Misurare l'Incertezza Economica: risultati longitudinali usando un modello di transizione a classi latenti

Francesca Giambona, Laura Grassini and Daniele Vignoli

Abstract Economic uncertainty has become an increasing important factor in explaining socio-economic household behaviour, especially for its implications in household choices and demographic dynamics. Accordingly, an operational definition and a measure of economic uncertainty are needed. To this aim, the main purpose of this contribution is to measure economic uncertainty of Italian families by using the 2008-2011 and 2012-2016 longitudinal Italian SILC (Statistics on Income and Living Conditions) data in a latent transition analysis (LTA) approach. LTA is applied, in order to: *i*) to classify Italian households into homogenous classes characterized by different levels of economic uncertainty, and *ii)* to assess whether changes in latent class membership occurred in the time span selected.

***Abstract** L'incertezza economica è un fattore di rilievo nello spiegare le dinamiche socio-economiche delle famiglie. Al fine di analizzare l'effetto della incertezza economica sulle scelte familiari è necessario, per prima cosa, fornire una definizione (operativa) e una misura dell'incertezza economica. Il presente lavoro ha lo scopo di misurare l'incertezza economica delle famiglie italiane, utilizzando i dati longitudinali dell'indagine sul reddito e sulle condizioni di vita 2008-2011 e 2012-2016. L'applicazione di un modello di transizione a classi latenti (LTA), permetterà di: i) classificare le famiglie in classi omogenee caratterizzate da diversi livelli di incertezza economica, e ii) valutare se si sono verificati cambiamenti nell'appartenenza a una classe latente nell'arco di tempo selezionato.*

1 Introduction

Uncertainty is one of the key aspects of the globalizing world, of our “risk society”, and economic uncertainty has become a notable factor in explaining socio-economic behaviours, especially for its implications in family choices and demographic dynamics (Scherer, 2009; Blossfeld & Hofmeister, 2006; Blossfeld, Mills, & Bernardi, 2006). Recently, a number of studies have focused the attention on the impact of economic uncertainty on childbearing decisions (Kind and Kleibrink, 2013; Kreyenfeld, 2010, 2015; Kreyenfeld et al., 2012; Özcan, Mayer, & Luedicke, 2010; Pailhé & Solaz, 2012), also for Italy (e.g., Barbieri et al., 2015; Vignoli et al., 2012). Despite the timely and key relevance of the notion of “Economic Uncertainty” for contemporary societies, however, scholars have been so far rather imprecise regarding its definition and operationalization.

Economic uncertainty is a relative concept – relative to expectations that economic prospects may be stable at a given level. Nonetheless, economic uncertainty is, by its very nature, non-observable. Hence, in demographic and sociological research, it is customarily operationalized as an individual risk factor, mainly related to the labour market (e.g. unemployment, short-term contract jobs, underemployment, involuntary part-time, or a combination of these; Mills and Blossfeld 2013; Kreyenfeld, Andersson, Pailhé 2012). Such an approach, however, focuses solely on the objective side of uncertainty.

A significant downside economic risk – i.e. a hazard or danger – looming in the individuals’ economic future, which they are unable to adequately insure against or avoid or ignore (Osberg & Sharpe 2014). Recently, various empirical concepts have been proposed to distinguish the objective aspects of economic insecurity (Ranci et al., 2017) from subjective feelings such as a sense of uncertainty (Mau, Mewes, & Schöneck, 2012). Previous research has largely failed to recognize that individuals, depending on the extent to which they feel and tolerate uncertainty, might differ with respect to how they react and take decisions in uncertain economic situations (Bernardi et al. 2009; Kreyenfeld 2010). In all, although demographic actors routinely face various types of economic uncertainty, the effects of economic uncertainties are often unclear and hard to assess, in part due to the absence of valid measures.

In this paper, we aim to measure economic uncertainty by acknowledging both its subjective and objective sides. To this end, we propose a synthetic measure of economic uncertainty that acknowledges the multidimensional and latent nature of the concept, through a latent transition analysis (LTA) (Collins and Lanza, 2010).

We apply LTA to the longitudinal data from Italian section of the EU-SILC (Statistics on Income and Living Conditions), related to 2008-2011 and 2012-2016 waves in order to compare empirical findings during and after the Great Recession.

2 Methods

In analysing latent variable models, latent transition analysis (LTA) and latent class analysis (LCA) are related methods. LCA is a statistical method used to group individuals (cases, units) into classes (categories) of an unobserved (latent) variable. It is a statistical procedure for identifying class membership probabilities among statistical units (e.g., individuals, families, and so on), using the responses provided to some chosen set of observed variables. In LCA, the class membership probabilities (i.e., the probability that an individual belongs to a certain class) and the item response probabilities conditional upon class membership (i.e., the probability for an individual to provide a certain response to a specific item given that she/he has been classified in a specific latent class) are estimated and, according to the item response probabilities, observations are grouped (clustered) into classes (Collins and Lanza, 2010; Magidson & Vermunt 2000; Lazarsfeld, 1950). A questionable issue is about the number of classes selected. Theoretically and conceptually, classes may be identified according with some *a priori* research assumption, then statistical criteria can be used to confirm theoretical expectations. Criteria for assessing the number of classes suggest several statistical methods. For instance, Nylund, Asparouhov and Muthén (2007) indicate the Bayesian Information Criteria (BIC) as the best one, so that the number of classes is selected by minimizing the BIC value.

Usually, when longitudinal data are to be analyzed, research questions deal not only with latent class membership but also with changes over time. LTA is a type of latent Markov model and is a variation of the LCA designed to model not only the latent class membership, but also the transitions over time in latent class membership. In LCA, latent classes represent stable sets of characteristics or states of behavior, whilst in LTA, individuals may change latent classes over time. Thus, in this framework, the term “latent statuses” is used instead of “latent classes”, as subgroup membership is not assumed stable over time.

Three sets of parameters are estimated in LTA. First, latent status membership probabilities are estimated for each time. Second, transition probabilities reflect the probability of transitioning from a particular latent status at time t to another latent status at time t+1. Third, a set of item-response probabilities reflects the correspondence between the observed indicators of the latent variable at each time period and latent status membership, in much the same way that factor loadings link observed indicators to latent variables in factor analysis. That is, in addition to the number of classes and the size of classes being subject to change, it is interesting to locate the households that are stayers (in the same class at each wave) and those who are movers.

Specifically, we want to distinguish between households that move to a more positive class (minor uncertainty) and those who move to a less positive class.

3 Data and some first results

The European Union survey named Statistics on Income and Living Conditions (EU-SILC), started in 2003, is aimed at gathering comparable cross-sectional and longitudinal individual level data on income, poverty, social exclusion and living conditions in 27 participating countries. Here, we consider the longitudinal the SILC section for 2008-2011 and 2012-2015 Italian waves. For each household we select some items related to economic uncertainty. We selected a set of objective and subjective items of the EU-SILC questionnaire related to the following dimensions: *financial strain* (arrears on utility bills, on mortgage or rental payments, capacity to afford a meal with meat/fish every second day, ability to make ends meet); *housing* (tenure status); *goods possession* telephone, computer, dishwasher, car and TV colour); *occupational status* (temporary/not temporary job).

We recall that the item-response probabilities in LTA play the same role as in LCA; namely, they represent the basis for assigning labels to latent statuses. BIC value and substantial interpretation of classes, suggest a partition into 5 classes (latent statuses).

Table 1 displays the percentage of households classified in each class for the first time. Latent variable is specified to be ordinal, thus state 1 groups households with lower values of economic uncertainty up to state 5, which groups households with the higher level of economic uncertainty. In state 1 households are owner of their home, have durables goods, have a permanent job, don't have arrears in utility bills or on mortgage or rental payments, make easily ends meet and are able to afford a meal with meat/fish every second day.

Table 1: latent states composition

	Latent State (*)				
	1	**2**	**3**	**4**	**5**
2008-2011	0,205	0,336	0,280	0,139	0,041
2012-2015	0,146	0,221	0,396	0,189	0,048

(*) 1-5: from positive to negative status

In Table 2 the transition probability matrix shows that in the period of the Great Recession (2008-2011), the probability of remaining in the same class is lower than in the post-recession period (2012-2015). Households in better states (1,2) are more "stable" in 2012-2015 respect to 2008-2011 (95% in 2008-2011, 99% in 2012-2015). This is more evident for households in 2008-2011 in intermediate position (state 3) that "move" to better states (state 2 in particular). This happens also for states 4 and 5 for both time periods, but especially in 2008-2011. Mainly, households in better states (1,2) tend to be more stable than the others; whilst households in worse states tend to improve their position, in particular households experimented the Great Recession.

Table 2: transition probability matrix

	State[-1]						**State[-1]**

Intentions to leave Italy or to stay among foreigners: some determinants of migration projects

Le intenzioni degli stranieri di restare o lasciare l'Italia: alcune determinanti dei progetti migratori

Ginevra Di Giorgio, Francesca Dota, Paola Muccitelli and Daniele Spizzichino[1]

Abstract The topic of migration intentions and return migration has been analyzed by different theoretical approaches (Stark (1996); Dustmann (2003)) but still the process of migration decision-making and behaviour is not fully understood (Arango (2000)). On basis of Istat survey "Social Condition and Integration of Foreign Citizens" (SCIF, 2011-2012), this paper aims to explore the migration project of foreign citizens resident in Italy. Using a binomial logistic regression model, has been studied the association of different determinants (socio-demographic characteristics, migration background, personal relationships in Italy, social integration in host country) with the intention of staying permanently in Italy.

Abstract *Il tema delle intenzioni migratorie e delle migrazioni di ritorno è stato analizzato seguendo diversi approcci teorici (Stark (1996); Dustmann (2003)). L'affermarsi di letture diverse e in parte contrastanti rimanda alla complessità di fattori che entrano in gioco nel definire e orientare le intenzioni migratorie (Arango (2000)). A partire dai dati dell'indagine Istat "Condizione e Integrazione Sociale dei Cittadini Stranieri" (SCIF, 2011-2012), questo lavoro si propone di esplorare le intenzioni migratorie degli stranieri che vivono in Italia attraverso un modello di regressione logistica binomiale considerando alcune determinanti (socio-demografiche, del background migratorio, le relazioni interpersonali e alcuni indicatori di integrazione sociale).*

Key words: foreign citizens; migration projects; return behaviour.

1 Background

The issue of return migrations and intention of stay in host country has been analyzed by different theoretical approaches (Stark (1996)); Constant, Massey (2002)). The neoclassical theory associates the decision to return to the country of origin to the lack of integration process in the receiving country, by considering migration as an exclusively individual experience. Instead, the new economic theory of migration considers the return migration as a factor of success of migration experience in which the family plays an important role (Dustmann (2003)). Moreover, the social capital theory (Coleman (1988)) and network analysis approach take into account the role of social networks in return home decision. Therefore no theory is enough to explain factors associated to the intention of return home or stay in host country. However each one refers to the complexity of factors correlated to migrants' decision or intentions.

Since some decades Italy has been a country of immigration with a rising number of migrants. Moreover in the last few years the share of long-term residents has increased (Conti, Strozza (2012)). However, the last census recorded about one million foreigners less then the population register. Likely they have left Italy to re-emigrate to the country of origin or to a third country (onward migration) (Blangiardo (2012)). According to recent studies, based on regional data, the percentage of migrants intending to leave Italy has considerably increased (Terzera (2015)). Therefore, a focus on migrants' intentions seems likely current. The intentions of mobility may vary according to the family and employment conditions or legal status in Italy (Toma, Castagnone (2015); Barbiano di Belgioso (2016)).

2 Research hypotheses and goals

According to the recent debate in the literature, the intention to remain in Italy is not considered only as a positive outcome of the migration project. Indeed, the study aims to explore migrant's intentions (to stay in Italy or to return to the country of origin), taking into account the possible determinants that play an important role to define the migration project.

This study contributes to highlight the importance of socio-demographic characteristics (gender, age, citizenship, education level and employment status), as well as the individual migratory background (migratory intentions at the start, age at the arrival in Italy, years of stay). Moreover it is considered as relevant the family situation in migration (presence of family members in the country of origin or in the receiving country, mixed family, etc.). In fact, the migratory project, regardless of the direction of intentions (stay or return to the country of origin), can represent the outcome of a family choice. The survey data allow a multidimensional analysis of the factors associated to the intentions of individuals living in the family. Similar importance is given to the relational context and to the contacts maintained with the country of origin (periodic return to country of origin) and to some aspects related to social integration in the receiving country (perception of discrimination, knowledge of the Italian language).

3 Data and methods

The analysis of migratory projects was carried out on the data of the sample survey on “Social Condition and Integration of Foreign Citizens” (SCIF), launched for the first time by Istat (Italian National Institute of Statistics) between 2011 and 2012, in partnership with other Italian Institutions[1.]

The SCIF sample survey aims to provide a collection of information about many features of socio-economic inclusion of migrants in Italy in order to explore living condition of resident foreigners. There is a focus on several aspects: family composition, education, migratory path, employment status, discrimination, health conditions and accessibility of health services, migrant integration, citizen's security and victimization, housing conditions. The survey data provides a framework on characteristics, behaviors, attitudes and opinions of the foreign citizens in Italy, as a integration and complement to administrative sources, currently produced by Istat.

SCIF sample survey’s target population is foreign population resident in Italy. The sampling unit is the households resident in Italy with at least one component with foreign citizenship. The family is defined as a group of people living together and related by marriage, kinship, affinity, adoption, protection or affection. In addition to members of the family, people without family ties with residence in Italy have been also interviewed. In the SCIF survey, foreign citizens are identified by citizenship, not by the place of birth.

All the members of 9,553 families were interviewed using CAPI (Computer Assisted Personal Interviewing) techniques. In terms of individuals with foreign citizenship, the survey involved 20.379 people.

The choice of the survey is given by the opportunity to study not only the orientation of migratory projects, but also to investigate the relationship between these and the individual, family and relational sphere of the migrant. To verify the empirical evidence that emerged in the literature, the different association of the factors influencing the migratory pathways was evaluated through logistic regression. The use of this model makes possible to estimate the probability to want to stay permanently in Italy as opposed to the desire to return to one's country of origin (β>0

[1] This experience was co-funded in collaboration with the Ministry of Interior for a project funded by the European Fund for the Integration of Third-Country Nationals.

means an higher propensity to settle down in Italy). The sample used to estimate the model is made up of around 16,000 foreign citizens aged over 15 years.

4 Results

Over 70% of all interviewed migrants had planned to stay in Italy: what are individual, familiar and migratory experience determinants associated to the intentions to stay in Italy?

Results of logistic model confirm the importance of some determinants related to migration background, social integration and socio-demographic characteristics on migration project.

By taking into account migration background emerges how foreigners arrived in Italy with the intention to settle down permanently are likely to confirm same intention at the interviewing (β=3.18). As well as, migrants long-stayers in Italy are more likely to declare to stay compared to short-stayers (β=0.72). Moreover migrants who have never came back to the country of origin (β=0.21) unlike people who came back at least once.

Migrants with a good proficiency of Italian language have higher probability to plan to stay in Italy too (β=0.35). On the economic side, intention to leave Italy is related to less participation to labour market (no labour force β=-0.16), a condition that should makes more difficult socio-economic inclusion.

The intention to stay is higher among foreigners who have settled down in Italy, with own family and a wide friendship network. Compared to those who live alone, couples with children (β=0.31) and single-parent families of mothers (β=0.5) have a higher association with the propensity to stay in Italy. As expected, among people who live with other Italians, the probability of stay in Italy is higher than those who live in families of foreigners only (β=1.16). On the contrary, people with partner in country of origin declare more propensity to go back (β=-1.07).

The citizenship and the ethnic group pattern of social settlement in Italy have an impact on intentions of migrants to stay or come back to the country of origin. Compared to Romanians, Moldovans are more likely to declare to stay, whereas Filipinos have lower propensity to settle down in Italy. Citizenship of origin seems to play a fundamental role to define intentions of migrants as well as years of stay in host country. Therefore the interaction effect between years of stay and citizenship has been taken into account. Filipinos, regardless of during of stay, are always oriented to go back to the country of origin. Instead, Moldovans have higher probability to want to stay in Italy among long stayers (β=0.46 for 5-9 years of stay, β=0.52 for over 10 years of stay). Only among long-stayers, Chinese and Tunisians are more likely to declare the propensity to return to their homeland.

5 Intentions to leave Italy or to stay among foreigners: some determinants of migration projects

Wages differentials in association with individuals, enterprises and territorial characteristics

L'associazione tra differenziali retributivi e caratteristiche individuali, di impresa e territoriali

S. De Santis, C. Freguja, A. Masi, N. Pannuzi, F. G. Truglia[1]

Abstract The availability of new databases integrated by ISTAT allows to draw a territorial map of the private sector employment at the census level, with reference to wage levels and characteristics of individuals and enterprises. The purpose of this paper is to provide a representation of wages and of the most significant variables, referring to individuals, enterprises and territory, mainly contributing to determine wages. After having identify the main factors, it is possible to study the joint distribution of enterprise and worker main characteristics on different areas of the Country, revealing, sometimes unexpected, profiles, which may also help the implementation of local policies. The analysis is conducted on private sector employees, representing three-quarters of the employees and more than half of job positions, and it is focused on unilocalised enterprises with less than 50 employees and with dependent workers, amounting to 1 million 404 thousands enterprises and 7 million 847 thousand job positions.

The work described in this paper is carried out as part of the Istat project "Indicators for inequality analysis: integration of sources and measurement innovations for a multidimensional phenomenon", with the support of a Scientific Commission of experts from different institutions.

Abstract *La disponibilità di nuove basi dati integrate dall'ISTAT consente di tracciare una mappa territoriale dell'occupazione del settore privato a livello censuario, con riferimento ai livelli salariali e alle caratteristiche dei singoli lavoratori e delle imprese. Lo scopo di questo articolo è fornire una rappresentazione dei salari e delle variabili, riferite a individui, imprese e territorio, che principalmente contribuiscono a determinare la distribuzione dei salari. Dopo aver identificato i principali fattori, è possibile analizzare la distribuzione congiunta delle caratteristiche principali dell'impresa e dei lavoratori in diverse aree del Paese, rivelando profili, a volte inattesi, che possono anche aiutare l'attuazione delle politiche locali. L'analisi è condotta sui dipendenti del settore privato, che rappresentano i tre quarti dei dipendenti e più della metà delle posizioni lavorative, e si focalizza sulle imprese unilocalizzate con meno di 50 addetti e con dipendenti, pari ai 1 milione 404 mila imprese e 7 milioni 847 mila posizioni lavorative.*

Key words: wage differentials, municipalities spatial analysis, inequalities.

1. Premise

Wages play a key role in determining labour supply; at the same time, labour costs are fundamental drivers for business location choices, along with a mix of factors affecting productivity levels in host areas (infrastructures, human capital, legality, business environment, orientation of productive specialization, etc.).

The analysis of wages differentials is notoriously complex, both because multiple factors act simultaneously, and because the available information often is quantitatively and qualitatively inadequate (Porcari et al., 2007).

This paper aims to provide a detailed and comprehensive representation of wages and of the most significant variables, referring to individuals, enterprises and territory, mainly contributing to determine wages distribution.

The analysis is conducted only on private sector employees: they represent three-quarters of the total number of employees (77%) and more than half of job positions (56%); however, it should be pointed out that in the short term the analysis can be extended to self-employed and public servants.

The traditional information asset, represented by ISTAT's social and economic surveys, is today enhanced with an important piece of information coming from the integration of both administrative and statistical data sources. In particular, all administrative sources on labour market can be linked, exploiting the fact that each source is LEED (Linked Employer-Employed Data) and allows to study the joint distribution of enterprise and worker main characteristics (ISTAT, 2016).

The information allows the definition of new aggregates in a statistically consistent way and great detail. It is always possible to add information for unplanned dimensions of analysis (e.g. information collected by survey at both employer and employee levels) and to deepen relationships or association structures.

For this reason, the data bases - obtained from administrative data suitably corrected and integrated - are "statistical products" themselves.

2. Data information

This paper counts on the availability of statistical registers obtained from multiple sources, conveniently integrated at micro-data level: the ASIA statistical register and the "information system on employment"; the RACLI thematic register, extension and part of the aforementioned "information system on employment"; the Extended register Frame-SBS[2].

The first register presents a three-level information structure: enterprise, employee, and employment relationship. At the enterprise level, the statistical register of active enterprises integrates information from public and private administrative sources, and statistical sources; it represents the main source for business demography, the basis for all the ISTAT surveys on enterprises (it identifies the reference population for sampling designs and weighting systems) and it is also used for National Accounts estimates.

At the levels of employee and its employment relationship, the ASIA-Employment archive - derived from the employment database (DB-Occupazione) and annually updated after the updating of the active enterprises register - allows to build the different occupational profiles and to produce wide information on main demographic characteristics of employees and employment relationships.

RACLI is a thematic register on the labour market and an extension of the information system on employment, with reference to wages and inputs of labour. It represents the main innovation within the structural statistics on labour costs and it is mainly based on social security sources.

Finally, Extended Frame-SBS is the register for annual economic data on all active enterprises, based on administrative data integrated with the main surveys on enterprises. This database provides a detailed and multidimensional mapping of enterprises for structural and dynamic analysis of production equipment.

3. Preliminary results

In 2014, the Italian private enterprises are 4 million and 359 thousand, for a total of 4 million 721 thousand local units and 16 million 189 thousand employees. 78% of these enterprises work in the services sector and hires 67% of the total employees. The Italian enterprises system is characterizes by having more small or micro enterprises than the EU average: 95.4% have less than 10 employees and, all together, they employ 46.3% of the total private dependent labour force.

Job positions in the active enterprises correspond to: i) 11.3 million of dependent workers, ii) almost 5 million of independent, iii) 345 thousand of external and iv) 175 thousand of temporary workers. Among the dependent workers, 3 out of 4 occupy a full-time position and 9 out of 10 have a permanent contract.

[2] Data are available for 2011-2014 years and, referring to each individual job position, can be aggregated, for example, at the municipal level, allowing statistically significant estimates.

Our analysis is focused on unilocalised enterprises of the private sector with less than 50 employees and with dependent workers, amounting to 1 million 404 thousands enterprises[3]. They represent about one third of private enterprises: the enterprises with dependent employees amount to 1 million 463 thousands and, among them, 1 million 404 thousands have local units only within the municipality of registration[4]. In these companies, the job positions are 7 million 847 thousands.

The wages map (Figure 1- first map[5]) highlights the existence of several extended areas with wages average levels higher than the national mean (HH clusters). It follows the evidence that enterprises with higher value added are also those paying with higher wage levels and that their territorial distribution appears to be somewhat outlined (Cardinaleschi et al., 2015).

More than a fifth (21.9%) of the total municipalities (7,856[6]) belongs to HH extended areas and they are mainly concentrated in the North of Italy: in Lombardia, Emilia Romagna, Veneto and Bolzano they represent about half of the region municipalities (respectively 56.7%, 55.4%, 49.3% and 46.6%). On the other hand, less than a fifth (18.5%) of the municipalities belongs to LL areas, but the share reaches 79% in Calabria, 61% in Campania and represents almost half of the municipalities in Sicilia (47.8%), Puglia (46.3%) and Basilicata (45.4%). Quite small is the number of municipalities representing a point of discontinuity, because they have values of wages higher (1.4%) or lower (1.7%) than the contiguous municipalities; the share of isolated municipalities is only 0.2%.

The wages map is quite similar to the labour cost map (Fig.1-third map). The areas with higher values (19.6% of the municipalities) are mainly in Lombardia (53.3% of the region municipalities), Emilia-Romagna (48.2%) and, above all, Bolzano (92.2%). In the Centre-South there are almost exclusively large areas with labour costs lower than the average (19.5% of the municipalities): Calabria, Campania, Puglia and Sicilia present the highest share of municipalities belonging to the LL cluster (73.1%, 66.2%, 58.8% and 56%).

Also the second map (added value per employee) show a similar profile, even if the LL areas seem to be less wide than in the other two maps. It highlights the existence of several extended areas with high value added per employee (cluster HH),

[3] Waiting for the availability of the Frame territorial extension (Barbieri et al. 2017), the analysis is restricted to unilocalised active enterprises with less than 50 employees and with dependent employee. They represent about 33% of the total: on 4.264 thousands active enterprises, 4.240 thousands have less than 50 employees; they decreases to 1.463 thousands if only enterprises with dependent employees are considered; finally, 1.406 are unilocalised (not having local units outside the municipality of registration).

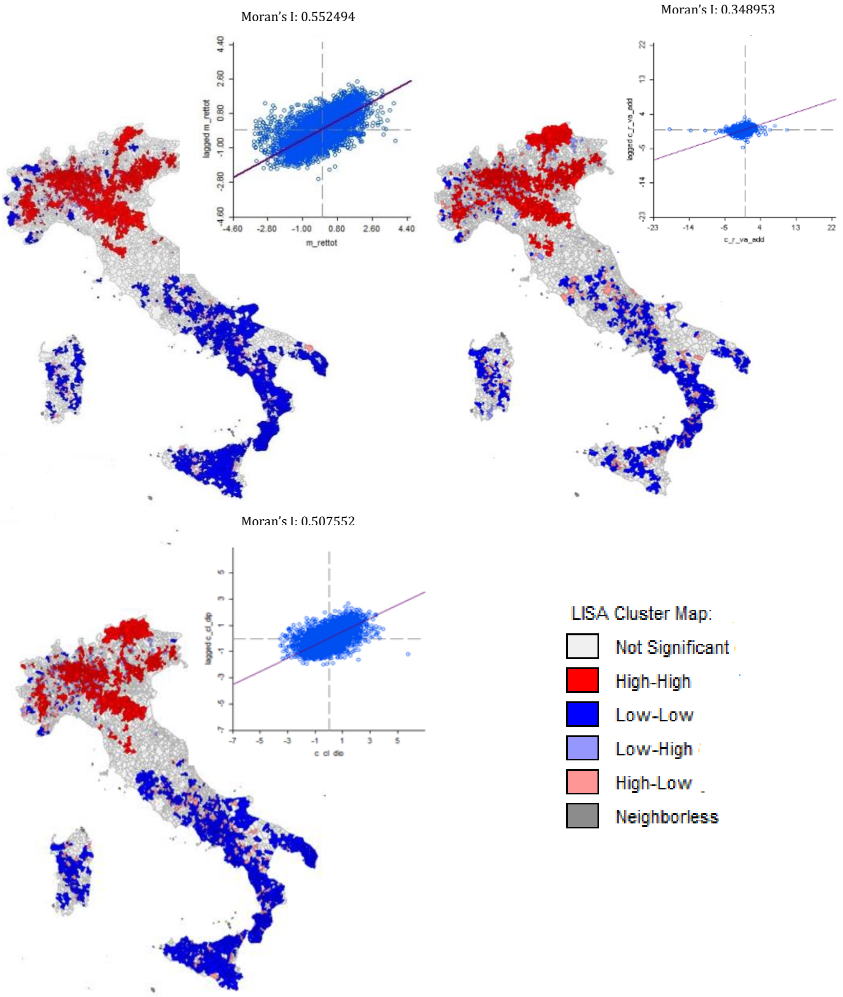
[4] It refers to the legal address municipality.

[5] By the Moran index, the municipalities can be clustered as follows (in addition to the cluster of municipalities not giving a significant contribution to global autocorrelation and to the cluster of municipalities not confining with other municipalities - minor islands): 1. High-High (HH)- contiguous units with values of the variable *x* (wage level) higher than the mean; 2. Low-Low (LL) - contiguous units with values of the variable *x* lower than the mean; 3. High-Low (HL) - units with values of the variable *x* higher than their contiguous units; 4. Low-High (LH) - units with values of the variable *x* lower than their contiguous units. The first two clusters are composed of homogeneous units (referring to the variable of interest), while the last two clusters concern abnormal cases or *enclaves* (Anselin, 2002).

[6] The municipalities' number is lower than the total because in some municipalities there are not active enterprises; moreover other 20 municipalities are excluded from the first map because they represent outliers in consequence of their negative values for the value added per employee.

that contain about a fifth (19.5%) of the municipalities. These areas represent almost half of the region municipalities in Lombardia (49.1%), Emilia Romagna (44.3%) and Veneto (40.6%) and the share rises to 92.2% in Bolzano.

Figure 1: High/low wages (first map), value added per employee (second map) and labour cost (third map). Years 2014



On the other hand, the extended areas with value added per employee lower than the average include over one-tenth of the total municipality (12.2%). They represent about one-fifth of Lazio's municipalities, a fourth in Campania, Puglia, Sicilia and Sardegna and more than 40% in Molise; the share reaches 60.7% in Calabria.

Small is the number of municipalities representing a point of discontinuity: 1.6% those having a values added per employee higher than the contiguous municipalities and 2.2% those having a lower value; the share of isolated municipalities stays at 0.2%. Obviously, for all the considered maps the extended areas with values higher/lower than the average do not necessarily present the same levels.

This kind of analysis can be useful in policies implementation. Just to give an example, it can support the European Structural and Investment Funds design, taking into consideration Classification of municipalities according to degree of remoteness (De Santis et al., 2017). Less than one fourth of the analysed municipalities (22.3%) are in Peripheral or Ultra-peripheral areas [7]", but the share decreases to 2.7%, 4.1% and 4.5% among the HH cluster, considering the wages, the cost of labour and value added per employee respectively. For the LL municipalities, the share reaches 47.6%, 40.7% and 48.2%.

After having individuated areas with wages, labour cost and productivity levels higher or lower than the mean, it is possible to study the enterprises and their employees, contributing to clarify the mechanisms underlying the relationship between local wage differentials, salary rigidity and economic performance.

In order to identify the factors that mainly contribute to determine wage levels in Italy, a regression model can be estimated. Exploiting the information asset coming from the integration of different sources, it is possible to study the joint distribution of enterprise and worker main characteristics on different areas of the Country.

Such a detailed view of the territory and of the distribution of different segments of workers reveals particular, sometimes unexpected, profiles, supporting the definition and the implementation of local policies that are recognized as a crucial option within the broader context of regional policies.

The Transition to Motherhood among British Young Women: Does housing tenure play a role?

Diventare madri fra le giovani donne bruitanniche: la proprietà dell'abitazione gioca un ruolo?

Valentina Tocchioni, Ann Berrington, Daniele Vignoli and Agnese Vitali[1]

Abstract A positive link between homeownership and fertility is usually presumed. Nevertheless, couples' preferences to become homeowners before having their first child has been undermined by the dramatic changes in the UK housing market over recent decades, causing a marked fall in homeownership rates among young adults. Using prospective longitudinal data from the British Household Panel Survey (1991-2008) and the United Kingdom Household Longitudinal Survey (2009-2016), and applying multilevel discrete-time event-history techniques, we investigate whether and how the link between housing tenure and motherhood has changed over recent decades in Britain, and whether the link is moderated by local area characteristics including housing markets.

Abstract *Secondo la letteratura, la relazione sussistente fra la proprietà dell'abitazione e la fecondità è positiva. Tuttavia, la tendenziale preferenza delle coppie a divenire proprietarie di abitazione prima di diventare genitori è stata minata dai drammatici cambiamenti intercorsi nel mercato immobiliare britannico negli ultimi decenni, determinando una sostanziale caduta dei tassi di proprietà delle case tra i giovani adulti. Usando i dati longitudinali del British Household Panel Survey (1991-2008) e del United Kingdom Household Longitudinal Survey (2009-2016), e applicando modelli di sopravvivenza multilivello (tempo discreto), l'obiettivo è di valutare se e come la relazione sussistente tra il possesso dell'abitazione e la nascita del primo figlio sia cambiata negli ultimi decenni in Gran Bretagna, e se questa sia moderata dalle caratteristiche del mercato immobiliare a livello locale.*

Key words: Britain, fertility, housing tenure, event-history analysis, panel data, multilevel models

1 Introduction

Housing markets affect fertility both directly and indirectly [7]. Direct links from housing to childbearing include the preference to be a homeowner before having children [5, 6, 9]. Even more, housing markets act on fertility through their impact on the ability of young adults to become residentially independent of the parental home. In western countries including the UK, family formation whilst co-residing in the parental home is unusual – family formation usually either coincides with, or follows residential independence from parents. Thus parent adult-child co-residence *delays* partnership formation and hence first births [3, 8].

Among young people, rates of homeownership in the UK have plummeted over the past 25 years (from 67% of 25-34 year olds in 1991 to 36% in 2014) [10]. This is a result of a number of factors not least the increase in house prices over the period, coupled with stagnation or decline in wages and security of employment [2]. The increased uncertainty in young people's lives thus makes private renting the only affordable solution for many young adults who decide to live independently [12]. Unlike in other European countries where private rented accommodation is highly regulated, tenants in the UK have very few rights, dealing with an expensive and very insecure dwelling. Private rented accommodation does not provide the same level of security of tenure as compared to either homeownership or social renting. Everything else being equal we might therefore expect childbearing to be postponed whilst in private rented accommodation, until security of tenure, either within owner occupation, or the social rented sector can be met. However, as the possibility of homeownership continues to recede for most young adults more are still renting at ages when entry into parenthood traditionally occurs.

Housing affordability and availability vary geographically due to local variations in housing costs, average wages and in the stock of social housing available in an area [11]. It is thus important to consider regional differences in entry into parenthood, and the potential role of local housing markets in influencing fertility behaviour.

To sum up, in the UK homeownership is increasingly unaffordable and many young adults are living in privately rented accommodation at later ages, and at stages in their life course when family formation typically takes place. We therefore ask the question as to whether the positive link between homeownership and fertility remains in recent years, which is an issue that needs still to be addressed in Britain. Indeed as noted previously for France, the cost of homeownership might compete with the costs of childbearing and childrearing, favouring childbearing among renters [4]. More specifically, we address the following questions: *Has the probability of becoming a mother whilst in private rented accommodation as opposed to owner occupier or social rented increased since 1991? Is this increase explained by the* *socio-economic and demographic characteristics of women in the different housing tenures? To what extent does the relationship between housing tenure and the progression to the first birth differ according to the local house prices?*

The paper follows with the description of the data and methods used for the analyses. Then, main results are presented, according to the three research questions. A concluding section closes the paper.

2 Data and methods

The study is based on a sample of women generated from the eighteen waves of the British Household Panel Survey (BHPS), in combination with data from the first seven waves of Understanding Society, the UK Household Longitudinal Study (UKHLS). In total our time period spans 1991-2016. We consider all women aged 18-42, who are living independently of the parental home and who were interviewed at least for two consecutive waves.

Multilevel discrete-time event-history analysis [1] is applied to exploit the transition to the first child's conception resulting in a live birth, taking account of the hierarchical structure of the data with women clustered within local authority districts (LADs). Woman's age is the baseline hazard. Observation starts at the first interview living independently after 18, and is censored either when the woman has a first conception, at last wave, when the woman retreats from the survey, when she returns to the parental home, or when she reaches age 44, whichever occurs first. Observations are weighted in order to take into account the changing population target over time. The key explanatory variable is current housing tenure, distinguishing among homeowners, private renters, and social renters.

3 Results

Table 1 shows the predicted probability from the hazard models of conceiving a first child according to housing tenure and calendar period. The predicted probability of conceiving a first child is significantly higher for women who are homeowners compared to those who are private renters until 2012; then, for the years 2013-2016 no significant difference emerges between homeowners and private renters. At first sight, the positive link between homeownership and fertility - which emerges clearly during the 1990 and 2000 - has changed over the last decade, with an increased proportion of private renters who have a first child in the last years.

Table 1: Predicted probabilities and confidence intervals of conceiving a first child according to housing tenure and calendar period. 1991-2016.

Housing tenure #Calendar period	Pred. Prob.	Confidence interval
owner#1991-1999	0.083	[0.072; 0.093]
owner#2000-2007	0.066	[0.056; 0.075]
owner#2008-2012	0.084	[0.073; 0.095]
owner#2013-2016	0.057	[0.046; 0.068]
social rent#1991-1999	0.049	[0.023; 0.075]
social rent#2000-2007	0.070	[0.037; 0.104]
social rent#2008-2012	0.066	[0.041; 0.090]
social rent#2013-2016	0.031	[0.010; 0.052]
private rent#1991-1999	0.037	[0.024; 0.050]
private rent#2000-2007	0.035	[0.023; 0.047]
private rent#2008-2012	0.048	[0.037; 0.058]
private rent#2013-2016	0.036	[0.025; 0.047]

Controlling for age group.

After controlling for all confounders (see Table 2), previous results are not confirmed for the last period, and the predicted probability of conceiving a first child is significantly higher for homeowners compared to private tenants (but only slightly). Nevertheless, over the last 25 years the predicted probabilities have decreased for homeowners, whereas the proportion of young adults who are conceiving a first child as private tenants has increased, net of all confounders.

Table 2: Predicted probabilities and confidence intervals of conceiving a first child according to housing tenure and calendar period. 1991-2016.

Housing tenure#Calendar period	Pred. Prob.	Confidence interval
owner#1991-1999	0.067	[0.058; 0.076]
owner#2000-2007	0.049	[0.042; 0.057]
owner#2008-2012	0.066	[0.057; 0.076]
owner#2013-2016	0.043	[0.034; 0.052]
social rent#1991-1999	0.032	[0.014; 0.049]
social rent#2000-2007	0.045	[0.022; 0.068]
social rent#2008-2012	0.047	[0.028; 0.065]
social rent#2013-2016	0.023	[0.007; 0.038]
private rent#1991-1999	0.023	[0.014; 0.032]
private rent#2000-2007	0.021	[0.013; 0.028]
private rent#2008-2012	0.032	[0.024; 0.039]
private rent#2013-2016	0.025	[0.017; 0.033]

Controlling for age group, partnership, education, parental social class, economic activity, equivalised income (in quintiles), overcrowding, and country of birth outside UK.

In a final step, we add a second-level covariate that takes into account the variability in house prices among the LADs, through the selling price of the 25th percentile house in a given LAD among the 20% lowest (1st quintile), up to 20% most expensive (5th quintile) across the country.

We find that, among homeowners, the probability to conceive is highest in LADs where the house prices of the least expensive houses lies in the 4th quintile of the LAD's distribution. In other words, homeowners will be more likely to have a first child if they own a house in an area where the house prices are higher than the country's average. Among private renters, the probability to have a first child is highest in LADs where the house prices of the least expensive houses lies in the 3rd quintile of the LAD's distribution. Moreover, in this area that represents the country's average for house prices, the higher probability of becoming a mother whilst as homeowner as opposed to private renter is only slightly significant. To sum up, once taken into account women's socio-economic and demographic characteristics, as well as household features and contextual information, the predicted probability of conceiving a first child remains higher for homeowners compared to private tenants, but the context plays a role in shaping the propensity to childbearing in private rented accommodation as opposed to owner occupier.

Table 3: Predicted probabilities and confidence intervals of conceiving a first child according to housing tenure and lower quartile house prices. 1991-2016**.**

Housing tenure#House prices	Pred. Prob.	Confidence interval
owner#1° quintile	0.055	[0.045; 0.065]
owner#2° quintile	0.049	[0.039; 0.058]
owner#3° quintile	0.056	[0.046; 0.066]
owner#4° quintile	0.075	[0.063; 0.087]
owner#5° quintile	0.053	[0.044; 0.063]
social rent#1° quintile	0.036	[0.019; 0.054]
social rent#2° quintile	0.035	[0.014; 0.057]
social rent#3° quintile	0.050	[0.021; 0.079]
social rent#4° quintile	0.054	[0.022; 0.086]
social rent#5° quintile	0.026	[0.009; 0.042]
private rent#1° quintile	0.026	[0.016; 0.036]
private rent#2° quintile	0.022	[0.013; 0.031]
private rent#3° quintile	0.034	[0.022; 0.045]
private rent#4° quintile	0.026	[0.017; 0.034]
private rent#5° quintile	0.024	[0.017; 0.031]

Controlling for age group, calendar period, partnership, education, parental social class, economic activity, equivalised income (in quintiles), overcrowding, and country of birth outside UK.

4 Conclusion

In the UK there has been a rapid increase in the last couple of decades in the number of young people living in private rented accommodation into their late twenties and thirties. This paper suggests that as a result of this increase the likelihood of becoming a parent whilst in private rented accommodation has increased slightly. By linking the individual survey data to administrative data on house prices by local authority district, we have shown that local housing contexts do play a role. Further research is required to better understand the possible expansion of having a first child whilst in private rented accommodation among other social strata of the population, as well as the potential consequences on young families' social security as private renters in place of homeownership in the years to come.

Robust statistical methods for credit risk

Metodi statistici robusti per il rischio di credito

A. Corbellini, A. Ghiretti, G. Morelli and A. Talignani

Abstract Credit risk is a relevant problem faced by banks and financial institutions. The traditional statistical models which are generally used to quantify the credit risk present several drawbacks. First, in their standard versions they are not robust and do not take into account that the data may be corrupted by several outliers. Second, when a parametric model is employed, the variable selection procedure might be severely affected by the so called masking and swamping effects. This work extends robust statistical methods to credit risk analysis, showing how the traditional approach can be greatly improved through robust methods.

Abstract *La gestione del rischio di credito è un problema particolarmente rilevante per tutte le banche e le istituzioni finanziarie. I modelli statistici tradizionalmente utilizzati per quantificare tale rischio presentano diversi svantaggi. Quando il dataset contiene alcuni outliers il fit che si ottiene attraverso i metodi di stima standard può risultare distorto e inconsistente. Inoltre, il metodo di selezione delle variabili può essere severamente influenzato dagli effetti di masking e/o swamping. L'obiettivo di questo lavoro è quello di estendere i metodi statistici robusti all'analisi del rischio di credito, mostrando come l'analisi può essere fortemente migliorata utilizzando un approccio robusto.*

Key words: Credit Risk, Forward Search, Lasso, Outliers, Robustness

1 The Credit Risk framework

Credit risk is defined as the risk of default on a debt that may arise from a borrower failing to make the required payments. In order to quantify how likely a borrower will be unable to meet his debt obligation, it is customary to use the so called probability of default (PD). The PDs have been introduced in the the Basel agreements, that took into account new developments in the measurement and management of banking risks for those institutions that agreed to use the "internal ratings-based" (IRB) approach. In this approach, financial institutions and banks are allowed to use their own internal measures as primary inputs to the capital calculation. These measures, require the estimation of a set of indexes that describe the risk exposure of the institution. These risk measures are subsequently converted into risk weights and further into regulatory capital requirements by means of risk weight formulas specified by the Basel Committee. In this work we will focus on the estimate of the PD, showing how the standard statistical methods generally proposed in literature can be greatly improved when a robust approach is adopted. In literature several statistical models have been proposed to estimate the PD. Some commonly adopted examples are: logistic regression models, discriminant analysis, classification trees and so on. The main drawback of all of these procedures is that they are not robust against slight deviations from the model assumptions. In fact, real data are generally corrupted by a random number of outlying units, i.e, units that do not share the same characteristics of the majority of data. It is well known in the literature that neglect outliers might have a severe impact on the analysis, leading to biased and inconsistent estimates and misleading inference. Furthermore, when facing real data, the analyst is generally required to perform a variable selection, as many are often available, but some might not be relevant to drive the PD. As a consequence, when a parametric model such as the logistic regression is adopted, it is common practice to employ a variable selection technique. However, standard variable selection techniques such as stage-wise algorithms or the widespread LASSO may be seriously affected by few outliers, leading to miss-selected variables.

To show the great improvements that can be achieved with a robust analysis our work will consider a real data set made available by an Italian Bank, which we kindly acknowledge, but do not report for confidentiality.

2 A Forward Search approach to the LASSO

We consider a set of observations $z_i = (y_i, x_i'), i = 1, \dots, n$, where y_i is a binary variable and x_i' is a vector of p features relative to the ith company.

We estimate the default probability of a firm by a logistic discriminant function, that is,

$$Pr(y_i = 1|x_i) = \frac{e^{x_i'\beta}}{1+e^{x_i'\beta}} = \frac{1}{1+e^{-x_i'\beta}} \qquad i = 1,\ldots,n.$$

$x_i' = (x_{i1},\ldots,x_{ip})$ is the vector of predictors, i.e. firm-specific characteristics and financial indexes and β is a vector of p unknown parameters.
The parameters are generally estimated by maximizing the log-likelihood function,

$$\ell(\beta) = \sum_{i=1}^{n}[y_i x_i'\beta - \log(1+e^{x_i'\beta})]. \tag{1}$$

In the data set considered one of the major concerns was to extract, from the p original features, a subset of k highly significant predictors. The LASSO (Hastie and Tibshirani, 2009) [2], performs a variable selection by means of a regularization or penalization parameter.

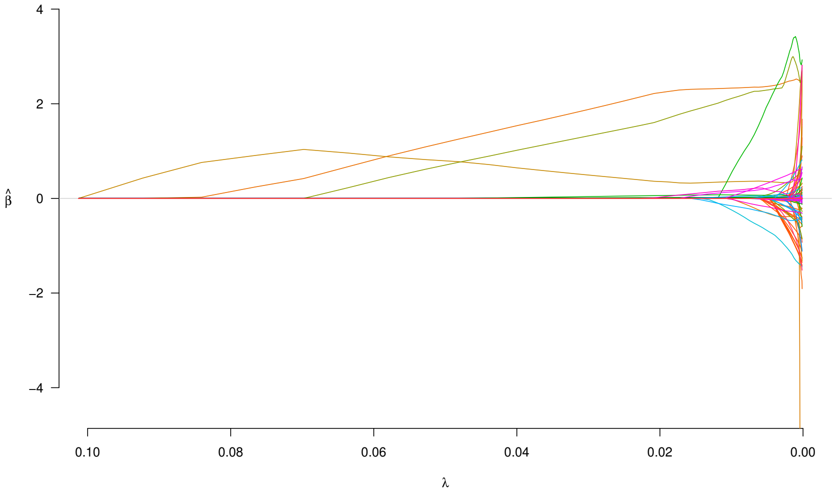

Fig. 1 Plot of the trajectories of the estimated coefficients, as a function of λ, obtained with the group LASSO with no outliers

When the LASSO is applied to the logistic model, the resulting penalized version of the log-likelihood function to be maximized becomes

$$\ell_{\lambda}^{L}(\beta) = \sum_{i=1}^{n}[y_i x_i'\beta - \log(1+e^{x_i'\beta})] + \lambda \sum_{j=1}^{p} |\beta_j|.$$

By selecting a value of λ sufficiently large, the L_1 penalty used in the LASSO, forces some of the coefficient estimates to be exactly equal to zero. The selection of λ is generally performed by cross validation and in the trivial case $\lambda = 0$ the log-likelihood (1) is maximized.
We will denote the optimal value of λ obtained by cross validation with λ_{optim}.
In our case, we have p predictors, h of which are qualitative (with $h \ll p$), and it is common to code those variables with dummies. However, it might happen that, a group of dummies represents the same variable, therefore it is compulsory to assume that the p predictors belong to G distinct groups. Notice that each quantitative variable form a distinct group. The parameter ρ_g is such that we either select or neglect the entire group. This is the standard approach suggested by Yuan e Lin (2007) [4] via the group LASSO, expanded by Meier, Van De Geer and Bühlmann (2008), [3] where groups of features can be included together into or out of a model. The group LASSO estimator is obtained by maximizing the following penalized log-likelihood function

$$\ell_{\lambda}^{GL}(\beta) = \sum_{i=1}^{n}[y_i x_i'\beta - \log(1+e^{x_i'\beta})] + \lambda \sum_{g=1}^{G} \sqrt{\rho}_g ||\beta_g||_2$$

where β_g is the vector of parameters associated with the predictors in group g.
In our work we propose a novel use of the Forward Search , see Atkinson and Riani (2000) [1], coupled with a LASSO regularization technique. This allows to detect multiple outliers and perform a selection of the most significant explanatory variables in a robust way.

In order to detect outliers and departures from the fitted regression model, the Forward Search uses the group LASSO to fit the model to subsets of m observations. The initial subset of m_0 observations is chosen robustly as follows:

1 fit the group-LASSO and select λ_{optim} by performing a cross validation

2 obtain the residuals for all the observations given the k features obtained at the previous step

3 sort all the residuals

4 repeat steps from 1-3 ten-thousand times and store the results in a data matrix

5 the subset of units that minimize the median of the residuals is selected.

After the initial subset has been obtained, the search procedure starts. The subset is increased from size m to $m+1$ by forming the new subset from the observations with the $m+1$ smallest residuals. For each m ($m_0 \leq m \leq n-1$), by a graphical monitoring of the maximum standardized residual among the units included in the set,

$s_{i,max}$, and the minimum standardized residual for the units excluded from the fit, $s_{i,min}$, it is possible to detect a potential outlier.
It is worth to be noted that, as outlined at step 2, at each iteration of the Forward Search, the residuals are calculated for all units, notwithstanding the fact that these residuals are stemming from different sets of variables. Moreover, since in the Forward Search at each step the residuals are ordered, and several units or groups of units might join and leave the subset, some problems concerning the identification of the model may arise. To overcome this drawback we impose that in every subset generated by the search at each step, there will be a percentage of defaulted firms equal to the original percentage found in the whole data. The defaulted firms included in the subset are selected among those with smallest residual.

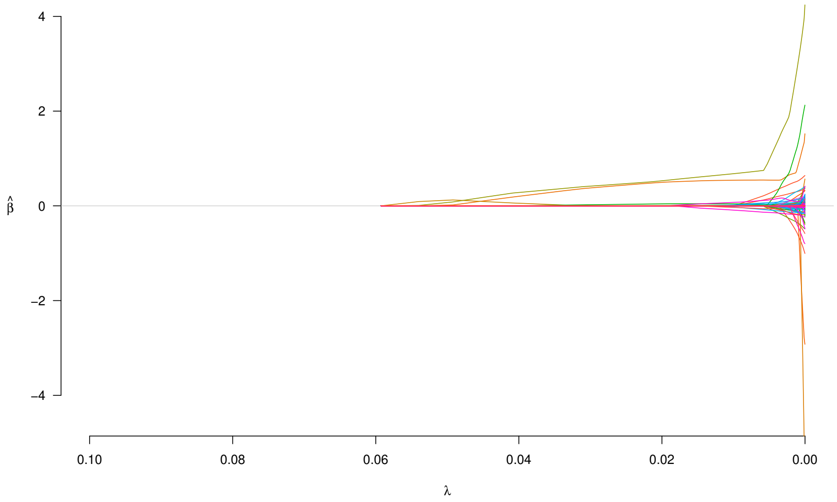

Fig. 2 Trajectory plot of the estimated coefficients, as a function of λ, obtained with the group LASSO when a 15% contamination is introduced

3 Preliminary results

As we have previously mentioned standard statistical techniques can be seriously affected by the presence of outliers in the data.
In order to show the impact that a small contamination might provoke on the group LASSO we introduce a 15% contamination into the Bank dataset and subsequently we perform the group-LASSO on the contaminated data.

The contamination is performed by adding a percentage of 15% additive outliers to the response variable Y. Figure 1 and Figure 2 show the trajectories of the estimated parameters over different values of lambda, before and after the contamination.
The different trajectories in the two plots show clearly that when some contamination is introduced the spurious units affect consistently the variable selection technique.
Figure 3 highlights the effect that the spurious units introduced have on the cross validation. First, the λ_{optim} selected in the contaminated scenario results lower than the one selected with the clean data. Second, the cross validation error in the contaminated case results sensibly larger for all the values of λ. Last, but not least, the number of groups selected with the introduction of the additive outliers drops remarkably to a number of 14.

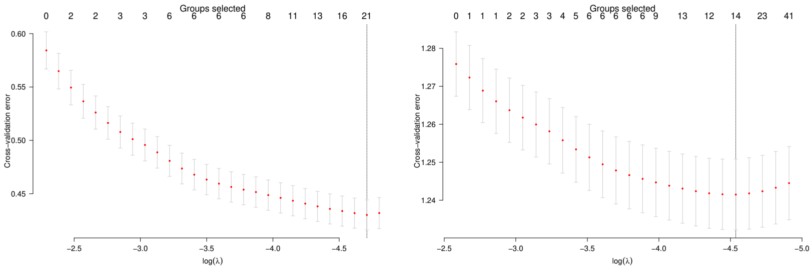

Fig. 3 Plots of λ estimates. Left panel, uncontaminated data, right panel, 15% of contamination

The significant drop in the number of selected groups as well as the increase in the cross validation error, suggest that there were swamping and masking effects induced by the introduction of several outliers.
The aim of our work is to perform a robust calibration of the value of λ whose choice is not affected by the spurious units and, at the same time, identify the most influential units by means of the forward plots.

Depth-based portfolio selection

Data depth per la selezione di portafoglio

Giuseppe Pandolfo, Carmela Iorio and Antonio D'Ambrosio

Abstract The estimation of multivariate location and scatter is the cornerstone of the classical multivariate statistical methods widely used in portfolio selection problems. However, they are not robust. We propose to use an alternative non-parametric approach based on the weighted L^P depth as robust location and scatter estimator in order to deal with extreme events in asset returns analysis. We first review weighted L^P depth along with its main properties and then discuss its application to portfolio selection through a small simulation study.

Abstract *Le depth functions La stima dei parametri di location e dispersione rappresentano la pietra miliare dei classici metodi statistici multivariati utilizzati nella selezione di portafoglio. Tuttavia questi metodi non sono robusti. Proponiamo, quindi, l'utilizzo di un metodo non parametrico basato sulla weighted L^P depth come stimatore robusto di location e dispersione nel caso di eventi estremi nell'analisi dei rendimenti. Forniamo la definizione e le proprietlla weighted L^P depth*, e mostriamo la sua applicabilitla selezione di portafoglio attraverso uno studio di simulazione.

1 Introduction

Portfolio selection concerns how to allocate capital over a number of assets to maximize the "return" on the investment and minimizing the "risk". The first mathematical model for portfolio selection was introduced by Markowitz (1952). In this model, the "return" on a portfolio is measured by the expected value of the random portfolio return, and the associated "risk" is given by the variance of the portfolio return. This mean-variance model has had a great impact on the economic modelling of financial markets and represents the milestone of the modern portfolio theory. Despite the success of the mean-variance model, its solutions are often very sensitive to perturbations in the parameters of the problem. Indeed, when the sample distribution deviates even slightly from the assumed distribution, the efficiency of classical estimators may be drastically reduced. Robust estimators, on the other hand, are not as efficient as maximum likelihood estimators when the underlying model is correct, but their properties are not as sensitive to deviations from the assumed distribution. In order to reduce the sensitivity of the Markowitz-optimal several techniques were proposed in the literature. Among the proposals we recall Vaz-de Melo and Camara (2005) who used the M-estimators, Perret-Gentil and Victoria-Feser (2005) who adopted a translated biweight S-estimator, while Welsch and Zhou (2007) used the minimum covariance determinant estimator and the winsorization. DeMiguel and Nogales (2009) proposed a class of policies that are constructed using both on M- and S-estimators. For an overview on the robust methods used for in portfolio selection we refer to Fabozzi, Huang and Zhou (2010).

In recent years, attention on portfolio selection strategies based on non-parametric and semi-parametric techniques have been also shown to exist (see e.g., Ben Salah et al., 2018 and Iorio et al., 2018)

Despite the growing interest on non-parametric and/or robust methods for portfolio selection, to the best of authors knowledge there is no literature on the exploitation of data depth functions to this purpose. Hence, in this paper we propose to adopt a non-parametric approach based on the weighted L^p depth to perform robust location and scatter estimation in financial applications.

In the following we first recall the definition of data depth function and review the notion of L^p depth, then the results of a small simulation are offered to the reader.

2 Data depth concept

Many statistical techniques in multivariate analysis assume normality of the distribution of the data. This assumption is often disputable and thus other, non-parametric, approaches are worth to be considered. One is based on the so called *data depth*, which is a way to measure the depth or outlyingness of a given point with respect to a multivariate data cloud or its underlying distribution. This concept was originally introduced to generalize the concepts of the median and the quantiles to a multivariate framework. The principle is very simple. For a distribution F in $\mathbb{R}^d$, a depth function, denoted by $D(x;F)$, provides a certer-outward ordering of points in $x \in \mathbb{R}^d$.

Zuo and Serfling (2000) provided general notions of depth function on $\mathbb{R}^d$ and presented four reasonable properties that a depth function (bounded and non-negative) should possess, that is:

P1 **Affine invariance**. The depth of a point $x \in \mathbb{R}^d$ should not be dependent on the underlying coordinate system or, in particular, on the scales of the underlying measurements.

P2 **Maximality at center.** For a distribution having a uniquely defined "center", the depth function should attain maximum value at this center.

P3 **Monotonicity relative to deepest point.** As a point $x \in \mathbb{R}^d$ moves away from the "deepest point" (the point at which the depth function attains maximum value) along any fixed ray through the center, the depth at x should decrease monotonically.

P4 **Vanishing at infinity.** The depth of a point x should approach zero as $\|x\|$ approaches infinity.

Let $\mathscr{P}$ denote the class of distributions on Borel sets on $\mathbb{R}^d$, while F_X denote the distribution of a given random vector X belonging to the class of random vectors X

There are several notions of data depth in the literature.

Definition 1. Let the mapping $D(\cdot,\cdot) : \mathbb{R}^d \times \mathscr{P} \to \mathbb{R}_+$ satisfy P1, P2, P3 and P4. That is, assume:

(i) $D(Ax+b, F_{AX+b}) = D(x, F_X)$ holds for any random vector $X \in \mathbb{R}^d$ and any $d \times d$ nonsingular matrix A, and any d dimensional vector b.

(ii) $D\left(\theta, F\right) = \sup_{x \in \mathbb{R}^d} D(x,F)$ holds for any $F \in \mathscr{P}$ having centre θ.

(iii) For any $F \in \mathscr{P}$ having deepest point θ, $D(x,F) \leq D(\theta + \alpha(x?\theta), F)$ holds for $\alpha \in [0,1]$; and

(iv) $D(x,F) \to 0$ as $\|x\| \to \infty$, for each $F \in \mathscr{P}$.

Then $D(\cdot;F)$ is called a statistical depth function.

The sample version of a depth function $D(\cdot;F)$ is denoted by $D(\cdot;F_n)$, where F is replaced with an empirical measure F_n, computed on a sample $X_n = \{x_1, \ldots, x_n\}$.

There are several notions of data depth function available in the literature. The halfspace, simplicial, Mahalanobis and L^p depths are some of the most popular ones. The notion of data depth has been also extended to the functional space (see e.g., Lopez-Pintado and Romo, 2009) and on the spheres (see e.g., Liu and Singh, 1992 and Pandolfo et al., 2017).

In this paper, we adopt the notion of weighted L^p depth introduced by Zuo (2004) because of its ease of computation and (local and global) robustness properties.

2.1 The weighted L^p depth

Zuo and Serfling (2000) defined the L^p depth based on the L^p-norm. Different distances (norms) were used with equal weights. However, in practice, the importance (weight, cost, penalty, or incentive) may not be the same for different distances (norms). This motivates to adopt this notion of depth, that is define as follows:

$$WL^pD(x;F) = \frac{1}{1+Ew\left(\|x-X\|_p\right)},$$

where w is a weight function on $[0,1)$, $X \sim F$ and $\|\cdot\|$ denotes the L^p-norm (when $p=2$ we have the Euclidean norm), w is assumed to be non-decreasing and continuous on $[0,\infty)$. The weighted L^p depth possesses some desirable properties of depth functions. It is translation invariant (can be affine invariant for $p=2$ under some modification), maximized at the center of a (centrally) symmetric distribution for convex w, decreasing when a point moves along a ray stemming from the deepest point, and vanishing at infinity. For more related discussions see Zuo and Serfling (2000).

The weighted L^p depth-induced medians (multivariate location estimator) are globally robust with the highest breakdown point for any reasonable estimator. The weighted L^p medians are also locally robust with bounded influence functions for suitable weight functions. Unlike other existing depth functions and multivariate medians, the weighted L^p depth and medians are computationally feasible and easy to calculate in high dimensions. The price to be paid is the lack of affine invariance.

3 Simulation study

In this section, we present a small Montecarlo simulation to investigate the performance of the weighted L^p depth-based estimators of the mean and covariance matrix, for both contaminated and non-contaminated simulated data.

Following Toma and Leoni-Aubin (2015), and DeMiguel and Nogales (2009), we use simulations to generate asset returns data following a distribution that deviates slightly from the normal distribution. Specifically, we considered the multivariate normal distribution $F \sim N(\mu_F, \Sigma_F)$ with mean $\mu_F = 0$ and Σ_F a $N \times N$ covariance matrix with variances equal to 1 and covariances all equal to 0.2, with N denoting the total number of assets. We generated samples of size $T = 100$ according to the following contaminated model:

$$F_\varepsilon = (1-\varepsilon)F + \varepsilon G, \tag{1}$$

where G is a contaminating distribution and ε is the fraction of the data that follows the contaminating distribution $G \sim N(\mu_G, \Sigma_G)$ with $mu_G = -4$ and $\Sigma_G = 4\Sigma_F$. We considered $N \in \{2,5,10,20\}$ and three different contamination levels $\varepsilon \in \{0\%, 2.5\%, 5\%\}$ to investigate how the estimates change when the asset returns deviate from normality.

The estimates of location and scatter were obtained through the weighted L^2, with all the observations having same weight. More in detail, in case of location, the estimator is defined as:

$$L(F) = \int x w_1 \left(L^2 D(x,F)\right) dF(x) \Big/ \int w_1 \left(L^2 D(x,F)\right) dF(x),$$

then a weighted L^2 depth scatter estimator is defined as

$$S(F) = \frac{\int (x - L(F))(x - L(F))^T w_2(D(x,F))\, dF(x)}{\int w_2(D(x,F))\, dF(x)}$$

where w_2 are suitable weight function that can be different from w_1.

For each setting, we generated $R = 250$ samples and for each sample we computed the depth estimates of location and scatter. The performances are evaluated through the empirical mean squared error (EMSE) given by

$$EMSE = \frac{1}{R}\sum_{i=1}^{R} \left\|\hat{\theta}_i - \theta_0\right\|^2$$

where $\theta_0 = (\mu_F, vech(\Sigma_F))'$ and $\hat{\theta}_i = \left(\hat{\mu}_i, vech\left(\hat{\Sigma}_i\right)\right)'$ is an estimate corresponding to the i-th sample, while $vech(\Sigma)$ is "the vector half", namely the $N(N+1)/2$-dimensional column vector obtained by stacking the columns of the lower triangle of Σ, including the diagonal, one below the other.

Results are presented in Table 1. The mean squared errors generally increase along with the number of assets (i.e., the sample size). However, for low dimensions ($N = 2$ and 5), the L^2 depth-based method estimates appear to be less affected by the contamination.

4 Final comments

In this paper we suggest to exploit the use of the weighted L^p depth function to perform robust estimation in financial settings. The very first results obtained through simulations are promising. Further research are needed to determine how to assign (depth-)weights to the observations, and to investigate the behaviour in real data applications.

Table 1: Empirical mean squared errors of WL^2 depth estimates.

Estimating large-scale multivariate local level models with application to stochastic volatility

Stima di modelli local level di grandi dimensioni con applicazioni ai modelli di volatilità stocastica

Matteo Pelagatti and Giacomo Sbrana

Abstract We derive the closed-form solution to the Riccati equation for the steady-state Kalman filter of the multivariate local linear trend model. Based on this result we propose a fast EM algorithm that provides approximated maximum likelihood estimates of the model's parameters and apply it to large-scale stochastic volatility models.

Abstract *Deriviamo la soluzione dell'equazione di Riccati relativa al filtro di Kalman in steady-state per il local linear trend multivariato. Utilizziamo tale risultato per proporre un algoritmo EM, che calcola un'approssimazione della stima di massima verosimiglianza dei parameteri del modello. Applichiamo tale metodo di stima a modelli di volatilità stocastica di grandi dimensione.*

1 Introduction

Multivariate stochastic volatility (SV) models are useful for portfolio managers only if they can be applied to portfolios of tens or hundreds of assets. Indeed, in the GARCH literature the most successful multivariate models are those, such as the Constant Conditional Correlation (CCC) and the Dynamic Conditional Correlation (DCC) that, by splitting the estimation processes is a sequence of computationally feasible steps, make the application to large portfolios possible. However, the SV

Giacomo Sbrana
NEOMA Business School, 1 Rue du Marechal Juin, 76130 Mont-Saint-Aignan, France e-mail: giacomo.sbrana@neoma-bs.fr

literature is till lacking of a computationally feasible procedure to estimate large scale models, possibly dividing the estimation process into sub-steps.

In this work we consider the multivariate extensions of the SV models of Harvey et al (1994) and Alizadeh et al (2002), which have a state-space representation as multivariate local linear trend models, provide the steady-state Kalman filter recursions by solving the related Riccati equation in closed form and propose an EM algorithm that approximates the (quasi) maximum likelihood estimate of SV model.

2 Main results

It is well known that, for time-invariant state-space models, the Kalman filter eventually converges to the steady-state solution such that the error covariance matrix satisfies the so called algebraic Riccati equation. Explicit solutions for such matrix equation are in general not available. A notable exception is represented by the univariate local level model (see Harvey, 1989) because the Kalman filter covariance matrix reduces to a scalar. In this paper we show that an analytical solution exists also for the multivariate local level model (also known as multivariate exponential smoothing or exponentially weighted moving average or EWMA). In what follows we use this convention: $\boldsymbol{M}$ is a matrix and $\boldsymbol{M}'$ is its transpose, $\boldsymbol{m}$ is a column vector such that $\boldsymbol{m}'$ is a row vector. A lower-case letter, such as x, represents a scalar. Finally, 0 is used indiscriminately for matrices, vectors and scalars.

Consider the time-invariant state-space representation of the multivariate exponential smoothing process:

$$\begin{aligned} \boldsymbol{y}_t &= \boldsymbol{\alpha}_t + \boldsymbol{\varepsilon}_t, & \boldsymbol{\varepsilon}_t &\sim \mathrm{WN}(\boldsymbol{0}, \boldsymbol{\Sigma}_\varepsilon) \\ \boldsymbol{\alpha}_{t+1} &= \boldsymbol{\alpha}_t + \boldsymbol{\eta}_t, & \boldsymbol{\eta}_t &\sim \mathrm{WN}(\boldsymbol{0}, \boldsymbol{\Sigma}_\eta) \end{aligned} \tag{1}$$

where WN denotes a white noise sequence. In what follows it is assumed that $\boldsymbol{\Sigma}_\varepsilon$ and $\boldsymbol{\Sigma}_\eta$ are symmetric positive definite matrices and $\mathbb{E}(\boldsymbol{\varepsilon}_t \boldsymbol{\eta}_t') = 0$. Note that all vectors and matrices in (1) have dimension d and $d \times d$ respectively. The Kalman filter recursions for this model can then be written as follows:

Innovation : $\boldsymbol{v}_t = \boldsymbol{y}_t - \boldsymbol{a}_t$,
Innovation variance : $\boldsymbol{F}_t = \boldsymbol{P}_t + \boldsymbol{\Sigma}_\varepsilon$,
Kalman gain : $\boldsymbol{K}_t = \boldsymbol{P}_t \boldsymbol{F}_t^{-1}$,
Prediction : $\boldsymbol{a}_{t+1} = \boldsymbol{a}_t + \boldsymbol{K}_t \boldsymbol{v}_t$,
Prediction error : $\boldsymbol{P}_t = \boldsymbol{P}_t - \boldsymbol{P}_t \boldsymbol{F}_t^{-1} \boldsymbol{P}_t + \boldsymbol{\Sigma}_\eta$.

In the steady-state the the covariance matrix $\boldsymbol{P}_t$ converges to the so called algebraic Riccati equation, that is,

$$\boldsymbol{P} = \boldsymbol{P} - \boldsymbol{P}(\boldsymbol{P} + \boldsymbol{\Sigma}_\varepsilon)^{-1} \boldsymbol{P} + \boldsymbol{\Sigma}_\eta, \tag{2}$$

where $\boldsymbol{P}$ is a symmetric positive definite matrix. The following proposition provides the analytical (matrix) solution of (2), that is the algebraic link between $\boldsymbol{P}$ and the pair $\boldsymbol{\Sigma}_\varepsilon$, $\boldsymbol{\Sigma}_\eta$.

Theorem 1. *Consider the system as in (1) where $\boldsymbol{\Sigma}_\eta$ is positive semi-definite while $\boldsymbol{\Sigma}_\varepsilon$ is strictly positive definite. Moreover, consider the following Cholesky decomposition $\boldsymbol{\Sigma}_\varepsilon = \boldsymbol{M}\boldsymbol{M}'$ and defining $\boldsymbol{Q} = \boldsymbol{M}^{-1}\boldsymbol{\Sigma}_\eta \boldsymbol{M}^{-1'} = \boldsymbol{\Psi}\boldsymbol{\Delta}\boldsymbol{\Psi}'$ such that for the last eigendecomposition $\boldsymbol{\Psi}$ is a matrix of eigenvectors (i.e. $\boldsymbol{\Psi}\boldsymbol{\Psi}' = \boldsymbol{I}$) and $\boldsymbol{\Delta} =$* $\mathrm{diag}(\delta_1, \delta_2, \cdots, \delta_d)$ *is a diagonal matrix of eigenvalues. Then there exists a unique positive definite solution for $\boldsymbol{P}$. The solution is*

$$\boldsymbol{P} = \frac{1}{2}\boldsymbol{M}\boldsymbol{\Psi}\left[\boldsymbol{\Delta} + (\boldsymbol{\Delta}^2 + 4\boldsymbol{\Delta})^{\frac{1}{2}}\right]\boldsymbol{\Psi}'\boldsymbol{M}'. \tag{3}$$

Going back to the Kalman filter recursion, it is immediate to see that, in steady state, the only step to compute is the *prediction step*, because all the other quantities are time-invariant. Also the implementation of the smoothing process results greatly simplified. Indeed, the smoothing algorithm proposed by de Jong (1988, 1989) (see also Ansley and Kohn, 1985; Koopman, 1997) becomes $\boldsymbol{r}_n = \mathbf{0}$, $\boldsymbol{N}_n = \mathbf{0}$,

$$\boldsymbol{r}_{t-1} = \boldsymbol{F}^{-1}\boldsymbol{v}_t + \boldsymbol{L}'\boldsymbol{r}_t \tag{4}$$

$$\boldsymbol{N}_{t-1} = \boldsymbol{F}^{-1} + \boldsymbol{L}'\boldsymbol{N}_t\boldsymbol{L} \tag{5}$$

where $\boldsymbol{L} = \boldsymbol{I} - \boldsymbol{K}$ is also time-invariant.

The maximum likelihood estimation of a model in state space form using the EM algorithm is fully discussed by Shumway and Stoffer (2017) (see also Koopman, 1993; Durbin and Koopman, 2001). In practice, the EM algorithm for the multivariate local level can be implemented using the simple updating expressions (3.5), (3.6) and (3.7) of Section 3 in Koopman (1993). More specifically, for model (1) these expressions can be restated as follows:

$$\boldsymbol{\Sigma}_\varepsilon(\iota+1) = \boldsymbol{\Sigma}_\varepsilon(\iota) + \boldsymbol{\Sigma}_\varepsilon(\iota)\boldsymbol{\Theta}_e\boldsymbol{\Sigma}_\varepsilon(\iota) \tag{6}$$

$$\boldsymbol{\Sigma}_\eta(\iota+1) = \boldsymbol{\Sigma}_\eta(\iota) + \boldsymbol{\Sigma}_\eta(\iota)\boldsymbol{\Theta}_r\boldsymbol{\Sigma}_\eta(\iota) \tag{7}$$

where $\iota = 0, 1, \ldots$. Here $\boldsymbol{\Sigma}_\varepsilon(0)$, $\boldsymbol{\Sigma}_\eta(0)$ are the starting values. In addition,

$$\boldsymbol{\Theta}_r = \frac{1}{n}\sum_{t=1}^{n}(\boldsymbol{r}_t\boldsymbol{r}_t' - \boldsymbol{N}_t) \tag{8}$$

where $\boldsymbol{r}_t$ and $\boldsymbol{N}_t$ are constructed as in (4) and (5), and

$$\boldsymbol{\Theta}_e = \frac{1}{n}\sum_{t=1}^{n}(\boldsymbol{e}_t\boldsymbol{e}_t' - \boldsymbol{D}_t) \tag{9}$$

with

$$\boldsymbol{e}_t = \boldsymbol{F}^{-1}\boldsymbol{v}_t - \boldsymbol{K}'\boldsymbol{r}_t \tag{10}$$

and

$$\boldsymbol{D}_t = \boldsymbol{F}^{-1} + \boldsymbol{K}'\boldsymbol{N}_t\boldsymbol{K}. \tag{11}$$

Using the steady-state filter and smoother, we obtain a computationally feasible procedure to approximate the maximum likelihood estimation of the multivariate local level model.

Algorithm 1 (Approximate maximum likelihood estimation) *Fix arbitrary initial covariance matrices $\boldsymbol{\Sigma}_\varepsilon$ and $\boldsymbol{\Sigma}_\eta$ and iterate as follows.*

1. *Obtain $\boldsymbol{P}$ from equation (3) and compute the steady-state Kalman filter matrices and start the Kalman filter with $\boldsymbol{a}_1 = \boldsymbol{y}_1$ (see Harvey, 1989, p. 26).*
2. *Run $\boldsymbol{a}_t = \boldsymbol{K}\boldsymbol{y}_t + (\boldsymbol{I} - \boldsymbol{K})\boldsymbol{a}_{t-1}$ and for $t = 2, \dots, n$.*
3. *Run the steady-state smoothing formulae (4), (5), (10), (11), (8) and (9).*
4. *Run the EM step updating the parameters using (6) and (7).*
5. *Go to step 1. until the likelihood increment is negligible.*

Table 1 compares the execution time and the precision of our algorithm to exact MLE on simulated vector time series of dimension up to $d = 20$. For $d = 100$ our algorithm provides estimation in few minutes, while it was not possible to get results for MLE.

3 Application to multivariate stochastic volatility models

In this section, we demonstrate how the stochastic volatility (SV) models of Harvey et al (1994) (from now on HRS) and Alizadeh et al (2002) (from now on ABD) can be successfully estimated on large portfolios using our Algorithm 1. In particular, while Harvey et al (1994) discuss how to estimate small scale multivariate stochastic volatility model using state space methods, Alizadeh et al (2002) cover only the univariate model. Therefore, we first show how to extend the model by Alizadeh et al (2002) to the multivariate case and then apply our approximate maximum likelihood estimation to a large portfolio of stocks.

Let y_{it} be the, possibly mean-adjusted, return of stock $i \in \{1, 2, \dots, d\}$ at time $t \in \{1, 2, \dots, n\}$, then the multivariate stochastic volatility model Harvey et al (1994) consider is defined by

$$\begin{aligned} y_{it} &= \exp(h_{it}/2)\zeta_{it}, \\ h_{it+1} &= h_{it} + \eta_{it}, \end{aligned} \tag{12}$$

where $\exp(h_{it})$ plays the role of the time-varying variance, whose logarithm evolves according to a random walk. The random vectors $\boldsymbol{\zeta}_t$ and $\boldsymbol{\eta}_t$ obtained by stacking the random variables $\{\zeta_{1t}, \dots, \zeta_{dt}\}$ and $\{\eta_{1t}, \dots, \eta_{dt}\}$, respectively, into vectors are assumed to be normally distributed with zero means and covariance matrices $\boldsymbol{\Sigma}_\zeta$ and $\boldsymbol{\Sigma}_\eta$. The matrix $\boldsymbol{\Sigma}_\zeta$ is constrained to be a correlation matrix. Harvey et al (1994) model the logarithm of the squared return, so that equation (12) can be rewritten as

$$\begin{aligned} \log(y_{it}^2) &= h_{it} + \log(\zeta_{it}^2), \\ h_{it+1} &= h_{it} + \eta_{it}, \end{aligned} \tag{13}$$

This set of equations can be easily cast into the linear state space form as

$$\begin{aligned} \boldsymbol{w}_t &= \boldsymbol{h}_t + \boldsymbol{\varepsilon}, \\ \boldsymbol{h}_{t+1} &= \boldsymbol{h}_t + \boldsymbol{\eta}_{it}, \end{aligned} \tag{14}$$

where the i-th element of $\boldsymbol{w}_t$ is equal to $\log(y_{it}^2) + 1.27$ and $\boldsymbol{\varepsilon}_t$ is a non-Gaussian random i.i.d. sequence whose ij-th element of the covariance matrix $\boldsymbol{\Sigma}_\varepsilon$ is given by equation B.9 in Harvey et al (1994).

Harvey et al (1994) propose to estimate the unknown covariance matrices $\boldsymbol{\Sigma}_\varepsilon$ and $\boldsymbol{\Sigma}_\eta$ by Gaussian quasi maximum likelihood, approximating the distribution of $\boldsymbol{\varepsilon}_t$ with a normal with the same mean and covariance matrix. The log-variances h_{it} can be estimated using Kalman filtering and state smoothing, which in this case provide just best linear estimates.

Alizadeh et al (2002) propose a stochastic volatility model based on the logarithm of stock price ranges (daily maximum minus daily minimum) instead of log-squared returns. Let $v_{it} = \log(P_{it}^{\max} - P_{it}^{\min})$ be the sequence of daily log-ranges, with $P_{it}^{\max}$ and $P_{it}^{\min}$ representing the maximum and minimum price of stock i for the day t. If each price process is well described by a Brownian motion, than the distribution of the log-range is approximately Gaussian (cf. Alizadeh et al, 2002, Table I and Figure 1). Assuming that the approximation remains valid also in a multivariate context, then we can write a multivariate stochastic volatility model based on log-ranges exactly as in equation (14), where now the generic element of $\boldsymbol{w}_t$ is $w_{it} = v_{it} - 0.43$, and the errors ε_{it} have all the same standard deviation $\sigma_\varepsilon = 0.29$ (cf Alizadeh et al, 2002, Table I).

We estimated both SV models for a portfolio composed by 94 daily stock returns belonging to the SP100 index ranging from 2007-01-04 to 2017-04-28 ($n = 2598$). As customary in many large scale multivariate GARCH models, we split the estimation process in two steps: first, we estimated the correlation matrix of the returns, from which we obtained the covariance matrix $\boldsymbol{\Sigma}_\varepsilon$, and then we applied our Algorithm 1 by running the EM update only for the matrix $\boldsymbol{\Sigma}_{\boldsymbol{\eta}}$, as in equation (7), and using the $\boldsymbol{\Sigma}_\varepsilon$ estimated in the first step.

If we concentrate on the correlation matrix of the disturbances that drive the h_{it} processes, we notice that all correlations are positive, but those of model HRS are generally larger than those of model ABD. The same message can be derived from the cumulated eigenvalues plot in the left panel of Figure 1: for model HRS the first three principal components cover more than 90% of the variance, while the same share of total variance is reached for model ABD with 20 components. If we use the scores of the first principal component of the estimated $\boldsymbol{h}_t$ in the two models and take the suitable transforms to derive volatility indicators, we get the volatility profiles depicted in the right panel of Figure 1. The profiles are similar, but they differ in some extreme event and in the level, which is higher for the HRS model.

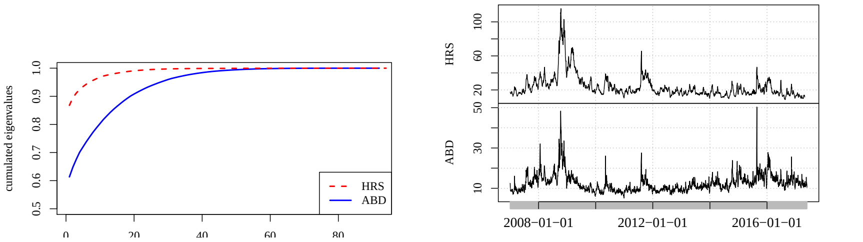

Fig. 1 Left) cumulated eigenvalues of the correlation matrix derived from $\boldsymbol{\Sigma}_\eta$ estimated in the two models. Right) Ensemble volatility indicators derived from the first principal component scores

Health and Clinical Data

Is retirement bad for health? A matching approach

Il pensionamento fa male alla salute? Una analisi causale

Elena Pirani, Marina Ballerini, Alessandra Mattei, Gustavo De Santis

Abstract The aim of this paper is to assess the causal impact of the transition from work to retirement on individual health in various European countries in recent years. The health effects of this transition are far from clear: the specialized literature reports both positive and negative consequences, however, most of the early studies focus on associations rather than causal relationships. We estimate causal effects of retirement on three measures of health and well-being – self-rated health, depression, quality of life – using a propensity score matching approach under the assumption of selection on observables on data coming from SHARE, the longitudinal Survey on Health, Ageing and Retirement in Europe, in the years between 2004 and 2016. Our results suggest that the transition from work to retirement negatively affect self-rated health almost everywhere in Europe; nevertheless, the quality of life seems to improve, especially in Continental and Mediterranean countries.

Abstract L'obiettivo di questo lavoro è valutare l'impatto causale del pensionamento sulla salute individuale in vari paesi europei. La letteratura riporta effetti sia positivi che negativi del pensionamento sulla salute e benessere degli individui, tuttavia, la maggior parte degli studi precedenti si concentra sulle associazioni piuttosto che sulle relazioni causali. Considerando tre misure di salute – salute percepita, depressione e qualità della vita – sulla base dei dati delle indagini SHARE svolte tra il 2004 e il 2016, stimiamo gli effetti causali del pensionamento sulla salute utilizzando l'approccio del propensity score matching sotto l'ipotesi di assenza di confondimento. I risultati suggeriscono che il pensionamento ha effetti negativi sulla salute percepita in tutti i paesi europei, mentre la qualità della vita sembra beneficiarne, soprattutto nei paesi dell'Europa continentale e mediterranea.

Key words: Retirement; Europe; Share; Causal inference.

1 Retirement and health: a complex connection

The effects on health of the transition from work to retirement are unclear. Several scholars argue that retirement itself is a stressful event (e.g., Carp 1967; MacBride 1976), which can lead to a break with support networks and friends, and may be accompanied by feelings of loneliness, uselessness, or obsolesce (MacBride 1976). Others claim instead that retirement is a health-preserving life event: it is a relief from work-related stress (Eibich 2015), and encourages health-improving behaviors – such as quit smoking – or increased physical activity (Eibich 2015; Insler 2014).

A strand of the literature reports a significant increase in health after retirement (e.g. Blake and Garrouste 2012; Charles 2004; Coe and Zamarro 2011; Insler 2014; Latif 2013; Neuman 2008), whereas other researchers find significant negative effects on both objective and subjective health measures (e.g. Behncke 2012; Dave et al. 2008; Sahlgren 2012), and also on cognitive functions (Bonsang et al. 2012; Mazzonna and Peracchi 2012). Bound and Waidmann (2007) showed a short-term positive relationship between retirement and health for men but not for women.

In a large part of the previous studies, the focus was on the *association* between health and retirement, and comparisons between the retired and those still working were usually not adjusted for health characteristics before retirement: this adjustment is instead crucial for drawing inference on the causal effects of retirement on health (Coe and Zamarro 2011).

In this paper, we aim to assess the *causal* impact on health of the transition from work to retirement by applying a propensity score matching approach under the assumption of selection on observable to the data of the Survey on Health, Ageing and Retirement in Europe (SHARE). We refer to several European countries, and analyse the heterogeneity of the causal effects across different geographical areas.

2 Data and method

Our empirical analyses were based on SHARE, the Survey on Health, Ageing and Retirement in Europe, which is a panel including five regular waves plus a wave on people’s life histories (wave 3, SHARELIFE, which, however, is not considered here because it collected very different information compared to the regular waves and excluded some of the variables we need). In each wave, SHARE data cover the key areas of life (health, socio-economic status social and family networks, etc.) of more than 60,000 individuals aged 50 or over. We focused on the period between 2004 and 2016 and on a subset of the SHARE countries that participated in at least three consecutive waves (Austria, Belgium, Czech Republic, Denmark, Estonia, France, Germany, Italy, the Netherland, Slovenia, Sweden, Switzerland, and Spain), and for which we had all the information we needed for our analysis.

We selected three health and well-being indicators. As a general measure of health, we used self-rated health, dichotomizing the original 5-point scale into good (excellent, very good, good) and poor (fair, poor) perceived health (preliminary analyses considering the original formulation proved consistent results). Because of its subjective nature, self-rated health may change across populations (Prinja et al., 2012); however, various studies proved its power in predicting objective health conditions (Egidi and Spizzichino, 2006), physical and emotional well-being (Bayliss et al., 2012), and even mortality (Idler and Benyamini, 1997). Moreover, we used a composite indicator of depression constructed from the 12 basic items of the EURO-D scale (Prince et al., 1999): depressed mood, pessimism, suicidality, guilt, sleep, interest, irritability, appetite, fatigue, concentration, enjoyment and tearfulness. This scale, which ranges from 0 (not depressed) to 12 (very depressed), was developed in an effort to derive a common scale of depression symptoms, especially in later life, based on different indicators in several European countries. Finally, we considered a theoretically grounded measure of quality of life, i.e., a composite indicator based on four subscales corresponding to four life domains (Hyde et al., 2003; Mehrbrodt et al., 2017): control (C), autonomy (A), self-realization (S) and pleasure (P). After reversing the original scale, this indicator, which was proved to represent a reliable indicator of quality of life in the context of research on ageing (Wiggins et al., 2008), scored between 0 (high quality of life) and 36 (low quality of life).

Because our objective was the estimation of a causal effect of entering retirement on individual well-being in the short run, we focused on the subsample of those who were in the labor market (employed or self-employed) in the waves $t=1,2,4$ of the survey and were either in the labor market or retired in the waves $t=2,4,5$. Those who got out of the labor market for other reasons (e.g., unemployment) were discarded from our subsample.

We followed the “potential outcome” approach (e.g., Imbens and Rubin, 2015). For each unit i, $i=1,\ldots, n$, we considered a vector X_i of background variables. Let D_i denote the treatment variable indicator, equal to 1 if unit i retires between two consecutive waves of the survey – waves $w1$ and $w2$; waves $w2$ and $w4$, or waves $w4$ and $w5$ – and zero otherwise. Under the Stable Unit Treatment Value Assumption (SUTVA) (Rubin, 1980), for each unit i there are two potential outcomes at a future point in time after treatment (at waves $w4$, $w5$ or $w6$): the value of the health outcome Y if unit i retired – $Y_i(1)$ – and the value of Y at the same future point in time if the unit did not retire – $Y_i(0)$. The causal effect of the transition from work to retirement for each unit is defined as a comparison of the treatment and control potential outcomes, $Y_i(1)$ and $Y_i(0)$, typically their difference. In this paper we focus on Average Treatment Effects on the Treated (ATT effects), that is, the effects of the transition from work to retirement averaged over the subpopulation of units who actually retired: ATT = $\mathrm{E}[Y_i(1) - Y_i(0) \mid D=1]$.

Because we used observational data, we needed to introduce some assumptions on the treatment-assignment mechanism to draw inference on the causal effects of interest. We assumed unconfoundedness (or selection on observables), which implies that, conditioning on the observed covariates, an experimental-like context is reproduced. Formally, unconfoundedness requires that the treatment assignment is independent of the potential outcomes: $D_i \perp (Y_i(0), Y_i(1))|\mathrm{X}_i$. We also assumed that there was sufficient overlap in the joint distribution of the covariates between treated and control subjects: $0 < P(D_\mathrm{i}=1|X_i=x) < 1$ for each *i*. Under these assumptions, we applied a statistical matching technique, the purpose of which was to select a sub-group of control subjects (who did not retire between two subsequent waves) who were, in all respects, as similar as possible to the treated subjects, i.e., those who retired from work. We matched individuals based on the propensity score, or the probability of entering retirement conditional on the observed covariates. The propensity score is a balancing score, that is, covariates are independent of the treatment conditional on the propensity score. Moreover, if the unconfoundeness and the overlap assumptions hold conditional on covariates, they also hold conditional on the propensity score (Rosenbaum and Rubin 1983). Therefore, matching on the propensity score is sufficient to remove confounding.

The variables on which we constructed our propensity score included individual socio-demographic characteristics (e.g., age, living arrangement, relatives alive, level of education) and health-related behaviours and health conditions (e.g., smoking and drinking, mobility index, as well as self-rated health, quality of life, and depression). We also introduced the type and the sector of work, even if we acknowledge that these aspects only partially account for important aspects of working life, such as stressing factors or autonomy in decisions, which could importantly contribute to individual’s health and wellbeing. We imposed an exact matching on country of residence and gender. On the basis of the estimated propensity score, for each of the 1124 retired individuals we selected as a match the closest individual – i.e., a person of the same sex, from the same country and with very similar pre-treatment characteristics – among the 6250 potential controls (1-to-1 nearest neighbor matching; Abadie and Imbens 2011).

3 Preliminary results

The check of the covariate balance (i.e., similarity of treated and controls individuals in terms of covariates) proved that the matching procedure was successful: after matching, the differences between the two groups (retired an non-retired) in terms of socio-demographic, work-related and health covariates either disappeared (best case) or were drastically reduced (not shown here). We proceeded then to the estimation of the causal effect of retirement on health, by computing the Average Treatment Effects on the Treated (ATT) using a matching estimator.

The first part of Table 1 reports the ATT effects of retirement on the three well-being indicators considered, computed for all the SHARE countries together. Our results show a worsening of self-rated health after retirement; conversely, they also convey the impression of a slightly improvement in terms of (less) depression and (higher) quality of life. Note however that these two latter estimated effects are very small in absolute terms and not statistically significant.

In order to account for the heterogeneity of people living in the different European countries, we estimated the ATT effects separately for the Nordic countries (Denmark and Sweden), Continental countries (Austria, Belgium, France, Germany, the Netherland, and Switzerland), Mediterranean countries (Spain and Italy), and East European countries (Czech Republic, Slovenia, Estonia). The negative effect of retirement on self-rated health persisted for all European areas, even if with a loss of significance for East European countries.

Considering European countries altogether masks some territorial differences for the other two well-being indicators: both depression and quality of life levels increase for retired people in Continental and Mediterranean countries (although the effect is not statistically significant for the second group, maybe due to the small sample size). On the contrary, in Nordic countries retirement seems to determine a detrimental effect also on depression and quality of life (but again results are not statistically significant), whereas for Eastern European countries the effect on the two well-being variables diverges.

Table 1: Estimated ATT effects and their standard errors, for all countries, and by groups of countries. SHARE 2004-2016.

			Self-rated health	Depression	Quality of life
All countries	treated (n=1124),	ATT	0.09	-0.12	-0.17
	matched controls (n=1124)	*Std Err*	*0.01*	*0.07*	*0.21*
By group of countries:					
Nordic	treated (n=194),	ATT	0.09	0.13	0.29
	matched controls (n=194)	*Std Err*	*0.03*	*0.15*	*0.44*
Continental	treated (n=474),	ATT	0.08	-0.10	-0.91
	matched controls (n=474)	*Std Err*	*0.02*	*0.11*	*0.31*
Mediterranean	treated (n=116),	ATT	0.12	-0.14	-0.13
	matched controls (n=116)	*Std Err*	*0.05*	*0.22*	*0.68*
East European	treated (n=340),	ATT	0.04	-0.24	0.68
	matched controls (n=340)	*Std Err*	*0.03*	*0.15*	*0.44*

In our analysis the richness of background (i.e., pre-treatment) information allowed us to adjust treatment comparisons for a large set of pre-treatment characteristics – in terms of health, life-style behaviors, socio-demographic characteristics and factors linked to the (previous) working condition – and thus the assumption of selection on observable appears to be plausible. Under this assumption, we found that the effects of retirement on health vary not only according to the context of reference, but also depending on the specific health/well-being indicator considered.

It is thus worth to investigate more in detail the mechanisms through which retirement affects the various dimensions of health and well-being. Specifically, aspects such as family types and intergenerational relationships, social relationships, embeddedness in social network, and job characteristics will be examined in our future research.

The emergency department utilisation among the immigrant population resident in Rome from 2005 to 2015

L'accesso al pronto soccorso da parte degli immigrati residenti a Roma tra il 2005 e il 2015

Eleonora Trappolini, Laura Cacciani, Claudia Marino, Cristina Giudici, Nera Agabiti, Marina Davoli

Abstract

Health inequalities affecting migrant population have been largely analysed in the literature, but only scarce studies have been published on migrant's utilisation of Emergency Departments (EDs). The aim of this study is to analyse trends of EDs utilisation for the population resident in Rome during the period 2005-2015, overall and for specific causes. By comparing immigrants' access with that of the host population, the study evaluates differences in the healthcare utilisation rate between these populations. The analysis is based on a dynamic cohort aged 25 to 64 years old in each year and defined using data from the Municipal Register of Rome. Results on the overall utilisation rate show a lower use of the EDs by the immigrant population with respect to the host population, although this gap has started to decrease in the years after the 2008. Even if the overall utilisation rates show similar trends between Italians and immigrants, different patterns have been detected for specific causes.

Abstract

Le disuguaglianze di salute legate alla condizione migratoria sono state oggetto di numerose analisi in letteratura. Tuttavia, nel panorama europeo, gli studi sull'accesso degli immigrati al servizio di pronto soccorso risultano ad oggi scarsi e spesso contraddittori. Questo contributo è volto ad analizzare l'accesso al pronto

soccorso da parte della popolazione italiana e straniera residente a Roma tra il 2005 e il 2015.
L'analisi si basa su una coorte dinamica di età compresa, ogni anno, tra 25 e 64 anni, definita utilizzando i dati dell'Anagrafe Comunale di Roma. I risultati mostrano un minore accesso all'emergenza per gli stranieri rispetto agli Italiani, anche se il gap mostra una riduzione dopo il 2008. In generale le due popolazioni mostrano comportamenti simili, mentre emergono differenze dal confronto per specifiche cause di accesso.

Key words: Emergency Department utilisation, Immigrant population, Dynamic cohort, Time trends, Rome

1 Introduction

During the last decades, the number of immigrants in Italy has continued to increase, reaching 5,047,028 (8.3%) in 2016 (Istat, 2016). On this basis, migration is no longer a transient phenomenon as in the 1970s, but it should be considered as a structural component of our society.

The WHO Commission on Social Determinants of Health recently highlighted the rise of new health inequalities between and within countries due to differences in social class, gender and ethnicity, as far as inequalities in the access to healthcare services among migrants and natives (Malmusi et al., 2010). Access to healthcare should be seen as no less important than housing and education for the wellbeing. Actually, it can be considered a proxy of the integration process (Ingleby et al., 2008).

At present, only scarce and often contradictory data have been published on migrant's utilisation of healthcare services in Europe (Norredam et al., 2004; Rué et al., 2008), and even less information is available on migrant's utilisation of Emergency Departments (EDs). Although the literature shows different scenarios (Zinelli et al., 2014; De Luca et al., 2013), there is a general consensus about the immigrants' higher use of emergency room services than that of non-migrants (Cots et al., 2007; Ruud et al., 2015). In Italy, a retrospective analysis based on 2005 Italian Health Conditions Survey, carried out by the Italian National Statistical Office, registered a higher Emergency Department utilisation rate by immigrants, notably from Morocco, other African countries and Albania (De Luca et al., 2013). These differences may be partly explained first of all by obstacles in the access to primary care, which are related to the migrant status, but also by different factors mainly related to the perceptions of illness or to the so called *health literacy.*

In Italy, some recent studies investigated the health of immigrants (Pacelli et al., 2016; Cacciani et al., 2011); however, as far as we know, no evidence is available about the health service utilisation of Italians and immigrants during the recent Great Recession.

While immigrant flows have increased rapidly in the last decade, we hypothesize that under the conditions to which immigrants are exposed because of their status, they might not use the medical system in the same way as the Italian population.

The objective of this study is twofold. Firstly, it investigates the possible differences in the EDs utilisation between immigrant and Italian residents in Rome. Secondly, it compares the EDs utilisation between the periods before and after the 2008.

2 Materials and methods

An observational study based on a dynamic cohort, defined using data from the Municipal Register of Rome, has been performed to evaluate the healthcare utilisation rate of Italians and that of the immigrant population, during the last decade.

The study population includes all residents in Rome, aged 25 to 64 years old between 1st January 2005 and 31st December 2015 in each year (2,184,467 individuals). Emergency Department data, gathered from the Regional Health Information System on Emergency Care in Lazio, were linked to the subjects using an individual anonymised code. An average of 390,000 visits by year has been observed. The available data include information about gender, birthdate, birthplace, citizenship, as well as medical information. Diagnoses and procedures are coded according to the ICD-9-CM.

The outcome variable is the overall number of EDs contacts. The immigrant status is the exposure variable (immigrants vs Italians). The most appropriate information to identify immigrants is still being debated (Malmusi et al., 2010). This study defines as immigrants those individuals without the Italian citizenship, distinguishing them between immigrants coming from High Migratory Pressure Countries (HMPCs)[1] and coming from Highly Developed Countries (HDCs). Since we are dealing with people resident in Rome, other migrant categories have been excluded. In order to explore differences in the emergency access, we performed descriptive analyses which aimed to investigate the pattern of EDs use by immigrants living in Rome (overall and for specific causes[2]), comparing it with that of the resident Italian population. Crude utilisation rates (URs), using person years, and direct age-standardized URs, by gender and for both immigrants and Italians, have been computed using the Italian population residing in Lazio at 1st January 2014 as standard population. The following age groups have been considered: 25-29, 30-34, 35-39, 40-44, 45-49, 50-54, 55-59, 60-64.

Negative binomial regression was used to estimate rate ratios (RRs) with 95% confidence intervals in order to evaluate differences in the EDs utilisation between

[1] Central-Eastern Europe (including Poland and Romania), North Africa, Sub-Saharan Africa, Asia (except for Israel and Japan), and Central and South America

[2] Mental disorders (ICD-9-CM 291-312), injuries (ICD-9-CM 800-959), and cardiovascular diseases (ICD-9-CM 401-445).

immigrants and Italians, adjusting for gender, age, socio-economic position (SEP)[1], and stratifying by time period.

3 Results

The total number of ED contacts during the period 2005-2015 was 4,297,981.

Immigrants as a whole had a lower UR than Italians, and this trend was similar in all age groups, except for the youngest women aged 25-29 (39.9 x 100 py compared to 37.5 x100 py for Italians). Women had higher overall URs than men in all groups of geographical origin (Fig. 1.a).

Of the two immigrant groups examined, those coming from HDCs registered the lowest rates. As figures show, even if the highest rate belongs to Italians, a similar trend between Italians and immigrants coming from HMPCs has been detected. Although the overall UR, both for men and women, varied slightly over the study period (Fig. 1.a), the access for specific causes showed different patterns. For the specific causes analysed, men always registered higher URs compared to women, except for both the causes related to mental disorders, where we observed a higher but constant UR among women coming from HMPCs, and injuries where women coming from HDCs registered a higher UR (Fig. 1.b). Concerning contacts for injuries we observed decreasing patterns especially among Italian men (Fig. 1.c). While the UR for mental disorders was fairly constant and that for injuries was declining, the contacts for cardiovascular-related causes registered an increasing pattern among all groups, especially for immigrants. In addition, immigrant men registered a higher UR with respect to Italian women (Fig. 1.d).

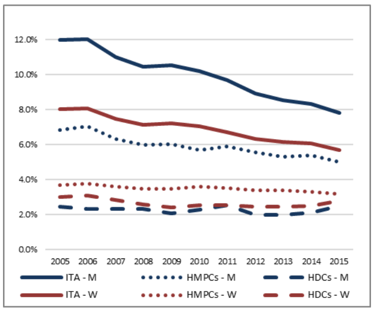
[1] The SEP indicator (from 1 higher to 4 lower) is based on the characteristics of the census block of residence (that is the smallest territorial unit for which population data were available).



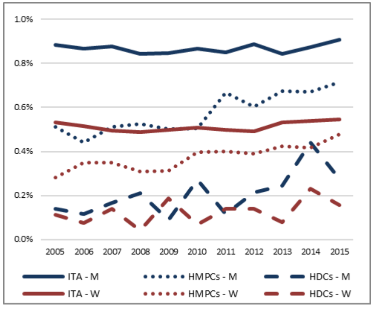


Table 1 shows the results from the Negative Binomial regression analysis. Italians were used as the reference group when comparing area of origin, men were used as a reference group when comparing gender and those with a high socio-economic position were used as a reference group when comparing the SEP. Age was considered as a continuous variable. An overall highly significant association was found between EDs utilisation rates and area of origin (p<0.0001). When controlling for age, gender and socio-economic position, immigrants registered a lower UR compared with Italian residents. A highly significant association was also found between the socio-economic position and utilisation. Table 1 shows how URs increase with decreasing SEP. Moreover, women registered higher URs with respect to men and the URs decrease with age. Comparing the period before and after the 2008, results show that patient behaviours are fairly constant in the two periods, however during the years analysed a reduction in the gap between the Italian population and the immigrant population (HMPCs) has been observed.

Table 1. Negative Binomial regression: rate ratios (with 95% confidence intervals) of ED utilisation for immigrant compared to Italian resident population in Rome, adjusted for age, gender, and socio-economic position, and stratified by time period. Lazio, years 2005-2015.

	Pre-2008		Post-2008	
	RRs	95% CI	RRs	95% CI
Area of origin:				
Italy	1		1	
HMPCs	0.743	(0.736 - 0.750)	0.800	(0.787 - 0.811)
HDCs	0.335	(0.324 - 0.345)	0.360	(0.351 - 0.369)
Gender and Age:				
Man	1		1	
Woman	1.013	(1.000 - 1.010)	1.088	(1.083 - 1.093)
25-64	0.983	(0.982 - 0.984)	0.986	(0.986 - 0.987)
Socio-ec. position:				
Higher	1		1	
Middle	1.099	(1.091 - 1.106)	1.104	(1.097 - 1.111)
Fairly	1.230	(1.221 - 1.239)	1.240	(1.232 - 1.248)
Lower	1.508	(1.496 - 1.519)	1.508	(1.498 - 1.519)

Our results show lower utilisation of the ED (overall) among immigrants during the period 2005-2015, in Rome. This result is consistent with previous reports of healthcare utilisation by the immigrant population and was probably due to the *healthy immigrant effect* (Carrasco-Garrito et al., 2007; Norredam et al., 2007) where recently arrived immigrants have better health status than natives because of a previous *selection process* in each country of origin. Consideration should be also given to the fact that we are dealing with immigrants who are resident in Rome, it means they have a residence permit and most of them have a work, thus they are also positively selected compared to other migrant categories. Moreover, other studies have shown no relationship between the perceptions of need, willingness to seek health services and ethnicity (Adamson et al., 2003), and more evidence is provided towards the hypothesis that barriers occur at the access of the services (Okie et al., 2007).

However, it would be interesting to analyse the access for specific causes, in which we detected different patterns, and to explore the hospitalization. Furthermore, even if the relationship between the SEP and the ED utilisation was expected, in this context the SEP was used for adjusting the exposure, but because the mechanism behind the interaction of this two variables is complex, further insights are necessary. Concerning comparative analyses, we will also should consider other factors which may have contributed to the modification in the EDs utilisation, as the Great Recession and the austerity policies implemented by the region.

Multi-State model with nonparametric discrete frailty

Modelli multi-stato con termine di frailty discreto nonparametrico

Francesca Gasperoni, Francesca Ieva, Anna Maria Paganoni, Chris Jackson and Linda Sharples

Abstract In this work, we propose a novel semi-Markov multi-state model with a nonparametric discrete frailty and an application to an administrative clinical database about heart failure patients from a Northern Region of Italy. In particular, we investigate a illness-death model with recovery in which the states space is composed by hospital admission, hospital discharge and death, as unique absorbing state. The available data are grouped longitudinal time-to-event data, indeed for each patient we know the times of admission and discharge of all hospitalizations (2005-2012), the time of death (if it occurs) and the healthcare provider (grouping factor). Thanks to this model, we can investigate the effect of covariates, detect the presence and a pattern of latent populations of healthcare providers across transitions.

Abstract *In questo lavoro proponiamo un modello multi-stato di tipo semi-Markov con una termine random discreto noparametrico e un'applicazione ad un database amministrativo clinico riguardante pazienti affetti da scompenso cardiaco in una regione del Nord Italia. In particolare, ci concentriamo su un modello di tipo illness-death con guarigione, in cui lo spazio degli stati è composto da ammissione in ospedale, dimissione dall'ospedale e morte, unico stato assorbente. amo a disposizione sono dati longitudinali di tipo tempo all'evento e raggruppati, infatti per ogni paziente siamo a conoscenza dei tempi di ammissione, dimissione (nell'arco di tempo 2005-2012) e momento del decesso, se avvenuto, e la struttura ospedaliera (fattore di raggruppamento). Tramite questo modello possiamo investigare l'effetto delle covariate, individuare la presenza di possibili popolazioni latenti di strutture ospedaliere su ciascuna transizione e possibili pattern fra le transizioni.

Key words: Multi-state model, nonparametric discrete frailty, clinical administrative database

1 Multi-State models with frailty

Multi-State models are mathematical models through which we deal with both competing and progressive events. In multi-state framework, we model the history of a statistical unit (i.e., the clinical history of a patient) through a multi-state process $(X_t)\ t \geq 0$, where X_t denotes the state occupied by the statistical unit at time t. We define the set of the possible states as $S = \{0,1,2,...,J\}$ and $X_t \in S$. The mathematical quantities that define a multi-state process are the transition probability matrix, **P**(s,t) and the initial state of the process X_0. The elements of the transition probability matrix are defined as:

$$P_{lj}(s,t) := P(X_t = j | X_s = l, H_s), \quad s \leq t \quad j,l \in S; \tag{1}$$

which means that the element (l,j) of **P**(s,t) is the probability of moving from state l to state j between times s and t, given H_s, which is the history of the process up to time s. More formally, H_s is defined as the filtration generated by the process itself, $H_s = \mathscr{F}_{s^-}$. A typical assumption consists in the Markovianity of the process, which states that there is a complete independence between the future and the past:

$$P_{lj}(s,t) := P(X_t = j | X_s = l), \quad s \leq t \quad j,l \in S. \tag{2}$$

Eq (2) states that the next state to be visited and the transition time depends only on the present state. Putter et al. [13] referred to Markov multi-state models as 'clock forward' models, while mentioned 'clock reset' models as semi-Markov multi-state models. According to semi-Markov assumption, the evolution of the process depends on the last occupied state and on the sojourn time. Another important quantity in multi-state models is the transition intensity, which is the instantaneous probability of executing a transition:

$$\lambda_{lj}(t) := \lim_{\Delta t \to 0} \frac{P(X_{t+\Delta t} = j | X_t = l)}{\Delta t}, \quad j,l \in S. \tag{3}$$

If the transition intensity is time-dependent we have time-inhomogenous Markov process, if it is constant we have time-homogenous Markov process.

Several authors explored the theory behind multi-state processes [1] [6] [8] [13], and few packages have been published in R [2] [7]. However, only few authors dealt with multi-state models with frailty. Frailty terms are random terms that are usually introduced in modelling time-to-event data with a twofold aim: on one hand, for taking into account the unexplained heterogeneity of the data and, on the other hand, for taking into account a grouped structure of data. The greatest part of them proposed semi-markov Markov multi-state models [3] [10] [11]. The proposed frailties were generally transition-specific and group-specific (shared frailty) [10] [11], or subject-specific [3] [15]. Ripatti et al. [14] proposed mixed frailty terms, some of which shared across transitions, while Liquet et al. [10] proposed a joint frailty to link two transitions. However, all of them included parametric frailties, such as Gamma, Normal or Compound-Poisson.

2 Semi-Markov multi-state model with a nonparametric discrete frailty term

In this work, we propose a novel multi-state model for grouped and longitudinal data. In particular, we introduce a transition-specific nonparametric discrete frailty term. This kind of frailty has been proposed in the simpler framework of time-to-event data [5] and it allows to avoid any a priori specification of the shape of the frailty and to detect possible clusters of groups (latent populations of known groups, such as hospitals).

The hazard function for individual i in group j in transition l is:

$$\lambda^l(t; X_{ij}^l, w_k^l, z_{jk}^l) = \prod_{k=1}^{K^l} \left[\lambda_0(t)^l w_k^l \exp((X_{ij}^l)^T \beta^l) \right]^{z_{jk}^l}. \tag{4}$$

Mathematical assumptions and notations are the same as the ones in time-to-event framework [5]. In Eq.(4), we can recognize a Cox model (a nonparametric part made by an unspecified baseline function $\lambda_0(t)$, and a parametric exponential part made by a vector of patient-specific covariates X_{ij} and the associated regression parameters β) with a nonparametric frailty term $\mathbf{w}^l$. This term is modeled through a random variable with discrete distribution, with an unknown number of points in the support. In particular, we assume that each group j can belong to one latent population k, $k = 1, ..., K^l$, with probability π_k^l. In this case, $[w_1, ..., w_K]^l$ are the points in the support of $\mathbf{w}^l$, K^l is the support's cardinality and $\mathbf{P}\{w^l = w_k^l\} = \pi_k^l$. Also the number of latent population K depends on l, which means that the number of latent population detected is transition-specific. In order to build the model, we introduce an auxiliary indicator random variable z_{jk}^l which is equal to 1 if the j-th group belongs to the k-th population in the l-th transition, so $z_{jk}^l \overset{i.i.d}{\sim} Bern(\pi_k^l)$. The requirement $\sum_{k=1}^K z_{jk}^l = 1$, for each j and l, is equivalent to the assumption that each group belongs to only one population in each transition.

3 Application to a clinical administrative database

The proposed semi-Markov multi-state model with nonparametric discrete frailty has been applied to clinical administrative data related to patients with a diagnosis of heart failure and treated in the Lombardia Region, Italy. Despite of the fact that multi-state models are perfect tools for studying chronic conditions, they have been modestly used for investigating heart failure [4].

We propose a illness-death multi-state model with recovery, see Fig. 1, in which the state space S is composed by: hospital admission, hospital discharge and death (as unique absorbing state). We model the hazard function for each possible transition, $\lambda^l(t)$ ($l \in \{1,2,3,4\}$), according to Eq (4) and we set the same regression parameters for all transitions: age, gender, a binary variable which is 1 if the patient has more than three comorbidities and the number of procedures.

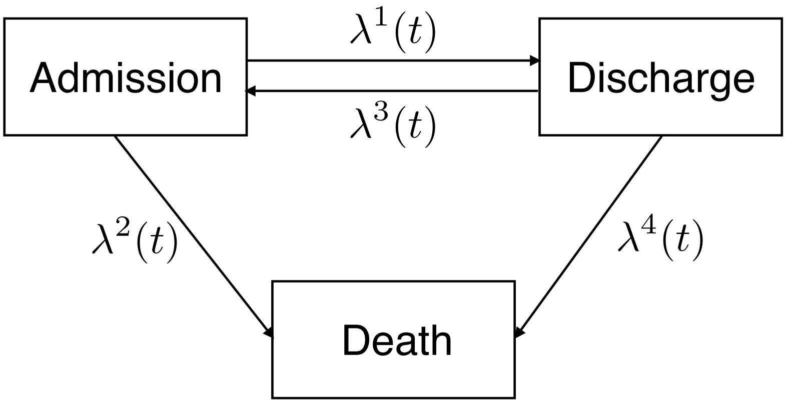

Fig. 1 Multi-state model proposed for the application to clinical administrative data.

The observed time window in the clinical administrative database that we studied is 2005 - 2012. In order to observe the complete clinical history of patients, we selected a cohort with only those patients whose first discharge was recorded between 2006 and 2007. Moreover, we selected those healthcare providers with 20-1,500 patients, in order to have more robust results. Than, the initial cohort is composed by $40,048$ patients.

For the sake of brevity, we report here only the results related to the first transition. In the first transition, we detected 7 latent populations (see Fig. 2). We observed that a patient hospitalized in a healthcare provider that belongs to latent population 7 has a higher risk (of 3.79 points) with respect to a patient with the same characteristics and hospitalized in a healthcare provider that belongs to latent population 1. The effect of covariates is coherent to what has been observed in a previous work on the same pathology [4]. Aging, having more than three comorbidities and having undergone a procedure lead to a lower risk of transition, which means a longer length of stay. Males have a higher risk of being discharged with respect to women.

The same evaluation can be done for the other transitions. For all of them, we decided to select the number of latent populations according to BIC index, which is, together with AIC, a very popular index in finite mixture model literature [12]. The other index that we show is the one proposed by Laird [9], which tends to overestimate the number of latent populations.

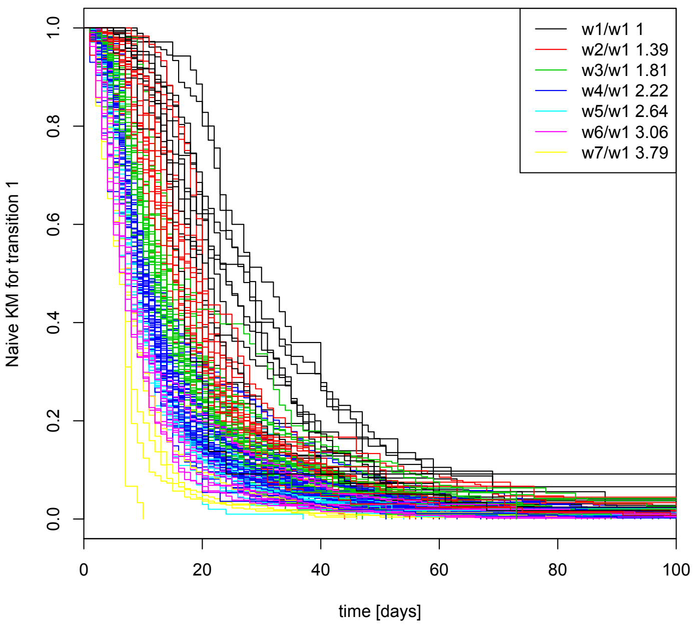

Fig. 2 Naive Kaplan-Meier for transition 1, a zoom in the first 100 days. The KM are naive because the considered censoring is not independent from the realization of the event of interest [13].

4 Conclusions

In this work, there are two sources of novelty: the inclusion of nonparametric discrete frailty in a semi-Markov model and the detection of latent populations of healthcare providers across transitions. The obtained results can be easily read and exploited by healthcare managers in decision making process, but also by clinicians in explorative analysis of clinical administrative databases.

Table 1 Estimates obtained through the proposed procedure in the first transition.

Transition	Latent populations	π	$\mathbf{w}/w_1$	β
1	K_{BIC} = 7 K_{AIC} =10 K_{Laird} = 11	π_1 = 0.09 π_2 = 0.14 π_3 = 0.25 π_4 = 0.28 π_5 = 0.12 π_6 = 0.08 π_7 = 0.04	w_1/w_1 = 1 w_2/w_1 = 1.39 w_3/w_1 = 1.81 w_4/w_1 = 2.22 w_5/w_1 = 2.63 w_6/w_1 = 3.06 w_7/w_1 = 3.79	β_{AGE} = -0.006 β_{SEX} = 0.069 β_{3COM} = -0.267 β_{NPRO} = -0.387

A Functional Urn Model for CARA Designs

Giacomo Aletti, Andrea Ghiglietti, and William F. Rosenberger

Abstract We present a general class of covariate-adjusted response-adaptive (CARA) designs introduced in [1], which is based on a new functional urn model. We show strong consistency concerning the allocation probability and the proportion of subjects assigned to the treatment groups, in the whole study and for each covariate profile, allowing the distribution of the responses conditioned on covariates to be estimated nonparametrically. We also establish joint central limit theorems for these quantities and the joint sufficient statistics, which allow construction of inference procedures.
Abstract *In questo lavoro presentiamo una classe generale di disegni covariate-adjusted adattivi alla risposta (CARA) introdotti in [1], che è basato su un nuovo modello d'urna funzionale. Inoltre, dimostriamo la forte consistenza della probabilità di allocazione e della proporzione di soggetti assegnati ai gruppi dei trattamenti, nell'intero studio e per ciascun valore delle covariate, permettendo alla distributione delle risposte condizionate alle covariate di essere stimata in maniera non parametrica. Infine, abbiamo stabilito alcuni teoremi centrale del limite congiunti di queste quantità e delle statistiche sufficienti, che permoettono la costruzione di procedure inferenziali.*

Key words: asymptotics, clinical trials, covariate-adjusted response-adaptive designs, randomization

1 Introduction

In CARA designs the patients in the trial are randomly assigned to $d \geq 2$ treatment groups with an allocation probability that depends on the current patient covariate profile and on the previous patients' covariates, allocations and responses (e.g. see [3]). In this framework, it is desirable that the proportion of subjects of each covariate profile assigned to the treatments converges to a desired target, defined as a function of the response distribution conditionally on the covariates.

Ideally, the analysis of the ethical and inferential properties of the experimental designs should be based on theoretical results concerning the asymptotic behavior of the allocation proportion and adaptive estimators, and none of the previous work on CARA designs is able to provide such results. In fact, since the allocation and the estimation process depend on both the responses and the covariates, CARA designs are very complex to be formulated in a rigorous mathematical setting. Two papers, in particular, formalize CARA in a rigorous mathematical framework. The first of these is the groundbreaking paper of [4], in which consistency and second-order asymptotic results concerning both adaptive estimators and allocation proportions have been proved for a very wide class of CARA designs. In the second [2], compound optimal design theory was used to find target allocations of interest, and these target allocations are attained using an accelerated biased coin design.

Here we present a class of CARA designs introduced in [1], in which the allocation probability may depend on nonparametric estimates of the response distribution, and the patients' covariate profiles are not identically distributed.

2 The model

For any $n \geq 0$, let $\mathbf{Y}_n = (Y_n^1, .., Y_n^d)^\top$ be a vector of functions, with $Y_n^j : \tau \mapsto (0,1)$, where τ is the covariate space. For any $t \in \tau$, $\mathbf{Y}_n(t)$ represents an urn containing $Y_n^j(t)$ balls of color $j \in \{1, .., d\}$ and $\mathbf{Z}_n(t) = \mathbf{Y}_n / \sum_{j=1}^d Y_n^j$ indicates the proportion of the colors.

When subject n enters the trial, his covariate profile T_n is observed. Then, a ball is sampled at random from the urn identified by T_n (i.e. with proportions $\mathbf{Z}_{n-1}(T_n)$), its color is observed and represented by $\bar{\mathbf{X}}_n$: $\bar{X}_n^j = 1$ when the color is $j \in \{1, .., d\}$, $\bar{X}_n^j = 0$ otherwise. Then, subject n receives the treatment associated to the sampled color and a response $\bar{\xi}_n$ is collected. The functional urn is then updated as: $\mathbf{Y}_n = \mathbf{Y}_{n-1} + D_n \mathbf{X}_n$, where $\mathbf{X}_n$ and D_n are appropriately defined. Specifically, the weighting function $\mathbf{X}_n : \tau \mapsto [0,1]^d$ should be such that, for any $t \in \tau$ and $j \in \{1, .., d\}$, $\sum_{j=1}^d X_n^j(t) = 1$ and $\mathbf{E}[X_n^j(t) | \mathscr{F}_{n-1}, T_n] = Z_n^j(t)$, where $\mathscr{F}_{n-1}$ is the σ-algebra of the information related with the first $(n-1)$ patients. This is straightforward for $t = T_n$ by setting $X_n^j(T_n) = \bar{X}_n^j$, since $\bar{X}_n^j$ is conditionally on $\mathscr{F}_{n-1}$ and T_n Bernoulli distributed with parameter $Z_n^j(T_n)$. Then, we define a family of Bernoulli random variables $\{\check{X}_n^j(t); t \in \tau\}$ with parameters $\{Z_n^j(t); t \in \tau\}$, representing the color that would be sampled in the trial if the covariate profile of subject n was equal to any $t \in \tau$. Finally, we use the quantile function that links this family to compute $\mathbf{X}_n(t)$ for all $t \in \tau$ as $\mathbf{X}_n := \mathbf{E}[\check{\mathbf{X}}_n | \mathscr{F}_{n-1}, T_n, \bar{\mathbf{X}}_n]$. Analogously, we can define the replacement functional matrix $D_n : \tau \mapsto [0,1]^{d \times d}$ as $D_n := \mathbf{E}[\check{D}_n | T_n, \bar{\mathbf{X}}_n, \bar{\xi}_n]$, where $\check{D}_n(t)$ is a function of a random variable having the same distribution of the response observed from a subject with covariate profile t, i.e. the response that would be observed in the trial if the covariate profile of subject n was equal to any $t \in \tau$. Naturally, $D_n(T_n) = \check{D}_n(T_n)$. Since the quantile functions of the response distributions are typically unknown, D_n is computed by using the corresponding (parametric or nonparametric) estimators obtained with the information in $\mathscr{F}_{n-1}$.

The key feature of the design is that quantile functions are used to update *all* urns, not just the urn for which $T_n = t$. In theory there could be an uncountably infinite number of urns, with only a finite subset of them used for patient allocation. However, in clinical practice, mathematically "continuous" covariates are really not continuous; for instance, cholesterol is represented by integer values, likely in some range, that would, for all intents and purposes, make it a finite discrete covariate. However, the procedure is well-defined for uncountably infinite urns, and first order asymptotic properties can be obtained, although some of the covariate-specific metrics do not make sense in that context. When we move to second-order asymptotics, we partition τ into K strata, which could be intervals of a continuous set.

3 Consistency Results

We now present some consistency results for (i) the probability of allocation of the subjects for each covariate profile ($\mathbf{Z}_n(t)$), (ii) the proportion of subjects associated to each covariate profile assigned to the treatments ($\mathbf{N}_{t,n}/\sum_{j=1}^{d} N_{t,n}^{j}$, where $\mathbf{N}_{t,n} := \sum_{i=1}^{n} \bar{\mathbf{X}}_i \mathbf{1}_{\{T_i=t\}}$), (iii) the proportion of subjects assigned to the treatments ($\mathbf{N}_n/n$, where $\mathbf{N}_n := \sum_{i=1}^{n} \bar{\mathbf{X}}_i$). Consider the following assumptions:

(A1) for any $t \in \tau$ and $n \geq 1$, $D_n^{\top}\mathbf{1} = \mathbf{1}$ (*constant balance*);
(A2) denoting by $H(t) := \mathbf{E}[\breve{D}_1(t)]$ the average replacement when the covariate profile is t, we assume that $H(t)$ is irreducible, diagonalizable and there exists $\alpha > 0$ such that $\mathbf{E}[|\mathbf{E}[D_n(t)|\mathscr{F}_{n-1}, T_n, \bar{\mathbf{X}}_n] - H(t)|\mathscr{F}_{n-1}] = O(n^{-\alpha})$.

Denote by $\mathbf{v}(t)$ the right eigenvector of $H(t)$ associated to $\lambda = 1$, with $\sum_{j=1}^{d} v^j(t) = 1$, and let μ_{n-1} be the probability distribution of T_n conditioned on $\mathscr{F}_{n-1}$. Then,

(a) for any probability measure ν on τ, we have $\int_{\tau} \|\mathbf{Z}_n(t) - \mathbf{v}(t)\| \nu(dt) \overset{a.s.}{\to} 0$;
(b) if $\sum_{i=1}^{n} \mu_{i-1}(\{t\}) \overset{a.s.}{\to} \infty$, we have $\|\mathbf{N}_{t,n}/\sum_{j=1}^{d} N_{t,n}^{j} - \mathbf{v}(t)\| \overset{a.s.}{\to} 0$;
(c) if $\int_{\tau} |\mu_n(dt) - \mu(dt)| \overset{a.s.}{\to} 0$, we have $\|\mathbf{N}_n/n - \int_{\tau} \mathbf{v}(t)\mu(dt)\| \overset{a.s.}{\to} 0$.

The convergence results consider a general covariate space τ. In order to show second-order properties, we now partition τ into K finite elements, which could, for instance, be K intervals of a continuous covariate space. This partitioning induces K urns used to allocate subjects with covariate profiles in the set $\{1,...,K\}$. In clinical trials practice, K must be considerably smaller than the total sample size.

4 Central Limit Theorems

We now present further assumptions that are required for establishing the second-order asymptotic properties.

- **Finite partition of the covariate space.** We assume that the covariate space τ is composed by a finite number $K \in \mathbb{N}$ of distinct elements. When τ contains infinite elements, we can take a partition of τ, i.e. $\{\tau_1,..,\tau_K\}$ such that $\cup_k \tau_k = \tau$ and $\tau_{k_1} \cap \tau_{k_2} = \emptyset$ for $k_1 \neq k_2$, and consider these sets to be the elements of τ, i.e. $\tau := \{\tau_1,..,\tau_K\}$. To facilitate the notation, without loss of generality in the sequel we redefine $\tau = \{1,..,K\}$ and $\mu_{n-1}(t) = \mu_{n-1}(\{t\}) = \mathbb{P}(T_n = t|\mathscr{F}_{n-1})$ for any $t \in \tau$.
- **Conditional response distributions.** The analog of the null hypothesis in classical inferential statistics is given here by assuming that the conditional response distributions $\pi_t^1,..,\pi_t^d$ are known for any $t \in \tau$. As a direct consequence, we have that $D_n = D_n^*$ and $H_n = H$ with probability one for any $n \geq 1$.
- **Eigenvalues of the limiting generating matrix.** Denoting $\lambda_H^*(t)$ the eigenvalue of $Sp(H(t)) \setminus \{1\}$ with largest real part, assume that $\max_{t\in\tau} \mathscr{R}e(\lambda_H^*(t)) < 1/2$.
- **Dynamics of adaptive estimators.**

- *(Covariate-stratification approach)* For some $t \in \tau$ and $j \in \{1,..,d\}$, consider that there are features of interest θ_t^j related with the distribution π_t^j of the responses to treatment j conditionally on the covariate profile t. Then, we assume that the corresponding adaptive estimator $\hat{\theta}_{t,n}^j$ is strongly consistent and its dynamics can be expressed as follows: there exists $n_0 \geq 1$ such that for any $n \geq n_0$

$$\hat{\theta}_{t,n}^j - \hat{\theta}_{t,n-1}^j = -\frac{\bar{X}_n^j \mathbb{1}_{\{T_n=t\}}}{N_{t,n}^j}(f_{t,j}(\hat{\theta}_{t,n-1}^j) - \Delta\mathbf{M}_{t,j,n} - \mathbf{R}_{t,j,n}), \tag{1}$$

where
  (i) $f_{t,j}$ is a Lipschitz continuous function such that $f_{t,j}(\theta_t^j) = 0$;
  (ii) $\Delta\mathbf{M}_{t,j,n} \in \mathscr{F}_n$ is a martingale increment such that $\mathbb{E}[\Delta\mathbf{M}_{t,j,n}|\mathscr{F}_{n-1}, T_n, \bar{X}_n^j] = 0$, and it converges stably to $\Delta\mathbf{M}_{t,j}$ with kernel K independent of $\mathscr{F}_{n-1}$:
  $\mathscr{L}(\Delta\mathbf{M}_{t,j,n}|\mathscr{F}_{n-1}, T_n = t, \bar{X}_n^j = 1) \overset{a.s.}{\to} K(t,j)$;
  (iii) $\mathbf{R}_{t,j,n} \in \mathscr{F}_n$ is such that $n\mathbb{E}[\|\mathbf{R}_{t,j,n}\|^2] \to 0$.
  Moreover, let $f_{t,j}$ be differentiable at θ_t^j, denote by $\lambda^*_{\theta_t^j}$ the eigenvalue of $Sp(\mathscr{D}f_{t,j}(\theta_t^j))$ with largest real part and assume that $\min_{t\in\tau}\mathscr{R}e(\lambda^*_{\theta_t^j}) > 1/2$. We also assume that for some $\delta > 0$,

$$\sup_{n\geq 1}\mathbb{E}\left[\|\Delta\mathbf{M}_{t,j,n}\|^{2+\delta} | \mathscr{F}_{n-1}\right] < +\infty a.s., \tag{2}$$

and

$$\mathbb{E}\left[\Delta\mathbf{M}_{t,j,n}(\Delta\mathbf{M}_{t,j,n})^\top | \mathscr{F}_{n-1}\right] \xrightarrow[n\to+\infty]{a.s.} \Gamma_{t,j}, \tag{3}$$

where $\Gamma_{t,j}$ is a symmetric positive matrix.
- *(Covariate-adjusted approach)* For some $j \in \{1,..,d\}$, consider that there are features of interest β^j related with the entire family of distributions $\{\pi_t^j; t \in \tau\}$ of the responses to treatment j conditionally on the covariates. Then, we assume that the corresponding adaptive estimator $\hat{\beta}_n^j$ is strongly consistent and its dynamics can be expressed as follows:

$$\hat{\beta}_n^j - \hat{\beta}_{n-1}^j = -\frac{\bar{X}_n^j}{N_n^j}(f_j(\hat{\beta}_{n-1}^j) - \Delta\mathbf{M}_{j,n} - \mathbf{R}_{j,n}), \tag{4}$$

where the quantities in (4) fulfill the same conditions presented above for the dynamics (1).

We first provide the convergence rate and the joint asymptotic distribution concerning the quantities of interest in the design in the framework of covariate-stratification response-adaptive designs. This result is established in the following central limit theorem. We introduce the variables independent of $\sigma(\mathscr{F}_n; n \geq 1)$: $T \in \tau$ with distribution $\mu(t)$, $\bar{\mathbf{X}} \in \{0,1\}^d \in \mathscr{S}$ such that $\mathbb{P}(\bar{X}^j = 1|T) = v^j(T)$, $D := \mathbb{E}[\check{D}|T, \bar{\mathbf{X}}, \xi]$, where the distribution of ξ conditioned on $\{T = t\}$ and $\{\bar{X}^j = 1\}$ is π_t^j.

Theorem 4.1. *Define* $\mathbf{W}_n := (\mathbf{Z}_n(t), \mathbf{N}_{t,n}/w(\mathbf{N}_{t,n}), \hat{\theta}_{t,n}, t \in \tau)^\top$, $\mathbf{W} := (\mathbf{v}(t), \mathbf{v}(t), \theta_t, t \in \tau)^\top$. *Then,*

$$\mu_n(t) \xrightarrow{a.s.} \mu(t) = f_{\mu,t}(\mathbf{v}(t), \theta_t), \qquad \mathbf{W}_n \xrightarrow{a.s.} \mathbf{W}, \tag{5}$$

$$\sqrt{n}(\mathbf{W}_n - \mathbf{W}) \xrightarrow{\mathscr{L}} \mathscr{N}(\mathbf{0}, \Sigma), \qquad \Sigma := \int_0^\infty e^{u(\frac{\mathbf{I}}{2}-A)}\Gamma e^{u(\frac{\mathbf{I}}{2}-A^\top)}du, \tag{6}$$

where

$$A := \begin{pmatrix} A_{ZZ} & 0 & 0 \\ -I & I & 0 \\ 0 & 0 & A_{\theta\theta} \end{pmatrix}, \qquad \Gamma := \begin{pmatrix} \Gamma_{ZZ} & \Gamma_{ZN} & \Gamma_{Z\theta} \\ \Gamma_{ZN}^{\top} & \Gamma_{NN} & 0 \\ \Gamma_{Z\theta}^{\top} & 0 & \Gamma_{\theta\theta} \end{pmatrix},$$

and A_{ZZ}, $A_{\theta\theta}$, Γ_{NN}, $\Gamma_{\theta\theta}$ *are block-diagonal matrices whose* t^{th} *block is*

(i) $A_{ZZ}^{tt} = (I - H(t) + \mathbf{v}(t)\mathbf{1}^{\top})$;
(ii) $A_{\theta\theta}^{tt}$ *is a block-diagonal matrices whose* j^{th} *block is* $[A_{\theta\theta}^{tt}]^{jj} := \mathscr{D} f_{t,j}(\theta_t^j)$;
(iii) $\Gamma_{NN}^{tt} := \mu^{-1}(t)(diag(\mathbf{v}(t)) - \mathbf{v}(t)\mathbf{v}^{\top}(t))$;
(iv) $\Gamma_{\theta\theta}^{tt}$ *is a block-diagonal matrices whose* j^{th} *block is*
$[\Gamma_{\theta\theta}^{tt}]^{jj} := (v^j(t)\mu(t))^{-1}\mathbb{E}[\Delta\mathbf{M}_{t,j}(\Delta\mathbf{M}_{t,j})^{\top}|T = t, \bar{X}^j = 1]$;

and Γ_{ZZ}, Γ_{ZN}, $\Gamma_{Z\theta}$ *are matrices defined as follows: for any* $t_1, t_2 \in \tau$

(v) $\Gamma_{ZZ}^{t_1t_2} := \mathbb{E}[D(t_1)\mathbf{g}(t_1, T, \bar{\mathbf{X}})\mathbf{g}^{\top}(t_2, T, \bar{\mathbf{X}})D^{\top}(t_2)] - \mathbf{v}(t_1)\mathbf{v}^{\top}(t_2)$;
(vi) $\Gamma_{ZN}^{t_1t_2} := H(t_1)G(t_1,t_2)diag(\mathbf{v}(t_2)) - \mathbf{v}(t_1)\mathbf{v}^{\top}(t_2)$;
(vii) $[\Gamma_{Z\theta}^{t_1t_2}]^j := \mathbb{E}[D(t_1)\mathbf{g}(t_1,t_2,\mathbf{e}_j)\Delta\mathbf{M}_{t_2,j}^{\top}|T = t_2, \bar{X}^j = 1]$;

where $\mathbf{g}$ *is a d-multivariate function with values in* $\mathscr{S}$ *and* $G(t_1,t_2)$ *is a matrix with columns* $\{\mathbf{g}(t_1,t_2,\mathbf{e}_j); j \in \{1,..,d\}\}$.

We now provide the convergence rate and the joint asymptotic distribution of the quantities interest in the design in the framework of covariate-adjusted response-adaptive designs. This result is established in the following central limit theorem.

Theorem 4.2. *Define* $\mathbf{W}_n := (\mathbf{Z}_n(t), t \in \tau, \mathbf{N}_n/n, \hat{\beta}_n)^{\top}$, $\mathbf{W} := (\mathbf{v}(t), t \in \tau, \mathbf{x}_0, \beta)^{\top}$. *Then,*

$$\mu_n(t) \xrightarrow{a.s.} \mu(t) = f_{\mu,t}(\mathbf{x}_0, \beta), \qquad \mathbf{W}_n \xrightarrow{a.s.} \mathbf{W}, \tag{7}$$

$$\sqrt{n}(\mathbf{W}_n - \mathbf{W}) \xrightarrow{\mathscr{L}} \mathscr{N}(\mathbf{0}, \Sigma), \qquad \Sigma \ := \int_0^{\infty} e^{u(\frac{\mathbf{I}}{2} - A)} \Gamma e^{u(\frac{\mathbf{I}}{2} - A^{\top})} du, \tag{8}$$

and

$$A := \begin{pmatrix} A_{ZZ} & 0 & 0 \\ A_{NZ} & A_{NN} & A_{N\beta} \\ 0 & 0 & A_{\beta\beta} \end{pmatrix}, \qquad \Gamma := \begin{pmatrix} \Gamma_{ZZ} & \Gamma_{ZN} & \Gamma_{Z\beta} \\ \Gamma_{ZN}^{\top} & \Gamma_{NN} & 0 \\ \Gamma_{Z\beta}^{\top} & 0 & \Gamma_{\beta\beta} \end{pmatrix},$$

where again and A_{ZZ}, $A_{\beta\beta}$, $\Gamma_{\beta\beta}$ *are block-diagonal matrices whose* t^{th} *or* j^{th} *block is*

(i) $A_{ZZ}^{tt} = (I - H(t) + \mathbf{v}(t)\mathbf{1}^{\top})$;
(ii) $A_{\beta\beta}^{jj} = \mathscr{D} f_j(\beta^j)$;
(iii) $\Gamma_{\beta\beta}^{jj} := (\mathbb{E}[v^j(T)])^{-1}\mathbb{E}[\Delta\mathbf{M}_j(\Delta\mathbf{M}_j)^{\top}|\bar{X}^j = 1]$;

and

(iv) $A_{NN} := I - \sum_{s=1}^{K} \mathbf{v}(s)\mathscr{D}_N f_{\mu,s}(\mathbf{x}_0, \beta)^{\top}$;
(v) $A_{N\beta} := -\sum_{s=1}^{K} \mathbf{v}(s)\mathscr{D}_{\beta} f_{\mu,s}(\mathbf{x}_0, \beta)^{\top}$;
(vi) $\Gamma_{NN} := diag(\mathbb{E}[\mathbf{v}(T)]) - \mathbb{E}[\mathbf{v}(T)]\mathbb{E}[\mathbf{v}^{\top}(T)]$;

and A_{NZ}, Γ_{ZZ}, Γ_{ZN}, $\Gamma_{Z\beta}$ *are matrices defined as follows: for any* $t_1, t_2 \in \tau$

(vii) $A_{NZ}^{t_2} := -\mu(t_2)I$;

(viii) $\varGamma_{ZZ}^{t_1t_2} := \mathbb{E}[D(t_1)\mathbf{g}(t_1,T,\bar{\mathbf{X}})\mathbf{g}^\top(t_2,T,\bar{\mathbf{X}})D^\top(t_2)] - \mathbf{v}(t_1)\mathbf{v}^\top(t_2)$*;*
(ix) $\varGamma_{ZN}^{t_1} := H(t_1)\mathbb{E}[G(t_1,T)diag(\mathbf{v}(T))] - \mathbf{v}(t_1)\mathbb{E}[\mathbf{v}^\top(T)]$*;*
(x) $\varGamma_{Z\beta}^{t_1j} := \mathbb{E}[D(t)\mathbf{g}(t_1,T,j)\Delta\mathbf{M}_j^\top|\bar{X}^j = 1]$.

where we recall that $\mathbf{g}$ *is a* d*-multivariate function with values in* $\mathscr{S}$ *and* $G(t_1,t_2)$ *is a matrix with columns* $\{\mathbf{g}(t_1,t_2,\mathbf{e}_j); j \in \{1,..,d\}\}$.

Remark 4.1. *We recall that Theorem 4.1 allows inferential procedures based on stratified estimators, while Theorem 4.2 allows inference on covariate-adjusted regression parameters representing the covariate-adjusted treatment effect.*

Assessment of the INLA approach on gerarchic bayesian models for the spatial disease distribution: a real data application

Valutazione dell'approccio basato su INLA in modelli gerarchici bayesiani per la distribuzione spaziale di malattia: un'applicazione a dati reali

Sommario The use of approximate methods as the INLA (Integrated Nested Laplace Approximation) approach is being widely used in Bayesian inference, especially in spatial risk model estimation where the Besag-York-Molliè (BYM) model has found a proper use. INLA appears time saving compared to Monte Carlo simulations based on Markov Chains (MCMC), but it produces some differences in estimates [1, 2]. Data from the Veneto Cancer Registry has been considered with the scope to compare cancer incidence estimates with INLA method and with two other procedures based on MCMC simulation, WinBUGS and CARBayes, under R environment. It is noteworthy that INLA returns estimates comparable to both MCMC procedures, but it appears sensitive to the a-priori distribution. INLA is fast and efficient in particular with samples of moderate-high size. However, care must to be paid to the choice of the parameter relating to the a-priori distribution.

Sommario *L'uso dei metodi basati sull'approssimazione di Laplace come INLA (Integrated Nested Laplace Approximation) è ampiamente utilizzato nell'inferenza Bayesiana, specialmente in modelli di rischio spaziale dove il modello di Besag-York-Molliè (BYM) ha trovato un uso appropriato. INLA permette un risparmio di tempo computazionale rispetto alle simulazioni Monte Carlo basate su Catene Markov (MCMC), ma produce alcune differenze nelle stime [1, 2]. Vengono considerati i dati del Registro dei Tumori del Veneto con lo scopo di di confrontare le stime ottenute con INLA rispetto a due procedure basata su MCMC, WinBUGS e CARBayes, svolte in ambiente R. E' importante notare che INLA restituisce stime comparabili ad entrambe le procedure MCMC, ma è sensibile alla distribuzione a priori. INLA è un metodo rapido ed efficiente, in particolare con campioni di elevata numerosità. Tuttavia, occorre prestare attenzione alla scelta del parametro relativo alla distribuzione a priori.*

Key words: BYM model, Cancer Registry, INLA, Laplace approximation, Bayesian methods

1 Introduction

In recent literature, the use of approximate methods in Bayesian inference has reported a great popularity. The Laplace approximation proposed by [Rue H., 2009] with the INLA acronym (Integrated Nested Laplace Approximation) has been adapted to the parameter estimations of an increasing number of statistical models; in addition, several papers have reported its use in wide range of real data applications. INLA offers the opportunity to perform Bayesian analyses through numerical integration avoiding extensive iterative computation; it usually implies a lower computational time respect to the classical Monte Carlo simulations based on Markov Chains (MCMC) with dedicated software (WinBUGS, OpenBUGS or JAGS). The major gain of INLA is the replacing of long chains used by MCMC methods to produce a-posteriori estimates of the coefficients distribution with a Laplace approximation of the a-posteriori distribution. Among hierarchical Bayesian models, the Besag-York-Molliè (BYM) model [4] has became popular for the analysis of spatial distribution of occurrences in epidemiology (disease risk, mortality, etc...), in financial services (investments, prices) and in demography and sociology (deprivation index, unemployment rate, etc..). The availability of the INLA package for R software [5] has allowed an easy and friendly implementation of INLA for BYM models. However, recent publications show that INLA produces considerable differences in estimates [1, 2] and research on this topic remains already unexplored. The aim of the study is to compare risk estimates produced by INLA with those one of the MCMC simulations using a series of real data applications instead of simulations.

2 Materials and methods

2.1 Veneto Cancer Registry

We consider all the cases of malignant cancers occurring in the year 2013 in the Veneto Region, one of the largest Region in Italy covering about five million of inhabitants. The area covered by the Veneto Cancer Registry includes the 96% of the territory (Figure 1). Every cancer case has been coded with the X version of International Classification of the Diseases (ICD-X) and has been aggregated at the municipality level (n=556 municipalities). In our comparison we consider 7 different primitive sites that have different number of cases: all the sites except skin, Hodgkin's lymphoma, myeloma and pancreas cancer among men; cancer of breast, cervix and cancer of esophagus among women.

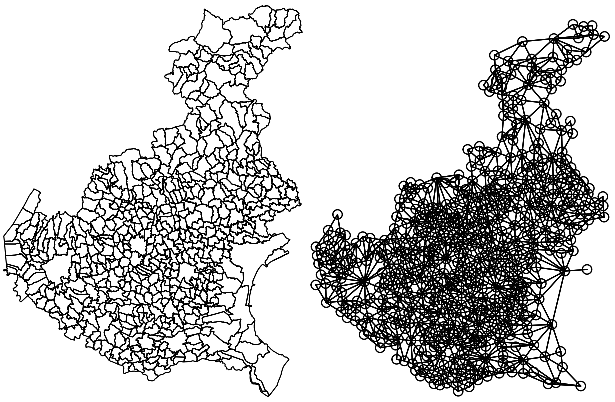

Figura 1 Boundaries and adjacency matrix of the 556 municipalities.

2.2 BYM model

The Standardized Incidence Ratios (SIR) have been estimated by means of a BYM model. The number of observed cases O_i is assumed to follow a Poisson distribution as

$$O_i \sim Poisson(\lambda_i) \tag{1}$$

where λ_i is the mean/variance parameter. Considering e_i the expected number of cases for the $i-th$ area calculated by an indirect standardization using the registry pool as reference, the estimated SIR is connected to the linear predictor η_i as follows

$$log(SIR_i) = log(\frac{\lambda_i}{e_i}) = \eta_i = (\alpha + \mu_i + \nu_i), \tag{2}$$

where α is the intercept quantifying the average incidence rate in all the 556 municipalities, while μ_i and ν_i are the correlated and uncorrelated spatial effects, following a normal distribution. While τ_ν is assumed to be distributed as a white noise ($\nu_i \sim N(0, \frac{1}{\tau_\nu})$), the μ_i distribution is modelled using an intrinsic conditional autoregressive structure (ICAR) as follow

$$\mu_i \sim N(\frac{1}{n_j} \sum_{\partial j} O_j, \frac{1}{n_j \tau_\mu}) \tag{3}$$

where O_j are the cases observed in ∂j which denotes the n_j municipalities bordering the *i-th* area, *i-th* area excluded. The precision parameters τ_μ and τ_ν follow a Gamma distribution. SIR has been estimated by INLA using R-INLA and by MCMC procedures using R2WinBUGS and CarBayes packages under R environment. For MCMC simulation, we took into account the results of 15.000 iterations discarding the first 5.000 as burn-in.

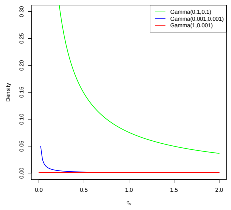

Figura 2 Distributions of the parameter τ_μ.

The study considers three different distributions for the precision of the spatial parameter τ_μ: $\Gamma(0.1,0.1)$, $\Gamma(0.001,0.001)$ and $\Gamma(1,0.001)$. The parameter of the precision related to the uncorrelated spatial effect has been fixed to be distributed as a $\Gamma(0.001,0.001)$.

3 Results

The main characteristics of the selected cancer sites are reported in Table 1. The sites are ordered decreasing the number of observed cases. A high number of male cases (15'416) is registered taking into account all the cancer sites except the skin; conversely, a low number of cervix cancers among women is reported, equal to 200, less than 1 per municipality. The average number of cases for municipality is always lower than the variance estimates indicating an over-dispersion. The p-values associated to the Moran's I test applied to empirical SIR ($\frac{o_i}{e_i}$) support the spatial independence for the distribution of each considered primitive site.

Cancer site	**Total cases**	Average	Variance	Moran's I test (p-value)
All sites (men)	15'416	27.7	5063.8	0.430
Breast (women)	4'372	7.9	535.5	0.185
Pancreas (men)	535	1.0	8.10	0.065
Cervix cancer (women)	200	0.4	1.5	0.796
Myeloma (men)	199	0.4	1.2	0.758
Hodgkin's lymphoma (men)	101	0.2	0.6	0.483
Esophagus (women)	59	0.1	0.4	0.163

Tabella 1 Characteristics of the selected cancer sites and p-value associated to Moran's I test for the empirical SIR.

SIR estimates are calculated for each selected cancer site varying the distribution of the precision parameter τ_μ computing the Pearson correlation index between INLA and MCMC-based estimates. The results are reported in Table 2. The correlation indices ranges from 0.344 in esophageal cancer with a-priori distribution $\tau_\mu \sim \Gamma(1,0.001)$, which indicates a poor agreement between INLA and CARBayes estimates, to 0.998/0.996 relatively to all male cancer sites with $\tau_\mu \sim \Gamma(0.1,0.1)$ resulting in a perfect overlapping between INLA and WinBUGS/CARBayes methods. The degree of agreement between INLA and MCMC procedures depends on: 1) the a-priori distribution of the variance of spatial component; 2) the number of incident cases. Overall, the best agreement (all r' Pearson indices >0.9) is obtained choosing a $\Gamma(0.1,0.1)$ for the τ_μ. As reported in Table 3 INLA returns estimates faster than MCMC procedure (about 15/20 times).

		Distribution of τ_μ		
Cancer site	**MCMC procedures**	$\Gamma(0.1,0.1)$	$\Gamma(0.001,0.001)$	$\Gamma(1,0.001)$
All cancers (men)	WinBUGS / CarBayes	0.998 / 0.996	0.992 / 0.987	0.990 / 0.985
Breast (women)	WinBUGS / CarBayes	0.997 / 0.995	0.994 / 0.988	0.992 / 0.983
Pancreas (men)	WinBUGS / CarBayes	0.997 / 0.995	0.987 / 0.949	0.983 / 0.976
Cervix cancer (women)	WinBUGS / CarBayes	0.986 / 0.945	0.966 / 0.947	0.961 / 0.872
Myeloma (men)	WinBUGS / CarBayes	0.910 / 0.966	0.925 / 0.963	0.948 / 0.969
Hodgkin's lymphoma (men)	WinBUGS / CarBayes	0.981 / 0.917	0.763 / 0.850	0.930 / 0.882
Esophagus (women)	WinBUGS / CarBayes	0.955 / 0.935	0.858 / 0.937	0.802 / 0.344

Tabella 2 Correlation index between INLA and MCMC-based methods on SIR estimates by distribution of τ_μ.

Although r's pearson index indicates a high agreement between INLA estimates compared to the MCMC-based methods, the graphical analysis permits to verify the presence of marked differences in the estimated risks (Figure 3), for example, relatively to the Myeloma SIR. The difference is marked considering the spatial distribution of the esophageal cancer incidence among women obtained by a comparison between INLA and CARBayes procedures (Fig. 4) that in Table 2 reports a weak agreement.

Procedures	$\Gamma(0.1,0.1)$	$\Gamma(0.001,0.001)$	$\Gamma(1,0.001)$
INLA	5.50	4.04	9.7
WinBUGS	87.25	90.99	85.93
CARBayes	68.7	64.1	68.9

Tabella 3 Computation time for INLA, WinBUGS and CARBayes esophageal SIR estimates.

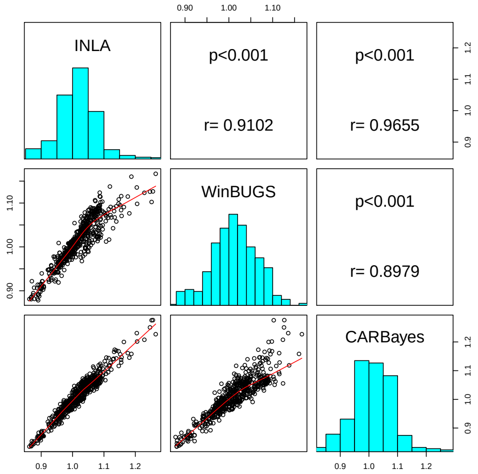

Figura 3 Esophagus SIR distribution among women with $\tau_\mu \sim \Gamma(0.1,0.1)$ estimated with INLA and with two MCMC-based procedures (WinBUGS and CARBayes).

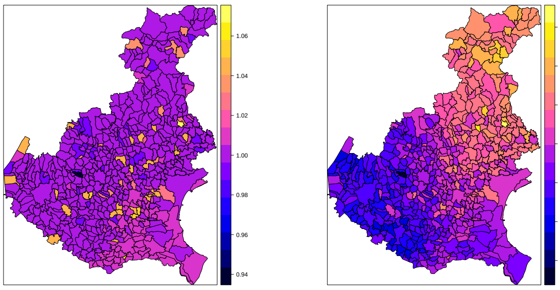
4 Conclusions

In presence of non-informative a-priori distributions, INLA and MCMC procedures reported different estimates, even more clean-cut considering low sample size. INLA confirms to be a fast and efficient method for spatial risk estimation and, in general, for hierarchical Bayesian models [6, 7]. However, in order to avoid an over-smoothing of the risks and/or excessive imprecision of the estimates, particular attention must to be paid to the choice of the a-priori distribution for the variance of the spatial component. Further analyses are required in order to assess the comparability of INLA and MCMC estimates looking at the distribution of the uncorrelated spatial parameter and at the presence of spatial dependence.



(a) INLA SIR estimates $\tau_\mu \sim \Gamma(1, 0.001)$

(b) CARBayes MCMC SIR estimates $\tau_\mu \sim \Gamma(1, 0.001)$

Hidden Markov Models for disease progression

Hidden Markov Models per la progressione di patologia

Andrea Martino, Andrea Ghiglietti, Giuseppina Guatteri, Anna Maria Paganoni

Abstract Disease progression models are a powerful tool for understanding and predicting the development of a disease, given some longitudinal measurements obtained from a sample of patients. These models are able to give some insights about the disease progression through the analysis of patients histories and could be also used to predict the future course of the disease in an individual. In particular, Hidden Markov Models (HMMs) are a useful tool for disease modeling since they allow to model situations where the state of the disease is not observable, by giving the possibility to incorporate some priors and constraints. We applied our models to a simulated dataset by considering a generalization of HMMs with continuous time and multivariate outcome.

Abstract *I modelli di progressione di patologia sono un potente strumento per comprendere e prevedere lo sviluppo di una patologia, date delle misurazioni longitudinali ottenute da un campione di pazienti. Questi modelli sono in grado di arricchire la conoscenza sulla progressione della patologia attraverso l'analisi della storia dei pazienti e possono anche essere usati per predire il corso futuro della patologia di un individuo. In particolare, gli Hidden Markov Models (HMMs) sono un utile strumento per la modellazione di patologia in quanto permettono di costruire un modello in situazioni in cui lo stato della patologia non è osservabile, dando la possibilità di incorporare delle prior e dei vincoli. Abbiamo applicato i nostri modelli a un dataset simulato considerando una generalizzazione degli HMM a tempo continuo e risposta multivariata.*

Key words: disease progression modeling, Hidden Markov Models, multivariate data

1 Introduction

Many chronic diseases can be naturally represented in terms of staged progression. Hidden Markov Models (HMMs) are a popular method for modeling disease progression and estimating the rates of transition between the stages of a disease. For this reason, we introduce a HMM for disease progression which takes into account the possibility of modeling multivariate observations with correlated components. Although discrete-time HMMs are often used to model disease progression, they are not very suitable in practice because the measurement data should be regularly sampled at discrete intervals and state transitions can only occur at these discrete times. Since we are interested in using our model to study the Heart Failure (HF) pathology and hospitalizations for HF patients occur irregularly in time, we consider a continuous time HMM, in which both the transitions between the hidden states and the observations can occur at arbitrary continuous times (for further details, see [1, 2]).

2 The model

A continuous time HMM is very suitable for modeling disease progression, which is a continuously evolving process. Even though the continuous time HMM adds more flexibility to the models with respect to the discrete time HMM, this comes with a higher computational cost. Indeed, in this case not only the hidden states are unobserved but the transition times are unknown too. Moreover, although HMMs often consider the case where the observations are sampled from a discrete distribution which can only take a finite number of values, in our analysis we have considered observations composed by both continuous and discrete values.

Let us denote $(\mathbf{O}_1, \mathbf{O}_2, \dots, \mathbf{O}_K)$ the set of observations, univariate or multivariate data, observed at K irregularly-distributed continuous points in time $(t_1, t_2, \dots, t_K)$, such that we have two levels of hidden informations: the state of the Markov chain is hidden and the state transitions are also hidden, since it is not known if other transitions occur between two consecutive observations. For any observation $\mathbf{O}_k$ we denote the probability of being in a state $s(t_k)$ at time t_k, often called as *emission probability*, as $p(\mathbf{O}_k|s(t_k))$. As for continuous time Markov chains, we can define the finite and discrete state space S, the state transition rate matrix Q and the initial state probability distribution π. The elements q_{ij} in the matrix Q represent the rate of a process's transition from state i to state j for $i \neq j$, while the elements q_{ii} must be specified such that each row of the matrix sums up to zero ($q_i = \sum_{j \neq i} q_{ij}, q_{ii} = -q_i$) [1]. Moreover, if the process is time-homogeneous, the sojourn time in each state i

is exponentially distributed with parameter q_i, while q_{ij}/q_i indicates the probability of the next transition of the process from state i to state j.

As done in [3], if we consider a continuous time HMM which is fully observed, the complete joint likelihood of the data can be written as

$$CL = \prod_{k'=0}^{K'} q_{y_{k'},y_{k'+1}} e^{-q_{y_{k'}}\tau_{k'}} \prod_{k=0}^{K} p(\mathbf{O}_k|s(t_k)) = \prod_{i=1}^{|S|} \prod_{j=1,j\neq i}^{|S|} q_{ij}^{n_{ij}} e^{-q_i\tau_i} \prod_{k=0}^{K} p(\mathbf{O}_k|s(t_k))$$

where $(t'_0, t'_1, \dots, t'_{K'})$ are the K' state transition times with $Y' = \{y_0 = s(t'_0), \dots, y_{K'} = s(t'_{K'})\}$ being the corresponding states of the Markov chain, $\tau_k = t_{k+1} - t_k$ is the time interval between two observations while $\tau_{k'} = t'_{k'+1} - t'_{k'}$ is the time interval between two transitions and n_{ij} is the number of transitions from state i to state j.

3 Parameter estimation

For the computation of the rate transition matrix Q, several methods based on EM algorithms have been proposed in [3]. We now focus on the estimation of the emission probability matrix $B = \{b_j(\mathbf{O}_k)\}$ where $b_j(\mathbf{O}_k) = p(\mathbf{O}_k|s(t_k) = j)$ is the probability of being in a state j at time t_k, while observing $\mathbf{O}_k$. This estimation is usually straightforward if we are considering an univariate outcome. In general, since we consider multivariate observations, we also want to model the correlation among the variables.

As usually done, if the observations are only symbols chosen from a finite alphabet, a discrete probability density can be used to model the data and estimate the matrix B. This approach is not generally enough since we consider observations coming from both discrete and continuous distributions. In order to use a continuous observation density, we have to consider some restrictions for the estimation of the probability density function (pdf). We can represent the pdf in its most general representation as a finite mixture which can be written as

$$b_j(\mathbf{O}) = \sum_{m=1}^{M} c_{jm}(\mathbf{O}) \mathscr{D}[\mathbf{O}, \boldsymbol{\mu}_{jm}, \mathbf{U}_{jm}], \quad 1 \leq j \leq N$$

where $\mathbf{O}$ is the vector being modeled, N is the number of statistical units, $c_{jm}(\mathbf{O})$ is a non negative mixture coefficient for the mth mixture in state j and $\mathscr{D}$ is a pdf with mean vector $\boldsymbol{\mu}_{jm}$ and covariance matrix $\mathbf{U}_{jm}$ for the mth mixture component in state j. We implemented a normalized version of the forward-backward algorithm and a Baum-Welch algorithm (see [5]) by using our matrix B in a continuous time framework. All the analysis have been carried out using the software R ([4]).

4 Simulation study

We applied our model to multivariate longitudinal data, which are repeated observations of multiple response variables. Since the data are correlated over time and multiple responses are measured at the same time, special treatments are required to analyze the data. In particular, the easiest approach would be to ignore the correlation, which would lead to some loss of information. Therefore, to flexibly characterize the distribution of the emission probabilities, we modelled the correlation among the observation components for each multivariate outcome.

We generated a sample $(x_1,y_1),\dots,(x_N,y_N)$ of $N = 1000$ observations for $n = 50$ statistical units, in order to have 20 observations for each statistical unit. For each one of them, we have a sequence of pairs which is the realization of a 3-state Markov process. Given the state j of the Markov process, each pair of the sample is a realization of the joint distribution (X,Y), where $X \sim Be(p)$ and $Y = XY_1 + (1-X)Y_2$, with $Y_i \sim N(\mu_{ij},\sigma_{ij}^2)$ independent of X. We used the following parameters to generate the data:

- **State 1**: $p = 0.2, \mu_{11} = 0, \mu_{21} = 3, \sigma_{11} = 0.5, \sigma_{21} = 0.8.$
- **State 2**: $p = 0.9, \mu_{12} = 1, \mu_{22} = 5, \sigma_{12} = 0.5, \sigma_{22} = 0.8.$
- **State 3**: $p = 0.7, \mu_{13} = 4, \mu_{23} = 7, \sigma_{13} = 0.5, \sigma_{23} = 0.8.$

We applied our algorithm using $m = 2,\dots,5$ states and we can see the results we obtained in Table 1. A problem which naturally arises is that of selecting an appropriate model, e.g. of choosing the appropriate number of states for the HMM, so we need some criteria for model comparison. To address this problem, for each run of the algorithm we computed the Aikake Information Criterion as $\text{AIC} = -2\log L + 2p$ and the Bayesian Information Criterion as $\text{BIC} = -2\log L + plogT$, where L is the likelihood function of the fitted model, p is the number of unknown parameters and T is the number of observations. The values we obtained are showed in Fig. 1. According to both AIC and BIC, the model with three states is the most appropriate. As we can see for $m = 3$, the estimated values are very similar to the real ones, so we can conclude that by considering the correlation among the components of the outcome variables, we were able to obtain very good results.

5 Conclusion

In this work we built a model for longitudinal data with multivariate observations and showed that, if we consider the correlation among the components of the outcome, we can obtain very good results. The next step will consist in applying our algorithm to a real case study, with the data coming from an administrative dataset about hospitalizations which is in pre-processing, in order to study the progression of the Heart Failure pathology.

A simulation study on the use of response-adaptive randomized designs

Uno studio di simulazione sull'uso di disegni casuali adattivi alla risposta

Anna Maria Paganoni, Andrea Ghiglietti, Maria Giovanna Scarale, Rosalba Miceli, Francesca Ieva, Luigi Mariani, Cecilia Gavazzi and Valeria Edefonti

Abstract Response-adaptive designs have been proposed in randomized clinical trials to achieve ethical advantages by using sequential accrual information collected during the trial to update probabilities of treatment assignments. We propose the use of a response adaptive design based on urn models in a simulation study on a randomized clinical trial on the efficacy of home enteral nutrition in cancer patients after major gastrointestinal surgery. We compare results with the adaptive design with those previously obtained with the non-adaptive approach.

Abstract *I disegni adattivi alla risposta sono stati proposti nell'ambito degli studi clinici per ottenere vantaggi etici utilizzando le informazioni sequenziali raccolte durante lo studio per aggiornare le probabilità di assegnazione ai trattamenti. In questo lavoro si propone l'uso di un disegno adattivo di risposta basato su modelli d'urna in uno studio di simulazione basato su uno studio clinico dell'efficacia della nutrizione enterale domiciliare in pazienti oncologici dopo un intervento chirurgico*

Key words: Randomly Reinforced Urn model, Randomized trials, Response-adaptive randomization, Simulation study

1 Introduction

In statistical literature, urn models have been widely studied as mathematical tools to implement randomization in the context of clinical trials. These designs randomly assign those subjects that sequentially enter the trial to the treatment arms according to to the proportion of balls of different color sampled from a virtual urn. Recently, interest has been increased in the use of urn models, in which the probability to sample a ball of a certain type depends on the treatment performance observed on the subjects previously randomized [2, 1]. A popular class of such designs is the Randomly Reinforced Urn (RRU) model, which has been introduced in [2] for binary treatment responses and extended in [5] to handle continuous responses. In the RRU model, an urn containing balls of two colors is sequentially sampled and the subjects in the trial receive the treatments associated to the colors of the sampled balls. In addition, the urn composition is sequentially updated by adding new balls of the same color of the sampled ones, whose number depend each time on the response observed by the correspondent patient. For the purposes of this paper, we simply remind that a RRU design assigns patients to the superior treatment with a probability that converges to one as the sample size increases. Although the theoretical result of assigning most of the patients to the superior treatment is very attractive from the ethical point of view, the RRU design have rarely been implemented in clinical trials or in simulation studies based on a real set-up. In detail, we will simulate a large number of trials that follow the RRU model starting from the real-life data collected in a previously published Home Enteral Nutrition (HEN) randomized trial [3], where a non-adaptive design was originally adopted (see [4]). Comparing the performance of the RRU with that of the original non-adaptive design, we expect that the RRU design will: 1) assign fewer patients to the inferior treatment; 2) maintain similar inferential properties. This will turn out in an advantage in terms of both statistical performance and ethical responsibility.

2 Materials and Methods

The RRU model was here implemented in a simulation study based on results from a multicenter, controlled, open-label, two-parallel groups, randomized clinical trial conducted at the Fondazione IRCCS Istituto Nazionale dei Tumori (INT), Milan, Italy, and at the European Institute of Oncology, Milan, Italy, between December

2008 and June 2011 [3]. The enrolled subjects were adult ($>$ 18 years) patients with documented upper gastrointestinal cancer who were candidates for major elective surgery and showed a preoperative nutritional risk score that indicated a potential benefit from any nutritional intervention. A random permuted block design (stratified for referring center) randomly assigned patients before discharge to receive either HEN to cover the basal energy requirement (experimental group), or nutritional counselling by an expert dietitian, including oral supplements only when needed (Control Group - CG), in a 1:1 ratio. The treatment effect was defined as the difference between the mean "weight change" (weight after two months - weight at baseline) in the HEN and nutritional counselling arms (primary end-point). In total, 79 patients were initially randomized; however, as 11 patients had a missing two-months weight, the final analysis was performed on 68 patients, of which 33 patients were allocated to the HEN group and 35 to the CG. The main result of the primary end-point analysis was that the mean weight loss in the patients undertaking the HEN treatment was significantly lower than that in the CG, with a treatment effect estimated by the corresponding ANOVA model coefficient (95% confidence interval) of 3.2 (1.1-5.3) and a p-value from the corresponding two-sided t-test equal to $0.31\% < 2.94\%$. For this reason, the trial was stopped at the interim analysis and results from this analysis were published in [3]. So, the HEN was found to be the superior treatment in this trial.

To simulate the RRU design starting from the HEN trial data to derive the results for comparing the RRU design with the non-adaptive one, we performed the following main steps:

(A)using the HEN trial dataset [3]:

  (1)we estimated the parameters of the Gaussian distribution of the responses to the HEN group;
  (2)we estimated the parameters of the Gaussian distribution of the responses in the CG;
  (3)we computed the empirical distribution of the difference between arrival times of consecutive subjects;

(B)we simulated N independent trial samples based on the RRU model; for each sample, responses to both treatments and intervals between arrival times were randomly generated from distributions introduced in point (A);
(C)we computed from these N trials:

  (1)the empirical distribution of the number of subjects assigned to the inferior treatment $\mathscr{W}$;
  (2)the empirical power of the corresponding t-test.

The previous steps are detailed in the following.
To start, we considered three alternative set-ups of trial sample sizes equal to (a): $n = 58$;(b): $n = 68$; (c): $n = 78$, where the total sample size 68 of the HEN trial was used as the reference set-up and we moved $\pm 15\%$ from that to get other two reasonable sample sizes.
For each set-up, we performed $N = 10,000$ simulations of independent trials based

on the RRU design: in each run we have a virtual urn to be sampled and reinforced. Formally, we denote by (R_i^j, W_i^j) the urn composition and by $R_i^j/(R_i^j + W_i^j)$ the urn proportion in simulation $j = \{1,..,N\}$ at time $i \in \{1,..,n\}$.
All the urns start with the same (fixed) initial composition, i.e. $(R_0^j, W_0^j) = (R_0, W_0)$ for any $j = \{1,..,N\}$. Then, the urn composition (R_i^j, W_i^j) is updated in the following way

$$\begin{cases} R_i^j = R_{i-1}^j + \sum_{k \in (A_{i+1}^j \setminus A_i^j)} X_k^j \xi_{Rk}^j \\ \\ W_i^j = W_{i-1}^j + \sum_{k \in (A_{i+1}^j \setminus A_i^j)} (1 - X_k^j) \xi_{Wk}^j, \end{cases}$$

where X_k^j is a Bernoulli random variable with parameter $R_{k-1}^j/(R_{k-1}^j + W_{k-1}^j)$ indicating the treatment assignement, the set A_i^j here includes all the patients who arrived two months earlier than subject i and ξ_{Rk}^j, ξ_{Wk}^j are the subjects responses to treatment R and W respectively. Indeed, in the HEN trial, responses were available only two months after treatment administration.

In addition, as normality assumptions in the original data were not rejected, responses to both treatments were generated as independent Gaussian random variables with arm-specific means and variances computed using the HEN dataset and given by: $m_R = -0.315$ and $\sigma_R = 3.868$ for treatment $\mathscr{R}$ (HEN group), $m_W = -3.571$ and $\sigma_W = 4.789$ for treatment $\mathscr{W}$ (CG). Formally, we generated the following quantities:

(1)$\xi_{R1}^j, .., \xi_{Rn}^j \sim \mathscr{N}(m_R, \sigma_R^2)$ potential responses to treatment $\mathscr{R}$ (HEN group);
(2)$\xi_{W1}^j, .., \xi_{Wn}^j \sim \mathscr{N}(m_W, \sigma_W^2)$ potential responses to treatment $\mathscr{W}$ (CG),

where either ξ_{Ri}^j or ξ_{Wi}^j is observed, as each subject just receives one treatment.

3 Results

Table 1 shows some descriptive statistics of the empirical distribution of the number of subjects assigned to the inferior treatment, $N_W(n)$, and the empirical power of the t-test, $1 - \hat{\beta}$, for the different sample sizes n, in comparison with the corresponding results for the non-adaptive design, n_W and $1 - \beta$.

For all sample sizes under consideration [cases (a)-(b)-(c)], the mean and the median of $N_W(n)$ were smaller than n_W, the number of subjects assigned to the inferior treatment by the non-adaptive design. It follows that the RRU design provided 50% of probability (or more) to assign fewer subjects to the inferior treatment, as compared to the non-adaptive design. Although higher than n_W for all the sample sizes considered, the third quartile of $N_W(n)$ in the RRU design was very close to n_W for any n under consideration. In addition, the obtained values for the t-test empirical power under the RRU design were close, but slightly smaller than, the corresponding power values derived in the non-adaptive design.

Further information on the distribution of $N_W(n)$ is provided by the boxplots re-

n	$N_W(n)$				n_W	$1-\beta$	$1-\hat{\beta}$
	1^{st} quartile	Mean	Median	3^{rd} quartile			
(a) 58	19	25.6	25	31	29	0.88	0.83
(b) 68	**22**	**29.6**	**29**	**36**	**35**	**0.92**	**0.88**
(c) 78	25	33.6	33	41	38	0.94	0.92

Table 1 Summary statistics (1^{st} and 3^{rd} quartiles, mean, and median) of the empirical distribution of the number of subjects assigned to the inferior treatment, $N_W(n)$, and empirical power, $1-\hat{\beta}$, of the t-test for equal mean weight changes (corresponding to the treatment coefficient in the ANOVA model) for the different sample sizes n in the Randomly Reinforced Urn design, in comparison with the corresponding results for the non-adaptive design, n_W and $1-\beta$. We reported in bold typeface the results obtained with the same sample size of the original Home Enteral Nutrition trial.

ported in Figure 1. For any sample size, the median of $N_W(n)$ was below the dashed line indicating the number of subjects assigned to the inferior treatment by the non-adaptive design. Similarly, we confirmed that, although higher, the third quartile was closer than the median to the dashed line for the three cases under consideration. In addition, the probability that $N_W(n)$ was less than n_W was close to 75% for any sample size under consideration. Finally, although mostly symmetric, the empirical distributions of the number of subjects assigned to the inferior treatment showed a high level of variability. This variability increases, as the total sample size increases.

The relationship between health care expenditures and time to death: focus on myocardial infarction patients

La relazione tra spesa assistenziale e prossimità al decesso: studio dei pazienti affetti da infarto al miocardio

Luca Grassetti and Laura Rizzi

Abstract This study focuses on the relationship between health care expenditures (HCE) and time to death (TTD). This is a central theme of regional and national healthcare systems, given the current ageing of the population and the increasing expenditures. This study is aimed to investigate in-depth the causal-effect relationship between TTD and HCE. Existing regional health administrative archives have been used to build a cohort of patients with new-onset myocardial infarctions observed between 2003 and 2007. All patients are residents in the Italian region Friuli Venezia Giulia. Data on individual HCEs, socio-demographic and health status characteristics are included in the analysis, together with TTD. The econometric analysis is based on a sample selection approach necessary to account for the inflation patterns in the distributions of HCE and TTD. The main results suggest that the causal effect of TTD on HCEs ("red herring" hypothesis) is confirmed, while the reversal relationship is only partially revealed in the selection equation.

Abstract *Il presente studio analizza la relazione tra spese assistenziali e prossimità al decesso. Questo è un ambito di interesse primario dei sistemi sanitari pubblici regionali e nazionali che si trovano ad affrontare il fenomeno dell'invecchiamento della popolazione e dei trend crescenti delle spese assistenziale. L'obiettivo principale perseguito è lo studio della relazione biunivoca tra spese assistenziali e prossimità al decesso. L'analisi si basa su una coorte di pazienti affetti da infarto al miocardio, residenti nella regione italiana del Friuli Venezia Giulia, osservati nel periodo 2003-2007. La costruzione del database è derivata dai database amministrativi sanitari regionali. Il database include i dati individuali relativi alle spese sanitarie, alle caratteristiche socio-demografiche, alle proxy dello stato di salute e alla prossimità al decesso. Per l'analisi econometrica è stato adottato un approccio*

di sample selection, data la presenza di punti di massa nelle distribuzioni di probabilità delle spese sanitarie e del tempo al decesso. I risultati confermano il rilevante effetto della prossimità al decesso sulle spese assistenziali (nota come ipotesi "red herring"), mentre la relazione di causalità inversa risulta confermata solo in relazione al modello di selezione.

Key words: Administrative Data, Health Care Expenditures, Health Econometrics, Sample Selection Models, Time To Death

1 Aim and context of analysis

The aim and the context of this study are tied to central themes of modern health care policy (*Health, demographic change, and wellbeing is one of the societal challenges in the European programme Horizon 2020*) such as increasing trends of health care expenditures (HCE); the role of time to death (TTD) and the ageing of the population on HCE patterns; and the increasing burden of healthcare profiles due to medical innovations. In particular, we focus on a relevant challenge: the relationship between TTD and HCE, focusing on whether TTD affects HCE (TTD as a determinant of budget growth) or if the reciprocal relationship holds (care profiles affecting health outcomes).

The health economics literature presents different approaches to HCE: some studies consider HCE dynamics within the macro-econometric framework (see, for instance, [11]), while a wide range of works is devoted to assessing the determinants of HCE both at micro and macro-level (a review on the topic can be found in [6] and [12]). These kinds of studies focus on the analysis of the relationship between diseases and health care utilization, or on the distribution of HCE across individuals and cohorts. Moreover, HCEs are often considered in the analysis of the relationship between the ageing of the population and TTD, which has driven the *Red Herring* literature on the significant effect of TTD on the increase of HCEs ([4], [5], [8], [13] and [15] are some examples of these works). The literature devoted to the assessment of TTD determinants is mainly characterized by epidemiological (survival) analyses, while studies on the effect of HCE on TTD are rare (see [4] again). Given the differences in these existing research approaches, the following competing hypotheses are evaluated in this study: compression of morbidity (TTD causal effect hypothesis) according to which health care expenditures are determined by proximity to death; expansion-of-morbidity hypothesis based on the assumption that prolonging life means prolonging morbidity and increasing costs. We wish to explore both given hypotheses separately for different sources of HCE, by considering administrative datasets and trying to measure TTD more accurately.

The phenomena of interest of this study present the so-called inflation issue. In particular, HCEs are often zero-inflated measures, while the TTD presents a double inflated distribution (determined by sudden deaths and by survivals). In order to deal with these issues, the econometric literature has developed some "alternative" approaches (in particular, for the HCEs analysis): latent class models ([3]); sample selection models ([7]); two-part models ([1], [2] and [9]); copula probit models (as in [14]). Finally, to deal with TTD double inflated distribution it is possible to apply the solution proposed in [10].

2 Study design

Many empirical analyses on the relationship between HCE and TTD are classified as population-based studies. A specifically structured administrative database has been developed for this research. In particular, we consider a cohort type dataset of all the patients with an incident case of acute myocardial infarctions (AMI) observed in the period 2003-2007 in Friuli Venezia Giulia (Italy).

2.1 Cohort and variables

To determine the final cohort, four steps have been followed: first 11530 patients are identified selecting all the hospital admissions with a diagnosis of AMI (ICD-9 code 410*) in the Hospital Discharge Register in the period 2003-2007; within the selected cases 10700 patients are admitted with incident AMI; the size of the dataset is reduced to 9962 to consider patients who are resident in FVG at admission date. In order to deal with homogeneous patients, cases with the first intervention of AMI (no previous PTCA[1] or bypass surgery) are selected, thus identifying 9897 cases. The HCE and TTD of these patients are observed in a 5 years period (follow-up); HCEs (regarding inpatient cares, outpatient cares, and drugs) are measured by semesters while TTD is computed in days and truncated at 1825 for the survivors at the end of the 5th year.

The data are derived from the regional health data-warehouse. Data regarding HCEs are collected also for the two years before the entering event. An important role in the model specification is played by the TTD covariate definition and, given the peculiar double truncated TTD variable distribution, we considered both a factor variable identifying: sudden deaths (SD), patients died during the observational period (DDOP) and survivors (SURV), and a numerical variable (*days to death*), interacting with DDOP dummy only. The age and gender of the patients are collected, together with proxies of individual health status as dummies for pathology exemptions, dummies for PTCA or bypass surgery and a dummy for deceased. Finally, information on the area of residence (such as local health agency - LHA - and municipality) and the deprivation index (at the municipality level) are considered.

The cohort is characterized by 5766 males (58.3% of the total) with 68.2% of survivors. 45.5% of patients are more than 75 years old at the entering time and the

[1] Percutaneous transluminal coronary angioplasty

percentage of survivors is 97.8% for patients aged less than 45 decreasing to 36.6% in the oldest age class. The proportion of survivors decreases also by deprivation class (from 63.3% in the “very rich” to 56.9% in the “very deprived” class). Median values of all types of individual HCE are lower in the group of 6151 survivors and this is particularly clear for the median values of drugs expenditures (1010.9 and 1185.8 for dead patients, while 543.4 for the survivors).

3 HCE and TTD models and results

In the following sections, the HCE model is introduced and the main results on the determinants of health care expenditures are briefly discussed. The TTD model is then introduced and the main results, reported in Table 1, are discussed.

3.1 The HCE model

In the analyses, we adopted the sample selection paradigm. In particular, the Heckman-style selection model is applied separately to three kinds of health expenditures. The model for the HCEs can be defined as:

$$y_i^O = \begin{cases} 0 & \text{if } y_i^S = 0 \\ y_i^{O*} = X_i^O \beta^O + \varepsilon_i^O & \text{otherwise} \end{cases} \tag{1}$$

where y_i^O denotes the observed level of health expenditure, y_i^S is the variable defining the selection process (which can be estimated by considering a probit generalised linear model - selection equation) and y_i^{O*} represents the observed level of positive expenditures, modeled as a linear function of the explanatory variables X_i^O.

The results of this first step can be summarised as follows. The selection equations in the models for health expenditures present a significant relationship between age and outpatient and drug expenditures, while for inpatient care expenditures the “red herring” hypothesis is fully supported. Exemptions have positive effects on the probability of positive HCEs for all kinds of expenditures. The model estimation is developed separately for the different kinds of the health expenditures.

Going into greater details, males have a higher probability of HCE for inpatient care and being a male affects positively the expenditure for outpatient services. The age over TTD effect on the probability of HCE is clear for all age classes over 65 years, with an increasing effect on the amount of outpatient and drug expenditures. Survivors generally show a low probability of inpatient care and a larger probability of outpatient care. The same pattern is pointed out in expenditure model. Proxies of health conditions, represented by pathology exemptions, are, as expected, positively correlated with the probability of all types of expenditures but with greater effects on the amount of outpatient and drug demand. Moreover, strong positive relationships between types of HCEs are revealed, as expected. The HCE models point out further expected results in terms of factors affecting both the HCE likelihood and its amount. However, the TTD effect is not relevant as it is probably absorbed by the dummies included to account for sudden deaths and survivors, whose coefficients confirm the “red herring” proposition.

3.2 The TTD model

The Heckman-style selection model has also been applied in the estimation of TTD. The distribution of TTD presents two mass points generated by sudden deaths (0 days) and 5 years survivals (1825 days). For this reason, the selection model has been specified by considering an ordinal probit model (as in [10]). The bias-corrected linear model has been estimated by considering the specific inverse Mills ratios (for the ordinal model) on the patients who died during the observational period. In order to obtain better estimation results, we considered a Box-Cox transformation of the days to death.

Table 1 shows the TTD model estimation results. TTD is only partially connected to health expenditures. In particular, in the selection equation, all the coefficients of expenditure sources are significant. The HCEs affect survival status in the selection step. Notwithstanding, in the outcome equation only the logarithm of inpatient care expenditure is significant. The significance of the coefficient of the inverse Mills ratio confirms the necessity to adopt the sample selection model.

4 Conclusions

This study has assessed the role of TTD on HCE and has confirmed, in general, the "red herring" hypothesis. Moreover, this hypothesis has not always been confirmed in our framework. The role of HCE has been studied to verify the simultaneity between HCE and TTD. This last analysis involved a non-standard econometric approach and it has been developed by using a suitable measure of TTD (presenting a double inflated distribution). The adoption of ordinal selectivity in the analysis of the role of HCE on TTD allows us to study the peculiar behaviour of the phenomenon. The results of the empirical analyses show that the role of HCE on TTD (reversal relationship) is significant, in particular for the selection equation.

A multivariate extension of the joint models

Un'estensione multivariata dei modelli congiunti

Marcella Mazzoleni and Mariangela Zenga

Abstract The joint models analyse the effect of longitudinal covariates onto the risk of an event. They are composed of two sub-models, the longitudinal and the survival sub-model. For the longitudinal sub-model a multivariate mixed model can be proposed. Whereas for the survival sub-model, a Cox proportional hazards model is proposed, considering jointly the influence of more than one longitudinal covariate onto the risk of the event. The purpose of the work is to extend an estimation method based on a joint likelihood formulation to the case in which the longitudinal sub-model is multivariate through the implementation of an Expectation-Maximisation (EM) algorithm.

Abstract *I modelli congiunti analizzano l'effetto delle covariate longitudinali sul rischio di un evento. Sono composti da due sotto-modelli, quello longitudinale e quello di sopravvivenza. Per il sotto-modello longitudinale si puó proporre un modello misto multivariato, mentre per quello di sopravvivenza viene proposto un modello a rischi proporzionali di Cox, dove le covariate longitudinali influenzano congiuntamente il rischio dell'evento. Lo scopo del lavoro é di estendere un metodo di stima basato sulla massimizzazione della verosimiglianza congiunta al caso in cui il sotto-modello longitudinale è multivariato attraverso l'implementazione di un algoritmo Expectation-Maximization (EM).*

1 Introduction

The joint models analyse the effect of longitudinal covariates onto the risk of an event. They are composed of two sub-models, the longitudinal and the survival sub-model. For the longitudinal sub-model a multivariate mixed model can be proposed, considering fixed and random effects. Whereas for the survival sub-model, a Cox proportional hazards model is usually proposed, considering jointly the influence of more than one longitudinal covariate onto the risk of the event.

The joint models are often used in medical research because in clinical trails the aim is to analyse two subgroups, placebo and treated, in order to study the longitudinal covariates that could influence the survival time.

The first authors that extended the joint model to the case in which the longitudinal sub-model is multivariate are Xu and Zeger [10]. A Markov chain Monte Carlo algorithm was used to estimate parameters in the model, extending the univariate estimation method introduced by Xu and Zeger [11] and Faucett and Thomas [2]. The authors applied the model and the estimation method to the Schizophrenia trial data of risperidone. Albert and Shih [1] proposed a regression calibration approach for jointly modelling multiple longitudinal measurements and discrete time-to-event data. The authors proposed a two-stage regression calibration approach. Recently Hickey et al. [5] proposed a interesting review of all the model and estimation methods for the joint modelling of time-to-event and multivariate longitudinal outcomes. Despite developments, software to estimate the parameters of these model is still lacking. For this reason, Hickey et al. [4] implemented a new package in software R, the joineRML package. This package fits the joint model proposed by Henderson et al. [3], extended to the case of multiple continuous longitudinal measures. The association between time-to-event and longitudinal data is captured by a multivariate latent Gaussian process. The parameter are estimated using a Monte Carlo Expectation Maximization algorithm.

The purpose of the paper is to extend an estimation method based on a joint likelihood formulation used in the univariate case [6] to the case in which the longitudinal sub-model is multivariate. The parameters are estimated maximising the likelihood function, using an Expectation-Maximisation (EM) algorithm. In addition, in the M-step a one-step Newton-Raphson update is used, as for some parameters estimators, it is not possible to obtain closed-form expression. In addition, a Gauss-Hermite approximation is applied for some of the integrals involved.

2 Model and estimation method

The longitudinal and the survival sub-models compose the joint models. Concerning the survival sub-model, in this paper a proportional hazard model is used, which is defined as a function of the $m_{iq}(t)$ that denotes the true and unobserved value of the longitudinal covariate q for subject i:

$$h_i(t|M_i(t),\omega_i) = h_0(t)\exp\left[\gamma'\omega_i + \sum_q \alpha_q m_{iq}(t)\right] \tag{1}$$

where $M_i(t) = \{m_{iq}(s), 0 \leq s < t, \forall q = 1,\ldots,Q\}$ indicates the history of the true unobserved longitudinal processes up to time t, α_q quantifies the effect of the longitudinal outcome q onto the risk of an event, $h_0(t)$ indicates the baseline hazard function, and ω_i are the covariates that influence the risk of the event with coefficient γ. Concerning the longitudinal sub-model, a linear multivariate mixed model is proposed:

$$y_{iq}(t) = m_{iq}(t) + \varepsilon_{iq}(t) \tag{2}$$

where q is the longitudinal variable index, $y_{iq}(t)$ is composed by the $m_{iq}(t) = x'_{iq}(t)\beta_q + z'_{iq}(t)b_{iq}$ and by a random error term $\varepsilon_{iq}(t) \sim N(0,\sigma^2)$, and β_q are the fixed effects for $x_{iq}(t)$, while b_{iq} are the random effects for $z_{iq}(t)$. In addition, $b'_i = (b'_{1q},...,b'_{iQ}) \sim N(0,D)$ and $b_{1q},...,b_{nQ}$ and $\varepsilon_{1q},...,\varepsilon_{nQ}$ are independent.
There are two classes of estimation method, the two-stage approach and the joint likelihood formulation. The two-stage approach is biased but less computationally demanding, while the joint likelihood is more efficient but computationally slower. The two-stage approach is based on two steps. In the first one the random effects are estimated using a least-squares approach, while in the second step the estimates previously found are used to impute appropriate values of $m_{iq}(t)$ that are substituted in the classical partial likelihood of the Cox model. The joint likelihood could be based on maximum likelihood, a Bayesian estimation of joint models using MCMC, or some hypothesis concerning the normal distribution of random effects or of covariates. Rizopoulos [6] proposed a new method of estimation based on the joint likelihood formulation, maximising the log-likelihood function through the Expectation-Maximisation (EM) and the Newton-Raphson algorithm.
The aim of the paper is to extend this method of estimation [6], to the case in which the longitudinal sub-model is multivariate. Starting from the classical log-likelihood equation, for each subject i it can be defined as:

$$\begin{aligned}\log p(T_i,\delta_i,y_i;\Theta) &= \log\int p(T_i,\delta_i,y_i,b_i;\Theta)db_i\\ &= \log\int p(T_i,\delta_i|b_i;\theta_t,\beta)\left\{\prod_q p(y_{iq}|b_{iq};\theta_y)\right\}p(b_i,\theta_b)db_i\end{aligned}$$

where $\Theta = (\theta'_t,\theta'_y,\theta'_b)'$ denotes the full parameter vector, with θ_t denoting the parameters for the event time outcome, θ_y the parameters for the longitudinal outcomes, and θ_b the unique parameters of the random-effects covariance matrix. In formula, $\theta_y = [\beta',\sigma^2]$ where $\beta = [\beta_1,...,\beta_q,...,\beta_Q]$ and $\sigma^2 = [\sigma_1^2,,...,\sigma_q^2,...,\sigma_Q^2]$; $\theta_t = [\gamma',\alpha_1,...,\alpha_q,...,\alpha_Q,\theta_{h_0}]$ where θ_{h_0} is used in the case in which the baseline hazard is parametric; and $\theta_b = [vech(D)]$. It is possible to separate the log-likelihood in three parts, where each part is related only to a part of the vector of parameters involved.
For maximising the log-likelihood function the Expectation-Maximisation (EM) al-

gorithm is used where the random effects are treated as ”missing data”. Accordingly, for the E-step the expected value of the complete data log-likelihood function considering the random effects as the missing data is considered. A numerical integration procedures must be employed as an integral with respect to the random effects is employed, such as Guass-Hermite quadrature rule.
In the M-step it is possible to obtain the estimation for σ_q^2 and D in closed form solution. For the others parameters there is not a close solution, so it is necessary to use one-step Newton-Raphson update:

$$\hat{\beta}^{it+1} = \hat{\beta}^{it} - \left\{ \frac{\partial}{\partial \beta} S(\hat{\beta}^{it}) \right\}^{-1} S(\hat{\beta}^{it}) \quad ; \quad \hat{\theta}_t^{it+1} = \hat{\theta}_t^{it} - \left\{ \frac{\partial}{\partial \theta_t} S(\hat{\theta}_t^{it}) \right\}^{-1} S(\hat{\theta}_t^{it})$$

where $\hat{\beta}^{it}$ and $\hat{\theta}_t^{it}$ denote the values of β and θ_t at the current iteration. In addition, $S(\hat{\beta}^{it})$ and $S(\hat{\theta}_t^{it})$ denote the corresponding blocks of the Hessian matrix, evaluated at $\hat{\beta}^{it}$ and $\hat{\theta}_t^{it}$, respectively. For the evaluation of the blocks of the Hessian matrix, the numerical derivative routine is used.
At convergence the standard errors are evaluate with the empirical information matrix [7]:

$$I_e(\theta) = \sum_{i=1}^{n} s_i s_i' - n^{-1} \left(\sum_{i=1}^{n} s_i \right) \left(\sum_{i=1}^{n} s_i \right)' \tag{3}$$

where $s_i = \frac{\partial l_i(\theta)}{\partial \theta}$.
We implemented the algorithm in R software. The outline of the algorithm follows the points:

1. The initial values are estimated through the two-stage approach.
2. In the E-step the expected value of the complete data log-likelihood function is used considering the random effects as the missing data using, in addition, Guass-Hermite quadrature rule
3. In the M-step, for σ_q^2 and D it is possible to obtain closed form solution, while for the parameter γ, α_q and β_q a one-step Newton-Raphson update is implemented. Random effects and the baseline hazard are updated.
4. Iterate between step 2 and 3 until the algorithm converges, when the parameter estimates become stable.
5. At convergence, the standard errors for each parameter are calculated using empirical information matrix.

3 Application to Primary Biliary Cirrhosis dataset

We apply the algorithm to the primary biliary cirrhosis dataset (PBCSEQ) that is available from the package *Survival* in R [9]. The dataset established from Mayo Clinic consists of 312 clinical trial patients with primary biliary cirrhosis [8] followed up from 1974 to 1986. For each patient multiple laboratory results were collected at each visit of the follow-up. After analysing several possible models, two longitudinal covariates are considered: the level of serum bilirubin in mg/dl (*serBilir*), and the level of albumin in mg/dl (*albumin*). The observational time is expressed in days. In the survival sub-model, the exogenous covariate patient's age at registration in years (*age*) is analysed. Accordingly the longitudinal and the survival sub-models used are:

$$\begin{cases} y_{i1}(t) = \beta_{01} + \beta_{11}t + b_{i01} + b_{i11}t + \varepsilon_{i1}(t) \\ y_{i2}(t) = \beta_{02} + \beta_{12}t + b_{i02} + b_{i12}t + \varepsilon_{i2}(t) \\ h_i(t) = h_0(t)\exp[\alpha_1 m_{i1}(t) + \alpha_2 m_{i2}(t) + \gamma_1 age] \end{cases}$$

where $y_{i1}(t)$ is the *log(serBilir)* and $y_{i2}(t)$ is the *albumin*.
The results obtained using the new algorithm implemented are shown in Table 1, where every parameter results to be statically significant.

Table 1 Results of the joint model on PBCSEQ dataset

Parameter	Est.	SE	p-value
α_1 (*log(serBilir)*)	1.1700	0.1052	< 0.0001
α_2 (*albumin*)	-1.8784	0.1557	< 0.0001
γ_1 (*age*)	0.0510	0.0075	< 0.0001
β_{01} (*Intercept*)	0.6371	0.0134	< 0.0001
β_{11} (*Time*)	0.0005	$8.3434*10^{-06}$	< 0.0001
β_{02} (*Intercept*)	3.5345	0.0201	< 0.0001
β_{12} (*Time*)	-0.0003	$1.1751*10^{-05}$	< 0.0001

Log-likelihood -2957.639

In particular, the *log(serBilir)* affects positively the risk of death (a one point increase in the *log(serBilir)* is associated with a 3.2220 $(= \exp(1.1700))$ fold increase in the risk of death), while the *albumin* affects negatively the risk of death (a one point increase the *albumin* will give a 0.1528 $(= \exp(-1.8784))$ fold decrease in the risk of death). Moreover the exogenous variable, *age*, affects positively the risk of death (one point increase in *age* gives a 1.0523 $(= \exp(0.0510))$ fold increase in the risk of death). Analysing the longitudinal sub-models, the observational time affects positively $(\beta_{11} = 0.0005)$ the level of *log(serBilir)*, on the contrary it is negatively associated $(\beta_{12} = -0.0003)$ with the level of *albumin*.

4 Conclusions and ideas of further work

The aim of the paper is to extend the maximum likelihood estimation method proposed by Rizopoulos [6] to the case in which the longitudinal sub-model is multivariate. We presented the algorithm and applied it to the PBCSEQ dataset.

The results are encouraging and deal to several ideas of future work. Developing, for instance, deeper diagnostic analysis and dynamic predictions. Another idea for further work is extending the survival sub-model, studying the joint effect of more than one longitudinal covariate on more than one terminal event.

Multipurpose optimal designs for hypothesis testing in normal response trials

Disegni ottimi multi-obiettivo per la verifica di ipotesi

Marco Novelli and Maroussa Zagoraiou

Abstract This work deals with the problem of designing multiarm clinical trials for comparing treatments in order to achieve a compromise between the power of the classical Wald test of homogeneity of the treatment effects and ethical demands. In [5] the authors derived the target allocation maximizing the non-centrality parameter of Wald test for normal responses under a suitable ethical constraint reflecting the treatment effects. Starting from these results, in this paper we provide some important properties of this constrained optimal allocation, like e.g. its D_A-admissibility and its efficiency with respect to ethical and inferential criteria, taking into account estimation precision as well. Comparisons with some allocation proportions proposed in the literature are also presented.
Abstract *Questo lavoro riguarda il problema della pianificazione ottimale di esperimenti comparativi volti ad ottenere validi compromessi tra precisione inferenziale ed esigenze etiche. Prendendo in considerazione il modello normale, in [5] è stata derivata l'allocazione ideale dei trattamenti che massimizza la potenza del test di Wald basato sui contrasti, sotto opportuni vincoli etici legati agli effetti dei singoli trattamenti. L'obiettivo di questo articolo è quello di fornire alcune importanti proprietà di tale allocazione, ossia la D_A-ammissibilità e la sua efficienza rispetto a criteri sia etici che inferenziali, riguardanti anche la precisione di stima, effettuando inoltre opportuni confronti con altre allocazioni target proposte in letteratura.*

1 Introduction

The large majority of randomized clinical trials for treatment comparisons have been designed in order to achieve balanced allocation among the treatment groups, with the aim of maximizing inferential precision about the estimation of the treatment effects. The main justification concerns the so-called "universal optimality" of the balanced design (see e.g. [8]), especially in the context of the linear homoscedastic model, since it optimizes the usual design criteria for the estimation of the treatment contrasts, (like the well-known D-optimality minimizing the volume of the confidence ellipsoid of the contrasts), and it is nearly optimal under several optimality criteria, also under heteroscedasticity [6, 7].

Taking into account the problem of testing statistical hypothesis about the equality of the treatment effects, balance is still optimal in the case of two treatments, since it maximizes the power of the test for normal homoscedastic responses and it is asymptotically optimal in the case of binary outcomes (see e.g. [2, 3]). However, in the case of several treatments the balanced allocation may not be efficient, since it is significantly different from the optimal design for hypothesis testing and could be strongly inappropriate for phase III-trials, in which the ethical demand of individual care often induces to skew the allocations to more efficacious (or less toxic) treatments. To derive a suitable compromise between these goals, Baldi Antognini et al. [5] suggested a constrained optimal target which maximizes the power of the classical Wald test of homogeneity, subject to an ethical constraint on the allocation proportions reflecting the efficacy of the treatments. The aim of the present work is to push forward the results in [5], by providing some important properties of this constrained optimal allocation like, e.g., the D_A-admissibility, and its efficiency with respect to both ethical and inferential criteria, taking into account estimation precision as well. Comparisons with some targets proposed in the literature are also presented.

2 Notation and model

Consider a clinical trial where patients come sequentially and are assigned to one of K available treatments. At each step n, let $\delta_{kn} = 1$ if the nth patient is allocated to the kth ($k = 1, \dots, K$) treatment and 0 otherwise, where $\sum_{k=1}^{K} \delta_{kn} = 1$. Let Y_n be the normally distributed response of the corresponding subject, with $E(Y_n \mid \delta_{kn} = 1) = \mu_k$ denoting the treatment effect and $V(Y_n \mid \delta_{kn} = 1) = \sigma^2$ the unknown common variance; conditionally on the allocations, the responses are assumed to be independent. Furthermore, we denote by $\boldsymbol{\pi}_n^\top = (\pi_{1n}, \dots, \pi_{Kn})$ the vector collecting the proportion of patients assigned to the treatments up to that stage, where $\pi_{kn} = n^{-1} \sum_{i=1}^{n} \delta_{ki}$ ($k = 1, \dots, K$) and $\sum_{k=1}^{K} \pi_{kn} = 1$; also let $\hat{\mu}_{kn}$ ($k = 1, \dots, K$) be the MLE of μ_k, i.e. the sample mean, so $\boldsymbol{\mu}^\top = (\mu_1, \dots, \mu_K)$ and $\hat{\boldsymbol{\mu}}_n^\top = (\hat{\mu}_{1n}, \dots, \hat{\mu}_{Kn})$ are the vectors of the treatment effects and their estimates, respectively. In what follows we assume "the larger the better" scenario and the following ordering regarding the treatment effects $\mu_1 > \mu_2 > \ldots > \mu_K$.

After n steps the Fisher information matrix (conditional on the design) associated with $\boldsymbol{\mu}$ is $\mathbf{M} = \mathbf{M}(\boldsymbol{\mu} \mid \boldsymbol{\pi}_n) = \sigma^{-2}\text{diag}\,(\pi_{kn})_{k=1,\ldots,K}$. Several authors suggested target allocations $\boldsymbol{\rho}^\top = (\rho_1, \ldots, \rho_K)$ (with $\rho_k \geq 0$ and $\sum_{k=1}^K \rho_k = 1$) in order to optimize the estimation of the treatment effects by choosing suitable criteria regarding $\mathbf{M}(\boldsymbol{\mu} \mid \boldsymbol{\rho})$.

In the context of multiarm clinical trials, the inferential attention is usually devoted to the contrasts. So, letting $\mathbf{A}^\top = [\mathbf{1}_{K-1} \mid -\mathbf{I}_{K-1}]$, where $\mathbf{1}_r$ and $\mathbf{I}_r$ represent the r-dim vector of ones and the identity matrix, respectively, then the vector of contrasts wrt the first treatment (considered as the reference) is $\boldsymbol{\mu}_c = \mathbf{A}^\top\boldsymbol{\mu} = (\mu_1 - \mu_2, \ldots, \mu_1 - \mu_K)^\top$. Under well-known regularity conditions, the corresponding MLE $\hat{\boldsymbol{\mu}}_{cn} = \mathbf{A}^\top\hat{\boldsymbol{\mu}}_n$ is strongly consistent and asymptotically normal with $\sqrt{n}(\hat{\boldsymbol{\mu}}_{cn} - \boldsymbol{\mu}_{cn}) \hookrightarrow_d \mathscr{N}\left(\mathbf{0}, \mathbf{A}^\top\mathbf{M}^{-1}\mathbf{A}\right)$. Within this framework, the balanced design $\boldsymbol{\rho}^B$, namely $\rho_k = K^{-1}$ for every $k = 1, \ldots, K$ is the so-called D_A-optimal allocation, since it minimizes $\det[\mathbf{A}^\top\mathbf{M}^{-1}\mathbf{A}]$.

Whereas, taking into account the problem of testing hypothesis on the equality of the treatments effects, i.e., $H_0 : \boldsymbol{\mu}_c = \mathbf{0}_{K-1}$, versus the alternative $H_A : \boldsymbol{\mu}_c \neq \mathbf{0}_{K-1}$, where $\mathbf{0}_{K-1}$ is the $(K-1)$-dim vector of zeros, then the optimal design maximizing the power of the classical Wald test is $\boldsymbol{\rho}^* = (1/2, 0, \ldots, 0, 1/2)^\top$ (see [5]). Clearly, this optimal allocation is unsuitable both from the ethical and the inferential point of views.

Regarding ethics, Atkinson [1] proposed a target intended to skew the assignments towards the best treatment in order to minimize the exposure of patients to toxic (or inefficacious) treatments. In particular, denoting by $\bar{\mu} = K^{-1}\sum_{k=1}^K \mu_k = \boldsymbol{\mu}^\top\boldsymbol{\rho}^B$ the overall treatment mean, the target $\boldsymbol{\rho}^A_{(\gamma)}$ proposed by Atkinson is

$$\rho^A_{(\gamma)k} = \Phi\left(\frac{\mu_k - \bar{\mu}}{\gamma}\right) \Big/ \left[\sum_{i=1}^K \Phi\left(\frac{\mu_i - \bar{\mu}}{\gamma}\right)\right], \quad k = 1, \ldots, K.$$

In the same spirit, instead of $\Phi(\cdot)$ any non-negative increasing function can be used. An example is the exponential target $\boldsymbol{\rho}^E_{(\gamma)}$ given by

$$\rho^E_{(\gamma)k} = e^{\frac{\mu_k - \bar{\mu}}{\gamma}} \Big/ \left(\sum_{i=1}^K e^{\frac{\mu_i - \bar{\mu}}{\gamma}}\right) = e^{\frac{\mu_k}{\gamma}} \Big/ \left(\sum_{i=1}^K e^{\frac{\mu_i}{\gamma}}\right), k = 1, \ldots, K.$$

Clearly, small values of γ induce a strong ethical skew, while as γ increases more emphasis is given to inferential purposes. In particular, adopting $\boldsymbol{\rho}^E_{(\gamma)}$, the allocation proportion $\rho^E_{(\gamma)1}$ to the best treatment is decreasing as γ grows, since

$$\frac{\partial \rho^E_{(\gamma)1}}{\partial\gamma} = \frac{\sum_{i=1}^K e^{\frac{\mu_i + \mu_1}{\gamma}}(\mu_i - \mu_1)}{\left(\sum_{i=1}^K e^{\frac{\mu_i}{\gamma}}\right)^2 \gamma^2} < 0.$$

Note that such monotonicity property does not hold, in general, for $\boldsymbol{\rho}^A$ as we shall show in the last section.

3 Constrained optimal allocation and its D_A-admissibility

Adopting a constrained optimization framework, Baldi Antognini et al. in [5] derived the allocation maximizing the power of Wald test under a suitable ethical constraint reflecting the efficacy of the treatments. In particular, the optimal target $\tilde{\boldsymbol{\rho}}^\top{=}(\tilde{\rho}_1,\ldots,\tilde{\rho}_K)$ maximizing the non-centrality parameter $\phi(\tilde{\boldsymbol{\rho}}) = n\sigma^{-2}\boldsymbol{\mu}_c^\top\left[\mathbf{A}^\top \mathrm{diag}(\tilde{\boldsymbol{\rho}})^{-1}\mathbf{A}\right]^{-1}\boldsymbol{\mu}_c$ of the multivariate Wald test subject to the ethical constraint $\tilde{\rho}_1 \geq \tilde{\rho}_2 \geq \ldots \geq \tilde{\rho}_K$ is $\tilde{\boldsymbol{\rho}} = (1-t[K-1], t, \ldots, t)^\top$ if $t \leq K^{-1}$, while $\tilde{\boldsymbol{\rho}} = \boldsymbol{\rho}^B$ if $t > K^{-1}$, where $t = \sum_{k=2}^K(\mu_1-\mu_k)^2 / \left\{2\left[\sum_{k=2}^K(\mu_1-\mu_k)\right]^2\right\}$. Table 1 shows how the allocation $\tilde{\boldsymbol{\rho}}$ moves away from the balanced design as the distance between μ_1 and μ_2 increases, skewing the assignments to the superior treatment.

Table 1: The behaviour of the optimal constrained target $\tilde{\boldsymbol{\rho}}$ with $K=3$ as μ_2 varies.

μ_1	μ_2	μ_3	$\tilde{\rho}_1$	$\tilde{\rho}_2$	$\tilde{\rho}_3$	t
15	14	6	0.333	0.333	0.333	0.410
15	12	6	0.375	0.312	0.312	0.312
15	10	6	0.459	0.270	0.270	0.270
15	8	6	0.492	0.254	0.254	0.254

Following the definition of admissibility proposed in [4], it is easy to show that $\tilde{\boldsymbol{\rho}}$ is D_A-admissible, i.e. it does not exist another allocation which is simultaneously superior wrt both ethics and D_A-optimality. Indeed, when $t > 1/K$, $\tilde{\boldsymbol{\rho}} = \boldsymbol{\rho}^B$ and the D_A-admissibility is trivially satisfied, while for $t \leq 1/K$, $\boldsymbol{\mu}^\top(\tilde{\boldsymbol{\rho}} - \boldsymbol{\rho}^B) \geq 0 \iff \boldsymbol{\mu}^\top\tilde{\boldsymbol{\rho}} \geq \bar{\mu} \iff \mu_1(1-Kt) \geq \bar{\mu}(1-Kt)$ which is always true since $\mu_1 > \bar{\mu}$.

4 Comparisons

We now compare the performance of $\tilde{\boldsymbol{\rho}}$, $\boldsymbol{\rho}^B$, Atkinson's target $\boldsymbol{\rho}_\gamma^A$ and the exponential one $\boldsymbol{\rho}_\gamma^E$ both with $\gamma = 1$ and $\gamma = 3$. In particular, in Table 2 we consider the following criteria: i) an ethical measure of efficiency given by the ratio between the total expected outcomes and its optimal value, i.e., $E_E(\boldsymbol{\rho}) = \sum_{k=1}^K \mu_k\rho_k/\mu_1$, ii) an efficiency measure of statistical power $E_P(\boldsymbol{\rho}) = \phi(\boldsymbol{\rho})/\phi(\boldsymbol{\rho}^*)$ and the D_A-efficiency $E_{D_A}(\boldsymbol{\rho}) = \left\{\det\left[\mathbf{A}^\top\mathbf{M}^{-1}\left(\boldsymbol{\rho}^B\right)\mathbf{A}\right]/\det\left[\mathbf{A}^\top\mathbf{M}^{-1}(\boldsymbol{\rho})\mathbf{A}\right]\right\}^{\frac{1}{K-1}}$ for estimation.

Table 2: the case $K = 5$ treatments

	$\boldsymbol{\rho}^B$	0.792	0.485	1

Considering the statistical power, $\tilde{\boldsymbol{\rho}}$ has the best performance with a gain up to 13% with respect to any second best option. The rules $\boldsymbol{\rho}^{A}_{(1)}$ and $\boldsymbol{\rho}^{E}_{(1)}$ show the lowest statistical power but, at the same time, the highest ethical efficiency. Note that, as γ grows, more emphasis is devoted to inference. However, contrary to the exponential target, the Atkinson's allocation proportion to the best treatment, $\rho^{A}_{(\gamma)1}$, is not always decreasing in γ. Moreover, $\tilde{\boldsymbol{\rho}}$ performs very well also from the ethical point of view.

Regarding the D_A-efficiency, $\tilde{\boldsymbol{\rho}}$ is substantially superior with respect to $\boldsymbol{\rho}^{A}$ and $\boldsymbol{\rho}^{E}$ guaranteing at the same time an efficiency always greater than 80.3%. Note that, adopting $\boldsymbol{\rho}^{A}_{(1)}$ and $\boldsymbol{\rho}^{E}_{(1)}$ the D_A-efficiency often tends to zero and therefore the estimation precision may vanish.

Since ethics and inference are conflicting demands, a target showing high efficiency under one criterion may perform worst under other criteria. However, $\tilde{\boldsymbol{\rho}}$ represents a valid compromise between inferential (both in terms of power and estimation precision) and ethical concerns.

Additive Bayesian networks for an epidemiological analysis of swine diseases

Reti Bayesiane additive per un'analisi epidemiologica di malattie suine

Marta Pittavino and Reinhard Furrer

Abstract Additive Bayesian networks (ABNs) are types of graphical models that extend the usual generalized linear model (GLM) to multiple dependent variables through the representation of joint probability distribution. Thanks to their flexible properties, ABNs have been widely used in epidemiological analyses. In this work we present a veterinary case study where ABNs are used to explore multivariate swine diseases data of medical relevance. We then compare the results with a classical methodology. Finally, we highlight the key difference between a multivariable standard (GLM) and a multivariate (ABN) approach: the latter attempts not only to identify statistically associated variables, but also to additionally separate these into those directly and indirectly dependent with one or more outcome variables.

Abstract *Le reti Bayesiane additive (ABNs) sono tipi di modelli grafici che estendono l'usuale modello lineare generalizzato (GLM) a variabili multiple dipendenti attraverso la rappresentazione della distribuzione di probabilità congiunta. Grazie alle loro proprietà flessibili, le reti ABNs sono state ampiamente utilizzate nelle analisi epidemiologiche. In questo lavoro presentiamo un caso di studio veterinario in cui il metodo ABN viene utilizzato per esplorare dati multivariati su malattie suine di rilevanza medica. In seguito confrontiamo i risultati con una metodologia classica. Infine, evidenziamo la differenza chiave tra un approccio standard multivariabile (GLM) e uno multivariato (ABN): quest'ultimo tenta non solo di identificare le variabili associate statisticamente, ma anche di separarle ulteriormente in quelle direttamente e indirettamente dipendenti con una o più variabili d'esito.*

Key words: abn R package; data mining; machine learning; statistical modeling; structure discovery; zoonosis.

1 Introduction

A primary objective of many epidemiological studies is to investigate hypothesized relationships between covariates of interest, and one and more outcome variables, through analyses of appropriate data. From a data analysis perspective, this is often far from being trivial. Diseases and health conditions, which are a priority for control or eradication in humans and animals, are increasingly recognized to have highly complex determinants. Typically, the unknown stochastic processes, which generated these data, are highly complex, resulting in multiple correlation/dependencies between covariates and between outcome variables. Standard epidemiological and statistical approaches cannot adequately describe such inter-dependent multifactorial relationships. ABN modelling is a data mining/machine learning methodology, which has demonstrated to be ideally suited for such analyses [1, 2].

2 Material and methods

2.1 The data

We present data on disease occurrence in pigs provided by the industry body 'British Pig Health Scheme' (BPHS). The main objective of BPHS is to improve the productivity of pig in the UK, and reducing disease occurrence is a significant part of this process. The data we consider here comprise of a randomly chosen batch of 50 pigs from each of 500 randomly chosen pig producers in the UK. In total we deal with 25'000 observations, i.e. animals entering the human food chain at an abattoir: 'finishing pigs'. Each animal is assessed for the presence of a range of different disease conditions by a specialist swine veterinarian.

Then, the resulting variables are binary due to the presence or the absence of a specific disease. We consider here the following ten disease conditions, all abbreviated to ease the notation and described in [3]: enzootic-pneumonia (EP); pleurisy (PL); milk spots (MS); hepatic scarring (HS); pericarditis (PC); peritonitis (PT); lung abscess (AB); tail damage (TD); pyaemia (PY) and papular dermatitis (PD).

The presence of any of these conditions results in an economic loss to the producer. Either directly due to the relevant infected part of the animal being removed from the food chain, or indirectly in cases such as enzootic pneumonia, which may potentially indicate poor herd health and efficiency losses on the farm. An additional loss, though not directly monetary, is the presence of tail damage which may be suggestive of welfare concerns and linked to sub-optimal production efficiency. Milk spots and hepatic scarring result from infestation with Ascaris suum, which is particularly important as this is a zoonotic helminth parasite.

2.2 Additive Bayesian networks

A Bayesian network for a set of random variables $\boldsymbol{X} = \{X_1, \dots, X_n\}$ consists of:

- A *directed acyclic graph* (DAG) structure $\mathscr{S} = (V, E)$, where V is a finite set of vertices or nodes and E is a finite set of directed edges between the vertices. A

DAG is *acyclic*; hence, the edges in E do not form directed cycles. A random variable X_j corresponds to each node $j \in V = \{1, \ldots, n\}$ in the graph. We do not distinguish between a variable X_j and the corresponding node j.

- A set of parents for a node j is denoted by $\mathbf{Pa}_j$. A node j is said to be a *parent* of a node k if the edge set E contains an edge from j to k. P_j indicates the total number of parents for a node j : $\dim(\mathbf{Pa}_j) = P_j \geq 0$. $P_j = \emptyset$ for orphan nodes.
- A set of local probability distributions for all variables in the network called $\boldsymbol{\theta}_{\mathscr{B}}$. Each node j, with parent set $\mathbf{Pa}_j$, is parametrized by a local probability distribution: $P(X_j | \mathbf{Pa}_j)$.

Edges represent both *marginal* and *conditional dependencies*. The main role of the network structure is to express the conditional independence relationships among the variables in the model through graphical separation, thus specifying the factorization of the global probability distribution: $P(\boldsymbol{X}) = \prod_{j=1}^{n} P(X_j | \mathbf{Pa}_j)$.

We denote a Bayesian network (BN) model $\mathscr{B}$ for a set of random variables $\boldsymbol{X}$ by a pair $\mathscr{B} = (\mathscr{S}, \boldsymbol{\theta}_{\mathscr{B}})$. The DAG $\mathscr{S}$ defines the *structure*, and $\boldsymbol{\theta}_{\mathscr{B}}$ the *parametrization* of the model. In order to specify a $\mathscr{B}$ for $\boldsymbol{X}$, we must therefore specify a DAG structure and a set of local probability distributions.

An additive Bayesian network $\mathscr{A}$ consists of a Bayesian network $\mathscr{B}$ that generalizes the multinomial logistic regression model $\mathscr{M}$. The multinomial logistic regression model $\mathscr{M}$ can be integrated into a BN $\mathscr{B}$ by modelling each of its conditional probability table $P(X_j = s \mid \mathbf{Pa}_j = c) = \theta_{jcs}$ with a multinomial logistic regression model, where X_j is progressively the outcome variable and the resulting regression design matrix is constructed from $\mathbf{Pa}_j$, as showed in [4] and in detail in Figure 1.

X_1 is independent: $logit(\theta_1) = \beta_{1,0}$

X_2 is independent: $logit(\theta_2) = \beta_{2,0}$

X_3 is jointly dependent upon X_1, andX_2: $logit(\theta_3) = \beta_{3,0} + \beta_{3,1}X_1 + \beta_{3,2}X_2$

X_4 is conditionally dependent upon X_3: $logit(\theta_4) = \beta_{4,0} + \beta_{4,1}X_3$

X_5 is conditionally dependent upon X_3: $logit(\theta_5) = \beta_{5,0} + \beta_{5,1}X_3$

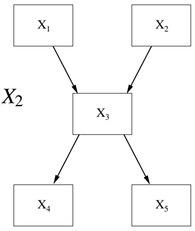

Fig. 1 A binary additive Bayesian network model $\mathscr{A}$ for five random variables.

2.3 Analysis with ABN

All analyses were conducted using the software R [5] and specifically the “abn” R package [6] which is available from CRAN “cran.r-project.org” with additional documentation and case studies at “http://www.r-bayesian-networks.org”.

Prior distributions were defined. All DAG structures were equally supported a priori with a uniform, i.e., uninformative, prior. It is possible to construct informative structural priors, i.e. penalizing models with more structural complexity, but as noted in [7] these are problematic to specify or lead to undesirable properties as in

[9]. Uninformative Gaussian priors were applied for the additive parameters at each node: specifically, independent Gaussian priors with mean zero and variance 1000.

As we are searching across DAGs - to identify optimally fitting structures - there is also the need for a prior on structures. The default being that each structure is equally supported a priori. It is possible to construct informative structural priors, for example to penalize models with more structural complexity, e.g. more arcs, but as noted in [6] these are problematic to specify in practice. In [8] an informative structural prior on the number of parents within an individual node is used, where this assumes that parent combinations with the same cardinality are equally likely. This prior gives equal weighting to a parent combination with cardinality zero and cardinality m1 which may not be entirely desirable. In the subsequent case study analyses an uninformative - flat - structural prior is used.

A two-steps procedure was used to identify a robust model.

The first step was to find an optimal ABN model $\mathscr{A}_1$. The process of identifying an optimal ABN is referred to in the literature as *structure learning* [8]. This was found with an order based exact search method [9]. The best goodness of fit to the available data was computed using the marginal likelihood (ML), equivalent to Bayes factors for models with equal structural priors and the standard Bayesian score function used in BN literature [7, 8]. The ML includes an implicit penalty for model complexity and in a binary additive Bayesian network for a node j is:

$$P(\mathscr{D}_j|\mathscr{S}) = \int_{-\infty}^{+\infty} \prod_{i=1}^{m} \left(\frac{e^{z_{ij}^T\boldsymbol{\beta}_j}}{1+e^{z_{ij}^T\boldsymbol{\beta}_j}}\right)^{x_{ij}} \left(\frac{1}{1+e^{z_{ij}^T\boldsymbol{\beta}_j}}\right)^{1-x_{ij}} \times \prod_{c=1}^{C_j} \frac{1}{\sqrt{2\pi}\sigma_c} e^{-\frac{(\beta_c-\mu_c)^2}{2\sigma_c^2}} \, d\boldsymbol{\beta}_j$$

where $\mathscr{D}_j$ are the observed data at node j, and consist of tuples of $[x_{ij}, z_{ij}^T]$. The parameter vector at node j is represented by $\boldsymbol{\beta}_j$, and has the same length as the possible parents configuration, denoted by C_j, then $\dim(\boldsymbol{\beta}_j) = C_j$. The marginal likelihood was estimated using the Laplace approximation at each node. To find the best model, the maximum number of parents allowed per node (number of covariates in each regression model at each node) was increased until the goodness of fit remained constant and thereby identified the same globally optimal ABN. The model selection procedure started from one possible parent per node and then the parent limit increased gradually until five possible parents per node [6].

In the second step, the model $\mathscr{A}_1$ was adjusted by checking it for overfitting using Markov chain Monte Carlo (MCMC) simulation implemented in JAGS (just another Gibbs sampler) [10]. A parametric bootstrapping approach was suggested in [8] which uses simulation to assess whether a chosen model comprises more complexity than could reasonably be justified given the observed data. Simulated datasets were generated with MCMC as iterations of an identical size as the original one, from the optimal model found in step one. An identical exact search for an optimal model structure was then performed exactly as in the first step, but applied to the bootstrapped data rather than original data. It was repeated 10240 times [6], a large enough number to get robust results, using the same parent limit per node as the one found in the initial search. Arcs present in less than 50% of the globally optimal ABNs - estimated from the bootstrapped data - were considered not to be robust and removed from the DAG generated in the first step. A most robust ABN model $\mathscr{A}_2$ fully adjusted for over-fitting was identified at the end of this second step, equivalent to a multivariate GLM.

2.4 Analysis with GLM

Data were analysed using the software R [5] and the “glm” function, available in the “stats” R package . As many different generalized linear models (GLMs), in particular multivariable logistic regression following the data structure, as the different number of variables were performed. Only two models based on the most significant variables and with the highest AIC score have been selected and shown.

3 Results with ABN and GLM

The resulting best fitting ABN comprised 12 arcs and a maximum number of three parents (Fig. 8 in [6]), for the variable PD (papular dermatitis) and PL (pleurisy). After the bootstrap analysis, four of the arcs in the globally optimal ABN were only weakly supported. Therefore the number of arcs was reduced from 12 to 8 (Fig. 7 in [6]). The final globally optimal additive Bayesian network model after adjustment for over-fitting is shown in Fig. 2 on the left. Three different epidemiological pathways can be identified resulting in variables indirectly linked together. The goodness of fit for this model is -44245.73. For example, forcing an additional arc connecting PC and AB gives a poorer log marginal likelihood of -44249.58.

The two GLM models with the most significant variables and the highest AIC score have PC (pericarditis) and AB (lung abscess) as response variables. Figure 2, in the middle and on the right, shows the two corresponding models. A GLM is simply a DAG where arcs are only allowed directly between the covariates and response variable. In each case we find that an arc is identified between PC and AB.

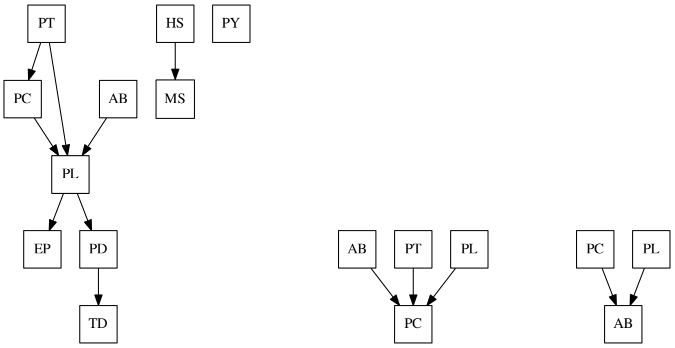

Fig. 2 Final ABN model of swine diseases data with 8 arcs after bootstrapping adjustment (left). Two globally optimal GLMs - one with PC as the dependent variable (middle), and a second with Abscess as the dependent variable (right).

4 Conclusion

In summary, we find that while the GLM analyses identifies a strongly supported statistical association between presence of pericarditis (PC) and lung abscess (AB); the ABN model does not support a direct statistical dependency between PC and AB. In the ABN model there is no arc connecting these variables, this relationship is via the intermediate variable pleurisy (PL).

This highlights the key difference between a multivariable GLM and a multivariate GLM (ABN). The former identifies variables which may be associated with the response (dependent) variable within a very restrictive model space: arcs are only allowed from covariates direct to the response variable. When considering the same data within a larger model space, which incorporates other relationships within the underlying epidemiological system which generated the observed data, then such variables may then only be supported as indirectly, rather than directly, related to the response variable. In [2, 11] there are further similar GLM and ABN examples.

These results provides a conceptual justification of the Yule-Simpson paradox, which states that an apparent relationship between variables may disappear or even be reversed when others are taken into account.

In conclusion, data analyses using ABNs have the potential to offer new insights into complex epidemiological systems.

Population Dynamics

Employment Uncertainty and Fertility: a Meta-Analysis of European Research Findings

Incertezza lavorativa e fecondità: una meta-analisi degli studi europei

Giammarco Alderotti, Daniele Vignoli and Michela Baccini

Abstract The impact of employment uncertainty on fertility represents a prominent topic in demographic research since ever. With the advent of the *Great Recession*, papers addressing this relation are now booming. Although uncertainty is usually deemed to be a negative condition, however, different fertility reactions are both advocated by sociological theories and supported by micro-level evidence, which is still fragmented and contradictory. In this article, we perform a meta-analysis (i.e., a quantitative literature review) of previous research findings for Europe in order to synthesize the existing literature and offer general conclusions about the (changing) size and direction of the impact of employment uncertainty on fertility across time and between countries.

Abstract *Il tema della relazione tra incertezza lavorativa e fecondità ha sempre avuto un ruolo centrale nella ricerca in ambito demografico, e la Grande Recessione lo ha reso ancora più nevralgico negli ultimi anni. Sebbene l'incertezza sia spesso considerata con accezione negativa, può infatti generare diversi tipi di reazione a livello di fecondità. Tali reazioni trovano supporto sia nelle teorie sociologiche, sia nell'evidenza empirica a livello micro, incompleta e talvolta contraddittoria. In questo lavoro, ci proponiamo di realizzare una meta-analisi (cioè una rassegna quantitativa della letteratura) degli studi europei, con lo scopo di sintetizzare i risultati sull'argomento e offrire conclusioni generali sul cambiamento della direzione e dell'impatto dell'incertezza lavorativa sulla fecondità nel tempo e tra paesi.*

Key words: economic uncertainty, fertility, family, employment, meta-analysis

1 Introduction and objective

The role of economic uncertainty as a key driver of fertility decision-making has long been part of demographers and sociologists' research agenda. The notion of economic uncertainty refers to clarity, or the lack thereof, about future economic activities (Bloom, 2014; Moore, 2016). For individuals, economic uncertainty reflects the likelihood of experiencing adverse labour market conditions over the life course. The crisis of the fordist model during the 1980s led to a structural incapability of jobs creation in Europe and a dramatic increase of (especially youth) unemployment rates. On the other side of the Ocean, the United States showed successful occupational outcomes. This success was imputed by social and economic observers to the 'flexibility' of the North American labour market, as opposed to European ones that were described as too 'rigid', i.e., protecting excessively permanent jobs (Cutuli and Guetto, 2013). Consequently, in the last two decades of the past Century, European labour markets experienced a strong process of deregulation, leading to a significant change in the international division of labour. The "re-regulation" of the labour market and other aspects of the globalization wave (such as privatizations and liberalizations) generated an unprecedented level of structural uncertainty in contemporary societies (Mills and Blossfeld, 2005; Standing, 1997, 2014). Such condition affected many workers and has been shown to have an impact on family formation as well (Blossfeld et al., 2006; Esping-Andersen, 1999). Since the advent of the *Great Recession*, then, papers addressing the effects of economic uncertainty on fertility intentions and behaviours are booming.

The magnitude and direction of the relationship between economic uncertainty and fertility are debated, because both negative and positive effects are supported by sociological theories and empirical evidence. An important contribution comes from the work of Prija Ranjan (1999), who concluded that increasing uncertainty about the future income leads young adults to postpone irreversible, long-term decisions, such as childbearing. On the other hand, the work by Debra Friedman and colleagues (1994) advocated that uncertainty may have a positive effect on fertility: when a woman has limited chances in the labour market, she might choose the "alternative career" of mother. Empirical evidence on this topic is mixed too and, at times, contradictory: some studies pointed out that economic uncertainty negatively affects fertility (e.g. Pailhé, 2012, Sutela, 2012, Hofman, 2013), others found a positive effect (e.g. Gutierrez, 2008, Perelli-Harris, 2006, Kreyenfeld, 2009), while some others a non-significant effect (e.g. de Lange et al., 2014).

All things considered, there is a sensible need to get a closer understanding of previous research to draw general conclusions about the size and the direction of the impact of economic uncertainty on fertility in Europe. To this end, we performed a quantitative literature review, namely a meta-analysis (e.g., Matysiak and Vignoli, 2008), to synthesise, merge and interpret all the evidence coming from the available literature on the topic. This technique allows for a systematic analysis of results coming from heterogeneous studies, standardised for the country of interest, the method applied, the sample selected, the control variables, the period covered by the study, and so forth.

2 Data and method

Economic uncertainty is a very broad and multifaceted concept, and it cannot be directly observed and measured. Nevertheless, employment uncertainty, intended as experiencing adverse labour market conditions, can be directly observed. It translates into a feeling of economic uncertainty for individuals because flexible working arrangements are often related to economic penalties (Scherer, 2009). Furthermore, a growing number of studies pointed to a connection between economic uncertainty, in the form of unemployment, temporary work contracts, and unstable labour market situations with fertility (Mills et al., 2011). Hence, in this work, we focus on employment uncertainty, measured through individuals' employment condition and type of contract. In detail, we consider: (i) fixed-time contracts, (ii) part-time employment, and (iii) unemployment as "treatments" opposed to a permanent employment position.

Four inclusion criteria were used to select the articles that could enter our meta-sample. First of all, we included articles and book chapters, disregarding conference papers and working papers to ensure a high-quality meta-analysis. Next, qualitative works are excluded as they did not test the effect under interest from the statistical point of view. Third, we included only micro-level studies to avoid ecological correlation fallacy. Finally, we restricted the search to studies in European countries because they display an interesting variation in fertility and labour market patterns, while also sharing certain economic, social, and cultural characteristics that minimize heterogeneity.

We collected articles using the electronic database Scopus (www.scopus.com), which is the largest abstract and citation database of peer-reviewed literature, summing up to more than 60 million records. After the search through electronic database, we performed a backward research to find articles that were possibly not included in the database. Finally, we sent the list of articles retrieved to a group of experts of the field, asking them to check if any important contribution was missing. At the time of writing, 76 articles have been coded and included in the meta-sample.

We perform separate meta-analyses for every treatment considered (i.e., fixed-time contracts; part-time employment; and unemployment). For each treatment, we conduct specific analyses considering the key moderators: gender and welfare regimes. In fact, the impact of economic uncertainty on fertility has been shown to present different connotations between genders (Blossfeld et al., 2005). In addition, it is a well-established fact that the pressures towards increasing labour market liberalizations in Europe have been moderated by country-specific institutions (Esping-Andersen, 1999).

3 Preliminary results and next steps

Preliminary results about the relationship between fixed-time contracts and fertility show that, on average, employment uncertainty has a significant negative effect on fertility. The OR of having a child for people with a fixed-time job with respect to people with an unlimited-time contract is 0.91. Such negative effect is even stronger for women (OR 0.88, highly significant), while it is weaker, on average, for men (OR 0.98, still significant). Interestingly, there are also important differences depending on the welfare state. For example, the OR of having a child for fixed-time workers compared to unlimited-time workers goes from 0.92 in countries such as the Netherlands and the UK, to 0.86 in Southern Europe, while it is not even significant in Germany. As a second step, we studied the role of other covariates by performing meta-regressions. Results show that fixed-time employment is more detrimental to childless individuals' fertility with respect to those who already have a child, and that some characteristics of the study (e.g., controlling for perceived economic uncertainty) play significant roles.

The next step is to move toward a Bayesian approach. The Bayesian meta-analysis (e.g., Baccini et al., 2008) makes heterogeneity assessments more robust. As a last step, we aim to perform a network meta-analysis (NMA). The NMA has been proposed as an extension of pairwise meta-analysis to facilitate indirect comparisons of multiple competing treatments – here identified by different markers of economic uncertainty: fixed-time contracts, part-time employment and unemployment – that have not yet been studied in head-to-head studies. Compared with pairwise meta-analyses, network meta-analyses allow the visualisation of a larger amount of evidence, estimation of the relative effectiveness among all treatments, and rank ordering of the treatments (Tonin et al., 2017).

What Shapes Population Age Structures in the Long Run

Verso dove tende la struttura per età corrente

Gustavo De Santis and Giambattista Salinari

Abstract We present and test a hypothesis that, to the best of our knowledge, is new in the demographic field: the age structure of any population in any period tends towards a specific shape, which can be identified in advance. This "attractor" is the age structure of the current stationary population, which we label RAS, or "reference age structure". There is no mathematical demonstration for this tendency: however, we show that it exists in practice, measure the speed of the convergence (of the current on the reference age structure), and discuss the theoretical and practical utility of the notion.

Abstract *In questo paper dimostriamo che la struttura per età corrente evolve nel tempo subendo la costante attrazione della struttura per età della popolazione stazionaria corrente, che qui chiamiamo RAS ("reference age structure", o struttura per età di riferimento). La tendenza alla convergenza non può essere dimostrata matematicamente, ma avviene empiricamente: qui lo si dimostra, si misura la velocità di questo processo e si discutono alcune delle implicazioni teoriche e pratiche della nostra scoperta, che, a quanto ci consta, rappresenta una novità in demografia*

Key words: Age structure, Stationary population, ECM (Error Correction Model).

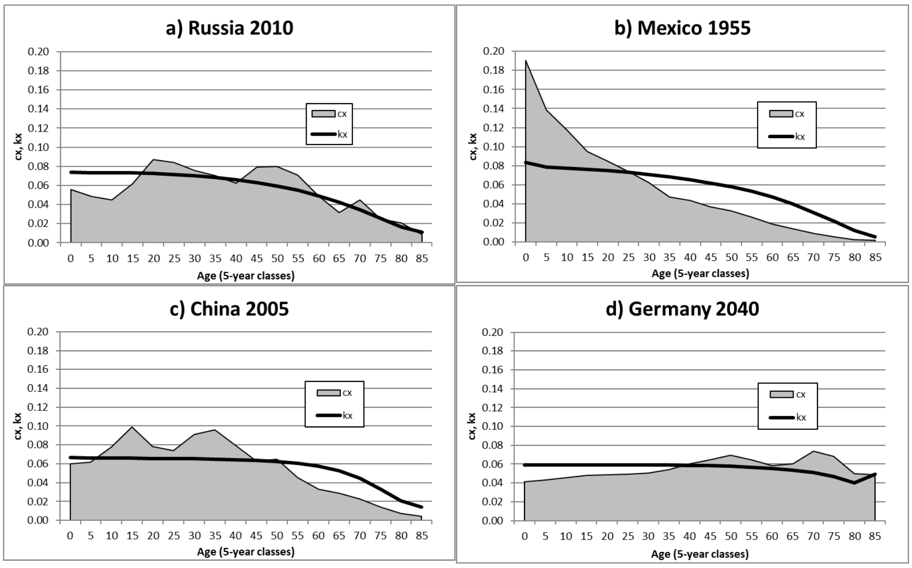
Two Age Structures: Actual and Stationary Populations

Let $c_{x,t}$ be the age structure of the population at time t, or current age structure. It is defined as the relative share of population aged x, P_x, to the total population P: $c_x=P_x/P$. Similarly, let $k_{x,t}$ be the age structure of the stationary population,

[1] Gustavo De Santis, University of Florence; email: gustavo.desantis@unifi.it;
Giambattista Salinari, University of Sassari; email: gsalinari@uniss.it.

calculated on the cross sectional life table in year t. If $L_{x,t}$ are the person-years lived at age x in year t and $T_{0,t}$ is their sum, or total number of person-years lived at all ages, the ratios $k_{x,t}$=$L_{x,t}$/T_0,t form the age structure of the stationary population in year t, which we also call "reference" age structure (or RAS) in this paper. Obviously, Σc_x=Σk_x=1. Selected examples of both are presented in Figure 1.

Figure 1: Actual (c_x) and reference (k_x) age structures of selected populations



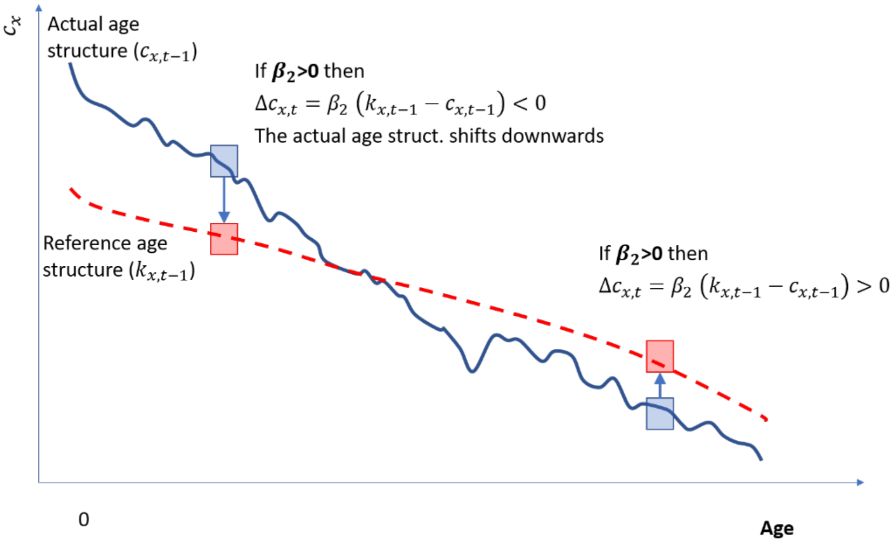
Source: UN (2017).

Our hypothesis is that the shares $c_{x,t}$ tend to move towards their reference counterpart $k_{x,t}$. To prove this, we run the following Error Correction Model (ECM) on UN (2017) data

$$\Delta c_{x,t} = \beta_0 + \beta_1 \, \Delta k_{x,t} + \beta_2 \, (k_{x,t-1}-c_{x,t-1}) + \varepsilon_{x,t} \qquad (1)$$

where $\Delta c_{x,t}$=$c_{x,t}$-$c_{x,t-1}$, $\Delta k_{x,t}$=$k_{x,t}$-$k_{x,t-1}$, and $\varepsilon_{x,t}$ is the error term. Our main object of interest is the coefficient β_2, which we expect to be significantly greater than zero. If this is true, the $c_{x,t}$ series tends to converge on the $k_{x,t}$ series. Figure 2, where we drew the profiles of the actual and of the reference age structure at time t-1 of a hypothetical population, gives a visual representation of what we expect will happen.

Figure 2: Hypothesised dynamic of the population structure



c_x
Actual age structure ($c_{x,t-1}$)
If β_2>0 then
$\Delta c_{x,t} = \beta_2 \left(k_{x,t-1} - c_{x,t-1}\right) < 0$
The actual age struct. shifts downwards
Reference age structure ($k_{x,t-1}$)
If β_2>0 then
$\Delta c_{x,t} = \beta_2 \left(k_{x,t-1} - c_{x,t-1}\right) > 0$
0
Age

Data and Empirical Results

The main results of our model, based on the most recent UN (2017) data and estimates, are presented in Table 1. Note, first, that each country provides 204 observations: 17 five-year age classes (0-4 to 80-84; while the last, open-ended one, 85 and over, is not used in the estimates) for 12 five-year periods (1950 to 2015; this makes 13, but we "lose" one, because we work on differences).

The estimates of β_2 are positive and significant in all of the world and in almost all of its (sub)regions. The only exception is Middle Africa, and the reason why this happens is, we submit, the fact that this part of the world is still going through its demographic transition, which is strong enough to obscure the underlying tendency (convergence of c_x on k_x) that we are focusing on here. The speed of convergence ranges between 2% and 40%, depending on the region, and is about 6% at world level. In other words, on average, 6% of the difference between $k_{x,t}$ (reference age structure) and $c_{x,t}$ (actual age structure) observed in year t disappears 5 years later, because the current age structure tends to move in the "right" direction (see again Figures 1 and 2), which is precisely what we wanted to prove.

To the best of our knowledge, this tendency had thus far gone unnoticed in the literature. We venture that there are two main reasons why this happened. The first is that this convergence cannot be proved mathematically. Indeed, the reverse is true: there are theoretical cases (not discussed here) in which it can be proved that convergence does *not* take place. The second reason is that convergence is a constant, but weak force, as our estimates of Table 1 indicate, which is easily obscured by others, such as strong migration flows, or the demographic transition. In the long run, however, or with a sufficient number of observations on data of reasonable quality, this tendency emerges and can be detected.

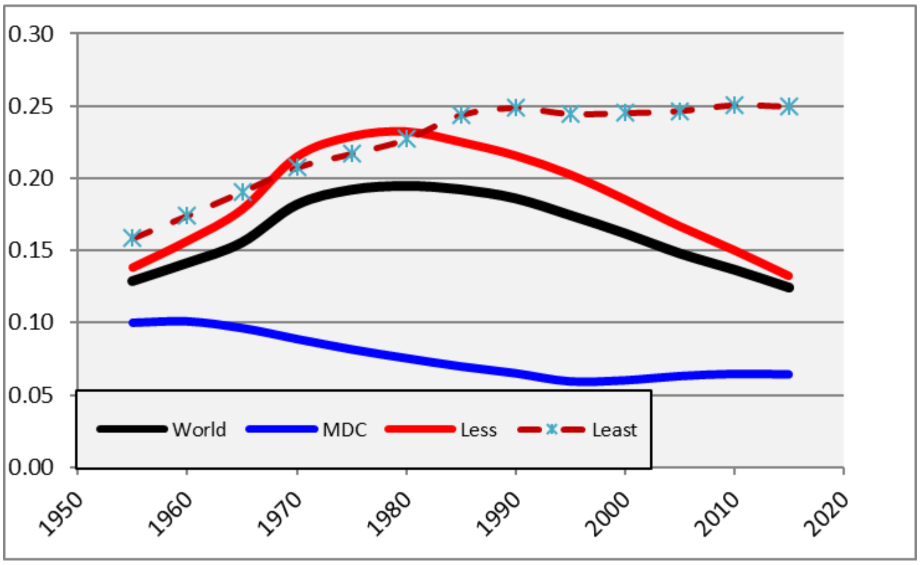
On the Distance Between the Actual and the Reference Age Structure

The distance between the actual ($c_{x,t}$) and the reference age structure ($k_{x,t}$) can be measured with the index of dissimilarity D_t, which indicates what share of the population should be in a different age class to result in a perfect coincidence between the two (c_x and k_x), in year t

$$D_t = \frac{1}{2}\sum_c \left|c_{x,t} - k_{x,t}\right| = \frac{1}{2}\sum_c \left|\frac{P_{x,t}}{P_t} - \frac{L_{x,t}}{T_{0,t}}\right| \qquad (2)$$

By construction, D_t ranges between 0 and 1, but in practice, it is virtually impossible in this kind of application (population shares by age classes) to find D_t outside the range 5-50% (discussion skipped here). Figure 3 shows that D_t (dissimilarity, or distance) has not decreased monotonically in the past 65 years, as our model (1) predicts: we argue that this is due to the fact that, in the "short" run, other forces prevail, first of all the demographic transition.

Figure 3: Dissimilarity index D_t between the actual (c_t) and the reference (k_t) age structure in selected world areas, 1950-2015



Note: MDC=More Developed Countries; Less/Least=Less/Least Developed Countries
Source: UN (2017) and own calculations.

Indeed, in more developed countries (whose demographic transition took place in the late 19th-early 20th century, i.e., left of the time scale displayed in Figure 3), D_t does decrease over time and is today about as low as it can reasonably be. In less developed countries, D_t *increased* until the 1980s (precisely because of the biases produced by the ongoing demographic transition following WW2) and decreased later. In the least developed countries (basically, Sub-Saharan Africa) convergence is not yet taking place, and the two age structures ($c_{x,t}$ and $k_{x,t}$) remain far from each other. (Convergence will occur in the next decades, according to the UN Projections, but this is not shown or discussed here.)

So what?

Our finding has several important implications, which we cannot fully develop here, for reasons of space. For instance, it affects the ongoing debate on the main causes of population ageing: is it (mainly) due to low fertility or low mortality? Our answer is simple: as the current age structure $c_{x,t}$ tends to "move" towards its reference counterpart $k_{x,t}$, which depends exclusively on survival, lower mortality is the underlying force that (slowly) drives the process of population ageing. Deviations from this path can be important, and they can last for some years, or even decades, but eventually the "attraction" of $k_{x,t}$ (i.e., the dominant role of the mortality regime) prevails.

A second application (among others) is in the field of pension systems. Our finding suggests that pension systems should be designed giving emphasis to the reference age structure $k_{x,t}$ and to its evolution over time, as the current age structure $c_{x,t}$ will eventually converge towards it. This takes time, admittedly, but pension systems are, or at least should be, intended to last for very many years: to base them on the reference age structure $k_{x,t}$ would make them much more long-lasting and robust than they usually are.

The impact of economic development on fertility: a complexity approach in a cross-country analysis

L'impatto dello sviluppo economico sulla fecondità: l' approccio della complessità in un'analisi cross-country

Niccolò Innocenti, Daniele Vignoli and Luciana Lazzeretti

Abstract This work focuses on the role of economic indicators on fertility from a cross-country comparative perspective. It relies on a new indicator of the economy of a country and on its perspective of future development – i.e. the economic complexity. We apply a Structured Equation Model to data on 70 countries from 1964 to 2015 to assess the impact of economic complexity on economic growth (Gross Value Added, employment, innovation) and, then, on total fertility. Preliminary results show that the relation between economic complexity and economic growth is positive for all countries, while a U-shaped relation between the economic complexity and fertility seems to emerge during the analysed time-span.

Abstract *Questo lavoro si concentra sul ruolo degli indicatori economici nello spiegare le variazioni di fecondità dei paesi basandosi su un nuovo indicatore in grado di indicare anche le future prospettive di sviluppo del paese, cioè la complessità economica. Abbiamo stimato un modello ad equazioni strutturali sui dati di 70 paesi per il periodo 1964-2015 per valutare gli effetti della complessità economica sulla crescita economica (valore aggiunto, occupazione, innovazione) e successivamente sul tasso di fecondità totale. I risultati preliminari mostrano una relazione positiva tra complessità e economica e crescita economica, mentre sembrano suggerire un modello a U per la relazione tra complessità economica e fecondità durante il periodo analizzato.*

Key words: Economic Development, Fertility, Cross-country analysis.

1 Introduction

While the first decade of the new millennium witnessed moderately increasing fertility rates in some countries across Europe, since the advent of the Great Recession policy makers in many countries see their current fertility levels as worryingly low. The social, economic, and demographic implications of persistently low fertility rates are largely known: the population age structure is impaired, which puts the whole welfare system under pressure and impacts the rules governing transfers between generations (Bryant, 2007; Dribe et al., 2017). A great share of studies focused on the relation between income or wellbeing and total fertility. Results, at the end, are in two different directions. In fact, there is evidence both of a positive impact of income on fertility and of a negative impact depending on different factors, such as the level of economic development of the country and of the positive or negative trend of such development (Myrskyla et al., 2009; Wang and Sun, 2016).

Our work relies on a new indicator of the economy of a country and on its perspective of future development – i.e. the economic complexity (EC). This recent strand of research, firstly developed by Hidalgo and Hausmann (2009), sustains a view of economic growth and development that gives a central role to the complexity of a country's economy. The idea is that a country with higher economic complexity will perform better in term of future economic growth (Gross Value Added – GVA, employment, innovations) (Hartmann et al., 2017). An important factor that leads our interest on EC as a determinant of fertility is that it includes many dimension often considered as important factors able to influence the fertility of a country, more than the already mentioned economic dimension, such as the accumulation of human capital or women's emancipation, features often associated to a lower fertility (Lehr, 2003). Put directly, we argue that EC could be used to predict the fertility development of a country. The complexity indicator is constructed following the approaches and methods proposed by Hidalgo and Hausmann (2009), using export data. We rely on the idea that the economic complexity of a country depends on the goods that are produced and thus exported, taking into account the relative composition of the export baskets of all other countries. More complex economies tend to produce more rare products in term of ubiquity and that relatively few countries are able to produce, due to the need of producing many other related/diverse products. The countries with a more complex economy are then able to use their comparative advantage (or their oligopoly) to perform better in term of rents and also of opportunities to diversify in more and more rare and complex products. On the contrary, countries that produce less complex products deal with a higher competition and thus tend to have less opportunities both in term of rents and in term of comparative advantage to diversify in more complex activities.

Importantly, different levels of economic complexity imply different job options, educational qualifications, and also different behaviour in private life that are likely to affect also family formation, as well as fertility timing and quantum.

2 Methodology

The paper presents a longitudinal cross-country analysis of 70 countries from 1964 to 2015. The country's total fertility – i.e. the Total Fertility Rate (TFR) – is drawn from the World Development Indicators. It is customarily defined as the number of children that would be born to a woman if she were to live to the end of her childbearing years and bear children in accordance with age-specific fertility rates of the specified year.

The data used to construct the complexity index are about the export of all the analyzed countries during the same period (1964-2015). To construct our index of EC we followed the methods proposed by Hidalgo and Hausmann (2009) and refined by Balland and Rigby (2017). We used, international trade data with products disaggregated according to the Standard International Trade Classification (SITC) at the 4-digit level and interpret them as a bipartite network.

We used export data as an adjacency matrix M*cp*, where M*cp* is equal to 1 if the country *c* is an important exporter of product *p* and equal to 0 if this is not the case. The country *c* is an important exporter of the considered product *p* and, thus, has a Revealed Comparative Advantage (RCA) if the share of product *p* in the export basket of the country *c,* divided by the share of product *p* in world trade, is higher than a threshold value *x*.

Mathematically:

$$\mathrm{RCA}cp = (\mathrm{E}cp/\mathrm{E}c)/(\mathrm{E}p/\mathrm{E}) > x$$

We then followed the method of reflections (for a detailed description of the properties see Hidalgo and Hausmann (2009)), using the RCA to compute the two components to construct the ECI, namely the diversity (in term of products) of each countries and the ubiquity (of the products produced by the country). After a series of *n* iterations of these measures at both products and country level we ended with a stable measure of ECI (we stop the iteration when the correlation with the previous is near 1, meaning that there are no significant information to capture by an additional use of the method of reflections).

The ECI is computed for each year of the period under investigation and for each country of the sample. Than an econometric analysis is performed to assess the relation among the ECI and the TFR. The method proposed is the use of structural equations to assess the impact of ECI on economic growth (GVA, Employment etc.) and then on TFR. Finally, we performed a robustness check to assess the direct relation among ECI and TFR.

The analysis will be performed using the whole sample as well as coherent sub-group, divided by economic development of countries from high, to low-income countries.

3 Results and preliminary conclusions

Preliminary results suggest a positive correlation between ECI and economic growth during the period under analysis. Interestingly, while the relation between ECI and economic variables is positive for all samples, when we analyze the impact on TFR the results show a U-shaped relation between ECI and TFR during the analyzed period. These results are in line with previous studies on the role of economic indicators on fertility. There is a clear association among EC of countries and fertility: in low-income and lower middle-income countries (associated also with an extremely low rank in terms of EC) there is a negative relation between EC growth and fertility. When the focus is on high-income countries, the results clearly show a positive correlation between EC growth and fertility rates.

Our findings are in line with those of Myrskyla et al. (2009), claiming that there is a reversal in fertility decline associated with human development, and this change i could be driven by the economic complexity, conceived as a driver of economic and human development of countries. This implies that highly developed countries benefit, in terms of fertility, by a further complexification of their economy.

The U-shaped pattern is related to the economic transition of countries in different stages of development. In low-income countries a higher level of complexity facilitates women's emancipation, a pursuit of higher education of individuals and women's entry into the labor market, leading to fertility reduction. In high-income countries a more complex economy is associated with economic opportunity, well-being and lower levels of economic uncertainty, leading to an increase of total fertility.

We continue the analysis by estimating a Structural Equation Model on the reciprocal relations between EC, economic growth and fertility.

A Probabilistic Cohort-Component Model for Population Forecasting – The Case of Germany

Un Modello a Componenti di Coorte per Previsioni della Popolazione – Il Caso della Germania

Patrizio Vanella[1] and Philipp Deschermeier[2]

Abstract The future development of population size and structure is of undeniable importance since planning in many areas of politics and business is conducted based on expectations about the future makeup of the population. Countries with both decreasing mortality and low fertility rates, as is the case for most countries in Europe, are in urgent need of adequate population forecasts to identify future problems for social security systems and overall macroeconomic development. The labor market will especially be affected by the retirement of the *baby boomer generation* and the resulting shortage of young skilled workers. This contribution proposes a stochastic cohort-component model that uses simulation techniques based on stochastic models for fertility, migration and mortality to forecast the population by age and sex. The results provide detailed insight into the future population structure, disaggregated into both sexes and 116 age groups. Moreover, the uncertainty in the forecast is quantified as prediction intervals for each subgroup. The underlying models for forecasting the demographic components have been developed in earlier studies and rely on principal component time series models.

Abstract *Il futuro sviluppo della grandezza e della struttura della popolazione è di importanza innegabile, poiché la pianificazione in molte aree di politica ed economia è condotta sulla base di aspettative sulla composizione futura della popolazione. Paesi con tassi di mortalità e fertilità in calo, fenomeno comune nella maggioranza dei paesi d'Europa, hanno un urgente bisogno di previsioni adeguate della popolazione per identificare i problemi futuri per il sistema d'assicurazione sociale e per lo sviluppo macroeconomico generale. Il mercato del lavoro sarà influenzato in particolare dai pensionamenti della generazione baby boom e dalla risultante scarsità di lavoratori giovani e qualificati. Questo studio propone un modello a componenti di coorte che usa tecniche di simulazione a base di modelli stocastici per fertilità, migrazione e mortalità, per predire la popolazione per età e sesso. I risultati offrono informazioni dettagliate sulla struttura della popolazione nel futuro, disaggregate per sesso e 116 gruppi d'età. Inoltre, l'incertezza della previsione è quantificata attraverso intervalli di previsione per ogni sottogruppo. I sottostanti modelli per predire le componenti demografiche sono stati sviluppati in precedenti studi e usano modelli di serie storiche (time series) con componenti principali.*

Key words: Population Forecasting, Stochastic Simulation

1 Future Development of the Demographic Components

We propose a population forecast based on a probabilistic cohort-component model developed through the combination of Vanella's (2017a: 543-549) model for forecasting age- and sex-specific survival rates *(ASSSRs)*, the forecast model for age-, sex- and nationality-specific net migration *(ASNSNM)* by Vanella and Deschermeier (2017: 6-23) and Vanella's (2017b: 11-24) model for forecasting age-specific fertility rates by sex of newborns *(ASSFR)*. Each partial model generates 10,000 scenarios stochastically by simulation of Wiener processes[3], which represent 10,000 scenarios for the future development of the population in Germany by age (*0-115*) and sex (*binary*).

Vanella (2017b: 21-22) incorporated the effect of international migration on fertility in his fertility forecast model. The inclusion of this fertility model into the population forecast model proposed here provides an opportunity to quantify the effects of international migration on the development of the population not only directly through

[1] Patrizio Vanella, Gottfried Wilhelm Leibniz Universität Hannover – Center for Risk and Insurance; email: pv@ivbl.de
[2] Philipp Deschermeier, Institut Wohnen und Umwelt Darmstadt; email: p.deschermeier@iwu.de
[3] See Vanella 2017c: 13 for an explanation of Wiener processes.

the migration process itself but also indirectly by altering the number of births due to the different reproductive behavior of migrants relative to that of the native population.

We now describe the procedure for population forecasting with our model. Let $P_{x,y,g,t}$ denote the population aged *x* years at the end of year *y* for sex *g* in trajectory *t*. The population update is performed through the following step-wise process.

Step I:
The forecast begins with an adjustment of the base population with regards to international migration flows in the first forecast year *y+1***.** The addition of international net migration aged *x+1* years of sex *g* in year *y+1* ($M_{x+1,y+1,g,t}$) to $P_{x,y,g,t}$ leads to the hypothetical subpopulation $\tilde{P}_{x+1,y+1,g,t}$ at the end of year *t+1* without any deaths:

$$\tilde{P}_{x+1,y+1,g,t} = P_{x,y,g,t} + M_{x+1,y+1,g,t}.$$

Step II:
The number of survivors from $\tilde{P}_{x+1,y+1,m,t}$ at the end of *y+1* are calculated through multiplication with the age- and sex-specific survival rate (*ASSSR*) $s_{x+1,y+1,g,t}$ for persons aged *x+1* years of sex *g* in year *y+1* and in trajectory *t*:

$$P_{x+1,y+1,g,t} = \tilde{P}_{x+1,y+1,g,t} * s_{x+1,y+1,g,t}.$$

Step III:
The mean female population in *y+1* in the reproductive age group is approximated:

$$F_{x,y+1,w,t} = \sum_{x=14}^{52} \frac{P_{x-1,y,w,t} + P_{x,y+1,w,t}}{2}.$$

This approximation presumes constant migration and mortality during a year because we rely on annual data. This approach is mathematically practical; moreover, we believe the possible error arising from this assumption is extremely small and therefore produces no fundamental error in the future population estimation.

Step IV:
The sex-specific live births $B_{y+1,g,t}$ are estimated:

$$B_{y+1,g,t} = \sum_{x=14}^{52} F_{x,y+1,w,t} * f_{x,y+1,g,t},$$

where $f_{x,y+1,g,t}$ denotes the ASSFR for females aged *x* years in year *y+1* conceiving babies of sex *g* in trajectory *t*.

Step V:
The number of survivors among the children born in *y+1* is calculated:

$P_{0,y+1,g,t} = B_{y+1,g,t} * s_{0,y+1,g,t}$.

In this way, the population by sex and age in year *y+1* in trajectory *t* is obtained.

The algorithm is illustrated in Figure 1.

Source: Own design

This process is then used to stochastically forecast the population by sex and age until the year 2040. The future development of the population is forecast by estimating the future course of the demographic components of fertility (through ASSFRs), migration (ASNSNM), and mortality (ASSSRs). The underlying variables are simulated indirectly on the basis of the stochastic trajectories of the PCs, which were derived in earlier studies. A quasi-two PC time series model, as proposed by Vanella (2017a: 543-549), is used to forecast the logistically transformed ASSSRs. The first PC is a general mortality index, similar to the classic Lee-Carter index. The second PC is a behavioral index representing differences in mortality between the two sexes associated with nutritional and smoking behavior. Migration flows are accounted for via the quasi-two PC forecast model for ASNSNM proposed by Vanella and Deschermeier (2017: 15-22). In this case, the first PC is a labor market index and the second PC addresses the migration resulting primarily from humanitarian or economic crises. The fertility model builds upon the results of the mentioned migration model. This component is forecast by the quasi-three PC model proposed by Vanella (2017b: 11-24). In this case, the first PC is associated with the tempo effect in fertility, i.e., the postponement of births from younger ages to older ages. The second PC is a quantum index used to address general trends in the quantity of reproductive behavior in a society. The third PC considers the impact of the migration level on fertility and is derived via econometric specification of the influence through the second PC of the migration model proposed by Vanella and Deschermeier (2017: 12-17).

2 Population Development in Germany until 2040

The combination of the resulting trajectories for the demographic components results in a probabilistic cohort-component model for forecasting the age- and sex-specific population for the ages 0-115 years. The initial population for the forecast is the age- and sex-specific population reported by Destatis for December 31, 2015. Population numbers for ages 100 years and over are not available in detail but are rather aggregated into an upper age group. Thus, we approximated the population in this age group through an own population update based on the death counts by age and sex.

In general, we observe greater uncertainty for males. Whereas the retirement-age population can be predicted relatively well, the uncertainty in the future working-age population is especially large for males due to the high uncertainty in the migration forecast for males (Vanella, Deschermeier 2017: 17-22). The uncertainty in the population of persons under 25 years of age arises from the fact that this portion of the population has not been born yet. Specifically, the uncertainty of persons under 25 years of age arises from migration, from the mortality of persons "below 1 year" and from uncertainty due to fertility.

The aging of the population is of high social and economic importance, as was stated earlier. Therefore, in addition to the overall age structure, the median age of the male and female populations is considered as a summary indicator for the future age schedule of the population. The median age of the population can be obtained from the simulation results because it is the exact age that cuts the population in half. This computation for all 10,000 trajectories can be used to extract PIs for the median age.

We observe a rejuvenation effect for the upcoming years due to high net migration during this period. The high net migration rates around the year 2015 combined with the high forecast values for the upcoming years leave a mark in the age structure of Germany. This can be seen in the age structure for the male and female populations in the year 2040. By that time, the majority of the population that immigrated during the high influx phase will be approximately 50 years old, while the baby boomer generation will be in their seventh decade of life. Over the forecast horizon, the median age traces this development by a rejuvenation effect for men and women. The probable decrease in the number of births after the middle of the 2020s and decreasing net migration and mortality (Vanella 2017a: 550) lead to an aging of the population structure, as represented by the increasing median ages after that point. Since a larger portion of migrants is male (Vanella, Deschermeier 2017: 20-22), the rejuvenation is stronger for males than for females.The driving factor behind the presented results on the population development is net migration. Following the net migration in 2015, the first years of the forecast result in high and above average values of net migration. In the long run, net migration is expected to decrease to 212,419 in 2040. Counterbalancing net migration, we take a look at the probabilistic forecast of Germany's natural growth until 2040, which is simply derived from the birth and death forecasts. Following the trend of the recent past, the number of births will continue rising until the mid-2020s. However, as the peek remains below 900,000 births per year for the median scenario, this development cannot be labeled a second baby boom. In comparison, the number of livebirths in the 1950s and 1960s exceeded 1.1 million annually (GENESIS-Online Datenbank 2018). Due to the shift in the age structure, the number of potential mothers is expected to shrink at some point, resulting in decreasing birth numbers in the long run. The aging of the population leads to a steady increase in the number and rate of older people, who have a higher probability of dying in a given year. This results in a steady increase in the number of deaths until 2040. As the median of the simulation is greater than 900 thousand persons in each year of the forecast, the natural population development until 2040 almost certainly will be negative during the forecast horizon. Therefore, a lack of high net migration would naturally lead to a decrease in population in Germany. The connection between natural population growth and net migration is therefore obvious since an old population with low fertility requires positive net migration to avoid shrinking and overaging. In the median trajectory, the natural decrease in the population will grow annually, stressing the importance of positive net migration, especially in the younger ages, to fill the shortages occurring in the labor market. As we will show by some important measures, our model provides a wide range of detailed analyses targeting specific topics of interest. The forecast results offer the possibility for a wide range of future studies, e.g., analyzing the effects of population changes on social security, the labor market or housing demand.

Mortality trends in Sardinia 1992-2015: an ecological study

Evoluzione della mortalità in Sardegna 1992-2015: uno studio ecologico

Vanessa Santos Sanchez, Gabriele Ruiu Marco Breschi, Lucia Pozzi

Abstract Sardinia has been for long times under the lens of biologists, demographers and social scientists for the high longevity of the population of some of its territories. However, and in some sense paradoxically, the island represents an ideal context to study the effect on human mortality produced by the environmental deterioration caused by the settlement of heavy industry. By the means of a spatial analysis we found that the largest increase in mortality rates in the period 1992-2015 are indeed in industrial areas.

Abstract *La Sardegna è stata per lungo tempo analizzata in ambito demografico, biologico e sociologico a causa della longevità registrata nelle popolazioni di alcuni suoi territori. Paradossalmente, questa regione rappresenta però un contesto ideale per studiare l'effetto prodotto sulla salute umana dalla presenza di industria pesante. Usando tecniche di analisi spaziale, si mostra infatti che il più alto incremento nei tassi di mortalità nel periodo 1992-2015 ha caratterizzato proprio le zone industrializzate.*

1 Introduction

[1] coined the expression "blue zone of longevity" (from hereon BZL) for indicating a rather limited and homogenous geographical area where the population shares the same lifestyle and environment and its longevity has been proved to be exceptionally high. Ogliastra (South-Eastern Sardinia, Italy) together with a small number of regions around the World has been acknowledged as a BZL. The peculiar characteristic of the blue zone individuated in Sardinia, is that among centenarians the female/male ratio is about 1.34 which is a value considerably lower than in the rest of Italy ([2]). This has obviously attracted many research efforts for trying to explain the extraordinary longevity of males ([3]) whilst, at least in recent time, less attention has been devoted to analysing the overall evolution of mortality in Sardinia. Generally, the Italian public considers Sardinia a place where the environmental conditions and the healthy diet have favoured male longevity. However, this is far from being true at least in some zones of the island. In particular, Sardinia represents an ideal context for studying the effect that highly polluting industrial sites, mining sites and military bases play on human health. To our knowledge, only [4] analysed the Sardinian age-standardized mortality rates, at the municipal level, for a quite short period (1997-2001) finding that among males it was higher than in Italy (84.4 vs 80.8) while the reverse occurred in females (50.9 vs 52.0). They also find that the industrial sites of Porto Torres (chemical plants were established in this Northern Sardinian city during the sixties) was characterized by an excess mortality for respiratory diseases, diseases of the digestive tract, liver cancer and lymphohaemopoietic cancer. An anomalously high incidence of lymphohaemopoietic cancer was found also among the population living near military sites (La Maddalena, Salto di Quirra). An excess of deaths for respiratory related problems was also found in other industrial zones (Portoscuso and Sarroch). We enlarge their analysis to capture the evolution of mortality from 1992 to 2015 and applying a spatial methodology originally proposed by [5]. Extending the time period allows establishing when the pollution related to industrial activity which initially hit men, because of the fact that the workforce in these sectors is almost entirely composed by males, has begun to affect also female population, thus denoting a deterioration of the environmental conditions.

1.1 Data and Methods

An ecological study of small areas was carried out for the 377 Sardinian municipalities existing in 2015, in the periods 1992-1997, 1998-2003, 2004-2009 and 2010-2015. Individual death entries for the period 1992-2015, broken down by municipality and sex, were used as case source.

Municipal populations, broken down by age group (20 five-years groups) and sex are obtained for each year. The person years for each period were calculated by adding the population of each year.

Mortality and population data have been derived from ISTAT database.

We used the 2001 deprivation index created by [6] as indicator of socioeconomic level. This index classifies municipalities into 5 levels, according to several variables: (i) low level of education, (ii) unemployment, (iii) non-home ownership, (iv) one parent family and (v) overcrowding. This classification is based on the quintiles of the distribution of factor scores, where level 1 municipalities are the richest ones and level 5 municipalities the least rich ones.

To calculate the number of expected cases, overall Sardinian specific age group, sex and period mortality rates were multiplied by each municipal person-years for the same age, sex and period pattern. Standardized mortality ratios (SMRs) were calculated as the ratio of observed to expected deaths.

Smoothed municipal relative risks (RRs) with their corresponding 95% credibility intervals, were calculated using the conditional autoregressive model proposed by [5]. This model fits a Poisson spatial model with two types of random effects, a non structured effect that takes into account the municipal heterogeneity, and a structured effect, the spatial term, that considers municipal contiguity. To define area contiguity we used the adjacent municipal boundaries.

The model takes the following form:

$$O_i \sim Po(E_i \lambda_i)$$

$$\log(\lambda_i) = \alpha + h_i + b_i$$

Where λ_i is the RR in area i, O_i is the number of observed cases, E_i is the number of expected cases, α is the intercept, h_i is the municipal heterogeneity and b_i is the spatial term.

To analyze the effect of deprivation on mortality, the index proposed by [6] was included in the models as a covariate.

The Bayesian estimation of the models was obtained using Markov Chain Monte Carlo (MCMC) simulation methods, through the Gibbs Sampling algorithm via free distribution software WinBUGS. Convergence of the estimators was achieved before 100.000 iterations for three Markov chains, with a burn-in of 10.000 iterations. The convergence was ensured by the algorithm proposed by [7] and the effective sample size of chains.

The free software R was used to create municipal maps of SMRs, smoothed RR estimates and posterior probabilities that smoothed RR was greater than one (PRPs). To calculate PRPs we used the criterion proposed by [8], considering PRPs greater than 0.8 as statistically significant.

2 Results

From 1992 to 2015 a total of 343,584 deaths was registered in Sardinia, 182,993 in men (53.3%) and 160,591 in women (46.7%).

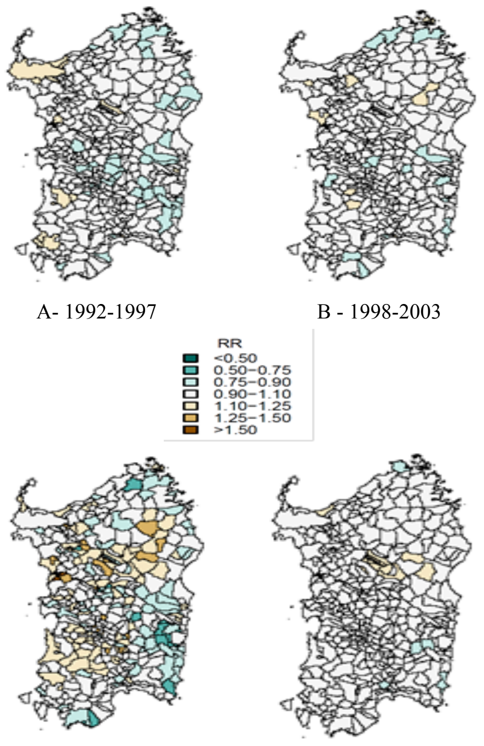
We did not observe any prevailing geographical mortality pattern in RRs for mortality throughout the 24 years of the study in either women or men.

For men, in the third period, municipalities in the northeastern provinces of Sassari, Olbia and Nuoro show an excess of mortality, with some RRs greater than 1.50 (municipalities of Sennariolo and Sagama). Figure 1 (panel a,b,c, d) shows the maps depicting the municipal distribution of mortality for each period for men.

In a different way, for women, in the last two periods, the municipalities of La Maddalena, Osilo and Ploaghe remain as the areas with the highest RRs, between 1.10 and 1.25.

Figure 2 (panel a, b, c, d) depicts the spatial pattern of the posterior probability of RR being greater than one for women. Municipalities with a statistically significant excess risk are shown in orange and areas with a low risk are shown in blue.

A high-risk pattern is observed in the province of Sassari throughout all periods. In the third period, some other municipalities present high risk in the province of Olbia, while in the last period a marked geographical pattern arises, with numerous high-risk municipalities in the northeastern areas of the island (Sassari and Olbia) together with a low-risk area in the central region.



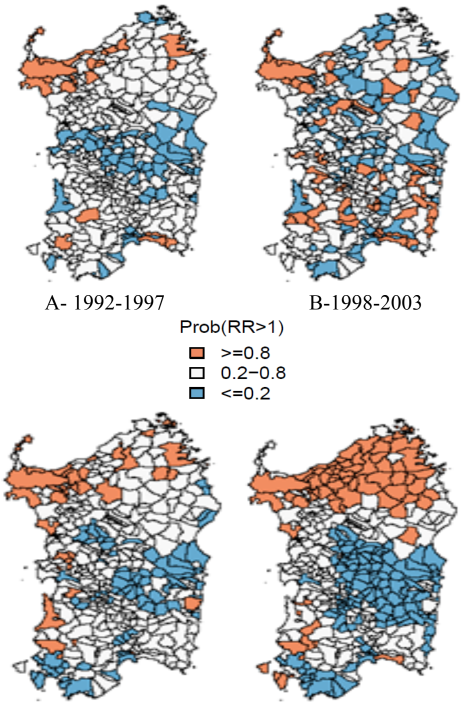
A- 1992-1997 B - 1998-2003

C- 2004-2009 D - 2010-2015

Figure 1: RR MEN 1992-2015

PRPs for men show (not reported here) in all periods an excess risk in northwestern and southwestern municipalities, in the provinces of Sassari, Medio-

Campidano and Carbonia-Iglesias. In the last two periods a high-risk pattern in the province of Nuoro emerges, the map showing a more pronounced cluster in the last period. Municipalities in the south, northeast and southeast show low risk of mortality and this pattern varies slightly throughout the study period. Table 1 shows for the first and the last period under analysis, the relationship between mortality and the deprivation index after including it in the estimated spatial model in the first and the last period of the study for men and for women.



A- 1992-1997 B-1998-2003

C- 2004-2009 D -.2010-2015

Figure 2: PRP Women

A slight increase in risk between the highest and lowest income categories can be observed in all periods, especially for men, but most credibility intervals are not statistically significant. For women, a threshold effect in the risk of death by level of deprivation emerges in the last two periods of study, while for men we cannot identify a similar temporal trend. For men, the first and second periods stand out, with almost all credibility intervals statistically significant.

Our results do not show a clear association between the deprivation index used and the risk of death, thus suggesting the necessity of studying other possible explanatory variables affecting mortality rates.

	5	1.18	0.34-2.64	1.19	0.22-3.97

3 Conclusions

The results of spatial analysis confirm those obtained by [3]. The largest increase in mortality rates in the period 1992-2015 was indeed recorded in the industrial areas of Northern Sardinia, and this worsening seems to be not ascribable neither to the age structure of the population nor to the level of deprivation.

Recent Developments in Bayesian Inference

Posterior distributions with non explicit objective priors

Distribuzioni a posteriori basate su distribuzioni a priori oggettive non esplicite

Erlis Ruli, Nicola Sartori and Laura Ventura

Abstract We introduce two methods useful to derive a posterior distribution for a parameter of interest, when only the first derivative of a log-prior is available. This is typically the situation when dealing with multidimensional parameters and objective priors. An example is illustrated using a predictive matching prior.

Abstract *In questo contributo vengono introdotti due metodi utili per derivare una distribuzione a posteriori per un parametro di interesse, quando è disponibile solo la derivata prima del logaritmo della distribuzioni a priori. Tale situazione si presenta tipicamente in presenza di parametri multidimensionali e distribuzioni a priori oggettive. Il metodo viene illustrato in un modello logistico con una matching prior predittiva.*

1 Introduction

Let $y = (y_1, \dots, y_n)$ be the available data, considered for simplicity as a random sample of size n, i.e. as a realization of a random variable $Y = (Y_1, \dots, Y_n)$ having independent and identically distributed components. Moreover, let $p(y;\theta) = \prod_{i=1}^{n} p(y_i;\theta)$ denote the probability density function of Y, with $\theta \in \Theta \subseteq \mathrm{I\!R}^k$, $k \geq 1$. We are interested in objective Bayesian inference on the unknown parameter θ, us-

ing the posterior distribution

$$\pi(\theta|y) \propto \pi(\theta)L(\theta), \tag{1}$$

where $\pi(\theta)$ is a prior for θ and $L(\theta) \propto p(y;\theta)$ is the likelihood function.

We consider the situation in which the prior distribution $\pi(\theta)$ is known only through its first derivative $\partial \log \pi(\theta)/\partial\theta$. This is typically the situation with defalut priors, such as matching priors (see, e.g., Datta and Mukerjee, 2004). In these cases, the posterior distribution (1) is not directly available, and it is only possibile to evaluate the first derivative of the log-posterior $t(\theta) = t(\theta;y) = \log\pi(\theta|y)$ given by

$$t_\theta(\theta) = t_\theta(\theta;y) = \frac{\partial}{\partial\theta}\log\pi(\theta|y) = \ell_\theta(\theta;y) + m(\theta), \tag{2}$$

where $\ell_\theta(\theta;y) = \partial \log L(\theta;y)/\partial\theta$ is the score function and $m(\theta) = \partial\log\pi(\theta)/\partial\theta$ is the derivative of the logarithm of the prior.

In this contribution we are interested in deriving the posterior density $\pi(\theta|y)$ such that $\partial\log\pi(\theta|y)/\partial\theta = t_\theta(\theta)$. In particular, we explore two methods for approximating $\pi(\theta|y)$ using MCMC and only $t_\theta(\theta)$ and its first derivative.

In the classical MCMC setting, the usual Metropolis-Hastings (MH) probability of acceptance of a candidate value $\theta^{(t+1)}$, given a chain at stage $\theta^{(t)}$, $\theta^{(t+1)} \sim q(\theta^{(t+1)}|\theta^{(t)})$, is

$$\min\left\{1, \frac{q(\theta^{(t)}|\theta^{(t+1)})}{q(\theta^{(t+1)}|\theta^{(t)})}\frac{\pi(\theta^{(t+1)}|y)}{\pi(\theta^{(t)}|y)}\right\}. \tag{3}$$

To evaluate (3), we must be able to evaluate

$$\frac{\pi(\theta^{(t+1)}|y)}{\pi(\theta^{(t)}|y)} = \exp\{t(\theta^{(t+1)}) - t(\theta^{(t)})\}, \tag{4}$$

in which normalizing constants, as is well known, are not needed. Here we propose two strategies for MCMC sampling even if $t(\theta) = \log\pi(\theta|y)$ is unknown, but its first and second derivatives are available in closed form. The first method (Section 2) considers an approximation based on a Rao score-type statistic based on (2). The second method (Section 3) is based on a local approximation through a Taylor expansion. We present an application to logistic regression with predictive matching priors (Section 4).

2 Method I: Approximation based on the Rao score statistic

A simple analytical way of using (2) is Bayesian statistic is to resort to a posterior distribution derived from a quadratic form of t_θ. This enables us to accomodate two important advantages of the Bayesian approach: the expressiveness of the posterior distribution and the convenient computational method of MCMC.

In particular, let $j(\theta) = -\ell_{\theta\theta}(\theta) = -\partial^2\ell(\theta)/\partial\theta^2$ be the observed Fisher information. Then the approximate posterior density takes the form

$$\pi(\theta|y) \mathrel{\dot{\propto}} \exp\left(-\frac{1}{2}t_\theta(\theta)^2 j(\theta)^{-1}\right) = \exp\left(-\frac{1}{2}\tilde{s}(\theta)\right), \tag{5}$$

where $\tilde{s}(\theta) = t_\theta(\theta)^2 j(\theta)^{-1}$ is a Rao score-type statistic based on (2) and the symbol "$\dot{\propto}$" means asymptotic proportionality to first order. In (4), (5) can be used for straightforward MCMC updating for the corresponding Bayesian posterior without any iterative optimization steps (Chernozbukov and Hong, 2003).

Here the idea is to recast (4) in terms of log-likelihood ratio type statistics and then replace the formers by Rao score tests. In particular,

$$\begin{aligned}\frac{\pi(\theta^{(t+1)}|y)}{\pi(\theta^{(t)}|y)} &= \exp\{(t(\theta^{(t+1)}) - t(\tilde{\theta})) - (t(\theta^{(t)} - t(\tilde{\theta}))\} \\ &\doteq \exp\{\tilde{s}(\theta^{(t)})/2 - \tilde{s}(\theta^{(t+1)})/2\}\end{aligned}$$

where $\tilde{\theta}$ is the posterior mode, such that $t_\theta(\tilde{\theta}) = 0$, and "$\doteq$" means asymptotic equality to first order.

3 Method II:I Local approximation through Taylor expansion

Assume, for notational simplicity, θ scalar. A Taylor expansion of $t(\theta)$ at θ_0 gives the approximation

$$t(\theta) \simeq t(\theta_0) + (\theta-\theta_0)t_\theta(\theta_0) + \frac{(\theta-\theta_0)^2}{2}t_{\theta\theta}(\theta_0), \tag{6}$$

where $t_{\theta\theta}(\theta) = (\partial t_\theta(\theta))/(\partial\theta)$. Using (6) we can approximate (4) using

$$\begin{aligned}t(\theta^{(t+1)}) - t(\theta^{(t)}) \approx\ & (\theta^{(t+1)} - \theta^{(t)})t_\theta(\theta_0) \\ &+ \frac{[(\theta^{(t+1)}-\theta_0)^2 - (\theta^{(t)}-\theta_0)^2]}{2}t_{\theta\theta}(\theta_0).\end{aligned} \tag{7}$$

Possible choices for θ_0 are $\theta^{(t)}$ or $\bar{\theta} = (\theta^{(t+1)} + \theta^{(t)})/2$. Note that

$$t_{\theta\theta}(\theta) = \ell_{\theta\theta}(\theta) + m_\theta(\theta) = \frac{\partial^2}{\partial\theta^2}\ell(\theta) + \frac{\partial}{\partial\theta}m(\theta) = \frac{\partial^2}{\partial\theta^2}\ell(\theta)\left\{1 + O(n^{-1})\right\}.$$

Hence, in (7) the quantity $t_{\theta\theta}(\theta)$ can be substituted by $\partial^2\ell(\theta)/\partial\theta^2$ with approximately the same level of accuracy.

4 Example: Predictive matching prior for logistic regression

In this section we discuss an example based on the logistic regression model and a predictive matching prior, i.e. a prior ensuring asymptotic equivalence of higher-order frequentist and Bayesian predictive densities (see, e.g., Datta and Mukerjee, 2004).

To give the expression of the proposed predictive matching prior, index notation and Einstein summation convention are convenient. Generic components of θ will be denoted by $\theta_r, \theta_s, \ldots$, with $r, s, \ldots = 1, \ldots, k$. First and second likelihood derivatives are ℓ_r and ℓ_{rs}. By equating the second-order asymptotic expansion of Corcuera and Giummolè (1999) of Bayesian predictive distributions and the frequentist modified estimative density of Komaki (1996), we obtain the proposed predictive matching prior, which is such that

$$t_{\theta_r}(\theta) = \frac{\partial_r \log \pi(\theta)}{\partial \theta_r} = -\frac{1}{2} i^{su}(\theta) \left(E_\theta\{\ell_{rsu}\} - E_\theta\{\ell_{rs}\ell_u\}\right), \tag{8}$$

where $E_\theta\{\cdot\}$ denotes expectation with respect to Y under θ and i^{rs} is the generic element of the inverse of $i(\theta) = E_\theta\{j(\theta)\}$. Note that the term on the right hand side of (8) corresponds to the Firth's adjustment (Firth, 1993) to the score function. In other words, if the prior density is choosen according to (8), then the right hand side of (2) is exactly the modified likelihood equation discussed by Firth (1993). In view of this, for general regular models, Firth's estimate coincides with the mode of the posterior distribution obtained using the default prior defined by (8). This prior thus validates the use of the method introduced by Firth (1993) for point estimation in the Bayesian framework.

Consider the binary logistic regression, where Y_i is Bernoulli with probability $\pi_i = P(Y_i = 1|x_i)$, where x_i is a known k-variate vector of regressors, $i = 1, \ldots, n$. The model can be expressed as

$$\log\left(\frac{\pi_i}{1-\pi_i}\right) = x_i^T \beta,$$

where β is an unknown vector of regression coefficients. The log-likelihood function for β is

$$\ell(\beta) = \sum_{j=1}^{k} \beta_j \sum_{i=1}^{n} x_{ij} y_i - \sum_{i=1}^{n} \log\left(1 + \exp^{\sum_{j=1}^{k} \beta_j x_{ij}}\right).$$

In this example the posterior distribution is analytically available since the predictive matching prior coincides with Jeffreys' prior, up to the normalisation constant, and hence classical MCMC can be performed. Therefore, we use it as a benchmark in order to assess the accuracy of the proposed approximation methods. We stress, however, that in many other practical cases, e.g. with non canonical links, (8) does not lead to Jeffreys' prior and and with Firth's adjustment, the posterior is not available, and thus classical MCMC is not possible. The Fisher information is $i(\beta) = j(\beta) = X^T WX$, where X is the design matrix, and W is a diagonal matrix with elements $(w_1, \ldots, w_n)$, with $w_i = \pi_i(1-\pi_i)$ $(1 \leq i \leq n)$. The modified likelihood equation (2) (Firth, 1993) and its first derivative is

$$t^*_{\beta_r}(\beta) = \sum_{i=1}^{n}(y_i - \pi_i)x_{ir} + t_{\theta_r}(\theta), \quad 1 \leq r \leq k.$$

For this model based on the canonical link, the posterior for β is available and is given by

$$\pi_J(\beta|y,X) \propto L(\beta;y)|i(\beta)|^{1/2}. \tag{9}$$

We compare the posterior (9) with its approximate versions obtained with Methods I and II, using the *endometrial* dataset. The latter has been first analysed by Heinze and Schemper (2002) and reports histology grade (HG, the binary response variable) and three risk factors (NV a binary indicator for the presence of neovasculation, PI the pulsality index of arteria uterina and EH the endometrium height) for 79 cases of endometrial cancer.

Consider the model with all the covariates included, i.e.,

$$\text{logit}(\pi_i) = \beta_0 + \beta_1 \texttt{NV}_i + \beta_2 \texttt{PI}_i + \beta_3 \texttt{EH}_i, \quad 1 \leq i \leq n. \tag{10}$$

Figure 1 compares the marginal posteriors of β_j $(0 \leq j \leq 3)$ obtained from (9) by classical MCMC with the corresponding approximations obtained by Method I (Taylor) and Method II (Rao). We generate 10^6 samples from (9) and from the two approximate posteriors, using the MH algorithm with a multivariate normal proposal distribution. The latter has scale matrix given by the negative of the inverse of the second derivative of $t(\theta)$. For (9) and the approximate posterior obtained by Method II the proposal was tuned to give approximately 0.4 acceptance rate; see Section 5 for the computational details. From Figure 1 we can conclude that the approximation obtained with Method I is very similar to the target (9), whereas the approximation obtained with Method II is less accurate.

5 Concluding remarks

In general, the higher is the acceptance rate the lower is the approximation error of Method I. We recognise that high acceptance rates in MCMC are generally not recommended because the posterior exploration of the MCMC algorithm for a finite time period may be too local. The issue of choosing an optimal acceptance rate is under investigation. However, a practical guidance to circumvent this issue would be as follows. Set a sequence of shrunken proposal matrices obtained by shrinking the main diagonal elements of the starting proposal scaling matrix, and with each of them generate an MCMC sample. Then, for this sequence of MCMC samples, which has increasing acceptance rates, monitor the shape of the resulting marginal

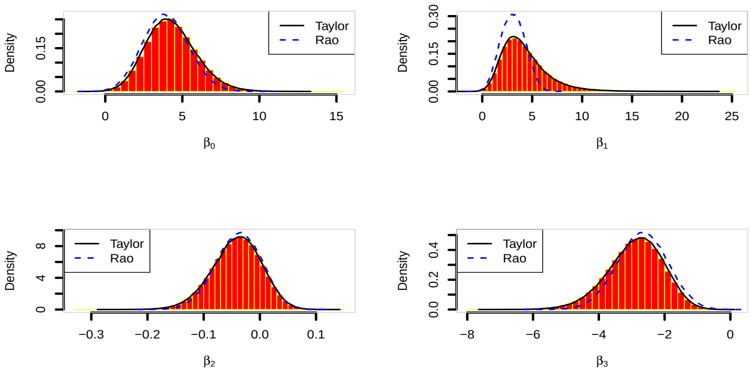

Fig. 1 Marginal posterior distributions for the logistic regression model with the *endometrial* data. The marginals of (10) are illustrated by histograms.

posteriors. If the shape of the latters is reasonably stable across two or three consequent posterior samples, then the MCMC sample with the lowest acceptance rate may by used for posterior inference. This is the strategy adopted in Section 4 which lead to an acceptance rate of 0.70.

A predictive measure of the additional loss of a non-optimal action under multiple priors

Una misura predittiva della perdita dovuta all'uso di un'azione non ottima in presenza di diverse a priori

Fulvio De Santis and Stefania Gubbiotti

Abstract In Bayesian decision theory, the performance of an action is measured by its posterior expected loss. In some cases it may be convenient/necessary to use a non-optimal decision instead of the optimal one. In these cases it is important to quantify the additional loss we incur and evaluate whether to use the non-optimal decision or not. In this article we study the predictive probability distribution of a relative measure of the additional loss and its use to define sample size determination criteria in one-sided testing.
Abstract L'analisi delle decisioni bayesiane prevede che la qualità di un'azione si misuri in termini della sua perdita attesa a posteriori. In alcuni casi può essere conveniente/necessario adottare una decisione non ottima al posto di quella ottima. Per valutare l'opportunità di questa scelta, è importante quantificare la perdita aggiuntiva che essa comporta. Oggetto di questo lavoro è lo studio della distribuzione predittiva di una misura relativa di tale perdita addizionale e il suo impiego per la scelta della numerosità campionaria nei problemi di test di ipotesi unilaterali.

the parameter. Let π_e and π_o denote their priors and let a_e and a_o be the actions that minimize the two posterior expected losses. Furthermore, let us suppose that the first decision makers is forced to take the action a_o, although it is not optimal from her/his point of view: under π_e, the posterior expected loss of a_o is in fact larger than the posterior expected loss of a_e. Finally, assume that the sample size of the experiment is selected by a third actor using the predictive distribution of the data based on the prior π_d, that, in general, is different from both π_o and π_e. The goal of the experiment planner is to determine the minimal sample size such that a relative predictive measure of the additional loss due to the use of a_o rather than a_e is sufficiently small.

Statistical decision problems under several actors have been previously considered, for instance, in [5], [6] and [4]. In this paper we extend to the testing problem the results of [3] (related to point-estimation) and we focus in particular on the one-sided testing set-up.

The outline of the article is as follows. In Section 2 we formalize the proposed methodology for a generic statistical decision problem: we introduce a relative measure of additional loss due to a non optimal action and the related predictive criterion for the selection of the sample size. In Section 3 the methodology is developed for a one-sided testing problem for a real-valued parameter. Results are then specialized to one-sided testing of a normal mean (Section 4) and some numerical examples are provided in Section 4.1. Finally, Section 5 contains some concluding remarks.

2 Methodology

Let $X_1, X_2, \ldots, X_n$ be a random sample from $f_n(\cdot|\theta)$, where θ is an unknown parameter, $\theta \in \Theta$. Let $a \in \mathscr{A}$ denote a generic action for a decision problem regarding θ and $L(a,\theta)$ the loss of a when the true parameter value is θ. We assume that two competing priors, π_o and π_e, are available for θ. Given an observed sample $\boldsymbol{x_n} = (x_1, x_2, \ldots, x_n)$, let $\pi_j(\theta|\boldsymbol{x_n})$ be the posterior distribution of θ from prior π_j, and

$$\rho_j(\boldsymbol{x_n}, a) = \mathbb{E}_{\pi_j}\left[L(a,\theta)|\boldsymbol{x_n}\right] = \int_{\Theta} L(a,\theta)\pi_j(\theta|\boldsymbol{x_n})d\theta$$

be the posterior expected loss of an action a, for $j = o, e$. Let a_j denote the optimal action with respect to $\pi_j(\theta|\boldsymbol{x_n})$. The performance of the action a_o when the expected loss is evaluated with respect to $\pi_e(\theta|\boldsymbol{x_n})$ is then $\rho_e(\boldsymbol{x_n}, a_o) = \mathbb{E}_{\pi_e}\left[L(a_o,\theta)|\boldsymbol{x_n}\right]$. If a_o is used instead of a_e, the *relative additional expected loss* is

$$\bar{A}_{o,e}(\boldsymbol{x_n}) = \frac{\rho_e(\boldsymbol{x_n}, a_o) - \rho_e(\boldsymbol{x_n}, a_e)}{\rho_e(\boldsymbol{x_n}, a_o)}.$$

When $\bar{A}_{o,e}$ is small the non-optimal action a_o performs well even under the prior assumptions represented by π_e. Before observing the data, $\bar{A}_{o,e}(\boldsymbol{X_n})$ is a sequence of r.v. that converges in probability to zero, as n increases. In order to define a sample size criterion we focus on $e_n = \mathbb{E}_{m_d}\left[\bar{A}_{o,e}(\boldsymbol{X_n})\right]$, where $\mathbb{E}_{m_d}[\cdot]$ denotes the expected value with respect to the sample data distribution, $m_d(\boldsymbol{x_n}) = \int_\Theta f(\boldsymbol{x_n}|\theta)\pi_d(\theta)d\theta$, where π_d is the design prior. Hence, for a desired threshold γ, $n^\star = \min\{n \in \mathbb{N} : e_n \leq \gamma\}$ is the optimal sample size that depends on three priors (π_d, π_e, π_o).

3 One-sided Testing

Consider the set up of one-sided testing, i.e. $H_1 : \theta \leq \theta_t$ vs. $H_2 : \theta > \theta_t$, with $\theta_t \in \mathbb{R}$. Let $\mathscr{A} = \{a^{(1)}, a^{(2)}\}$ be the two terminal decisions, where $a^{(i)}$ denotes the choice of H_i, $i = 1, 2$, and

$$L(a^{(1)}, \theta) = b_2 \times 1_{\{\theta:\theta>\theta_t\}}(\theta) \quad \text{and} \quad L(a^{(2)}, \theta) = b_1 \times 1_{\{\theta:\theta\leq\theta_t\}}(\theta)$$

their loss functions ($b_i > 0$, $i = 1, 2$), with $1_A(\cdot)$ the indicator function of the set A. Then the posterior expected losses of $a^{(1)}$ and $a^{(2)}$ are

$$\rho_j(\boldsymbol{x_n}, a^{(1)}) = b_2\,(1 - \mathrm{F}_j(\theta_t|\boldsymbol{x_n})) \qquad \text{and} \qquad \rho_j(\boldsymbol{x_n}, a^{(2)}) = b_1 \mathrm{F}_j(\theta_t|\boldsymbol{x_n}),$$

where $F_j(\cdot|\boldsymbol{x_n})$ is the c.d.f. associated to $\pi_j(\theta|\boldsymbol{x_n})$, $j = o, e$. In this case it is easy to check that the optimal decision function $a_j(\boldsymbol{x_n})$ is

$$a_j(\boldsymbol{x_n}) = \arg\min_{a\in\mathscr{A}} \rho_j(\boldsymbol{x_n}, a) = \begin{cases} a^{(1)} \text{ if } \boldsymbol{x_n} \in \mathscr{Z}_j^{(1)} \\ a^{(2)} \text{ if } \boldsymbol{x_n} \in \mathscr{Z}_j^{(2)} \end{cases} \qquad j = o, e.$$

where

$$\mathscr{Z}_j^{(1)} = \{\boldsymbol{x_n} :\ \rho_j(\boldsymbol{x_n}, a^{(1)}) < \rho_j(\boldsymbol{x_n}, a^{(2)})\} = \{\boldsymbol{x_n} :\ b_2\,(1 - \mathrm{F}_j(\theta_t|\boldsymbol{x_n})) < b_1 \mathrm{F}_j(\theta_t|\boldsymbol{x_n})\}$$

and $\mathscr{Z}_j^{(2)}$ is its complement. The posterior expected loss of the decision function $a_j(\boldsymbol{x_n})$ w.r.t. π_e is

$$\rho_e(\boldsymbol{x_n}, a_j) = \begin{cases} b_2\,(1 - \mathrm{F}_e(\theta_t|\boldsymbol{x_n})) \text{ if } \boldsymbol{x_n} \in \mathscr{Z}_j^{(1)} \\ b_1\,\mathrm{F}_e(\theta_t|\boldsymbol{x_n}) \qquad\quad \text{if } \boldsymbol{x_n} \in \mathscr{Z}_j^{(2)} \end{cases} \qquad j = o, e.$$

Therefore, noting that $\rho_e(\boldsymbol{x_n}, a_e) = \min\{b_1 \mathrm{F}_e(\theta_t|\boldsymbol{x_n}), b_2\,(1 - \mathrm{F}_e(\theta_t|\boldsymbol{x_n}))\}$, we obtain

$$\bar{A}_{o,e}(\boldsymbol{x_n}) = \xi_e(\boldsymbol{x_n}) 1_{\mathscr{Z}_{o,e}}(\boldsymbol{x_n}) \tag{1}$$

where

$$\xi_e(\boldsymbol{x_n}) = 1 - \min\left\{\frac{b_1}{b_2}\frac{\mathrm{F}_e(\theta_t|\boldsymbol{x_n})}{1 - \mathrm{F}_e(\theta_t|\boldsymbol{x_n})}, \frac{b_2}{b_1}\frac{1 - \mathrm{F}_e(\theta_t|\boldsymbol{x_n})}{\mathrm{F}_e(\theta_t|\boldsymbol{x_n})}\right\}. \tag{2}$$

and

$$\mathscr{Z}_{o,e} = \{\boldsymbol{x_n} \in \mathscr{X}^n : a_o(\boldsymbol{x_n}) \neq a_e(\boldsymbol{x_n})\} = \left(\mathscr{Z}_o^{(1)} \cap \mathscr{Z}_e^{(2)}\right) \cup \left(\mathscr{Z}_o^{(2)} \cap \mathscr{Z}_e^{(1)}\right)$$

is the set of $\boldsymbol{x_n}$ leading to conflicting terminal decisions under π_e and π_o respectively. Now, note that $\mathscr{Z}_j^{(1)}$ can be rewritten in terms of the ε-quantile of the posterior distribution of θ, $q_\varepsilon^j(\boldsymbol{x_n})$ with $\varepsilon = \frac{b_2}{b_1+b_2}$, namely

$$\mathscr{Z}_j^{(1)} = \left\{\boldsymbol{x_n} \in \mathscr{Z} : \frac{1 - \mathrm{F}_j(\theta_t|\boldsymbol{x_n})}{\mathrm{F}_j(\theta_t|\boldsymbol{x_n})} < \frac{b_1}{b_2}\right\} = \left\{\boldsymbol{x_n} \in \mathscr{Z} : \theta_t > q_\varepsilon^j(\boldsymbol{x_n})\right\}. \qquad (3)$$

Therefore

$$\mathscr{Z}_o^{(1)} \cap \mathscr{Z}_e^{(1)} = \left\{\boldsymbol{x_n} \in \mathscr{Z} : q_\varepsilon^M(\boldsymbol{x_n}) < \theta_t\right\} \text{ and } \mathscr{Z}_o^{(2)} \cap \mathscr{Z}_e^{(2)} = \{\boldsymbol{x_n} \in \mathscr{Z} : q_\varepsilon^m(\boldsymbol{x_n}) > \theta_t\},$$

where $q_\varepsilon^m(\boldsymbol{x_n}) = \min\{q_\varepsilon^e(\boldsymbol{x_n}), q_\varepsilon^o(\boldsymbol{x_n})\}$ and $q_\varepsilon^M(\boldsymbol{x_n}) = \min\{q_\varepsilon^e(\boldsymbol{x_n}), q_\varepsilon^o(\boldsymbol{x_n})\}$. Hence we have

$$\mathscr{Z}_{o,e} = \left\{\boldsymbol{x_n} \in \mathscr{Z} : q_\varepsilon^m(\boldsymbol{x_n}) < \theta_t < q_\varepsilon^M(\boldsymbol{x_n})\right\}. \qquad (4)$$

Finally, from (1)

$$e_n = \int_{\mathscr{Z}} \bar{A}_{o,e}(\boldsymbol{x_n}) m_d(\boldsymbol{x_n}) d\boldsymbol{x_n} = \int_{\mathscr{Z}_{o,e}} \xi_e(\boldsymbol{x_n}) m_d(\boldsymbol{x_n}) d\boldsymbol{x_n}$$

that, in general, must be computed via Monte Carlo approximation. From the above expression we can note that e_n is a monotone function of the Lebesgue measure of $\mathscr{Z}_{o,e}$. An alternative sample size criterion could be based on the predictive probability p_n of the samples yielding conflict. Recalling that, $\forall \boldsymbol{x_n} \in \mathscr{Z}$, $\xi_e(\boldsymbol{x_n}) \leq 1$, it is easy to check that $p_n = \mathbb{P}_{m_d}[\mathscr{Z}_{o,e}] = \mathbb{E}_{m_d}[1_{\mathscr{Z}_{o,e}}(\boldsymbol{X_n})]$ is always smaller than or equal to $e_n = \mathbb{E}_{m_d}[\xi_e(\boldsymbol{X_n}) 1_{\mathscr{Z}_{o,e}}(\boldsymbol{X_n})]$. Therefore, for a given γ, e_n always yields a smaller sample size. The idea is that in e_n the contribution of each sample corresponding to a conflicting decision depends on the strength of the discrepancy in evidence it gives to the two hypotheses, whereas in p_n, it is invariably equal to one.

4 Results for the Normal mean

Let us now further assume that $X_i|\theta \sim \mathrm{N}(\theta, \sigma^2)$, $i = 1, 2, \ldots, n$ and that $\pi_j(\cdot)$ are conjugate priors, i.e. $\theta|\sigma^2 \sim \mathrm{N}(\mu_j, \sigma^2/n_j)$, $j = o, e$. When σ^2 is assumed to be known, the posterior distribution of θ is Normal with mean $\mu_j(\boldsymbol{x_n}) = \frac{n_j\mu_j + n\bar{x}_n}{n_j+n}$ and standard deviation $\sigma_j(\boldsymbol{x_n}) = \frac{\sigma}{\sqrt{n_j+n}}$. In this case $\bar{A}_{o,e}$ can be expressed in terms of Φ, z_ε and $W_j(\boldsymbol{x_n})$, where $\Phi(\cdot)$ is the standard normal c.d.f., z_ε its ε-quantile and

$$W_j(\boldsymbol{x_n}) = \frac{\mu_j(\boldsymbol{x_n}) - \theta_t}{\sigma_j(\boldsymbol{x_n})}, \qquad j = o, e.$$

First, from Equation (2) we have

$$\xi_e(\boldsymbol{x_n}) = 1 - \min\left\{\frac{b_1}{b_2}\frac{1-\Phi(W_e(\boldsymbol{x_n}))}{\Phi(W_e(\boldsymbol{x_n}))}, \frac{b_2}{b_1}\frac{\Phi(W_e(\boldsymbol{x_n}))}{1-\Phi(W_e(\boldsymbol{x_n}))}\right\},$$

Then, from (3), it follows that

$$\mathscr{X}_j^{(1)} = \left\{\boldsymbol{x_n} \in \mathscr{X} : W_j(\boldsymbol{x_n}) = \frac{\mu_j(\boldsymbol{x_n}) - \theta_t}{\sigma_j(\boldsymbol{x_n})} < z_{1-\varepsilon}\right\}$$

and finally

$$\mathscr{X}_{o,e} = \{\boldsymbol{x_n} \in \mathscr{X} : W_m(\boldsymbol{x_n}) < z_{1-\varepsilon} < W_M(\boldsymbol{x_n})\}, \qquad (5)$$

where $W_m(\boldsymbol{x_n}) = \min\{W_o(\boldsymbol{x_n}), W_e(\boldsymbol{x_n})\}$ and $W_M(\boldsymbol{x_n}) = \max\{W_o(\boldsymbol{x_n}), W_e(\boldsymbol{x_n})\}$.

4.1 Numerical example

Let us consider $\theta_t = 1$ and let the design prior be a Normal density of parameters $\mu_d = 1.5$, $n_d = 10$. Thus, π_d assigns to H_1 a prior probability as small as 0.056. Figure 1 shows the behavior of e_n as n increases, under two alternative choices of μ_e for different values of the prior sample sizes n_e and n_o. In the former case, we assume that there is a certain contrast between the two priors: π_e, centred on the threshold θ_t (e.g. $\mu_e = 1$), expresses a neutral attitude towards the two hypotheses, whereas π_o favors the null hypothesis (e.g. $\mu_o = 0$). In the left panel of Figure 1 for small values of n (due to the predominant role of the prior weights n_e and n_o) e_n increases up to a maximum value and then it definitively decreases, tending to zero more and more rapidly for smaller values of the prior sample sizes n_e and n_o. In the latter set-up, the conflict between π_e and π_o is emphasized, π_e supports the alternative hypothesis H_2 and μ_e is even larger than μ_d (i.e. $\mu_o = 0$ and $\mu_e = 2$). As shown in the right panel, e_n monotonically decreases as a function of n from 1 to 0. As before, when the two conflicting priors are more and more concentrated, the expected value of $\bar{A}_{o,e}$ is uniformly larger and, consequently, a larger number of observations is required for the conflict to be resolved.

Finally in Figure 2 we illustrate by examples the relationship that holds in general between e_n and p_n, that is $p_n < e_n$, as commented in the final remark of Section 3.

5 Future research directions

The article leaves open the possibility of further developments, such as the application to non-normal models and to more challenging (not necessarily one-dimensional) testing set-ups. Moreover instead of considering only one prior π_e, we could extend our approach by considering an entire class of priors Γ. In this case, we

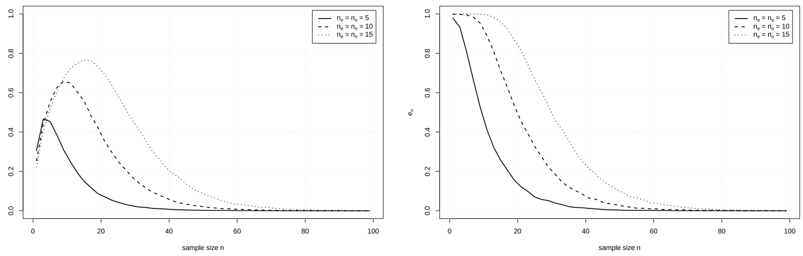

Fig. 1 e_n as a function of the sample size n, with $\mu_e = 1$ (*left panel*) and $\mu_e = 2$ (*right panel*) for different values of n_e and n_o, given $\theta_t = 1$, $\sigma = 1$, $\mu_d = 1.5$, $n_d = 10$, $\mu_o = 0$

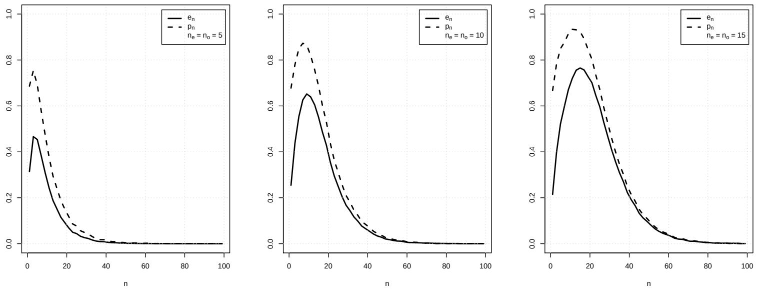

Fig. 2 Behavior of e_n and p_n for increasing values of n, with $\mu_e = 1$ (first row) and $\mu_e = 2$ (second row) for different values of n_o and n_e, given $\theta_t = 1$, $\sigma = 1$, $\mu_d = 1.5$, $n_d = 10$, $\mu_o = 0$.

would be interested in looking at the largest relative additional loss of a_o as π_e varies in Γ and the sample size is chosen by replacing e_n with $e_n^{\Gamma} = \mathbb{E}_{m_d}[\sup_{\pi_e \in \Gamma} \bar{A}_{o,e}]$.

Bayesian estimation of number and position of knots in regression splines

Stima Bayesiana del numero e della posizione dei nodi in spline di regressione

Gioia Di Credico, Francesco Pauli and Nicola Torelli

Abstract Regression splines, based on piecewise polynomials, are useful tools to model departures from linearity in the regression context. The number and location of the knots can be of interest in many contexts since they can detect possible change points in the relationship between the variables. This work is focused on the estimate of both number and location of knots in the simple case where linear truncated splines are chosen to represent the relationship, in this case, the position of the knot detects a change in the slope. In a Bayesian context, we propose a two-step procedure, to first determine the true number of knots and then to fit the final model estimating simultaneously location of knots and regression and spline coefficients.
Sommario *Le spline applicate a modelli di regressione con polinomi a tratti possono essere utili al fine di descrivere relazioni non lineari. In alcuni contesti e immaginando di limitare l'attenzione a splines con componenti lineari, può essere interessante conoscere il numero e la posizione dei nodi che sono quindi i cambi di pendenza della retta di regressione. Tuttavia, stimare numero e posizione dei nodi aggiunge una componente di stima non lineare al problema di ottimizzazione. Proponiamo una procedura in due passi che prima determina il numero ottimale dei nodi e poi ne stima la posizione, congiuntamente agli altri coefficienti del modello. La metodologia viene applicata qui ai modelli lineari adottando un approccio bayesiano.*

Key words: Regression splines, Stan, spike-and-slab priors, knot location

1 Introduction

When modelling the relationship between a response and some (continuous) covariates the linearity assumption turns out to be too restrictive in many contexts. Naive solutions to overcome this limitation such as categorization of the predictor or its polynomial representation have well-known drawbacks.

A viable alternative is represented by spline functions. They are defined as piecewise polynomials with a fixed degree whose joint points are called knots. Splines are highly flexible, in fact, varying the number and position of knots may lead to extremely different shapes and a major risk is to overfit the data. A classical approach consists in using an optimizing criterion with a suitable penalization to control the roughness of the function. Other techniques proposed in the literature include the use of variable selection to choose basis function [6], or employing samplers that allow for varying dimension of the parameter [2, 3].

Assuming that the number and position of knots may have an important and substantial interpretation, here we consider their estimation following one of the most recent approaches to variable selection in a Bayesian context. Estimating the positions of the knots is not an easy task and, for a fixed degree, regression coefficients and locations of knots have to be estimated simultaneously, turning the standard estimation procedure into a nonlinear optimization problem. In the sequel, we propose a method to estimate the number and position of knots with a two-step procedure.

2 Methods

Consider the model

$$y_i = z_i^\intercal \alpha + f(x_i) + \varepsilon_i, \quad i = 1, \ldots, n$$

where z is the covariates vector that enters linearly in the model, α is the vector of regression coefficients, x is a continuous variable evaluated through a smooth function $f : \mathbb{R} \to \mathbb{R}$, described with a spline with few knots and ε is an i.i.d. Gaussian random error component.

We restrict our analysis to those situations in which a low number of knots can be adequate and their positions are directly interpretable and of specific interest for the analysis. This is the case, for example, when truncated power basis (TPB) of order one is used since in this case positions of knots represent changing points for the slope. One of the main drawbacks of truncated power basis representation is that the basis is not orthogonal, which can lead to numerical instability and slow convergence of the optimization algorithm. Keeping a low number of knots alleviates the issue [5].

Let then

$$f(x) = \beta_0 + \beta_1 x + \sum_{k=1}^{K} \gamma_k (x - \xi_k)_+, \tag{1}$$

where ξ_k is the position of the k-th knot and K is the total number of knots, and

$$(x-\xi)_+ = \begin{cases} x-\xi, & \text{if } x \geq \xi \\ 0, & \text{otherwise} \end{cases} \tag{2}$$

is the truncated linear function. Given the number of knots, parameters estimation reduces to maximum likelihood estimate. A usual approach is to choose the knot locations using standard criteria (such as quantiles of the predictor distribution, uniformly distributed knots on the range of the independent variables and user-defined knots following a priori information [5]), estimate models with a different number and location of knots and compare them through standard criteria, such as AIC, BIC or GCV. This procedure often results in a not clear discrimination among all competing models.

In order to enhance the fit of the model, a possible extension is to consider locations of knots as parameters to be estimated along with other regression coefficients. In such a case, within a maximum likelihood approach, exploration of the objective function surface could locate local maxima leading to apparent solutions strongly dependent on starting values. A Bayesian specification of the model and exploring of the posterior distribution, possibly by using MCMC simulations, could prove in this case much more effective.

Our aim is to estimate both number and location of knots, thus a preliminary idea is to estimate several models with free knot locations and with increasing but fixed number of knots. Knots are constrained to be ordered and their prior distributions are Uniform on the range of the variable. Vague priors on the regression and spline coefficients are chosen (zero-centered normal with large variance). We will refer to this model as the no variable selection (NVS) model.

Models with an increasing number of knots were compared on the basis of diagnostic tools such as traceplots and $\hat{R}$ to check convergence of parameters and information criteria were used to choose the best model among the estimated ones. The main drawback of this procedure is a large number of models that one needs to consider and the implied computational effort in high dimensional problems. However, results obtained on simulated data on the basis of these diagnostic tools show that it can lead to reasonable estimates and that convergence of chains for knot related parameters is univocal only if the number of specified knots is lower or equal to the true one.

This prompted us to consider a two-step procedure:

- select the optimal number of knots considering a large, possibly, overparameterized model,
- fit the final model by simultaneously estimating locations of knots and regression and spline coefficients.

In the first step, we estimate a model having more knots than reasonably warranted. This leads to an overparameterized model where the posterior of some knot locations are expected to concentrate at the limits of the predictor range. To assess convergence of the spline parameters, our advice is to run several chains and look at the results of each chain separately. Indeed, overparameterizing the model may lead to chains which converge at different points. Since each knot location is uniquely linked to a spline coefficient, we evaluate the presence of a knot based on the analysis of the associated coefficient posterior distribution.

The concept underlying the proposed methodology is to perform variable selection on the basis functions, for this purpose we employ one of the most common approaches in Bayesian literature: that based on the definition of spike-and-slab priors. Several versions have been proposed in the literature [4] but, generally speaking, prior distributions for the regression coefficients are defined with a spike component, usually highly concentrated around zero, and a diffused slab part. This is the case of the stochastic search variable selection approach (SSVS), that defines a mixture distribution for each parameter that has to be selected [4]. This type of methodology gives us the opportunity to evaluate the presence of a variable through the marginal posterior distribution of the mixing proportion. Starting from the NVS model specification, we set a prior distribution on each spline parameter γ_k such that

$$\pi(\gamma_k|\lambda_k) = \lambda_k N(0,\sigma_{sl}) + (1-\lambda_k)N(0,\sigma_{sp}),$$

where the mixing proportion $\lambda_k \sim Beta(a,b)$, with $a = b$. Standard deviations of the two mixture components, σ_{sl} and σ_{sp}, are chosen to be respectively large and small. Appropriate values have to be evaluated taking into account the unit of measurement of dependent and independent variables.

Our method adapts the SSVS approach by assuming λ_k to be dependent on the knot location ξ_k. The prior distributions of the ordered knots remain defined as Uniform on the support of the variable X and independent from both the mixing proportion λ and the coefficient γ. Each coefficient γ_k, conditioned on the mixing parameter λ_k follows the same mixture distribution of two components specified in the SSVS approach described above, while each element of the mixing proportion vector λ is now defined as:

$$\lambda_k|\xi_k \sim Beta(a,b_k),$$

where a is a positive but very small value and $b_k : [\min(X);\max(X)] \to [a;1+a]$ is a U-shaped even function of the knot location which returns values close to $1+a$ when the knot is near the boundaries of the variable, while it is almost uniform and close to a elsewhere. In practice, the prior for the mixing parameter swings between a beta U-shaped distribution when the knot location is on plausible values and a beta distribution highly concentrated on zero when the knot is close to the boundaries. All the other prior distributions remain defined as in the previous model specification.

In the next section, we compare results from (i) the proposed method, named later on SSVSξ, with (ii) the ones obtained from the SSVS approach and (iii) the same model without a variable selection procedure, NVS.

3 Preliminary results

We simulate data from the linear regression model

$$y_i = 6 + 2x_i - 5(x_i - 2.7)_+ + 8(x_i - 4.3)_+ + \varepsilon_i, \quad i = 1, \ldots, 500,$$

where $\varepsilon_i \sim$ i.i.d. $N(0,3)$ and the predictor X is defined on the interval $[0;10]$. Two knots are placed respectively in 2.67 and 4.33. We set the parameter a of the mixing proportions λ for the SSVS and the SSVSξ models equal to 0.5. Moreover, we chose σ_{sl} equal to 100 and σ_{sp} equal to 0.1. Standard deviations of the prior distributions on spline coefficients and intercept were chosen equal to 100.

We run 10 chains with 2000 iterations each. Posterior inference is based on the last 1000 draws of each chain. To support the complete exploration of the posterior distribution, initial values for the location of the knots are chosen widely spread on the range of the predictor variable X. Spline coefficients and intercept are initialized at zero. The three models are fitted with a different number of knots (respectively with 2, 5 and 10 knots). The interest lies in the parameter estimates, both spline coefficients and knot locations, and in the analysis of the chains behavior.

The number of knots can be chosen in the SSVS and SSVSξ models looking at the plots in Fig 1. The x-axis represents the specified number of knots in the over-parameterized models, while the y-axis represents the posterior mean of the mixing proportion. Vectors of posterior means are sorted in descending order and each line corresponds to one chain. In both models performing variable selection, the selected number of relevant knots is always equal to 2, even if the SSVSξ approach makes a slightly clearer distinction with respect to the classic SSVS method.

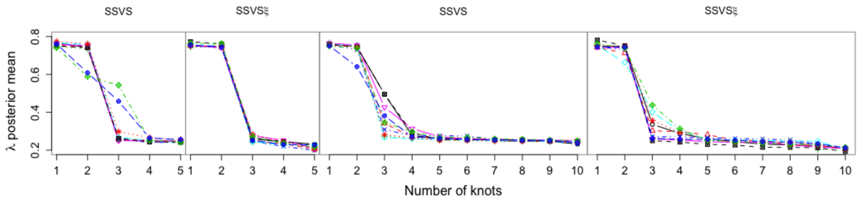

Fig. 1 Posterior means of the mixing parameters λ in the overparameterized SSVS and SSVSξ models with 5 and 10 knots.

The second step of the procedure is to estimate the models with the selected number of knots.

The three models are compared by means of diagnostic tools, such as traceplots, $\hat{R}$, effective sample size (n$_{eff}$) and analysis of marginal posterior distributions. Due to space constraints, in table 1 we report estimates only for the SSVSξ model, parameter estimates are close to the true parameter values. The greatest discrepancies among the model results are on the order of one decimal point. For the three models, $\hat{R}$ statistics equal to 1 suggest that the chains show good mixing, but differences in the n$_{eff}$ estimates highlight a lower estimate stability of SSVS model compared to the other two fitted models.

Table 1 Posterior distributions of the SSVSξ model parameters. The model is estimated with the true number of knots. $\hat{R}$ and n$_{eff}$ statistics.

Parameter	true	mean	sd	2.5%	50%	97.5%	Rhat	n$_{eff}^{SSVS\xi}$	n$_{eff}^{SSVS}$	n$_{eff}^{NVS}$
β_0	6	6.6	0.6	5.4	6.6	7.6	1.0	4644	762	3313
β_1	2	2.1	0.4	1.3	2.1	3.1	1.0	3039	667	2171
γ_1	-5	-4.5	0.7	-5.8	-4.5	-3.3	1.0	2290	287	3468
γ_2	8	7.4	0.6	6.3	7.3	8.5	1.0	2704	410	2690
ξ_1	2.7	2.4	0.2	1.9	2.4	2.8	1.0	3183	3105	2066
ξ_2	4.3	4.4	0.1	4.2	4.4	4.5	1.0	4634	597	5196
λ_1		0.7	0.3	0.1	0.8	1.0	1.0	9387	3717	
λ_2		0.7	0.3	0.1	0.8	1.0	1.0	8299	7027	

According to this limited evidence, SSVSξ approach should be chosen to perform the proposed procedure to estimate the number and location of the knots. Among the three tested models, SSVSξ gives us the best results in terms of estimation of the parameters and in terms of convergence of the algorithm.

Future developments involve (i) fitting more complex models considering also higher degree splines or multidimensional spline representation and (ii) comparing this procedure with alternative Bayesian approaches proposed in the literature (such as those mentioned in the Sec.1.

The importance of historical linkages in shaping population density across space

L'importanza della dimensione temporale nella modellizzazione spaziale della densità di popolazione

Ilenia Epifani and Rosella Nicolini

Abstract This study aims to investigate the extent to which history matters in shaping population distribution across space. In the wake of the current literature, the idea is to model individual location preferences by focusing on selected local determinants (neighborhood, education, income, amenities and distance from the CBD), while also taking into account temporal and spatial dependence in location choices. Our preliminary results revel the importance of segregation factors in shaping recent population density distribution.
Abstract *Il presente studio analizza l'importanza della dimensione temporale come determinante della distribuzione spaziale della densità di popolazione. In linea con i contenuti della letteratura contemporanea, la nostra idea è di modellizzare le scelte di localizzazione degli individui in base a delle preferenze strettamente relazionate con alcune determinanti territoriali specifiche (tipo di quartiere, educazione, reddito, amenità presenti nel territorio e distanza dal centro d'interessi -definito come CBD-) in aggiunta a condizioni di autocorrelazione spaziale e di dipendenza temporale del processo di decisione. Quest'ultima, in particolare, garantisce la condizione di coerenza intertemporale delle decisioni prese dagli individui. I nostri primi risultati rivelano che la combinazione delle precedenti determinanti genera un effetto segregazione che assume un ruolo di primo piano per approssimare la distribuzione spaziale della densità di popolazione.*

Key words: Bayesian inference, Hierarchical dynamic model, Population distribution, Spatial random effects

1 Introduction and Data Description

Individual location choices are often driven by environmental factors beyond subjective preferences or budget constraints. As widely discussed in the critical contribution by [8] the characteristics of a neighborhood play an extremely important role in shaping individual choices. Neighborhood features matter both at present but also in throught reputation effects. For instance, think of a neighborhood that consolidates its reputation as a ghetto versus another that recently started hosting people of different ethnic origins. The former is more likely to impact individual location decisions compared to the latter. This study develops around the interplay between the relevance of environmental factors and historical dimensions in location choices

of the population in Massachusetts in a monocentric framework. The idea is to define a dynamic statistical model that allows for accounting for the way past values of some selected location determinants (referring to both a specific place and surrounding territories) may influence the present individual location choice. Thus, we are able to tract potential changes in the relative weight of local determinants and spillover effects in location-choice decisions across time. As argued in [1], [2], the geographical structure of Massachusetts simplifies the setting and, the historical and consolidated attractiveness of Boston as a Central Business District makes it possible to focus on a monocentric distribution function.

We built a Bayesian dynamic Log-Normal Model with random spatial normal frailties to investigate census tract data coming from the NHGIS project [6], the US census and the American Community Survey (ACS) for the 14 counties in Massachusetts for the period 1970-2010. The comparability of the geographical units is based on the information obtained from the TIGER/Lines Finder project. A census tract is identified as an area in which 1500 to 8000 habitants live (with an optimal size of 4000 persons). The tract is often split into two (or more) subtracts when goes over that limit or when the spatial territory is affected by other structural changes. Unfortunately, there is no a clear mechanism that allows for tracking with precision these changes over time, whereas their number increased progressively: census tracts were 1950 in 1970, 1193 in 1980, 1323 in 1990, 1361 in 2000 and 1472 in 2010.

Let $Y_{ij}^{(t)}$ be the population density (per square mile) of the jth census tract within the ith county of Massachusetts at decade t, for $i = 1,\ldots,14$ and $t = 1970, 1980, 1990, 2000, 2010$. A preliminary explorative analysis of $Y_{ij}^{(t)}$ at county level reveals that the sample means per county exhibit temporal patterns different each from either county, but relatively stable within each county. Instead, the standard deviations proportionally shrink except for the most remote counties. These features suggest that the introduction of some spatial county random effects in the model can capture the heterogeneity among counties, whereas, the different patterns of the sample variances suggest a county-stratum variance heteroscedasticity.

In our analysis, the distance $D_{ij}^{(t)}$ of census tract i (in county j at decade t) from Boston is one of the key predictors of the density population and it is defined as a distance between two centroids: one being the centroid of the census tract with the highest population density (in a specific year) and the other being the centroid of any other remaining existing census-tract in the sample for that year. $D_{ij}^{(t)}$ is computed as the Euclidean value according to the geographical coordinates of the two centroids, as suggested by geographers. As our unit of reference (namely, census tracts) changes over time, distance $D_{ij}^{(t)}$ is a time-dependent predictor of the density population. Along with $D_{ij}^{(t)}$, we selected the ethnic composition, education and income as predictors for the population density. In particular, ethnic feature $M_{ij}^{(t)}$ of i th census tract is computed as the proportion of whites (over the total population). Income enters the statistical model via the income $I_{ij}^{(t)}$ per-capita per-census tract and via the Gini index $G_{ij}^{(t)}$ that measures the dispersion and inequality of income. Income $I_{ij}^{(t)}$ is not collected in 1970, so we can not use it in the regression for the first decade. Education in each census tract j enters the model via an index $E_{ij}^{(t)}$ obtained in the following way: first census-tracts were ranked according to the relative frequency of citizens having a high degree of education, then according to the relative frequency of persons having a low degree of education and hence the second value of ranking were substracted from the first. Finally, the presence of amenities is proxied by the proportion Z_i of free land (water areas) in county i: as discussed in [4], water can be considered a fundamental factor (or amenity) in creating recreational spaces for leisure time; moreover, as discussed in [2], it is reasonable to consider Z_i constant over time.

2 Bayesian Dynamic Hierarchical Log-Normal Models

Our empirical analysis is based on an augmented strategy. We begin with estimating a model without any kind of frailties. Then, we introduce some independent county-frailties. Finally, we elaborate a model with frailties having both a temporal and spatial dependence. In the light of previous remarks, we specified the following likelihood function

$$\begin{aligned}\log Y_{ij}^{(t)}|\boldsymbol{w}_t, \boldsymbol{\beta}_t, b_{0t}, b_{1,t}, \sigma_i^2 &\overset{\text{indep.}}{\sim} \\ &\overset{\text{indep.}}{\sim} \mathrm{N}\left(w_{it} + b_{0t} + b_{1t}Z_i + \beta_{1t}D_{ij}^{(t)} + \beta_{2t}M_{ij}^{(t)} + \beta_{3t}G_{ij}^{(t)} + \beta_{4t}E_{ij}^{(t)} + \beta_{5t}I_{ij}^{(t)} + \beta_{6t}I_{ij}^{(t)} \times D_{ij}^{(t)}\ ,\ \sigma_i^2\right), \quad (1)\end{aligned}$$

where $\boldsymbol{w}_t = (w_{1t}, \dots, w_{14t})$ is the vector of 14 county random effects at time t. The $\boldsymbol{w}_t$s' capture the common features shared by the census tracts (in the same county), but they are different from county to county; each w_{it} summarizes all the determinants of the population density, either unobservable or observable but neglected, common to all the census tracts in the ith county.

In order to disentangle the random county effects from the evolution of the coefficients associated with the distance from Boston as unique determinant of population distribution, estimations have been performed in different steps:

(a) running the regression including only distance without frailties (i.e. assuming $\beta_{2t} = \ldots = \beta_{6t} = 0$ and $\boldsymbol{w}_t = \boldsymbol{0}$),
(b) running the regression with all selected covariates without frailties (i.e. assuming only $\boldsymbol{w}_t = \boldsymbol{0}$),
(c) running the regression including only distance with frailties (i.e. assuming $\beta_{2t} = \ldots = \beta_{6t} = 0$),
(d) running the complete regression with frailties.

In all of these specifications, a temporal dependence has been introduced at the fixed effect level, by assuming a random walk for the dynamic regression parameters $\boldsymbol{B}_t := (b_{0t}, b_{1t}, \boldsymbol{\beta}_{1t})$ as in [9] and, we get

$$\boldsymbol{B}_0 \sim \mathscr{N}(\boldsymbol{0}, 10^4 \times I), \quad \boldsymbol{B}_t|\boldsymbol{B}_{t-1},\ \sigma_{b_0}^2, \dots, \sigma_{\beta_6}^2\ \sim \mathscr{N}(\boldsymbol{B}_{t-1}, diag\{\sigma_{b_0}^2, \sigma_{b_1}^2, \sigma_{\beta_1}^2, \dots, \sigma_{\beta_6}^2\}),\ \forall t.$$

This prior is quite comparable with the canonical way to deal with the classical idea of adaptive expectations. Instead, we accomodate the heteroscedasticity in the counties by adopting the following multiplicative structure of the population log-density variances borrowed by [5]:

$$\sigma_{y;i}^2 = \sigma^2 \times v_i, \quad \sigma^2 \sim \text{Inverse Gamma}(0.001, 0.001), \quad v_1, v_2, \dots, v_{14} \overset{iid}{\sim} \frac{\chi_r^2}{r}\,.$$

As for the county random frailties we test two alternative modelizations. To begin with, we assume a simple multiplicative hierarchical structure for $w_{1t}, \dots, w_{14t}$ across both time and counties:

$$w_{it} \overset{i.i.d}{\sim} \mathrm{N}(0, \sigma_w^2), \quad \forall i,\ \forall t\,. \quad (2)$$

Alternatively, we model a spatio-temporal dependence between counties by including a space weight matrix A at a county-level to indirectly link the neighboring counties, via pseudo lagged Conditionally Autoregressive county random effects. The space weight matrix A is introduced as an adjacency matrix. Its cells are organized as follows: $A_{ij} = 1$ if i, j are neighbors, and $A_{ij} = 0$ otherwise. Then, A is used in the modeling of the county random effects:

$$w_{it}|\boldsymbol{w}_{t-1} \sim \mathrm{N}(w_{it-1} + \rho A\boldsymbol{w}_{t-1}, \sigma_{w;i}^2), \quad (3)$$

with initial conditions $w_{i0} \overset{iid}{\sim} \mathrm{N}(0, 10^6)\ \forall i$, and $\sigma^2_{w;i} = \lambda / n_i$ if i has $n_i \geq 1$ neighbors, $\sigma^2_{w;i} = \tilde{\sigma}^2_w$ if i is an isolated (or island) county. Our rational is that census-tracts belonging to a same county share some common features (e.g., urban regulation) while there may or may not be some dependence across counties in the way citizens form their expectations.

We complete the prior distribution for the remaining unknown parameters, adding a diffuse uniform prior distribution for σ_w on the range $(0, 10)$ in case of independent frailties (2). Instead, for dynamic-spatial frailties (3) we choose: $\tilde{\sigma}_w \sim Uniform(0, 10)$, $\lambda \sim$ Inverse Gamma$(0.5, 0.0005)$, $\rho \sim Uniform(1/l_{min}, 1/l_{max})$ where l_{min}, l_{max} are the minimum and maximum eigenvalues of the restricted spatial weight matrix A when excluding the two island-counties: Nantucket and Dukes. See [5] and the Manual of GeoBUGS, 2014.

3 Model Selection and Estimation

In order to assess the goodness-of-fit of our model, we computed the Bayesian p-values of the six alternative specifications on the base of the discrepancy measure by [3], for the density population on the logarithm scale: $\sum_{i,j,t} \Big(log(Y^{(t)}_{i,j}) - \mathrm{E}(\log(Y^{(t)}_{i,j})\,|\mathbf{Data}) \Big)^2 / \operatorname{Var}(\log(Y^{(t)}_{i,j})\,|\mathbf{Data})\,)$. Then, a Bayesian comparison of the six alternative specifications were performed by means of the DIC of each model and, for each model and each year, bu means of the percentage of the Bayesian census tracts outliers, i.e. of the census tracts whose actual population density falls into one of the two 2.5 percent tails of the marginal posterior predictive density. Overall, Bayesian-p value suggest that all our specifications perform relatively well by producing relatively good fits, whereas the DIC values reveal that the best empirical specification has to include ethnic composition, education, income along with the physical distance to Boston and the county random frailties. Both the "complete" models with county random frailties have quite similar DIC values, which are definitely better than the model with only distance and without frailties. Under this perspective, one can conclude that there is not a relevant difference in adopting a dynamic-spatial frailty-strategy rather than independent frailties. The Bayesian percentage outliers for each of the six models remains quite low (always under 5 percent) from 1980 to 2010. Instead, for the year 1970, results are at odds with the ones for the other decades.

For 1970, no covariate but distance to Boston seems to be able to model population density distribution. This result confirms that from 1970 to 1980 the land organization in Massachusetts passed through important structural changes, as anticipated by [2]. Figure 1 shows a clear tendency to identify the distance from Boston as the principal driver of population density distribution. Estimations referring to 1970 are a bit at odds with respect to the other decades. Instead, from 1980 onward, the results are consistent. The ethnic composition of the neighborhood and the level of income are two dominant and constant effects. High-income persons tend to settle in the area in which they can enjoy the possibility to rent or buy individual dwelling properties: these places are located far from Boston. In 2010 differences in education among the various census tracts also seem to become a statistically important discrimination factor in location choices, moving in the same direction as ethnic composition and income. County random frailties make the presence of natural amenities (here Z) ineffective. The interaction term between income and distance amplifies the attractiveness of each tract-unit, emphasizing the presence of a mass effect for a number of selected features (in this case, income). The idea is to capture the attractiveness of a destination focusing on some selected features that intervene in shaping individual preferences for location choices despite the physical distance from the CBD.

As far as the heteroscedasticity of the counties, we notice from the plots in Figure 2(a) that all of the econometric exercises provide consistent estimations of the clustered-per-counties heteroscedasticity of the census population density, with the highest variance in the most remote counties: Norfolk, Plymouth, Essex, Dukes, Suffolk, Middlesex and Barnstable are heteroscedastic with a low level of variance, Hampden,

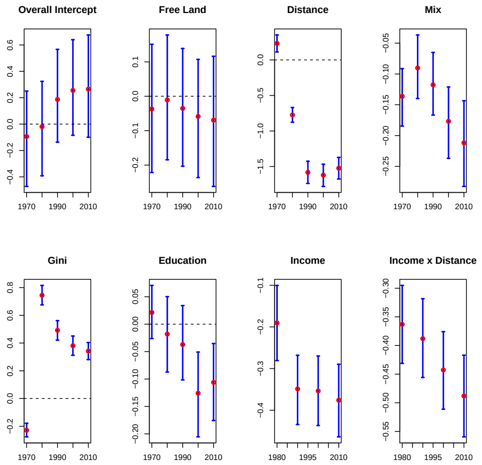

Fig. 1 Plot of the Bayesian estimates (posterior means) and posterior 90 percent Intervals of the regression coefficients in the *Complete Model with Independent Frailties* from 1970 to 2010. Data in 1970 for *Income* are not available. Legend: solid red circles: posterior mean.

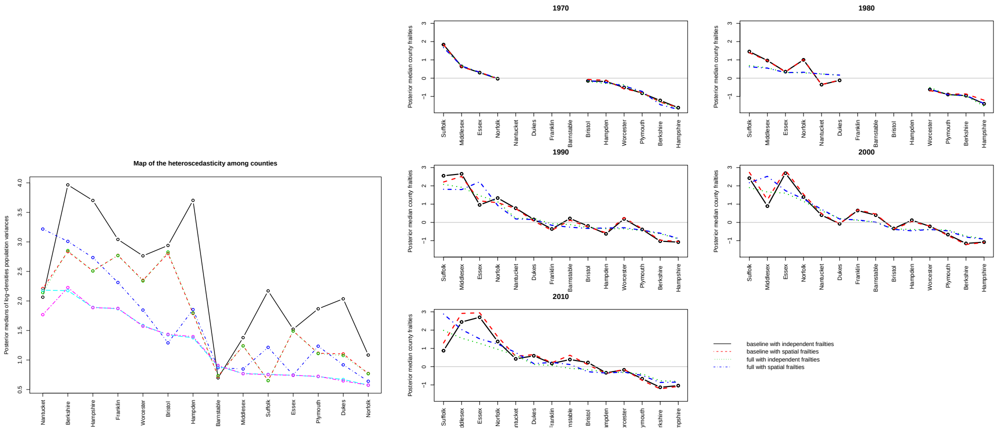
Bristol and Worcester have common variance, whereas Hampshire, Franklin, Berkshire and Nantucket are heteroscedastic with a high level of variance.

With regard to the county random heterogeneity, the picture of the posterior median values of the 14 county random frailties w_{it} in Figure 2(b) reveal that, on one hand the fitted frailties are quite identical under the two specifications, on the other hand, adding new local determinants of the density population along with the distance from Boston, compresses the frailty-predicted value toward zero. Although, under a temporal perspective, each frailty follows an autonomous evolutionary path, still, it is possible to detect some regularities. A structural break is definitely present between the first two decades (i.e. 1970 and 1980) and the rest (i.e., 1990, 2000 and 2010). Referring to the second period, the most remote counties (with respect to Suffolk) show frailty values that continue to be negative across time: the core counties (namely, those closest to Boston) display a strictly negative estimated median value, and the remaining countries –all far from Boston– either approach zero or are strictly positive. Hence, this study confirms that the populations of towns belonging to remote counties far from Boston consolidated low attractiveness in relation to Boston as the CBD across time.

4 Concluding Remarks

In this paper we propose a novel study to assess the determinants of population density distribution across space in Massachusetts. Our empirical strategy relies on the definition of a Bayesian framework in which we take into account temporal and county-spatial dependence for the assessment of population distribution at a census tract level over the period 1970-2010. Our main results confirm that the physical distance from Boston is the relative dominant covariate in defining population distribution across time. However, we detect an increasing segregation effect in modeling population distribution across time: the ethnic and income characteristics of a neighborhood exhibit a relevant impact in the location choice of citizens. These discriminating features are strong enough to be robust and keep being relevant even in the presence of county random frailties aimed at capturing county features not directly embedded. Nevertheless, the county spatial dependence (built around the county frailty effects) does not improve the quality of the estimation if it is compared to the case of spatial-independent frailties. As for preliminary insights delivered from our results, one can conclude that the driving forces of population distribution are mostly associated with elements featuring segregation effects rather than spatial distance to a place of interest. Hence, potential actions aimed at smoothing population concentration (or congestion effects) should target the impact of segregation features rather than centering on accessibility issues. In policy terms, these new outcomes could deliver interesting suggestions for implementing policies aimed at reducing concentration or congestion effects as well as limiting the formation of spatial areas suffering from segregation effects.



(a) (b)

Fig. 2 Posterior Medians of the of the population log-density variances in Figure 2(a) and of the county random frailties in Figure 2(b) from 1970 to 2010. (Non available census-tracts in counties Barnstable, Franklin, Hampden and Norfolkfor for 1970, 1980). Counties are sorted horizontally in decreasing order of their posterior frailty medians under model (2) with all determinants.

Recent Developments in Sampling

Species richness estimation exploiting purposive lists: A proposal

Stima della ricchezza specifica utilizzando liste mirate. Una proposta

A. Chiarucci[1], R.M. Di Biase[2], L. Fattorini[3], M. Marcheselli[4] and C. Pisani[5]

Abstract The lists of species obtained by purposive sampling can be used to improve the sample-based estimation of species richness. A new estimator is proposed as a modification of the difference estimator in which the species inclusion probabilities are estimated by means of the species frequencies from incidence data. An asymptotically conservative estimator of the mean squared error is also provided.

Abstract *Le indagini mirate producono liste floristiche che possono essere usate per migliorare la stima della ricchezza specifica ottenuta tramite campionamento probabilistico. Viene qui proposto un nuovo stimatore della ricchezza specifica basato sullo stimatore per differenza, stimando le probabilità di inclusione sulla base dei dati di incidenza. Viene anche proposto uno stimatore asintoticamente conservativo dell'errore quadratico medio.*

1 Introduction

Species richness, i.e. the number of species in a biological community, represents the simplest and most direct indicator of ecological diversity, largely used as the most convenient proxy for other components of biodiversity [6]. In the following, we will refer to plants, but analogous reasoning could be applied to limited mobility animals.

Species richness is an unknown parameter of the community under study, especially in large areas, and it can be evaluated by means of a purposive survey, as traditionally performed by ecologists, or estimated through probabilistic sampling.

In purposive sampling, species are recorded and listed by searching into specific sites expected to have a large number of species, high detection rates or high abundance of rare species. However, this is a subjective approach, so it does not allow any probabilistic statement about the accuracy and precision of species richness estimators.

On the other hand, in probabilistic sampling, species are identified and listed only if present in the selected samples. The estimates can be objectively evaluated through their sampling distributions, thus allowing for reliable comparisons across areas [e.g., 5]. Nevertheless, sample-based strategies *"are likely to miss the rare or unclassifiable habits that are likely to contribute most to regional diversity. ... Indeed, it is unlikely that such methods can outperform the guesses of experienced botanists"* [7, page 122]. Also in [7, page 122], the importance of probabilistic sampling in comparing species richness throughout time and space is recognized, even if *"it would be unwise to dismiss the efficient, yet subjective contributions of the expert botanist"*. However, at least to our knowledge, the species lists compiled by means of purposive surveys have never been used to improve species richness estimates arising from probabilistic sampling.

Therefore, we introduce a new species richness estimator, referred to as empirical difference (ED) estimator, exploiting both sources of information [2].

Section 2 contains some notations, while the ED estimator and a presumably asymptotic conservative estimator of its mean squared error are presented in Section 3. Section 4 contains a brief discussion on the improvement provided by list exploitation and concluding remarks.

2 Notation and setting

Consider a plant community within a delineated study area, so that each group of individual plants belonging to the same species may be viewed as a unit and the complete species list can be viewed as a population.

Referring to the species by their identifying numerical labels, the complete list of species can be represented by the set $\mathsf{C} = \{1, \ldots, K\}$. Since the complete list is usually unknown, the species richness K must be estimated. It should be noticed that species cannot be directly sampled because they constitute unknown assemblages of individual plants spread over the study area. Thus, the most effective way for sampling species is to sample individual plants, so that a species is sampled when at least one plant of that species is sampled.

The quantification of the first-order inclusion probabilities of species $\theta_1,\ldots,\theta_K$ entails the knowledge of all the units belonging to each species and their spatial distribution over the study area [5]. Consequently, even if the adopted sampling scheme ensures that the first-order inclusion probabilities can be determined directly or by some field measurements [e.g., 5] for (at least) the selected plants, the species inclusion probabilities cannot be quantified.

A study area cannot be adequately sampled by means of only one plot or transect and for this reason *n* independent replications of the sampling scheme [1] are usually performed, determining *n* samples of plants, which in turn give rise to *n* samples of species $\mathsf{G}_1,\ldots,\mathsf{G}_n$. The set of species observed in the whole survey is $\mathsf{G}_{(n)}=\bigcup_{i=1}^{n}\mathsf{G}_i$ and its size SO_n is the number of observed species.

For each replication *i*, $\mathbf{z}_i=\left[z_{i1},\ldots,z_{iK}\right]^{\mathsf{T}}$ is the *K*-vector in which the *j*th element z_{ij} is equal to 1 if the species *j* has been sampled and 0 otherwise. Usually, $\mathbf{z}_1,\ldots,\mathbf{z}_n$ are organized into a 0-1 matrix of *n* columns and SO_n rows, the *presence-absence* or *incidence data*. These *n* vectors are independent realizations of the random vector $\mathbf{Z}=\left[Z_1,\ldots,Z_K\right]^{\mathsf{T}}$ with expectation $\boldsymbol{\theta}=\left[\theta_1,\ldots,\theta_K\right]^{\mathsf{T}}$. Let $\mathbf{x}=\sum_{i=1}^{n}\mathbf{z}_i$ be the realization of the random vector $\mathbf{X}=\left[X_1,\ldots,X_K\right]^{\mathsf{T}}$, with $X_j\sim B\left(n,\theta_j\right)$. Because x_j is the number of replications in which the species *j* has been sampled, $x_j=0$ for all the undetected species. Thus, even if virtually $\mathbf{x}$ is a *K*-vector, it contains an unknown number of zeros [3].

3 The empirical difference estimator

The most common way to exploit auxiliary information is the difference (D) estimator and its modifications, such as the widely used generalized regression and ratio estimators [8, chapter 6]. In this paper, the ED estimator is yet another modification of the D estimator which uses as auxiliary information the species list, henceforth referred to as supporting list L.

Consider *Y* and Y^0 dichotomous variables such that $y_j=1$ for each species $j\in\mathsf{C}$ and $y_j^0=1$ if $j\in\mathsf{L}$ and 0 otherwise, so that Y^0 can be adopted as a proxy for the survey variable *Y*. When the supporting list is accurate, Y^0 is a good proxy for *Y*, given that the errors $y_j-y_j^0=1-y_j^0$ are equal to 0 for any species $j\in\mathsf{L}$.

Exploiting the y_j^0 s, $K=\sum_{j\in\mathcal{C}} y_j$ can be rewritten [8, chapter 6] as

$$K=\sum_{j\in\mathcal{C}} y_j^0+\sum_{j\in\mathcal{C}}\left(y_j-y_j^0\right)=M+\sum_{j\in\mathcal{C}}\left(1-y_j^0\right)$$

where M is the number of species in the supporting list and the second member is unknown and needs to be estimated from the sample using the Horvitz-Thompson criterion

$$\hat{K}_D=M+\sum_{j\in G_{(n)}}\frac{1-y_j^0}{\tau_j}=M+\sum_{j\in G_{(n)}-\mathcal{L}}\frac{1}{\tau_j}$$

where $\tau_j=1-\left(1-\theta_j\right)^n$ is the probability that species j is detected during the whole sample survey. The estimator $\hat{K}_D$ is unbiased with a closed-form variance, which could be unbiasedly estimated from the sample. However, it cannot be calculated since the θ_j s (and consequently the τ_j s) are unknown. The frequencies x_j s in which the species enter the n samples can be adopted to estimate the θ_j s as $\hat{\theta}_j=\left(x_j+1\right)/\left(n+1\right)$ [4], from which $\hat{\tau}_j=1-\left(n-x_j\right)^n/\left(n+1\right)^n$.

The ED estimator turns out to be:

$$\hat{K}_E=M+\sum_{j\in G_{(n)}-\mathcal{L}}\frac{1}{\hat{\tau}_j}$$

$\hat{K}_E$ is biased with expectation and variance which cannot be expressed in closed form. However, as opposite to other species richness estimators, its realizations are never smaller than the cardinality of the set $G_{(n)}\cup\mathcal{L}$. Furthermore, if the supporting list is perfect, the ED estimator invariably estimates the true species richness without error. Hence, besides the uncertainty due to the estimation of the inclusion probabilities, the uncertainty of $\hat{K}_E$ is completely due to the species in the set $\mathcal{C}-\mathcal{L}$, i.e. the species lost in the supporting list which can be partially recovered by the sample survey. It should be noticed that if $G_{(n)}-\mathcal{L}$ is the empty set, the ED estimator coincides with M.

Because the estimator is biased, there is no sense in estimating its variance. Rather, we should estimate the relative root mean square error

$$\mathrm{RRMSE}=\frac{\sqrt{\mathrm{MSE}\left(\hat{K}_E\right)}}{K}=\frac{\sqrt{\mathrm{E}\left\{\left(\hat{K}_E-K\right)^2\right\}}}{K}$$

Because neither of the mean nor the variance of $\hat{K}_E$ can be expressed in a closed form, we derived an upper bound of $\mathrm{MSE}\left(\hat{K}_E\right)$ to be subsequently estimated from the available information, in such a way that the resulting estimator should be presumably asymptotically conservative. In [2, appendix] it is proved that

$$\mathrm{MSE}(\hat{K}_E)\leq 2K(4e^{-1}+1)\sum_{j\in\mathcal{C}-\mathcal{L}}\left\{1-\theta_j(1-e^{-1})\right\}^n$$

whose right side can be estimated by

$$\hat{\mathrm{MSE}}(\hat{K}_E) = 2\hat{K}_E(4e^{-1}+1)\sum_{j\in G_{(n)}-L}\frac{\left\{1-\hat{\theta}_j(1-e^{-1})\right\}^n}{\hat{\tau}_j}$$

Also in this case, if $G_{(n)}-L$ is the empty set, the $\hat{\mathrm{MSE}}$ turns out to be 0. Consequently,

$$\mathrm{RR}\hat{\mathrm{MSE}}(\hat{K}_E) = \frac{\sqrt{\hat{\mathrm{MSE}}(\hat{K}_E)}}{\hat{K}_E} = \sqrt{\frac{2(4e^{-1}+1)}{\hat{K}_E}\sum_{j\in G_{(n)}-L}\frac{\left\{1-\hat{\theta}_j(1-e^{-1})\right\}^n}{\hat{\tau}_j}}$$

It should be noticed that the ED estimator is a consistent estimator of *K* with bias and variance approaching 0 as the number of replications increases. Indeed, from the $\mathrm{MSE}(\hat{K}_E)$ inequality follows that $\hat{K}_E$ converges in quadratic mean (and hence also in mean) to *K*, since $\lim_{n\to\infty} 2K(4e^{-1}+1)\sum_{j\in C}\left\{1-\theta_j(1-e^{-1})\right\}^n(1-y_j^0)=0$.

4 Discussion

In order to check the improvement provided by the exploitation of floristic lists, a simulation study was performed. $\hat{K}_E$ was compared to other species richness estimators, using nonparametric estimators of species richness.

The results of the simulation (for the full explanation of the simulation process and its results see [2]) show noticeable improvement in bias and precision provided by the proposed estimator, especially when the supporting list is accurate. Practically speaking, the proposed estimator is likely to be effective when efforts in compiling lists are mostly directed toward habitats that are likely to host rare species. It should be noticed that lists missing the most common species are not unrealistic, because botanists are often focused on searching the rarest species, sometimes neglecting the most common ones [7].

If most of the rare species are included in the supporting list, the ED estimator can represent an efficient solution and the RRMSE estimator is presumably conservative, since some underestimations only occur when the supporting lists miss rare species. At least to our knowledge, this is the first attempt to estimate the MSE in species richness estimation, as most papers dealing with this problem propose estimators of the sampling variance. However, the estimation of variance in species richness estimation is irrelevant, because the major part of the sampling error is due to bias.

It is worth noting that it is important to work with updated floristic lists, so as to avoid the inclusion of species no longer in the area and other taxonomical problems (e.g. synonyms of species that were split into two or species that were merged). Thus, these drawbacks could deteriorate the performances of estimators exploiting floristic lists.

Design-based exploitation of big data by a doubly calibrated estimator

Uno stimatore a calibrazione doppia per l'uso dei big data in un'ottica basata sul disegno

Maria Michela Dickson [1], Giuseppe Espa[2] and Lorenzo Fattorini[3]

Abstract Big data typically constitute masses of unstructured data, not always available for a whole population. When sampling only the sub-population where big data are available, but neglecting the remaining portion, this can be viewed as a fixed component of nonresponses, which sums the natural component of nonresponses present in each survey. In this paper, big data information is exploited to handle nonresponse, while a size variable available for the whole population is exploited to handle the neglected part of the population by means of a doubly calibrated estimation. Design-based expectation and variance are derived up to the first order approximation. A variance estimator is proposed. A Monte Carlo simulation exploring various scenarios demonstrates the efficiency of the strategy.

Abstract *I big data costituiscono una mole di dati non strutturata, non sempre disponibile per tutte le unità di una popolazione. Quando si campiona solo dalla sotto-popolazione per cui i big data sono disponibili, trascurando la restante parte, questo può essere visto come una ulteriore fonte di mancate risposte che si aggiunge a quella naturalmente presente in ogni indagine campionaria. Nel presente lavoro, viene proposto uno stimatore a doppia calibrazione, nel quale i big data vengono utilizzati per gestire le mancate risposte, mentre, per gestire la parte di popolazione trascurata nella selezione, viene utilizzata una variabile dimensionale disponibile per*

1. Introduction

In the last twenty years the availability of data has hugely increased, making possible developments in many fields of research, primarily in statistical sciences. More recently, this increase in data availability is also characterized by an increase in size of the amount of information collected, opening an extended debate around the term *big data*.

This new and potentially infinite source of data is connoted, on one side, by a not definite frame and, on the other side, by a real-time updating. Clearly the mentioned features represent pros and cons that researchers and practitioners must consider when using big data for statistical analysis (Tam, 2015). While the large amount of information is an unquestionable positive issue, the lack of a frame makes difficult the definition of a population of interest. This matter became relevant in sampling theory and in the consequent inference that can be done under a design-based perspective.

Nevertheless, in many practical circumstances, the opportunity of exploiting big data information may be an advantage in surveys. At the same time, considering only units provided by these additional information, could lead to a missed observation of the other units, which remain excluded from the study. For instance, it happens in socio-economic surveys on people living conditions, which tend to exclude units that cannot be contacted from the population, or in environmental studies, in which remote sensing information are not available for some areas. In this framework, these units never enter the sample and can be viewed as a fixed component of nonresponses, which sums the natural component of nonresponses present in each survey.

The aim of the present paper is to reach the desirable chance to take advantage from big data, when available, but make inference on a whole population in the above mentioned practical circumstances. So that, we propose an estimator that may permit to achieve this goal, by means of calibration estimators (Deville and Särndal, 1992). First, a calibration is used to correct for nonresponses from the sample to the population provided by big data, and, then, a second calibration is implemented on the whole population, leading to a *doubly calibrated estimator*. For the proposed estimator, expectation and variance are derived and a variance estimator is proposed. The efficiency and applicability of the strategy is showed by a Monte Carlo simulation study on a population that mirrors real characteristics.

2. Preliminaries, notation and methods

Let $U = \{u_1, \dots, u_N\}$ a population of N units. We denote with $y_j, j \in U$ the value for unit j of a survey variable Y. The aim is to estimate the population total

$$T_Y = \sum_{j \in U} y_j.$$

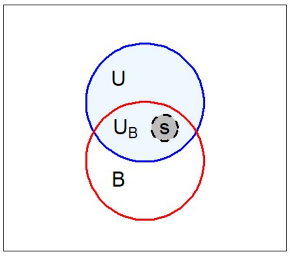
An auxiliary size variable Z is also available for each unit of U, such that the total $T_Z = \sum_{z \in U} z_j$ is known for any $z_j, j \in U$.

Moreover, a big data population B of M units intersects population U, so that we can define U_B as a sub-population of U composed by $N_B < N$ units. The total $T_{Y(B)} = \sum_{j \in U_B} y_j$ in U_B is unknown and it is the first quantity to be estimated in the procedure.

A sample S of size $n < N_B$ may be selected from the sub-population U_B by means of a fixed-size design having first and second order inclusion probabilities π_j, π_{jh} for any $h > j \in U_B$. As always happen in practice, the sample may be affected by nonresponses, so we define $R \subset S$ as the respondent sample. Note that the sampling scheme adopted to select S generates a sampling design on U_B but not on U.

To perform the first step of calibration, auxiliary information for U_B units are necessary. Let $\boldsymbol{x}_i = [x_{i1}, \dots, x_{iK}]$, with $i \in B$, the $\boldsymbol{X}$-vector of K auxiliary variables available in the population B of big data. The totals $\boldsymbol{T}_{X(B)} = \sum_{j \in U_B} \boldsymbol{x}_j$ and $T_{Z(B)} = \sum_{z \in U_B} z_j$ are known for all units in U_B. To better clarify the population setup, see Figure 1.

Figure 1: A stylized configuration of the population U_B, as the intersection between U and B, and sample S.



Because sample S is drawn from U_B, the H-T estimator (Horvitz and Thompson, 1953) of the total is $\hat{T}_{Y(B)} = \sum_{j \in S} \frac{y_j}{\pi_j}$ which is an unbiased estimator of $T_{Y(B)}$. Therefore, it would be a biased estimator of T_Y. However, considering nonresponses, the estimator

$$\hat{T}_{Y(B)/R} = \sum_{j \in R} \frac{y_j}{\pi_j} \neq \hat{T}_{Y(B)}$$

is a biased estimator even of $T_{Y(B)}$. In order to reduce the bias, following results proposed in Fattorini et al. (2013), it is possible to exploit auxiliary information $\boldsymbol{X}$ under a design-based point of view, obtaining the calibration estimator

$$\hat{T}_{Y(B)(cal)} = \hat{\boldsymbol{b}}_R^t \boldsymbol{T}_{X(B)}$$

where $\hat{\boldsymbol{b}}_R = \hat{\boldsymbol{A}}_R^{-1}\hat{\boldsymbol{a}}_R$ is the least-square coefficient vector of the regression of Y variable on $\boldsymbol{X}$ variables, performed on the respondent sample R, i.e. $\hat{\boldsymbol{A}}_R = \sum_{j\in R}\frac{x_j x_j^t}{\pi_j}$ and $\hat{\boldsymbol{a}}_R = \sum_{j\in R}\frac{y_j x_j}{\pi_j}$. The design-based properties of $\hat{T}_{Y(B)(cal)}$ were derived in Fattorini et al. (2013). In that paper, it has been demonstrated that the estimator is approximately unbiased and consistent if the relationship between Y and $\boldsymbol{X}$ is similar in both respondent and non-respondent sub-groups, and it has been derived variance estimation. So that, the authors provide a design-based solution to the problem of nonresponses.

The additional problem here is that we must estimate T_Y rather than $T_{Y(B)}$. However, because $\hat{T}_{Y(B)(cal)}$ is, at his best, an approximately unbiased and consistent estimator of $T_{Y(B)}$, it is a biased estimator of T_Y. Since the selection of S is only on U_B, the elements of $U - U_B$ cannot enter the sample. In this case, it is necessary to correct the estimator to reduce the bias due to the sample under-coverage. A choice may be to use the size variable Z, which is available for the whole population U. So that, the resulting *double calibration* estimator turns out to be

$$\hat{T}_{Y(\mathrm{d}cal)} = \frac{\hat{T}_{Y(B)(cal)}}{\hat{T}_{Z(B)}} T_Z = \frac{\hat{\boldsymbol{b}}_R^t \boldsymbol{T}_X}{\hat{T}_{Z(B)}} T_Z$$

where $\hat{T}_{Z(B)} = \sum_{j\in S}\frac{z_j}{\pi_j}$ is the H-T estimator of T_Z.

The double calibration estimator benefits of some desirable properties deriving from calibration but, for the sake of brevity, we do not report all proofs. However, following results of Fattorini et al. (2013), $\hat{T}_{Y(dcal)}$ is approximately unbiased if (i) the linear relationship between Y and $\boldsymbol{X}$ is approximately the same in the respondent and non-respondent sub-groups of U_B, and if (ii) the proportional relationship between Y and Z is approximately the same in the two sub-populations U_B and $U - U_B$. Under these conditions, following the consistency of the H-T estimator (see Isaki and Fuller, 1982) it is possible to derive that $\hat{T}_{Y(dcal)}$ converges in probability to T_Y.

Regarding variance and its estimation, following Särndal et al. (1992, p.175) the estimator $\hat{T}_{Y(dcal)}$ has an approximate variance equal to

$$V\left(\hat{T}_{Y(dcal)}\right) \approx \left(\frac{T_Z}{T_{Z(B)}}\right)^2 \sum_{h>j\in U_B} \left(\pi_j\pi_h - \pi_{jh}\right)\left(\frac{u_j}{\pi_j} - \frac{u_h}{\pi_h}\right)^2$$

Given that, the Sen-Yates-Grundy variance estimator (Sen, 1953; Yates and Grundy, 1953) is given by

$$\hat{V}_{SYG}\left(\hat{T}_{CAL}\right) = \left(\frac{T_Z}{\hat{T}_{Z(B)}}\right)^2 \sum_{h>j\in S} \frac{\left(\pi_j\pi_h - \pi_{jh}\right)}{\pi_{jh}}\left(\frac{\hat{u}_j}{\pi_j} - \frac{\hat{u}_h}{\pi_h}\right)^2$$

where $\hat{u}_j = \left(r_j y_j \boldsymbol{x}_j^t - r_j \hat{\boldsymbol{a}}_R^t \hat{\boldsymbol{A}}_R^{-1} \boldsymbol{x}_j \boldsymbol{x}_j^t - z_j \hat{T}_{Z(B)}^{-1} \hat{\boldsymbol{a}}_R^t\right)\hat{\boldsymbol{A}}_R^{-1}\boldsymbol{T}_x$, $j \in S$ are the empirical *influence values* (Davison and Hinkley, 1997) computed for each $j \in S$.

In order to expose the validity of the proposed methodology, in the next section a simulation study is presented.

3. Simulation study

A Monte-Carlo simulation is discussed in this section to investigate the performances of the proposed estimator. A population of $N = 10000$ units has been considered. No random model was adopted for generating nonresponses. The population covered by big data U_B constituted by 7500 units has been partitioned in respondent and non-respondent sub-groups. Therefore, the response pattern is a fixed characteristic of the units, just like the value of the survey variable. The size of respondent sub-group is equal to $N_R = 2250, 4500, 6750$ units, corresponding to 30%, 60% and 90% of the population units. We suppose available two auxiliary variables X_1 and X_2 for units included in U_B. These variables have been generated according to a normal distribution with mean equal to 1, variance equal to 1 and correlation coefficient equal to 0.20. The variable under estimation Y has been generated as

$$y_j = 1 + 0.5x_{1j} + 0.5x_{2j} + \varepsilon_j, \quad \forall j \in U$$

where ε_j is an error component with mean equal to 0 and variance constant, such that the model explains in one case, the 60% and, in another, the 90% of the variance of the y_js. In addition, a size variable Z is available for the whole population and it has been generated as $z_j = 2y_j + \gamma_j$, where γ_j is an error component with mean equal to 0 and variance proportional to $k|Y|$, with k set to assure correlation between Y and Z equal to 0.90. From the described populations, 10000 Monte-Carlo random samples of size $n = 100, 150, 250, 375, 500$ units have been selected by means of simple random sampling without replacement (SRSWOR). For each sample, relative Root Mean Square Error (rRMSE) and relative Bias (rB) have been computed. Table 1 and Table 2 report obtained results.

Table 1: Relative bias and relative RMSE for the population with model $R^2 = 0.60$ and correlation between Y and Z equal to 0.90

	$N_R = 2250$		$N_R = 4500$		$N_R = 6750$

375	0.0058	0.0895	0.0033	0.0835	0.0061	0.0829
500	0.0057	0.0764	0.0030	0.0718	0.0021	0.0701

Conclusions

Results show that in both populations, both relative Bias and relative RMSE decrease as sample size response portion increases. We have explored the case in which the size variable and the target variable are strongly correlated, confirming results gathered by Fattorini et al. (2013). Clearly, when the value of R^2 of the model used to generate Y is higher, performances of the estimator are better. However, we have considered very low sampling fractions and, nevertheless, the relative Bias rapidly decreases, becoming very close to zero with a sampling fraction equal to 5%. The behaviour of rRMSE complies this result, decreasing when the sample size and the size of respondents sub-group increase.

Design-based mapping in environmental surveys

Mappe basate sul disegno nelle indagini ambientali

L. Fattorini, M. Marcheselli and C. Pisani

Abstract The estimation of the values of a survey variable throughout a continuum of points or in a finite population of spatial units is investigated when a sample of points or units is selected by a probabilistic sampling scheme. At each point or for each spatial unit, the value is estimated using an inverse distance weighting interpolator and conditions ensuring its design-based asymptotic unbiasedness and consistency are summarized.
Abstract *La stima dei valori di una variabile di interesse in un continuum di punti o in una popolazione finita di unità spaziali è considerata quando un campione di punti o unità è selezionato tramite uno schema di campionamento probabilistico. In ogni punto o per ogni unità spaziale, il valore è stimato usando un interpolatore spaziale e sono discusse le condizioni che ne assicurano la correttezza asintotica e la coerenza in un approccio basato sul disegno.*

pattern of the variable of interest on the study region. For example, soil composition and mineral concentration are of interest in geology, soil and water pollution are crucial in ecology, species abundance and coverage are important in forestry.

Depending on the variable and the goals of the survey, the study region may be considered either a continuum of points or a finite population of spatial units, such as when the region is partitioned into a network of regular polygons or into a collection of irregular patches (e.g. Opsomer et al. 2007). Model-based estimation methods are adopted in most cases: uncertainty arises from the super-population probability model, which has been supposed to generate the surface or the population values, conditional on the sample of spatial units. By contrast, if any assumption about the super-population model generating the surface or the population values is avoided, uncertainty stems only from the sampling scheme and the surface or the population values are considered fixed.

Recently, in a design-based framework, Fattorini et al. (2018a) propose the use of the model-assisted inverse distance weighting interpolator (Bruno et al., 2013) for estimating a variable of interest when a finite population of spatial units is considered. Moreover Fattorini et al. (2018b) investigate the use of the inverse distance weighting interpolator to estimate the surface values in the continuous population setting. To render statistically sound a design-based map, conditions ensuring some sort of design-based asymptotic unbiasedness and consistency are obtained for both continuous and finite populations and asymptotically conservative estimators of the mean squared error are proposed (Fattorini et al., 2018a, 2018b).

2 Notation and setting

Consider a study region $\mathscr{A}$ of area A. Let $\mathscr{A}$ be a connected and compact set of $\mathbf{R}^2$. For $\mathbf{p},\mathbf{q} \in \mathscr{A}$, let $\|\mathbf{p}-\mathbf{q}\|$ be their distance, where $\|\cdot\|$ denotes a norm in $\mathbf{R}^2$.

If the value of the survey variable at $\mathbf{x}$, say $y(\mathbf{x})$, is defined for each point $\mathbf{x} \in \mathscr{A}$, the population is a continuum of points and the aim is the estimation of $y(\mathbf{x})$, at least ideally, for each $\mathbf{x} \in \mathscr{A}$ from a sample $(\mathbf{X}_1,\ldots,\mathbf{X}_n)$ of n points selected from $\mathscr{A}$ by means of a suitable sampling scheme (Cordy, 1993).

On the other hand, if $\mathscr{A}$ is partitioned into N spatial units $\mathbf{a}_1,\ldots,\mathbf{a}_N$ of area $a_1,...,a_N$, we are dealing with a finite population. In this case let U denote both the set of spatial units and the set of indexes $\{1,\ldots,N\}$. Moreover let y_j be the amount of the survey variable within $\mathbf{a}_j$ in such a way that $f_j = y_j/a_j$ is the density and the goal is estimating the value y_j for each $j \in U$ using a probabilistic sample S of n units selected from U. Because in most situations the a_js are known for all the population units, it is equivalent to interpolate the y_js or the f_js but density estimation is more suitable for working in an asymptotic scenario in which the a_js decrease and then the y_js may approach zero.

In both frameworks a model-assisted estimation may be performed by exploiting Tobler's law (Tobler, 1970) and adopting the inverse distance weighting interpolator (Bruno et al., 2013).

In the continuous population setting, following Fattorini et al. (2018b) the inverse distance weighting interpolator turns out to be

$$\hat{y}(\mathbf{x}) = I_{\{\cup_{i=1}^{n}(\mathbf{X}_i=\mathbf{x})\}} y(\mathbf{x}) + [1 - I_{\{\cup_{i=1}^{n}(\mathbf{X}_i=\mathbf{x})\}}] \frac{\sum_{i=1}^{n} y(\mathbf{X}_i)\phi(||\mathbf{x}-\mathbf{X}_i||)}{\sum_{i=1}^{n}\phi(||\mathbf{x}-\mathbf{X}_i||)}, \qquad (1)$$

where I_E is the indicator function of the event E and $\phi : [0,\infty) \to \mathbf{R}^+$ is a non-increasing continuous function on $(0,\infty)$, with $\phi(0) = 0$, $\lim\limits_{d \to 0^+} \phi(d) = \infty$.

In the finite population setting, quoting Fattorini et al. (2018a) the inverse distance weighting interpolator is

$$\hat{f}_j = I_{\{j \in S\}} f_j + [1 - I_{\{j \in S\}}] \frac{\sum_{i \in S} f_i \phi(||\mathbf{c}_j - \mathbf{c}_i||)}{\sum_{l \in S}\phi(||\mathbf{c}_j - \mathbf{c}_l||)}, \qquad (2)$$

where $\mathbf{c}_j$ is the centroid of the spatial unit $\mathbf{a}_j$, $j = 1, \ldots, N$.

3 Asymptotic results

The design-based expectation and variance of (1) and (2) cannot be expressed in closed form, giving no insights about the bias and precision. Therefore, conditions providing asymptotic design-based unbiasedness and consistency are needed.

3.1 Continuous population

Suppose a sequence of fixed-size designs to select a sample of n_k points $\mathbf{X}_1^{(k)}, \ldots, \mathbf{X}_{n_k}^{(k)}$, with $n_k \to \infty$ as k increases. Moreover, from (1), let $\hat{y}_k(\mathbf{x})$ be the inverse distance weighting interpolator for the k-th design. The asymptotic design-based properties of $\hat{y}_k(\mathbf{x})$ are derived as the sample size increases but the surface remains fixed.

To achieve design consistency suppose that y is a bounded measurable function on $\mathscr{A}$ and $\lim_{d \to 0^+} d^2\phi(d) = \infty$. Fattorini et al. (2018b) prove that, under mathematical conditions ensuring an asymptotic spatial balance of the sampling scheme as the sample size increases, if y is continuous at $\mathbf{x}$, $\hat{y}_k(\mathbf{x})$ is point wise design consistent at $\mathbf{x}$ while if y is continuous on $\mathscr{A}$ it is uniformly design consistent. Particularly, under uniform random sampling point wise design consistency holds while under systematic grid sampling and tessellation stratified sampling, if the study area is partitioned into a sequence of polygonal grids, $\hat{y}_k(\mathbf{x})$ is uniformly design consistent.

Moreover if y is a Lipschitz function in a neighbourhood of $\mathbf{x}$ and $\phi(d) = d^{-\alpha}$, with $\alpha > 2$, under systematic grid sampling and tessellation stratified sampling, design consistency is ensured with a $O(n_k^{(2-\alpha)/(\alpha+1)})$ convergence rate, and the use of very large α values in the distance function ϕ seems to be advisable. However, a trade-off choice of α between 3 and 5 seems suitable for moderate sample sizes, ensuring a convergence rate of at least $O(n_k^{-1/4})$. In many real situations, the Lipschitz assumption within patches partitioning the study area is quite reasonable. Indeed, often there are parts of the study region in which the surface changes smoothly throughout space, well approaching the Lipschitz condition, while sudden variations only occur on borders, which may be realistically approximated by curves of measure 0. Therefore the surface shares the Lipschitz condition almost everywhere.

3.2 Finite population

Consider a sequence $\{U_k\}$ of partitions of $\mathscr{A}$. Each partition U_k is constituted of N_k spatial units $\mathbf{a}_1^{(k)},\ldots,\mathbf{a}_{N_k}^{(k)}$ of area $a_1^{(k)},...,a_{N_k}^{(k)}$ and centroids $\mathbf{c}_1^{(k)},\ldots,\mathbf{c}_{N_k}^{(k)}$. Denote by $y_j^{(k)}$ the amount of the survey variable within $\mathbf{a}_j^{(k)}$ and by $f_j^{(k)}$ its density. Suppose that $N_k \to \infty$, i.e. $\mathscr{A}$ is partitioned into an increasing number of spatial units: it is natural to suppose also that $\sup_{j\in U_k} \mathrm{diam}(\mathbf{a}_j^{(k)}) \to 0$. Finally suppose a sequence of designs to select a sample of size n_k from U_k. Since U_k is a sequence of finite populations of increasing sizes, each constituted by different spatial units, the sequence differs from those customarily adopted to achieve asymptotic results in finite population inference, which are constituted of nested populations with increasing totals.

Let $\hat{f}_j^{(k)}$ be the inverse distance weighting interpolator for the k-th design: the goal is to determine its asymptotic design-based behavior as the partition of the study area becomes thinner and thinner. It should be noticed that the unit j of the kth population is lost in the subsequent populations. This problem can be handled by introducing two sequences of functions from $\mathscr{A}$ onto R^+, say

$$f_k(\mathbf{x}) = \sum_{j\in U_k} f_j^{(k)} I_{\{\mathbf{x}\in\mathbf{a}_j^{(k)}\}}, \qquad \mathbf{x}\in\mathscr{A}$$

$$\hat{f}_k(\mathbf{x}) = \sum_{j\in U_k} \hat{f}_j^{(k)} I_{\{\mathbf{x}\in\mathbf{a}_j^{(k)}\}} \qquad \mathbf{x}\in\mathscr{A}.$$

Practically speaking, the N_k densities of the kth population are substituted by a piecewise constant function in $\mathscr{A}$, which equals $f_j^{(k)}$ onto $\mathbf{a}_j^{(k)}$.

Suppose that there exists a Riemann integrable function f from $\mathscr{A}$ onto $[0,L]$, which gives the density of the survey variable for any $\mathbf{x}\in\mathscr{A}$ and that the spatial units not only have diameters approaching to 0, but there is no excessively elongated unit. The assumption on the distance function already adopted in the continuous setting is also needed.

Fattorini et al. (2018a) prove that, under mathematical conditions ensuring an asymptotic spatial balance of the sampling scheme, if f is continuous at $\mathbf{x}$, $\hat{f}_k$ is point wise design consistent at $\mathbf{x}$ while, if f is continuous on $\mathscr{A}$, it turns out to be uniformly design consistent. Under simple random sampling without replacement and stratified sampling with proportional allocation point wise design consistency holds while one per stratum stratified sampling and systematic sampling ensures uniform design consistency.

4 Mean squared error estimation

Any estimator of the mean squared error of the interpolators should not be computationally demanding. Therefore time-consuming resampling procedures, such as the bootstrap or jackknife, should be avoided.

Owing to Tobler's law, the value of the sampled point nearest to $\mathbf{x}$ is likely to be a good proxy for $y(\mathbf{x})$ and the density of the sampled unit nearest to unit j is likely to be a good proxy for f_j. Then, in the continuous setting a simple and asymptotically conservative estimator for the mean squared error of $\hat{y}(\mathbf{x})$ is

$$\hat{V}(\mathbf{x}) = \left\{\hat{y}(\mathbf{x}) - y(\mathbf{X}_{\mathrm{near}(\mathbf{x})})\right\}^2, \tag{3}$$

where near$(\mathbf{x})$ is the index of the sample location that is nearest to $\mathbf{x}$. The finite population counterpart of (3)

$$\hat{V}_j = (\hat{f}_j - \hat{f}_{\mathrm{near}(j)})^2,$$

where near(j) is the label of the sampled unit that is nearest to unit j, can be adopted to estimate the mean squared error of $\hat{f}_j$.

5 Simulation study

As to the continuous population setting, in Fattorini et al. (2018b) a simulation is performed on three artificial surfaces on the unit square, referred to as surf1, surf2 and surf3, and, respectively, defined at any point $\mathbf{x} = (x_1, x_2)$ as

$$y(\mathbf{x}) = C_1(\sin^2 x_1 + \cos^2 x_2 + x_1), \quad y(\mathbf{x}) = C_2(\sin 3x_1 \sin^2 3x_2)^2,$$

$$y(\mathbf{x}) = \begin{cases} C_3 x_1 x_2, & \min(x_1, x_2) < 0.5, \\ C_3(1 + x_1 x_2), & \text{otherwise} \end{cases}$$

where the constants C_1, C_2, and C_3 ensure a maximum value of 10. The first two surfaces are continuous while surf3 shows a discontinuity at the edge of the upper-right quadrant of the unit square.

For each surface, $R = 10{,}000$ samples of size $n = 25, 100, 225, 400$ are independently selected by uniform random sampling, tessellation stratified sampling and systematic grid sampling: the last two schemes are performed by partitioning the unit square into quadrats of equal size and then selecting one point per quadrat. Estimation is performed for each of the $N = 10,000$ centroids of the equally-spaced 100×100 grid by means of (1) using $\phi(d) = d^{-\alpha}$ with $\alpha = 2, 2.5, 3, 4$.

The simulation results confirm the theoretical findings: for both the continuous surfaces, a sharp decrease in the minima, maxima and averages of the absolute bias and mean squared error occurs for $\alpha > 2$ as the sample size increases while the decreases are less marked for $\alpha = 2$. For surf3, uniform design consistency is precluded and pointwise design consistency is ensured for $\alpha > 2$ for only the set of continuity points. As the sample size increases, sharp decreases occur for only the minima and averages of the absolute bias and mean squared error for $\alpha > 2$ while the maxima remain approximately constant. The decreases are less marked for $\alpha = 2$.

In the finite population setting, Fattorini et al. (2018a) adopt surf2 and surf3 to define two densities on the unit square. For any density, five spatial populations of sizes N=100, 400, 1600, 6400, and 25,600 are constructed by partitioning the unit square into grids of 10×10, 20×20, 40×40, 80×80, and 160×160 quadrats, respectively, and then taking the integrals of the density onto the quadrats as population values. For any population, $R = 10,000$ samples of size $n = N/10$ are independently selected by means of simple random sampling without replacement, one-per-stratum stratified sampling and systematic sampling. One-per-stratum stratified sampling and systematic sampling are performed by partitioning the grids into blocks of 2×5 contiguous quadrats and selecting one quadrat per block. Once the samples are selected, (2) is adopted to estimate densities for all the quadrats in the populations by using the same distance function adopted in the continuous framework. Simulation results support the theoretical results and are analogous to those obtained for continuous population.The continuity of surf2 for $\alpha > 2$ ensures point-wise design consistency under simple random sampling without replacement and uniform design consistency under sytematic and one-per-stratum stratified sampling. Uniform design consistency is precluded for surf3 and point-wise design consistency is ensured only away from the discontinuity lines for $\alpha > 2$ and for all the sampling schemes.

Testing for independence in analytic inference

Test di indipendenza nell'inferenza analitica

Pier Luigi Conti and Alberto Di Iorio

Abstract In analytic inference, data usually come from complex sampling designs, possibly with different inclusion probabilities, stratification, clustering of units. The effect of a complex sampling design is that sampling data are not *i.i.d.*, even if they are at a superpopulation level. This dramatically changes the probability distribution of usual test-statistics, such as Spearman's Rho. An approach based on a special form of resampling is proposed, and its properties are studied.
Abstract *Nell'inferenza analitica i dati generalmente provengono da disegni campionari complessi, che includono differenti probabilità di inclusione, stratificazione, grappoli di unità. L'effetto di un disegno di questo tipo è che i dati a livello campionario non sono* i.i.d.*, anche se lo sono a livello di superpopolazione. Di conseguenza, viene completamente modificata la distribuzione di probabilità delle statistiche-test comunemente utilizzate (come il Rho di Spearman). Nel presente lavoro viene studiato un approccio basato su una nuova forma di ricampionamento, di cui si studiano le proprietà.*

Key words: Independence tests, sampling design, asymptotics, empirical process, resampling.

1 Introduction

The use of superpopulation models in survey sampling has a long history, going back (at least) to [2], where the limits of assuming the population characteristics as *fixed*, especially in economic and social studies, are stressed. As clearly appears (cfr.

Pier Luigi Conti
Sapienza Università di Roma, P.le A. Moro 5, 00185 Roma, Italy, e-mail: pierluigi.conti@uniroma1.it

Alberto Di Iorio
Banca d'Italia; Via Nazionale, 91; 00184 Roma; Italy, e-mail: alberto.diiorio@uniroma1.it

[7], [5]), there are basically two forms of inference in a finite populations setting. The first one is *descriptive* or *enumerative* inference, namely inference about finite population parameters. This kind of inference is a static "picture" on the current state of a population, and does not take into account the mechanism generating the characters of interest of the population itself. The second one is *analytic* inference, and consists in inference on superpopulation parameters. This kind of inference is about the process that generates the finite population. In contrast with *enumerative* inference results, *analytic* ones are more general, and still valid for every finite population generated by the same superpopulation model.

In the present paper attention is focused on a special problem of analytic inference, namely testing for independence between two characters. The main consequence of using a sampling design with possibly different inclusion probabilities is that commonly used test-statistics based on ranks, such as Spearman Rho rank correlation or Gini G cograduation statistics are not distribution free under independence, and in general do not have the same distribution (neither finite sample, nor asymptotic) as in the case of *i.i.d.* sample data. This calls for the need of developing new test-statistics, suitable for data collected through a complex design. Since their distribution, both for a finite sample size and asymptotically, does have a complicate form depending on the superpopulation, the need of approximating their distribution arises. Unfortunately, the widespread Efron's bootstrap does not work in the present case, again because of the use of a complex sample design. In the sequel, a new resampling scheme will be proposed, and its properties studied. In particular, it will be shown that it is asymptotically correct.

Let $\mathscr{U}_N$ be a finite population of size N, and let X, Y be two characters of interest, defined on the population $\mathscr{U}_N$. Let further x_i, y_i be the values of characters X, Y for unit i $(= 1, \dots, N)$.

A sample s of size n is a subset of $\mathscr{U}_N$. The selection of s is performed according to a probabilistic sampling design. Formally speaking, for each unit i in $\mathscr{U}_N$, define a Bernoulli random variable (r.v.) D_i, such that the unit i is included in the sample if and only if (iff) $D_i = 1$, and let $\mathbf{D}_N = (D_1, \dots, D_N)$. A (unordered, without replacement) sampling design P is the probability distribution of $\mathbf{D}_N$. In particular, $\pi_i = E_P[D_i]$ $(\pi_{ij} = E_P[D_i D_j])$ is the first (second) order inclusion probability of unit i (pair of units i, j). The suffix P denotes the sampling design used to select population units.

The first order inclusion probabilities are frequently taken proportional to an appropriate function of the values of the *design variables*. The design variables may include strata indicator variables, as well as qualitative variables measuring cluster and unit characteristics (cfr. [5]); in what follows they are denoted by $\mathscr{T}_1, \dots, \mathscr{T}_L$, whilst $t_{i1}, \dots, t_{iL}$ are their values for unit i. As already said, we will assume that $\pi_i \propto z_i$, where $z_i = h(t_{i1}, \dots, t_{iL})$ is the value of $Z = h(\mathscr{T}_1, \dots, \mathscr{T}_L)$ for unit i.

Take now N real numbers $0 < p_i < 1$, $i = 1, \dots, N$, with $p_1 + \cdots + p_N = n$. The sampling design is a *Poisson design* with parameters $p_1, \dots, p_N$ if the r.v.s D_is are independent with $\pi_i = p_i$ for each unit i. The *rejective sampling*, or *normalized conditional Poisson sampling* ([4], [8]) corresponds to the probability distribution of the random vector $\mathbf{D}_N$, under Poisson design, conditionally on $n_s = n$.

The *Hellinger distance* between a sampling design P and the rejective design is

$$d_H(P, P_R) = \sum_{D_1,\dots,D_N} \left(\sqrt{Pr_P(D_N)} - \sqrt{Pr_R(D_N)} \right)^2 . \tag{1}$$

Our basic assumptions are listed below.

A1. $(\mathscr{U}_N;\ N \geq 1)$ is a sequence of finite populations of increasing size N.

A2. For each N, $(y_i, x_i, t_{i1}, \dots, t_{iL})$, $i = 1, \dots, N$ are realizations of a superpopulation $\{(Y_i, X_i, T_{i1}, \dots, T_{iL}),\ i = 1, \dots, N\}$ composed by *i.i.d.* $(L+2)$-dimensional r.v.s. In the sequel, the symbol $\mathbb{P}$ will denote the (superpopulation) probability distribution of r.v.s $(Y_i, X_i, T_{i1}, \dots, T_{iL})$s, and $\mathbb{E}$, $\mathbb{V}$ are the corresponding operators of mean and variance, respectively. Furthermore, if $Z_i = h(T_{i1}, \dots, T_{iL})$, the joint superpopulation d.f. of (Y_i, X_i, Z_i) will be denoted by

$$K(y, x, z) = \mathbb{P}(Y_i \leq y, X_i \leq x, Z_i \leq z), \tag{2}$$

and

$$H((y, x|z) = \mathbb{P}(Y_i \leq y, X_i \leq x|Z_i = z), \tag{3}$$

$$F(y|z) = \mathbb{P}(Y_i \leq y|Z_i = z),\ \ G(x) = \mathbb{P}(X_i \leq x|Z_i = z) \tag{4}$$

are the joint and marginal superpopulation d.f.s of Y_i and X_i (given Z).

A3. For each population $\mathscr{U}_N$, sample units are selected according to a fixed size sample design with positive first order inclusion probabilities $\pi_i \propto z_i$, with sample size $n = \pi_1 + \cdots + \pi_N$, and $z_i = h(t_{i1}, \dots, t_{iL})$, $i = 1, \dots, N$. It is assumed that

$$\lim_{N,n\to\infty} \mathbb{E}[\pi_i(1-\pi_i)] = d > 0. \tag{5}$$

Furthermore, the notation $x_N = (x_1, \dots, x_N)$ is used.

A4. The sample size n increases as the population size N does, with

$$\lim_{N\to\infty} \frac{n}{N} = f,\ \ 0 < f < 1.$$

A5. For each population $(\mathscr{U}_N;\ N \geq 1)$, let P_R be the rejective sampling design with inclusion probabilities $\pi_1, \dots, \pi_N$, and let P be the actual sampling design (with the same inclusion probabilities). Then

$$d_H(P, P_R) \to 0 \ \text{ as } N \to \infty,\ \ a.s. - \mathbb{P}.$$

A6. $\mathbb{E}[X_1^2] < \infty$, so that the quantity in (5) is equal to:

$$d = f\left(1 - \frac{\mathbb{E}[X_1^2]}{\mathbb{E}[X_1]^2}\right) + f(1-f)\frac{\mathbb{E}[X_1^2]}{\mathbb{E}[X_1]^2} > 0. \tag{6}$$

2 The problem

As already said, our goal is to construct an independence test for the two characters X, Y (conditionally on the design variables $T_j s$). For the sake of simplicity we will consider a single, discrete design variable T, taking values $T^1, \dots, T^k$. Hence, the hypothesis problem takes the form

$$H_0 : H(x,y|T) = F(x|T)G(y|T)$$
$$H_1 : H(x,y|T) \neq F(x|T)G(y|T)$$

A simple approach could consist in using a rank based test-statistic, such as the Spearman's Rho statistic or the Gini's cograduation statistic. Unfortunately, due to the use of the sample design, such statistics are not distribution free under H_0, neither exactly nor asymptotically. Hence, their use is inappropriate under general sampling designs.

In order to construct a test-statistic for the above problem, the general measure of monotone dependence proposed in [1] is extended to the present case. Given two continuous variables X,Y, let F and G be their marginal distributions, respectively, and let H be the joint distribution of the bivariate variable (X,Y). A general measure of the monotone dependence γ_g between X and Y, is a real-valued functional γ_g of the bivariate distribution $H(x,y)$ defined as follows

$$\gamma_g = \int_{\mathbb{R}^2} g(|F(x|T)+G(y|T)-1|) - g(|F(x|T)-G(y|T)|)\, dH(x,y|T), \quad (7)$$

where $g : [0,1] \to \mathbb{R}$ is a strictly increasing, continuous and convex function, with $g(0) = 0$ snd continuous first derivative. Under the null hypothesis of independence the latter quantity is equal to zero. If $g(s) = s^2$, then (7) reduces to the (un-normalized) Spearman's coefficient. If $g(s) = s$, then (7) reduces to the (un-normalized) Gini cograduation coefficient. In general, $\gamma_g = 0$ whenever X and Y are independent.

The basic idea is to estimate first H, F, G by their Hájek estimators

$$\widehat{H}(y, xvertt) = \sum_{i=1}^{N} \frac{1}{\pi_i} D_i I_{(x_i \leq x)} I_{(y_i \leq y)} I_{(T_i = t)} \Bigg/ \sum_{i=1}^{N} \frac{1}{\pi_i} D_i I_{(T_i=t)} \quad (8)$$

$$\widehat{F}(y) = \sum_{i=1}^{N} \frac{1}{\pi_i} D_i I_{(y_i \leq y)} I_{(T_i = t)} \Bigg/ \sum_{i=1}^{N} \frac{1}{\pi_i} D_i I_{(T_i=t)}, \quad (9)$$

$$\widehat{G}(x) = \sum_{i=1}^{N} \frac{1}{\pi_i} D_i I_{(x_i \leq x)} I_{(T_i = t)} \Bigg/ \sum_{i=1}^{N} \frac{1}{\pi_i} D_i I_{(T_i=t)} \quad (10)$$

and then in estimating the quantity γ_g with a plug-in approach, by replacing the distribution function is the distributions functions in (7) with their Hájek estimators. In this way, the test-statistic

$$\widehat{\gamma}_g = \frac{\sum_{i=1}^{N} \frac{1}{\pi_i} \left(g(|\widehat{F}(x_i|T_i) + \widehat{G}(y_i|T_i) - 1|) - g(|\widehat{F}(x_i|T_i) - \widehat{G}(y_i|T_i)|) \right) D_i}{\sum_{i=1}^{N} \frac{1}{\pi_i} D_i}. \quad (11)$$

is obtained.

Proposition 1. *Suppose that the conditions* $A1$*-*$A6$ *are met, and assume that the null hypothesis* H_0 *holds true. Then, the r.v.*

$$\sqrt{n}\widehat{\gamma}_g \quad (12)$$

tends in distribution to a normal r.v. with zero mean and variance σ_0^2*, as N, n increase.*

The asymptotic variance σ_0^2 of (12) does have a complicate form, and cannot be estimated on the basis of sample data. The basic idea is to approximate the distribution of (11) under H_0 by resorting to resampling.

Define S_j as the subset of sample units having value T^j of the design variable, and let n_j be the size of S_j, $j = 1, \dots, k$.

0. Repeat M times steps 1-4 below.
1. Generate a pseudo-population of size N by selecting unit i in the sample with probability $\pi_i^{-1} / \sum \pi_i^{-1} D_i$. To each unit i^* of the pseudo-population a value $T_{i^*}^*$ is attached, such that $T_{i^*}^* = T_i$ whenever $i^* = i$.
2. If $T_{i^*}^* = T^j$, then sample independently from S_j, and with probability $\pi_i^{-1} / \sum_{k \in S_j} \pi_k^{-1}$, a X-value $X_{i^*}^*$ and a Y-value $Y_{i^*}^*$. As a result, a pseudo-population $\mathscr{U}_N^*$ is obtained, such that for each unit $i^* \in \mathscr{U}_N^*$ a triplet $(Y_{i^*}^*, X_{i^*}^*, T_{i^*}^*)$ is defined. Furthermore, $Y_{i^*}^*$ and $X_{i^*}^*$ are independent conditionally on $T_{i^*}^*$.
3. Draw a pseudo-sample of size n from the population $\mathscr{U}_N^*$, using a high entropy sampling design P^* with first order inclusion probabilities π_{i^*} according to $A3$.
4 Compute the value $\widehat{\gamma}_g^*$ of the statistic (11) for the pseudo-sample drawn at step 3.

In this way, the M replicates

$$\sqrt{n}\widehat{\gamma}_{g,m}^*, \;\; m = 1, \dots, M \quad (13)$$

are obtained.

Consider next the empirical distribution function (edf) constructed on the basis of the M replicates (13):

$$\widehat{R}(u) = \frac{1}{M} \sum_{m=1}^{M} I_{(\widehat{\gamma}_{g,m}^* \leq u)} \quad (14)$$

and let $\widehat{R}^{-1}$ be the corresponding quantile function

$$\widehat{R}^{-1}(p) = \inf\{u : \widehat{R}(u) \geq u\}. \quad (15)$$

Let further Φ_{0,σ_0} be a normal distribution function with zero expectation and variance σ_0^2. Proposition 1 establishes that, as both N, n increase, under the null hypothesis H_0 the probability distribution function $Pr_{H_0}(\sqrt{n}\widehat{\gamma}_g \leq u)$ tends to $\Phi_{0,\sigma_0}(u)$, uniformly w.r.t. u. Next proposition establishes that, as the number M of replicates increases, the edf (14) tends to the *same* limiting law. This proves the (asymptotic) validity of the proposed resampling technique.

Proposition 2. *Suppose that the conditions* A1*-*A6 *are met, and assume that the null hypothesis* H_0 *holds true. Then, as N, n, M increase, the following results hold (with probability 1).*

$$\sup_u \left| \widehat{R}(u) - Pr_{H_0}(\sqrt{n}\widehat{\gamma}_g \leq u) \right| \to 0;$$
$$\sup_u \left| \widehat{R}(u) - \Phi_{0,\sigma_0}(u)) \right| \to 0;$$
$$\widehat{R}^{-1}(p) \to \sigma_0 z_{1-p}$$

where z_{1-p} *satisfies the relationship* $\Phi_{0,1}(z_{1-p}) = p$.

As a consequence of Proposition 2, the region

$$\widehat{R}^{-1}(\alpha/2) \leq \sqrt{n}\widehat{\gamma}_g \leq \widehat{R}^{-1}(\alpha/2) \tag{16}$$

is an acceptance region of approximative size α for testing independence.

A comparison between the proposed test and the one based on the "usual" Spearman statistic has been performed *via* simulation. The proposed test performs better than the "usual" one in terms of power, as well as in terms of closeness of the actual size to the nominal significance level.

Key words: Fractional factorial designs, Word-Length Pattern

1 Introduction

The theory of Orthogonal Arrays (OAs) has a long history and represents a major research topic for both methodology and applied Statistics. The need for efficient experimental designs has led to the definition of several criteria for the choice of the design points. All such criteria aim to produce the best estimates of the relevant parameters for a given sample size. As general references for OAs, the reader can refer to [5].

In particular, we consider only binary designs under the Minimum Aberration (MA) criterion, but we focus on the following problem. In several situations, it is hard to define *a priori* a fixed sample size. For example, budget constraints or time limitations may occur after the definition of the design, or even when the experiments are running, thus leading to an incomplete design. In such a situation, it is relevant not only to choose an OA with good properties, but also to define an order

Roberto Fontana
DISMA, Politecnico di Torino, e-mail: roberto.fontana@polito.it

Rapallo Fabio
DISIT, Università del Piemonte Orientale e-mail: fabio.rapallo@uniupo.it

of the design points, so that the experimenter can stop the sequence of runs and loose as little information as possible. While OAs with added runs are well studied, see for instance [2], less has been done in the case of OAs with removed runs. The order of the runs of an OA and the OAs with removed runs are both interesting topics, but the first one is mainly studied with the aim of minimizing the changes of the factor levels, see e.g. [8], while the second one is only considered in the framework of D-optimality, see [1]. In [7] and [8] several papers, describing practical problems where OAs with missing runs play a major role, are listed.

In this work, we consider the MA criterion for binary OAs and we study the behavior of the aberrations when p points are removed from an OA, for small values of p. The MA criterion is based on the Word-Length Pattern (WLP) introduced in [4]. In practice, the WLP is used to discriminate among different designs $\mathscr{F}_1, \ldots, \mathscr{F}_d$ by looking at the lexicographic minimum of the vector

$$A_{\mathscr{F}_i} = (A_0(\mathscr{F}_i) = 1, A_1(\mathscr{F}_i), \ldots, A_m(\mathscr{F}_i)) , \quad i = 1, \ldots, d.$$

2 Orthogonal Arrays and aberrations

Let us consider an experiment with m 2-level factors. The full factorial design is $\mathscr{D} = \{-1, 1\}^m$. We briefly recall here the basic definitions concerning Orthogonal Arrays and aberrations. For details refer to [3].

Definition 1. A fraction $\mathscr{F}$ is a multiset $(\mathscr{F}_*, f_*)$ whose underlying set of elements $\mathscr{F}_*$ is contained in $\mathscr{D}$ and f_* is the multiplicity function $f_* : \mathscr{F}_* \to \mathbb{N}$ that for each element in $\mathscr{F}_*$ gives the number of times it belongs to the multiset $\mathscr{F}$.

We recall that the underlying set of elements $\mathscr{F}_*$ is the subset of $\mathscr{D}$ that contains all the elements of $\mathscr{D}$ that appear in $\mathscr{F}$ at least once. We denote the number of elements of the fraction $\mathscr{F}$ by $\#\mathscr{F}$, with $\#\mathscr{F} = \sum_{x \in \mathscr{F}_*} f_*(x)$.

To describe the counting function of a fraction, we follow the theory in [3]. The simple terms of the form X_j, i.e., the j-th component function which maps a point $x = (x_1, \ldots, x_m)$ of $\mathscr{D}$ to its j-th component,

$$X_j \colon \mathscr{D} \ni (x_1, \ldots, x_m) \longmapsto x_j \in \{-1, 1\}$$

and the interactions $X^\alpha = X_1^{\alpha_1} \cdot \ldots \cdot X_m^{\alpha_m}$, $\alpha \in L = \{0, 1\}$ i.e., the monomial functions of the form

$$X^\alpha : \mathscr{D} \ni (x_1, \ldots, x_m) \mapsto x_1^{\alpha_1} \cdot \ldots \cdot x_m^{\alpha_m}$$

are a basis of all the real functions defined over $\mathscr{D}$. We use this basis to represent the counting function of a fraction according to the following definition.

Definition 2. The counting function R of a fraction $\mathscr{F}$ is a polynomial defined over $\mathscr{D}$ so that for each $x \in \mathscr{D}$, $R(x)$ equals the number of appearances of x in the fraction. A $0-1$ valued counting function is called an indicator function of a single-replicate fraction $\mathscr{F}$. We denote by c_α the coefficients of the representation of R on $\mathscr{D}$ using the monomial basis $\{X^\alpha,\ \alpha \in L\}$:

$$R(x) = \sum_{\alpha \in L} c_\alpha X^\alpha(x),\ x \in \{-1,1\}^m,\ c_\alpha \in \mathbb{R}.$$

Among the fractions of a full factorial design 2^m, we consider Orthogonal Arrays.

Definition 3. A fraction $\mathscr{F}$ factorially projects onto the I-factors, $I = \{i_1,\ldots,i_k\} \subset \{1,\ldots,m\}$, $i_1 < \ldots < i_k$, if the projection $\pi_I(\mathscr{F})$ is a full factorial design or a multiple of a full factorial design, i.e., the multiset $(\{-1,1\}^m, f_*)$ where the multiplicity function f_* is constant over $\{-1,1\}^m$.

Definition 4. A fraction $\mathscr{F}$ is an Orthogonal Array (OA) of strength t if it factorially projects onto any I-factors with $\#I = t$.

The connections between the OAs and the counting function are given in the proposition below.

Proposition 1. *A fraction is an OA of strength t if and only if all the coefficients $c_\alpha,\ \alpha \neq 0 \equiv (0,\ldots,0)$ of the counting function up to the order t are* 0.

Definition 5. The Word-Length Pattern (WLP) of a fraction $\mathscr{F}$ of the full factorial design $\mathscr{D}$ is the vector $A_\mathscr{F} = (A_0(\mathscr{F}), A_1(\mathscr{F}), \ldots, A_m(\mathscr{F}))$, where

$$A_j(\mathscr{F}) = \sum_{|\alpha|_0 = j} a_\alpha \quad j = 0,\ldots,m,$$

$$a_\alpha = \left(\frac{c_\alpha}{c_0}\right)^2,$$

$|\alpha|_0$ is the number of non-null elements of α, and $c_0 := c_{(0,\ldots,0)} = \#\mathscr{F}/\#\mathscr{D}$.

In the definition above, the number a_α is the aberration of the term X^α.

3 The effect on the WLP of the removal of one, two or three points

In this section we study the effect on the WLP of the removal of one, two or three points from an OA of strength t. With respect to the removal of one point outlined in Sect. 3.1 we obtain an analytical expression for the first $t+1$ terms of the WLP.

3.1 One removed point

Let us consider an orthogonal array $\mathscr{F}$ with n runs, m 2-level factors and strength t. The WLP of $\mathscr{F}$ is

$$A_{\mathscr{F}} = (A_0(\mathscr{F}) = 1, A_1(\mathscr{F}) = 0, \ldots, A_t(\mathscr{F}) = 0, A_{t+1}(\mathscr{F}), \ldots, A_m(\mathscr{F}))\,.$$

Let us consider a point $e = (e_1, \ldots, e_m) \in \mathscr{F}$ and the fraction $\mathscr{F}_e$ that contains all the points of $\mathscr{F}$ apart from e, $\mathscr{F}_e = \mathscr{F} \setminus \{e\}$. Let us denote by $R = \sum_\alpha c_\alpha X^\alpha$ the counting function of $\mathscr{F}$ and by $R_{\{e\}} = \sum_\alpha c_\alpha^{(e)} X^\alpha$ the counting function of the fraction made by the single point e. We can write

$$R_{\{e\}}(x_1, \ldots, x_m) = \frac{1}{2^m}(1 + e_1 x_1) \cdot \ldots \cdot (1 + e_m x_m)\,.$$

The aberration $a_\alpha^{(e)}$ of $R_{\{e\}}$ corresponding to the term α is

$$a_\alpha^{(e)} = \frac{(c_\alpha^{(e)})^2}{(c_0^{(e)})^2} = \frac{(\frac{1}{2^m} e_1^{\alpha_1} \cdot \ldots \cdot e_m^{\alpha_m})^2}{(\frac{1}{2^m})^2} = 1$$

because $(e_1, \ldots, e_m) \in \{-1, 1\}^m$. It follows that the aberration $a_\alpha^{(\mathscr{F}_e)}$ of the fraction $\mathscr{F}_e$ corresponding to the term α, for $1 \le |\alpha|_0 \le t$ is

$$a_\alpha^{(\mathscr{F}_e)} = \frac{(c_\alpha - c_\alpha^{(e)})^2}{(c_0 - c_0^{(e)})^2} = \frac{(c_\alpha^{(e)})^2}{(n/2^m - 1/2^m)^2} = \frac{1}{(n-1)^2}$$

because $c_\alpha = 0$ for $1 \le |\alpha|_0 \le t$. Consequently the terms $A_k(\mathscr{F}_e), k = 1, \ldots, t$ of the WLP of $\mathscr{F}_e$ are

$$A_k(\mathscr{F}_e) = \frac{\binom{m}{k}}{(n-1)^2}, k = 1, \ldots, t\,.$$

This means that $A_k(\mathscr{F}_e), k = 1, \ldots, t$ does not depend on the point e which has been removed. In Sect. 3.2 we study some real examples.

3.2 *Examples with one, two or three points*

Now we consider the effect on the WLP of the removal of one, two or three points from some OAs. The OAs are taken from the repository publicly available at http://pietereendebak.nl/oapage/, which has been created by Pieter Eendebak and Eric Schoen, see [6].

Let us consider one of the best OAs, with respect to the WLP criterion, in the class of OAs with $m = 5$ 2-level factors, $n = 12$ runs and strength $t = 2$. Let us denote this OA by $\mathscr{F}$ and its points by $e_1, e_2, \ldots, e_{12}$. Writing the runs as columns and the factors as rows, the fraction $\mathscr{F}$ is

$$\begin{array}{c} \begin{array}{cccccccccccc} e_1 & e_2 & e_3 & e_4 & e_5 & e_6 & e_7 & e_8 & e_9 & e_{10} & e_{11} & e_{12} \end{array} \\ \mathscr{F} = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 & -1 & -1 \\ 1 & 1 & 1 & -1 & -1 & -1 & 1 & 1 & 1 & -1 & -1 & -1 \\ 1 & 1 & -1 & 1 & -1 & -1 & 1 & -1 & -1 & 1 & 1 & -1 \\ 1 & 1 & -1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 & -1 & 1 \\ 1 & -1 & 1 & 1 & -1 & -1 & -1 & 1 & -1 & -1 & 1 & 1 \end{pmatrix} \end{array}$$

The WLP of $\mathscr{F}$ is $A_{\mathscr{F}} = (1,0,0,A_3(\mathscr{F}) = 1.111, A_4(\mathscr{F}) = 0.5556, A_5(\mathscr{F}) = 0)$.

Now we remove each of the twelve points from $\mathscr{F}$ and we compute the corresponding WLPs. The results are reported in Table 1. We observe that, according to the results of Sect. 3.1, $A_1(\mathscr{F}_e) = 5/(12-1)^2 = 0.041$ and $A_2(\mathscr{F}_e) = 10/(12-1)^2 = 0.083$. It is worth noting that there are two different WLPs. More specifically there are 10 fractions $\mathscr{F}_e$ with $A_3(\mathscr{F}_e) = 1.140$ and 2 fractions $\mathscr{F}_e$ with $A_3(\mathscr{F}_e) = 1.405$.

Table 1 WLPs of the twelve 11-run subsets of $\mathscr{F}$.

point[a]	$A_1(\mathscr{F}_e)$	$A_2(\mathscr{F}_e)$	$A_3(\mathscr{F}_e)$	$A_4(\mathscr{F}_e)$	$A_5(\mathscr{F}_e)$
e_1	0.041	0.083	1.140	0.636	0.008
e_2	0.041	0.083	1.140	0.636	0.008
e_3	0.041	0.083	1.405	0.372	0.008
e_4	0.041	0.083	1.140	0.636	0.008
e_5	0.041	0.083	1.140	0.636	0.008
e_6	0.041	0.083	1.140	0.636	0.008
e_7	0.041	0.083	1.140	0.636	0.008
e_8	0.041	0.083	1.140	0.636	0.008
e_9	0.041	0.083	1.140	0.636	0.008
e_{10}	0.041	0.083	1.405	0.372	0.008
e_{11}	0.041	0.083	1.140	0.636	0.008
e_{12}	0.041	0.083	1.140	0.636	0.008

[a] this column specifies the removed run.

Now, we remove all the possible 66 pairs of points $\{e_i, e_j\}, i, j = 1, \ldots, 12$, $i < j$ from $\mathscr{F}$. We denote the fraction obtained by removing the points e_i, e_j from $\mathscr{F}$ by $\mathscr{F}_{e_i,e_j}$. We obtain 7 different WLPs which are reported in Table 2.

Finally, we remove all the possible 220 subsets of three points $\{e_i, e_j, e_k\}$, $i, j, k = 1, \ldots, 12$, $i < j < k$ from $\mathscr{F}$. We denote the fraction obtained by removing the points e_i, e_j, e_k from $\mathscr{F}$ by $\mathscr{F}_{e_i,e_j,e_k}$. We obtain 12 different WLPs which are reported in Table 3.

The results show that WLPs depend on the *points* which are removed from a given OA and not simply on *their number*. Table 1 demonstrates that even when just one-single point is deleted there are two different WLPs. From Table 1 we can also conclude that the worst fractions in terms of WLPs are $\mathscr{F}_{e_3}$ and $\mathscr{F}_{e_{10}}$. However if we remove two points simultaneously, further investigations revealed that the best fraction in terms of WLP was $\mathscr{F}_{e_3,e_{10}}$ because $A_1(\mathscr{F}_{e_3,e_{10}}) = 0$.

Quantile Regression Coefficients Modeling: a Penalized Approach

Modelli Quantili Parametrici: un Approccio Penalizzato

Gianluca Sottile, Paolo Frumento and Matteo Bottai

Abstract Modeling quantile regression coefficients functions permits describing the coefficients of a quantile regression model as parametric functions of the order of the quantile. This approach has numerous advantages over standard quantile regression, in which different quantiles are estimated one at the time: it facilitates estimation and inference, improves the interpretation of the results, and is statistically efficient. On the other hand, it poses new challenges in terms of model selection. We describe a penalized approach that can be used to identify a parsimonious model that can fit the data well. We describe the method, and analyze the dataset that motivated the present paper. The proposed approach is implemented in the `qrcmNP` package in R.
Abstract *I coefficienti di una regressione quantilica sono funzioni iniettive dell'ordine del quantile. L'approccio standard è quello di stimare i quantili uno alla volta. Un metodo alternativo è quello di esprimere la forma funzionale dei coefficienti usando un modello parametrico. Questo approccio ha numerosi vantaggi: semplifica le procedure di stima e inferenza, migliora l'interpretazione dei risultati, e risulta statisticamente efficiente. Al tempo stesso, pone nuove sfide in termini di selezione del modello. La nostra proposta è quella di usare un metodo penalizzato che permetta di identificare un modello parsimonioso che rappresenti correttamente la funzione quantilica. In questo articolo descriviamo il metodo, e analizziamo il dataset che ha motivato il lavoro. L'approccio proposto è stato implementato nel pacchetto R `qrcmNP`.*

1 Introduction

Quantiles fully describe the conditional distribution of a response variable given covariates. Quantile regression (QR; [6]) and its generalizations (e.g., [3]) are the standard tools for quantile modeling. In QR, the conditional quantile function is usually written as

$$Q(p \mid \boldsymbol{x}) = \boldsymbol{x}^T \boldsymbol{\beta}(p), \tag{1}$$

where $\boldsymbol{x}$ is a q-dimensional vector of covariates, and $\boldsymbol{\beta}(p)$ is a vector of unknown coefficients describing the relationship between $\boldsymbol{x}$ and the p-th quantile of the response variable, $p \in (0,1)$. In standard quantile regression, different quantiles are estimated one at the time. When a grid of quantiles is computed, e.g., $p = 0.01, 0.02, \ldots, 0.99$, results can only be summarized graphically. The estimated coefficients are generally non-smooth functions of p and may suffer from high volatility, which can hinder their interpretability.

Recently, [5] suggested modeling the quantile regression coefficient functions, $\boldsymbol{\beta}(p)$, by using parametric functions. Model (1) is reformulated as follows:

$$Q(p \mid \boldsymbol{x}, \boldsymbol{\theta}) = \boldsymbol{x}^T \boldsymbol{\beta}(p \mid \boldsymbol{\theta}), \tag{2}$$

where $\boldsymbol{\theta}$ is a vector of model parameters. This approach is referred to as *quantile regression coefficients modeling* (QRCM) and permits modeling the entire quantile function, while keeping the quantile regression structure expressed by equation (1). Consider, for example, describing $\boldsymbol{\beta}(p \mid \boldsymbol{\theta})$ by k-th degree polynomial functions:

$$\beta_j(p \mid \boldsymbol{\theta}) = \theta_{j0} + \theta_{j1} p + \ldots + \theta_{jk} p^k, j = 1, \ldots, q.$$

Each covariate has $(k+1)$ associated parameters, for a total of $q \times (k+1)$ model coefficients. When either q or k are large, estimation may become difficult and the model may be poorly identified, causing the variability to grow out of control.

Among different approaches discussed in literature, the least absolute shrinkage and selection operator (LASSO; [9]) is the most used method to perform model selection. This procedure requires selecting a tuning parameter. In the literature, traditional criteria include cross-validation (CV), Akaike's information criterion (AIC), and Bayesian information criterion (BIC).

Numerous papers (e.g., [1, 10]) have investigated the estimation of penalized quantile regression models in high-dimensional setting using the L_1-norm of the coefficients, denoted by L_1-QR [1, 8]. These approaches, however, focus on model selection when estimating one quantile at a time. Generally, this is inefficient and makes it difficult to interpret the results, because some coefficients could be only significant at some quantiles.

We propose applying the L_1-penalty to the integrated loss function described by [5], which is minimized to estimate the unknown parameter $\boldsymbol{\theta}$ in model (2). We refer to this procedure as *penalized quantile regression coefficients modeling* (QRCMPEN).

The paper is structured as follows. We introduce a penalized estimator in Section 2, and propose criteria to select the tuning parameter in Section 3. Section 4 concludes the paper with the analysis of the dataset that motivated this research.

2 The estimator

We assume that model (2) holds, and adopt the following parametrization: $\boldsymbol{\beta}(p \mid \boldsymbol{\theta}) = \boldsymbol{\theta}\boldsymbol{b}(p)$, where $\boldsymbol{b}(p) = [b_1(p), \dots, b_k(p)]^{\mathrm{T}}$ is a set of k known functions of p, and $\boldsymbol{\theta}$ is a $q \times k$ matrix with entries θ_{jh} such that $\beta_j(p \mid \boldsymbol{\theta}) = \theta_{j1}b_1(p) + \ldots + \theta_{jk}b_k(p)$, $j = 1, \dots, q$. The conditional quantile function is then rewritten as $Q(p \mid \boldsymbol{x}, \boldsymbol{\theta}) = \boldsymbol{x}^T\boldsymbol{\theta}\boldsymbol{b}(p)$. The choice of the vector $\boldsymbol{b}(p)$, is something arbitrary when the model is not known in advance, indeed, an intuitive approach could be to choose functions as flexible as possible. Moreover, as discussed by [5], the values of $\boldsymbol{b}(0)$ and $\boldsymbol{b}(1)$ should reflect the assumptions about the support of the outcome, and the interpretation of parameters may be highly dependent on the model specification. Although all outcomes are bounded in practice, including unbounded functions facilitates modeling the tails of the distribution. As shown by [5], estimation is carried out by minimizing

$$\bar{L}(\boldsymbol{\theta}) = \int_0^1 L(\boldsymbol{\beta}(p \mid \boldsymbol{\theta}))\mathrm{d}p, \tag{3}$$

where $L(\boldsymbol{\beta}(p))$ is the loss function of standard quantile regression given by $L = \sum_{i=1}^{n} (p - I(y_i \leq \boldsymbol{x}_i^{\mathrm{T}}\boldsymbol{\beta}(p)))(y_i - \boldsymbol{x}_i^{\mathrm{T}}\boldsymbol{\beta}(p))$. This estimation procedure is referred to as *integrated loss minimization* (ILM), and implemented in the `qrcm` package in R.

This modeling approach is very flexible, and usually provides a good fit of the data. However, it tends to generate large models, causing overparametrization and loss of efficiency. To implement an automatic procedure for model selection, we modify the loss function (3) by introducing a L_1-norm penalizing factor:

$$\bar{L}_{\mathrm{PEN}}^{(\lambda)}(\boldsymbol{\theta}) = \int_0^1 L(\boldsymbol{\beta}(p \mid \boldsymbol{\theta})) + \lambda \sum_{j=1}^{q}\sum_{h=1}^{k} \mid \theta_{jh} \mid \mathrm{d}p, \tag{4}$$

where $\lambda \geq 0$. We refer to this estimation approach as *penalized integrated loss minimization* (PILM). To minimize $L_{\mathrm{PEN}}^{(\lambda)}(\boldsymbol{\theta})$ with respect to $\boldsymbol{\theta}$, we use a pathwise coordinate descent algorithm [4]. The described PILM estimator is implemented in the `qrcmNP` package in R.

3 Tuning parameter selection

With a given set of data, the true model is not known. Having adequate criteria for model selection is therefore crucial. In penalized regression, the tuning parameter

λ balances the trade-off between goodness of fit and efficiency. We denote by $\widehat{\boldsymbol{\theta}} := \widehat{\boldsymbol{\theta}}^{(\lambda)}$ the estimator of $\boldsymbol{\theta}$ obtained by minimizing (4) at a given value of λ. AIC- and BIC-type selectors are grid-search criteria that minimize $\text{Dev}^{(\lambda)} + c_n \cdot \text{df}^{(\lambda)}$, where $\text{Dev}^{(\lambda)}$ is the explained deviance of the model (a measure of goodness-of-fit defined below) corresponding to $\widehat{\boldsymbol{\theta}}$, c_n is a constant that could depend on the sample size n, and $\text{df}^{(\lambda)}$ reflects the number of nonzero elements of $\widehat{\boldsymbol{\theta}}$. To improve efficiency and computation, we propose standardizing both $\boldsymbol{x}$ and $\boldsymbol{b}(p)$. Following [7], we define $\text{Dev}^{(\lambda)} = \log \bar{L}^{(\lambda)}_{\text{PEN}}(\widehat{\boldsymbol{\theta}})$, i.e., the logarithm of the minimized loss function given by (4). The AIC and BIC criteria are given by

$$\text{AIC}^{(\lambda)} = \log \bar{L}^{(\lambda)}_{\text{PEN}}(\widehat{\boldsymbol{\theta}}) + n^{-1}\text{df}^{(\lambda)}, \tag{5}$$

$$\text{BIC}^{(\lambda)} = \log \bar{L}^{(\lambda)}_{\text{PEN}}(\widehat{\boldsymbol{\theta}}) + (2n)^{-1}\log(n)\text{df}^{(\lambda)}C_n, \tag{6}$$

where C_n is some positive constant, that diverges to infinity as n increase. The value $C_n = 1$ corresponds to the ordinary BIC.

4 Variables selection for inspiratory capacity

We applied the PILM estimator to a subset (n = 2201) of the data analyzed in [2]. The data refer to a study carried out in 1988-1991 in Northern Italy, and included 1063 males and 1138 females. The study aimed to estimate percentiles of inspiratory capacity (IC), a measure of lungs function. The following nine predictors were available: age, height, body mass index (BMI), sex, and indicators for current smoking, occupational exposure, cough, wheezing, and asthma.

We model the intercept using a linear combination of $\log(p)$ and $\log(1-p)$, that together define the quantile function of the asymmetric Logistic distribution, a very flexible model used to describe possibly skewed random variables with heavy tails, while the coefficients associated with the covariates were described by a shifted Legendre polynomial up to third degree, inclusive of an intercept. The maximal model had $3+4\times 9 = 39$ parameters. We used AIC and BIC to assess model fit. As shown by simulations, AIC criterion tends to select overparametrized models, while BIC criterion is more parsimonious with a higher ability to discard irrelevant covariates ($\boldsymbol{x}$) and basis functions ($\boldsymbol{b}(p)$). Results are reported in Table 1.

Table 1 Model selection based on AIC and BIC criteria. We report the number of parameters, the number of selected covariates, the optimal λ value, the value of the minimized loss function, and the p-value of a Kolmogorov-Smirnov goodness-of-fit test.

Criterion	n. of parameters	n. of covariates	λ	Loss	P-value KS
AIC	31/36	7/9	20.79	293.31	.77
BIC	19/36	4/9	60.47	294.01	.53

We used the model selected by BIC and estimated it again using unpenalized QRCM. The model is represented graphically in Figure 1. Because we were mostly interested in the low quantiles of IC, in Table 2 we only report the estimated quantile regression coefficients, $\widehat{\boldsymbol{\beta}}(p) = \boldsymbol{\beta}(p \mid \widehat{\boldsymbol{\theta}})$, at $p = 0.01$, $p = 0.05$, and $p = 0.50$. Age, height, BMI and sex were statistically significant. Figure 1 shows the regression coefficient functions for all covariates over the interval $p \in (0,1)$. Age had a negative effect at all quantiles, and the associated coefficient function showed an increasing linear trend. Per each one-year increase in age, the 1st and 5th percentile of IC decreased by about 0.014 and 0.013 liters respectively, while its median decreased by about 0.01 liters. Height and BMI both had a positive effect. Quantile regression coefficients were increasing, but had a non linear trend. For each one-centimeter increase in height, quantiles below the median increased by approximately 0.03 liters. For each unit increase of BMI, IC increased by 0.033 and 0.037 at the 1st and 5th percentile, respectively, and by 0.056 at the median. The coefficient function associated with the indicator of male gender was positive and increasing. This indicated that the distribution of IC in males was shifted towards upper values and had a longer right tail than that of females.

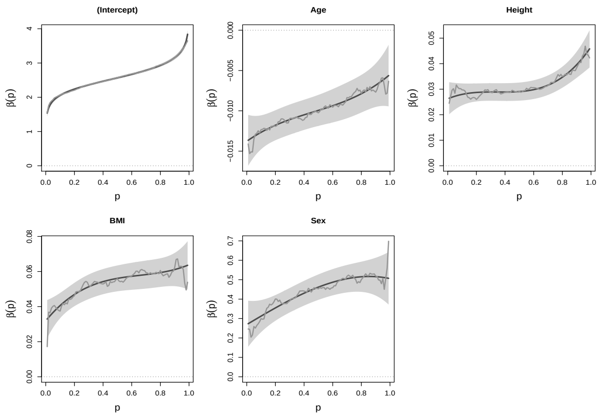

Fig. 1 ILM estimates of $\boldsymbol{\beta}(p)$ under the model selected by BIC. Confidence bands are displayed as shaded areas. The broken lines connect the coefficients of ordinary quantile regression estimated at a grid of quantiles. The dashed line indicates the zero.

Finally, comparing our proposal with standard penalized quantile regression [1, 8] we could observe that it is inefficient and makes it difficult to interpret results, as already mentioned in the introduction. Indeed, different variables are discarded for each percentile, i.e., sex and wheeze for $p = 0.01$, none for $p = 0.05$ and, smoke, occupational exposure, cough and wheeze for $p = 0.50$.

Table 2 Estimated quantile regression coefficients at $p = 0.01$, $p = 0.05$ and $p = 0.50$, obtained from the model selected by BIC. Estimated standard errors in brackets. The asterisk (*) denotes significance less than 0.05.

	$p = 0.01$	$p = 0.05$	$p = 0.50$
Intercept	$1.539(0.049)^*$	$1.893(0.029)^*$	$2.567(0.018)^*$
Age	$-0.014(0.002)^*$	$-0.013(0.001)^*$	$-0.010(0.001)^*$
Height	$0.026(0.003)^*$	$0.027(0.003)^*$	$0.029(0.002)^*$
BMI	$0.033(0.005)^*$	$0.037(0.004)^*$	$0.056(0.004)^*$
Male	$0.273(0.061)^*$	$0.291(0.051)^*$	$0.462(0.033)^*$

5 Discussion

We described a penalized approach that can be applied to the QRCM framework introduced by [5]. Modeling the conditional quantile function parametrically can be more efficient than estimating quantiles one at a time, as in ordinary quantile regression. Moreover, it permits performing model selection directly on the parameters that describe conditional quantiles, instead of proceeding quantile-by-quantile, as the penalized methods for quantile regression proposed so far.

Using this approach has the disadvantage that, as each covariate has multiple associated parameters, the number of model coefficients tends to be large. The PILM estimator demonstrated to select the correct model with a high probability. A computationally efficient algorithm is implemented in the `qrcmNP` package in R.

Simultaneous calibrated prediction intervals for time series

Intervalli di previsione simultanei calibrati per serie storiche

Giovanni Fonseca, Federica Giummolè and Paolo Vidoni

Abstract This paper deals with simultaneous prediction for time series models. In particular, it presents a simple procedure which gives well-calibrated simultaneous predictive intervals with coverage probability equal or close to the target nominal value. Although the exact computation of the proposed intervals is usually not feasible, an approximation can be easily obtained by means of a suitable bootstrap simulation procedure. This new predictive solution is much simpler to compute than those ones already proposed in the literature based on asymptotic calculations. An application of the bootstrap calibrated procedure to first order autoregressive models is presented.
Abstract *Questo lavoro riguarda la costruzione di intervalli di previsione simultanei per serie storiche. In particolare, presenta una semplice procedura per ottenere intervalli di previsione simultanei calibrati con probabilità di copertura uguale o molto vicina al valore nominale. Sebbene il calcolo esatto di questi intervalli non sia sempre possibile, essi si possono approssimare tramite un'opportuna procedura bootstrap. Le approssimazioni così ottenute hanno il vantaggio di essere molto più semplici da calcolare delle soluzioni asintotiche già note. Viene infine presentata un'applicazione della procedura di calibrazione bootstrap per la previsione in modelli autoregressivi del primo ordine.*

1 Introduction

In the statistical analysis of time series, a key problem concerns prediction of future values. Although, in the literature, great attention has been received by pointwise predictive solutions, in this paper we deal with the notion of prediction intervals, which explicitly takes account of the uncertainty related to the forecasting procedure. In particular, we assume a parametric statistical model and we follow the frequentist viewpoint, with the aim of constructing prediction intervals having good coverage accuracy.

It is well-known that the estimative or plug-in solution, though simple to derive, is usually not adequate. In fact, it does not properly take account of the sampling variability of the estimated parameters, so that the (conditional) coverage probability of the estimative prediction intervals may substantially differ from the nominal value.

Improved prediction intervals based on complicated asymptotic corrections have been proposed in a general framework by Barndorff-Nielsen and Cox (1996) and Corcuera and Giummolè (2006) and, for the case of time series models, by Giummolè and Vidoni (2010) and Vidoni (2004). A calibrating approach has been suggested by Beran (1990) and applied, for example, by Hall *et al.* (1999), using a suitable bootstrap procedure. Fonseca *et al.* (2011, 2014) extended this proposal and presented applications to one-step ahead prediction intervals for stationary time series models. Simulation-based prediction intervals for autoregressive processes are also considered by Kabaila and Syuhada (2007). Finally, there is an extensive literature on non-parametric bootstrap prediction intervals for autoregressive time series (see, for example, Clements and Kim, 2007 and references therein).

In this paper we extend the bootstrap calibration procedure proposed in Fonseca *et al.* (2011, 2014) to the multidimensional case. In particular this work is dedicated to the construction of joint prediction regions which are expected to contain a future sequence of observations with the required coverage probability. Although the specification of a multivariate prediction region may be quite general, we restrict our attention to joint regions of rectangular form, which are usually considered for forecasting future paths of time series observations. Recently, Wolf and Wunderli (2015) introduce a similar system of simultaneous prediction limits. In the last section, an application to simultaneous prediction within AR(1) models is presented.

2 Simultaneous calibrated prediction intervals

Given a discrete-time stochastic process $\{Y_t\}_{t\geq 1}$, we assume that $Y=(Y_1,\dots,Y_n)$, $n>1$, is observable, while $Z=(Z_1,\dots,Z_m)=(Y_{n+1},\dots,Y_{n+m})$, $m\geq 1$, is a future or not yet available random vector, corresponding to an m-dimensional sequence of future observations. The vector (Y,Z) is continuous with $g(z|y;\theta)$ and $G(z|y;\theta)$, $\theta\in\Theta$, the conditional multivariate density and distribution function of vector Z given

$Y = y$. In the presence of a transitive statistic U, y is substituted by the observed value u of U.

Given the observed sample $y = (y_1, \dots, y_n)$, a system of simultaneous α-prediction limits for vector Z is a set of functions $c^j_\alpha(y)$, $j = 1, \dots, m$, such that, exactly or approximately,

$$P_{Y,Z}\{Z_j \leq c^j_\alpha(Y), j = 1, \dots, m; \theta\} = \alpha, \tag{1}$$

for every $\theta \in \Theta$ and for any fixed $\alpha \in (0,1)$. In the presence of a finite dimensional transitive statistic, we usually consider the conditional coverage probability

$$P_{Y,Z|U}\{Z_j \leq c^j_\alpha(Y), j = 1, \dots, m|U = u; \theta\} = \alpha. \tag{2}$$

An α-level joint prediction region of rectangular form is readily obtained by specifying two suitable systems of lower and upper simultaneous prediction limits.

As we can see, for example in Ravishanker *et al.* (1991) and Alpuim (1997), simultaneous prediction limits for vector Z in a time series context are usually defined as

$$z_{j,\alpha} = z_{j,\alpha}(Y;\theta) = P_j + h_\alpha(\theta) se_j(\theta), \quad j = 1, \dots, m, \tag{3}$$

evaluated at $\theta = \hat{\theta}$, where $\hat{\theta} = \hat{\theta}(Y)$ is the maximum likelihood estimator for θ, or an asymptotically equivalent alternative. Here $P_j = P_j(Y;\theta)$ is a suitable unbiased point predictor for Z_j, such that $E_{Y,Z_j}(Z_j - P_j) = 0$, with prediction standard error $se_j(\theta) = \sqrt{V_{Y,Z_j}(Z_j - P_j)}$. Indeed, $h_\alpha(\theta)$ is a quantity satisfying

$$P_{Z|Y}\{\mathscr{E}_j \leq h_\alpha(\theta), j = 1, \dots, m|Y = y; \theta\} = F\{h_\alpha(\theta), \dots, h_\alpha(\theta)|y;\theta\} = \alpha,$$

with $\mathscr{E}_j = (Z_j - P_j)/se_j(\theta)$, $j = 1, \dots, m$, the standardized forecast errors with joint distribution function $F(e_1, \dots, e_m|y;\theta)$, conditional on $Y = y$.

In order to compute the prediction limits specified by relation (3), we need a vector of unbiased point predictors $P = (P_1, \dots, P_m)$, the associated vector of prediction standard errors $se(\theta) = \{se_1(\theta), \dots, se_m(\theta)\}$ and the quantity $h_\alpha(\theta) = \varphi^{-1}(\alpha|y;\theta)$, where $\varphi^{-1}(\cdot|y;\theta)$ is the inverse of function $\varphi(x|y;\theta) = F(x, \dots, x|y;\theta)$, which corresponds to the conditional distribution function $F(e_1, \dots, e_m|y;\theta)$ constrained to $\{(e_1, \dots, e_m) \in \mathbf{R}^m | e_1 = \dots = e_m = x\}$. For stationary linear models, we usually consider the optimal predictors $P_j = E(Z_j|Y)$, $j = 1, \dots, m$. Indeed, with this choice for the point forecasts, provided that we have a linear or a Gaussian process, the vector of the (standardized) forecasts errors $(\mathscr{E}_1, \dots, \mathscr{E}_m)$ is independent of Y.

The (unconditional) coverage probability of the estimative simultaneous prediction limits $\hat{z}_{j,\alpha} = z_{j,\alpha}(Y;\hat{\theta})$, $j = 1, \dots, m$, corresponds to

$$\begin{aligned}
P_{Y,Z}\{Z_j \leq \hat{z}_{j,\alpha}, j = 1, \dots, m; \theta\} &= E_Y[P_{Z|Y}\{Z_j \leq \hat{z}_{j,\alpha}, j = 1, \dots, m|Y;\theta\};\theta] \\
&= E_Y[P_{Z|Y}\{\mathscr{E}_j \leq (\hat{z}_{j,\alpha} - P_j)/se_j(\theta), j = 1, \dots, m|Y;\theta\};\theta] \\
&= E_Y[F\{a_1 + h_\alpha(\hat{\theta})b_1, \dots, a_m + h_\alpha(\hat{\theta})b_m|Y;\theta\};\theta] = D(\alpha, \theta),
\end{aligned}$$

where $a_j = a_j(Y,\theta) = (\hat{P}_j - P_j)/se_j(\theta)$ and $b_j = b_j(Y,\theta) = se_j(\hat{\theta})/se_j(\theta)$, $j = 1,\dots,m$, with $\hat{P}_j = P_j(Y;\hat{\theta})$.

Following the calibrating procedure proposed in Fonseca *et al.* (2014) for univariate prediction limits, we may consider function

$$\varphi_c(x|y;\hat{\theta},\theta) = D\{F(x,\dots,x|y;\hat{\theta}),\theta\} = D\{\varphi(x|y;\hat{\theta}),\theta\} \tag{4}$$

instead of $\varphi(x|y;\hat{\theta})$, in order to specify the quantity

$$h^c_\alpha(\hat{\theta},\theta) = \varphi_c^{-1}(\alpha|y;\hat{\theta},\theta) = \varphi^{-1}(D^{-1}(\alpha,\theta)|y;\hat{\theta}) = h_{D^{-1}(\alpha,\theta)}(\hat{\theta}),$$

with $\varphi_c^{-1}(\cdot|y;\hat{\theta},\theta)$ and $D^{-1}(\cdot,\theta)$ the inverse functions of $\varphi_c(\cdot|y;\hat{\theta},\theta)$ and $D(\cdot,\theta)$, respectively. It is easy to show that the calibrated simultaneous prediction limits thus obtained, namely

$$z^c_{j,\alpha}(Y;\hat{\theta},\theta) = \hat{P}_j + h^c_\alpha(\hat{\theta},\theta)\, se_j(\hat{\theta}), \quad j = 1,\dots,m, \tag{5}$$

present a coverage probability equal to the target nominal value α. Indeed, the specification of quantities $h^c_\alpha(\hat{\theta},\theta)$ from (4) determines simultaneous prediction limits satisfying relation (1) exactly for all $\alpha \in (0,1)$.

Whenever a closed form expression for $\varphi_c(x|y;\hat{\theta},\theta)$ is not available, we may consider a suitable parametric bootstrap estimator. Let y^b, $b = 1,\dots,B$, be parametric bootstrap samples generated from the estimative distribution of the data and let $\hat{\theta}^b$, $b = 1,\dots,B$, be the corresponding maximum likelihood estimates. Since $D(\alpha,\theta)$ is defined as an expectation, we define the following bootstrap estimator for (4)

$$\varphi^b_c(x|y;\hat{\theta}) = \frac{1}{B}\sum_{b=1}^{B} F\{\hat{a}^b_1 + h_\alpha(\hat{\theta}^b)\hat{b}^b_1,\dots,\hat{a}^b_m + h_\alpha(\hat{\theta}^b)\hat{b}^b_m|Y;\hat{\theta}\}|_{\alpha=\varphi(x|y;\hat{\theta})},$$

where $\hat{a}^b_j = (\hat{P}^b_j - \hat{P}_j)/se_j(\hat{\theta})$ and $\hat{b}^b_j = se_j(\hat{\theta}^b)/se_j(\hat{\theta})$, $j = 1,\dots,m$, with $\hat{P}^b_j = P_j(Y;\hat{\theta}^b)$. In this case, the associated α-level quantity permits the definition of a system of simultaneous prediction limits with coverage probability equal to α, apart from an error term depending on the efficiency of the bootstrap procedure.

3 Example: AR(1)

Let $\{Y_t\}_{t\geq 1}$ be a first-order Gaussian autoregressive process with

$$Y_t = \mu + \rho(Y_{t-1} - \mu) + \varepsilon_t, \qquad t \geq 1,$$

where μ and ρ are unknown parameters and $\{\varepsilon_t\}_{t\geq 1}$ is a sequence of independent Gaussian random variables with zero mean and unknown variance σ^2. We assume $|\rho| < 1$ so that the process is stationary. The observable random vector is

$Y = (Y_1,\dots,Y_n)$ and the next m realizations of the process are $Z = (Y_{n+1},\dots,Y_{n+m})$. The conditional distribution of Z given $Y = y$ is Gaussian with mean $\mu_{Z|Y} = (\mu_{n+1},\dots,\mu_{n+m})$, where $\mu_{n+1} = \mu + \rho(y_n - \mu)$, $\mu_{n+k} = \mu + \rho(\mu_{n+k-1} - \mu)$, $k = 2,\dots m$, and variance-covariance matrix Σ where $\Sigma_{ij} = \sigma^2\rho^{|i-j|}$. Indeed, Y_n is a transitive statistic and we evaluate the performance of simultaneous prediction limits by means of their coverage probability conditioned on the observed value y_n of Y_n, as in (2).

A simulation study shows the performance of the proposed predictive solution (5). Conditional coverage probabilities for estimative and bootstrap calibrated prediction limits of level $\alpha = 0.9$ are calculated by means of the simulation technique presented in Kabaila (1999), keeping the last observed value fixed to $y_n = 1$. The results for $m = 2,5$ future variables are collected in Table 1 and show that the bootstrap solution remarkably improve on the estimative one.

Table 1 AR(1) Gaussian model. Conditional coverage probabilities for simultaneous estimative and bootstrap calibrated prediction limits of level $\alpha = 0.9$, conditioned on $y_n = 1$; $m = 2,5$ future observations are predicted; μ is considered to be known and equal to 0; $\rho = 0.5, 0.8$, $\sigma^2 = 1$ and $n = 20$. Estimation is based on 1,000 Monte Carlo replications. Bootstrap procedure is based on 500 bootstrap samples. Estimated standard errors are always smaller than 0.011.

m	ρ	Estimative	Calibrated
2	0.5	0.872	0.898
	0.8	0.859	0.895
5	0.5	0.859	0.893
	0.8	0.857	0.884

Reversibility and (non)linearity in time series
Reversibilità e (non)linearità nelle serie storiche

Luisa Bisaglia and Margherita Gerolimetto

Abstract The recent literature has proposed a (limited) number of approaches to test for time reversibility, that is one of the main hypotheses in time series. A very interesting proposal is a Gini-based framework that, among other things, includes a test for time reversibility focussing on possible differences between backward and forward autocorrelations. This feature is indeed useful to identify models with underlying heavy tailed and non-normal innovations. In this paper we intend to shed some more light on this and investigate, via Monte Carlo simulations, on the possibility that this test can effectively have power in detecting some form of nonlinearity.

Key words: Reversibility, long memory, bootstrap

1 Introduction

Time reversibility is one of the main features of strictly stationary Gaussian linear stochastic processes. From an intuitive point of view, a stochastic process is said to be time-reversible if its probabilistic structure is invariant with respect to the reversal of the time indices. In an applications perspective, a check for time reversibility is a useful addition to existing diagnostics for stationary data since the absence of this feature (so the process is irreversible) signals the exclusion of serially independent or gaussian processes as candidate models.

Starting from the late Nineties the literature has discussed the issue of testing for time reversibility (Ramsey and Rothman, 1996; Hinich and Rothman, 1998; Chen *et al.*, 2000; Chen, 2003). Among the most recent contributes, Racine and Maasoumi (2007) proposed an approach based on an entropy measure of symmetry. Psaradakis

(2008) introduces a sample index of the deviation from zero of the median of the one-dimensional law of differenced data. Shelef and Schechtman (2016) develop a framework for time series anaylsis based on a set of Gini-based equivalents that, among other things, introduces a test for time reversibility focussing on possible differences between backward and forward (in time) autocorrelation. This feature is indeed useful to identify models with underlying heavy tailed and non-normal innovations. One of the nice advantages of this method is that is based on only first-moment assumption.

While there are several finite sample experiment documenting the capability of this class of test for time reversibility to recognize situations that depart from gaussianity, in particular heavy tailed innovations, there is nothing to our knowledge about the possibility that this test can effectively have power in dectecting some form of nonlinearity. Indeed, although nonlinearity does not necessarily imply time-irreversability, (see, e.g., Lewis *et al.*, 1989) time reversible nonlinear processes appear to be the execption rather than the rule (Tong, 1990). With this in mind, in this paper we propose a Monte Carlo experiment, where time reversibility is tested for a variety of the most common non-linear models. For some type of models, in particular TAR and Markov Switching, the results are very promising and require further investigation that is in the future research lines.

The paper is organizes as follows. In section 2 we recall the Gini-based time reversibility test. In section 3 we propose our Monte Carlo experiment and some selected results. Section 4 concludes.

2 Gini-based reversibility test

2.1 Overview

From a formal point of view, a strictly stationary discrete-parameter stochastic process Y_t is said to be time reversible if $(Y_{t1},...,Y_{th})$ and $(Y_{-t1},...,Y_{-th})$ have the same joint distributions for every $h \in \mathcal{N}$ and any h-tuple $(t_1,...,t_h)$ such that $-\infty < t_1 < ... < t_h < \infty$. Put it differently, Y_t is time reversible if looking forward and backward at the time series result in similar probabilistic structure. Weiss (1975) showed that time reversibility for finite order ARMA processes is a typically Gaussian property.

Shelef and Schechtman (2016) shows that time reversibility can be associated to some form of symmetry. This, in turn, can be investigated by observing the behaviour of the two Gini autocovariances at lag s.

$$\gamma^{G1}_{(t,t_{t-s})} = COV(Y_t, F(Y_{t-s})) \qquad \gamma^{G2}_{(t,t_{t-s})} = COV(Y_{t-s}, F(Y_t)) \tag{1}$$

The above expressions can be viewed as Gini autocovariances looking backward and forward. Under strictly stationarity conditions, the following equality hold for all t and s

$$\gamma^{G_1}_{(s)} = COV(Y_t, F(Y_{t-s})) = COV(Y_{t-j}, F(Y_{t-j-s})) \tag{2}$$

and

$$\gamma^{G_2}_{(s)} = COV(Y_{(t-s)}, F(Y_t)) = COV(Y_{(t-j-s)}, F(Y_{t-j})) \tag{3}$$

where $\gamma^{G_1}_{(s)}$ and $\gamma^{G_2}_{(s)}$ are time independent. Note that $\gamma^{G_1}_{(s)}$ and $\gamma^{G_2}_{(s)}$ are equal in case of time reversibility.

When stationarity holds, a Gini version of the autocorrelation function (ACF) between Y_t and Y_{t-s} can also be defined

$$\rho^{G_1}_{(s)} = \frac{\gamma^{G_1}_{(s)}}{\gamma^{G_1}_{(s=0)}} \qquad \rho^{G_2}_{(s)} = \frac{\gamma^{G_2}_{(s)}}{\gamma^{G_2}_{(s=0)}} \tag{4}$$

It is interesting to observe that for an $AR(1)$ process, $Y_t = \phi_0 + \phi_1 Y_{t-1} + \varepsilon_t$, we have that $\gamma^{G_1}_{(s)} = \phi^s \gamma^{G_1}_{(s=0)}$, then $\rho^{G_1}_{(s)} = \phi_1^s = \rho(s)$ and this indicates that the first Gini-ACF is equal to the traditional ACF, denoted by ρ_s.

Consistent Gini-ACFs estimates are the following (Shelef and Schechtman, 2016)

$$\hat{\rho}^{G_1}_{(s)} = \frac{\sum_{t=1}^{T-s}(Y_{t+s} - \bar{Y})(R(Y_t) - \bar{R}(Y_{1:(T-s)}))}{\sum_{t=1}^{T}(Y_t - \bar{Y})(R(Y_t) - \bar{R}(Y_{1:T}))} \tag{5}$$

and

$$\hat{\rho}^{G_2}_{(s)} = \frac{\sum_{t=1}^{T-s}(Y_t - \bar{Y})(R(Y_{t+s}) - \bar{R}(Y_{(s+1):T}))}{\sum_{t=1}^{T}(Y_t - \bar{Y})(R(Y_t) - \bar{R}(Y_{1:T}))} \tag{6}$$

where $R(Y_t)$ is the rank of Y_t and $\bar{R}(Y_{i:j}) = \sum_{t=i}^{j} R(Y_t)/(j-i+1)$.

The Gini-based framework by Shelef and Schechtman (2016) also includes Gini PACF, defined as the last coefficient of a partial Gini autoregression equation of order s

$$Y_t = \phi^{G_1}_{s1} Y_{t-1} + \phi^{G_1}_{s2} Y_{t-2} + ... + \phi^{G_1}_{ss} Y_{t-s} + \varepsilon_t$$

hence

$$\rho^{G_1}_{(j)} = \phi^{G_1}_{s1} \rho^{G_1}_{(j-1)} + ... + \phi^{G_1}_{ss} \rho^{G_1}_{(j-s)}$$

Plugging the second Gini ACF ($\rho^{G_2}_{(s)}$) in place of the first, leads to a second version of the Gini PACF, that can be called second Gini-PACF. As for the estimation, the two Gini-PACFs can be estimated solving for $\phi^{G_1}_{ss}$ and $\phi^{G_2}_{ss}$, $s = 1, 2, ...$ the implied two systems of equations.

2.2 Testing for time reversibility

Implied by the definition of time reversibility itself, a crucial feature of the Gini autocorrelations is that if the series is time reversible, the Gini-ACFs at the remarkable lags are equal. Hence, generally, if the Gini-ACFs differ, this should indicate that Y_t

and Y_{t-s} are not exchangeable and this in turn implies time irreversibility. In order to capture this feature in case of moving average, MA(q), processes whose ACFs cuts off after q lags, Gini-PACFs should also be taken into consideration. This leads (Shelef and Schechtman, 2016) to the following system of hypotheses at each lag s for the null hypothesis of time reversibility

$$H_{01} : \rho_{(s)}^{G_1} = \rho_{(s)}^{G_2} \quad and \quad H_{01} : \phi_{ss}^{G_1} = \phi_{ss}^{G_2} \tag{7}$$

The alternative hypothesis is that at least one of the two equation is violated (for further detail, see the original article by Shelef and Schechtman, 2016).

The logic followed by the authors aims at identifying large absolute differences between the sample Gini ACFs and PACFs, denoted by, respectively, $\hat{\theta}_{Gini-ACF(s)} = \hat{\rho}_{(s)}^{G_1} - \hat{\rho}_{(s)}^{G_2}$ and $\hat{\theta}_{Gini-PACF(s)} = \hat{\phi}_{ss}^{G_1} - \hat{\phi}_{ss}^{G_2}$. The test statistic then is

$$\sqrt{T}\left|\hat{\theta}_{Gini-ACF(s)} - \theta_{Gini-ACF(s)}, H_0\right| \quad and \quad \sqrt{T}\left|\hat{\theta}_{Gini-PACF(s)} - \theta_{Gini-PACF(s)}, H_0\right|$$

where under the null hypothesis the differences are equal to zero. In practice, large value of the test statistics support rejection of the null hypothesis.

Due to the complicated sampling distribution of the Gini-based estimators, that also involve additional restrictive assumption on the time series, critical values for this test tests are obtained via moving block bootstrap. All details about the algorithms are in Shelef and Schechtman (2016).

3 Reversibility and (non)linearity: preliminary Monte Carlo evidence

In their original paper, Shelef and Schechtman (2016) conduct a Monte Carlo experiment showing that at least at the first lags the proposed Gini-based time reversibility test reaches a reasonably high power when the innovations of the ARMA models are not Gaussian, but Pareto, lognormal and α–stable.

Here we intend to study the power of this test under a different setting, *i.e* in case the data generating process (DGP) is nonlinear. This is a very preliminary study and at this beginning stage we consider only some nonlinear DGPs. They are listed below, innovations are distributed as $N(0,1)$:

1. TAR(1,1), where

$$X_t = \begin{cases} -0.5X_{t-1} + a_t & X_{t-1} \leq 1 \\ 0.4X_{t-1} + a_t & X_{t-1} > 1 \end{cases}$$

$$X_t = \begin{cases} 2 + 0.5X_{t-1} + a_t & X_{t-1} \leq 1 \\ 0.5 - 0.4X_{t-1} + a_t & X_{t-1} > 1 \end{cases}$$

$$X_t = \begin{cases} 1 - 0.5X_{t-1} + a_t & X_{t-1} \leq 1 \\ 1 + a_t & X_{t-1} > 1 \end{cases}$$

2. MS(1), where

$$X_t = \begin{cases} -0.5X_{t-1} + a_t & s_t = 1 \\ 0.4X_{t-1} + a_t & s_t = 2 \end{cases}$$

with $p_{11} = p_{22} = 0.5,\ 0.9$.
3. $BL(0,0,1,1)$, where $X_t = a_t + 0.5X_{t-1}a_{t-1}$
4. $BL(0,0,2,1)$, where $X_t = a_t + 0.8X_{t-1}a_{t-1} + 0.5X_{t-2}a_{t-1}$

The number of Monte Carlo simulations is 2000, the number of bootstrap replications for the moving block bootstrap is 500 and the block size is 30 (following the findings by Shelef and Schechtman, 2016). The considered sample sizes are $T = 200, 500, 1000$.

Table 1 Percentages of rejection ($m = 1,2$ number of lags, nominal level 0.05)

	T=200		*T=500*		*T=1000*	
	$m=1$	$m=2$	$m=1$	$m=2$	$m=1$	$m=2$
DGP1: TAR(1,1)	37.7	20.0	72.8	35.3	96.8	50.3
DGP2: TAR(1,1)	42.8	18.8	88.8	41.2	100	61.4
DGP3: TAR(1,1)	45.8	24.8	79.5	49.6	91.6	50.4
DGP4: BIL(0,0,1,1)	22.4	12.4	45.6	17.4	62.8	35.5
DGP5: BIL(0,0,2,1)	27.6	17.4	57.6	28.7	73.6	43.6
DGP6: MS(1)	100	62.4	100	82.6	100	92.3
DGP7: MS(1)	100	90.8	100	93.8	100	95.7

Our empirical power results are shown in table 1. They clearly reveal a very interesting capability of the test to detect nonlinearity with the increase of T. As expected, the percentage of rejections is very high for the largest sample size ($T = 1000$), especially for TAR and MS model, but also for smaller values of T the behaviour is fairly good. In particular, for the MS DGPs the test detects successfully the nonlinear feature even at $T = 200$. Moreover, results are in line with the performance of the majority of nonlinearity test in literature (see Bisaglia and Gerolimetto (2014) for a recent survey on nonlinearity tests and a comparative Monte Carlo experiment). It should be remarked that, as emphasized by Shelef and Schechtman (2016), the performance tends to deteriorate with the increase of m.

As said at the beginning of this section, this is only a preliminary Monte Carlo experiment. Yet, we find these results promising, in particular the test appears to perform well for Markov Switching models (followed by TAR models). We reckon that this could be effectively an alternative route to check for nonlinearity. Some other investigations are in order both in terms of Monte Carlo simulations (e.g. comparison with analogous test provided in the literature) and possible improvement of the performance of the test, for instance by considering other resampling methods to obtain the critical values.

Heterogeneous effects of subsidies on farms' performance: a spatial quantile regression analysis

Effetti eterogenei dei sussidi sulle performance delle aziende agricole: un'analisi basata sulla regressione quantilica spaziale

Marusca De Castris and Daniele Di Gennaro1

Abstract Italian agricultural sector is characterized by a wide heterogeneity which can affect the effectiveness of rural policies and, by consequence, economic performances. Indeed, wide differences arise both at farm (i.e. sector, dimension, etc.) and regional levels. In particular, Giannakis and Bruggeman (2015) show how agricultural policies can provide enlarge regional disparities between advanced and lagged regions. In this paper, we analyse the differential impact of the policies by considering Italian lagged regions. The introduction of a Spatial Autoregressive Quantile model allows to take into account both spatial and farm-specific characteristic. Evidences are found in favour of significant and positive spatial spillovers of the policies, especially for the less performing farms.

Abstract *L'eterogeneità presente nel settore agricolo Italiano può influenzare l'efficacia delle politiche rurali e, conseguentemente, le performance economiche delle aziende. In tal senso, disparità possono emergere in relazioni ai fattori propri delle aziende agricole (settore, dimensione, ecc.) e del contesto regionale. Giannakis e Bruggeman (2015) mostrano come le politiche rurali incrementino le disparità tra aree avanzate ed arretrate. Limitando l'analisi ad alcune regioni del sud, abbiamo analizzato l'impatto differenziale degli incentivi considerando le caratteristiche spaziali delle aziende agricole attraverso una regressione quantilica spaziale. I risultati mostrano esternalità significative e positive delle politiche, soprattutto per le aziende con performance più basse.*

1 Introduction

This paper aims to evaluate the efficacy of Common Agricultural Policy (CAP) to improve performances by focusing on Italian lagged regions. Agricultural sector is deeply rooted in place-based production processes. The presence of spatial dependence produces biased estimates of the performances. This paper, using data on subsidies and economic results of farms from the RICA dataset, which is part of the Farm Accountancy Data Network (FADN), proposes a spatial Augmented Cobb-Douglas Production Function to evaluate the effects of subsidies on farm's performances. The major innovation of our study is the implementation of a micro-founded quantile version of a spatial lag model (Kim and Muller, 2004) to examine how the impact of the subsidies may vary across the conditional distribution of agricultural performances. Results show a significant decreasing shape along the distribution of the subsidies which becomes negligible for higher quantiles.

2 Data and Methodology

In 2008, EU-27 countries deal with a contraction of agricultural production, in real terms, and a deflationary trend on prices. Additionally, the volatility on both energy and fertilizer markets boosts input prices and contributes to an overall reduction of added value per worker and employment. Under this perspective, Italian case is of particular interest. Italian added value at factor cost increased by 2.4%, while the sectoral share of the GDP remains stable at the 2.3%. However, the good economic performances are not sufficient to reduce the gap between agriculture and the other economic sectors[1].

Indeed, Italy is characterized by several structural problems which affect agricultural performances. These issues include the presence of systematic differences between North and South, the lack of young farmers (only 13,2 % has less than 44 years) and the land abandonment on marginal areas, especially for high altitude zones.

The gap between North and South appear clear in terms of added value per worker unit. Although Southern regions grow more than the ones in the North (3.5% vs 0.6%), the average added value per worker unit is still well below Italian average (19300 vs 22000 €). In this paper, we consider how the structural weakness of Southern agriculture[2] can affect the efficacy of public support by focusing on the

[1] Agricultural added value at factor cost per worker unit is 24316 € (44% of the average of Italian economy).

[2] The development gap between North and South is not limited to primary sector. Indeed, regions located in the South of Italy are recognized, by European Commission, as less developed and transition regions. This classification is based on the levels of GDP and employment. Less developed (resp. transition) regions include the areas where GDP per head is less than 75% (resp. between 75 and 90%) of the EU average. The Italian less developed regions are Campania, Apulia, Calabria, Sicily and Basilicata, while transition regions are Abruzzo, Molise and Sardinia. However, we exclude Campania from our analysis

impact of agricultural policies on economic performances. For the year 2008, we exploit information from RICA dataset[1] by introducing five different variables in our analysis. The final dataset is composed by 1298 farms.

Variable	*Label*	*Unit*	*Description*
Value Added	VA	€	Total Revenues-Current Expenses
Labour	L	Unit	Full time worker
Capital Stock	K	€	Land+Agricutltural Fixed Capital
Land	G	Hectares	Utilised Agricultural Area
Subsidies	S	€	Total amount subsidies per farm

In this table we resume all the major determinants on value added formation in the primary sector: Labour, Fixed Capital, Land and Subsidies. The differential impact of all the different variables in determining and stimulating value added is considered by estimating a Cobb-Douglas APF. The dependent variable, value added, is a proxy of economic performances, while subsidies is a composite variable obtained by adding all the amount of the different public instruments allocated to every farm (i.e. we do not distinguish between National or European fund or between policies devoted to current activities, rural development or capital subsidies) and it can be considered as a global indicator of the public capital. In this sense, our baseline takes the form in:

$$\ln(\mathrm{Y}) = \ln \mathrm{A} + \alpha * \ln \mathrm{L} + \beta * \ln \mathrm{K} + \gamma * \ln \mathrm{G} + \delta * \ln \mathrm{S} \qquad (1)$$

Checking for the presence of spatial dependence, we found evidences of a significant spatial autocorrelation. In this way, our final model becomes:

$$ln(Y) = \rho \mathrm{W} * \ln(\mathrm{Y}) ln\, A + \alpha * ln\, L + \beta * ln\, K + \gamma * \ln G + \delta * ln\, S \qquad (2)$$

This equation takes the traditional form of a so-called Spatial Autoregressive Model[2] (SAR). Equation (2) introduces a spatial weight matrix, W. This matrix is based on a cut-off distance (33 km) ensuring the presence of at least one neighbour for every single farm. In this paper, considering the wide heterogeneity between different farms we make use of a Spatial Quantile version of a traditional SAR.

2.1 Spatial Quantile Regression

Quantile regression is an important method for including heterogeneous effects of covariates on a response variable (Koenker and Hallock, 2001). To include the

for a lack of comparability with the other southern regions, while Abruzzo and Molise are not considered for a lack of information about the farms located in these regions.

[1] Rica is part of the European Farm Accountancy data network (FADN) and it represents the only harmonized survey to collect micro-economic data on firms operating in agricultural. Italian RICA collects information on 11000 farms sampled at regional level. RICA's field of observation considers only the farm with at least 1 hectare of UAA or a production value greater than 2500 Euros.

[2] Lesage and Pace (2009) provide an in-depth analysis on the estimation of a SAR model and its decomposition of the marginal impacts.

presence of interactions, the quantile regression generalisation of the (linear) spatial lag model can be written as:

$$\mathrm{Y} = \rho(\tau)\mathrm{WY} + \mathrm{XB}(\tau) + \mathrm{u} \qquad (3)$$

where $Y = Q_{(\tau)}(Y|X)$ is the conditional quantile function of Y, τ refers to the selected quantile and $B(\tau)$ is the vector of the sensitivity coefficients of the conditional quantile on changes in value of the covariates X. Estimating spatial quantile regression for different quantiles allows to predict the distribution of the outcome variable at given values of the explanatory variables (McMillen and Shimizu,2017). Equation (3) underlines that the spatial parameter, ρ, is dependent from the considered quantile τ, allowing for different degree of spatial dependence across the conditional distribution.

In this paper we follow the two-stage estimation procedure in Kim and Muller(2004)[1].This approach were initially developed to control for endogeneity in "traditional" quantile regression model, but adjustments to deal with the spatial endogeneity in a Spatial Autoregressive quantile model were straightforward.

On the first step, a variable constituted by the spatial lag of Y (in our case Added Value) is regressed over a set of instruments, as in Equation (4):

$$\widehat{\mathrm{WY}} = \mathrm{Z}\theta(\tau) + \mathrm{u}, \qquad Z = [X, WX] \qquad (4)$$

Instruments are selected following the intuition in Kelejian and Prucha (1998). Low order interactions are needed to avoid linear dependence and retain full column rank of the set of instruments (Baltagi et al. ,2014). At the second stage, the variable $\widehat{\mathrm{WY}}$ is added on a quantile regression of Y on the X's.

$$\mathrm{Y} = \rho(\tau)\widehat{\mathrm{WY}} + \mathrm{XB}(\tau) + \mathrm{u} \qquad (5)$$

Clearly, τ refers to the same quantile in both equations (4) and (5). The consistency in this approach is guaranteed by estimating differentiated first stages for every quantile considered, while inference based solely on the second-stage of the procedure can be invalid. For this reason, standard errors for the overall two-stage procedure are bootstrapped.

3 Results

Results of the spatial autoregressive quantile regression are presented in Table 2 and Figure 1. While in Table 2 we report only the estimates for the tails (0.1 and 0.9) and the median of the distribution, Figure 1 represent the entire conditional distribution of the parameters (i.e. every percentile between 0.01 and 0.99).

In overall, results show that labour (Figure 5) is the major components in fostering economic performances with an elasticity of 0.8. The distribution across the quantiles is pretty stationary, highlighting the independence of labour from the level of economic performances (i.e. homogeneous effects).

[1] Chernozhukov and Hansen (2006) propose an alternative approach based on a generalisation of the instrumental variables framework to allow for estimation of quantile models.

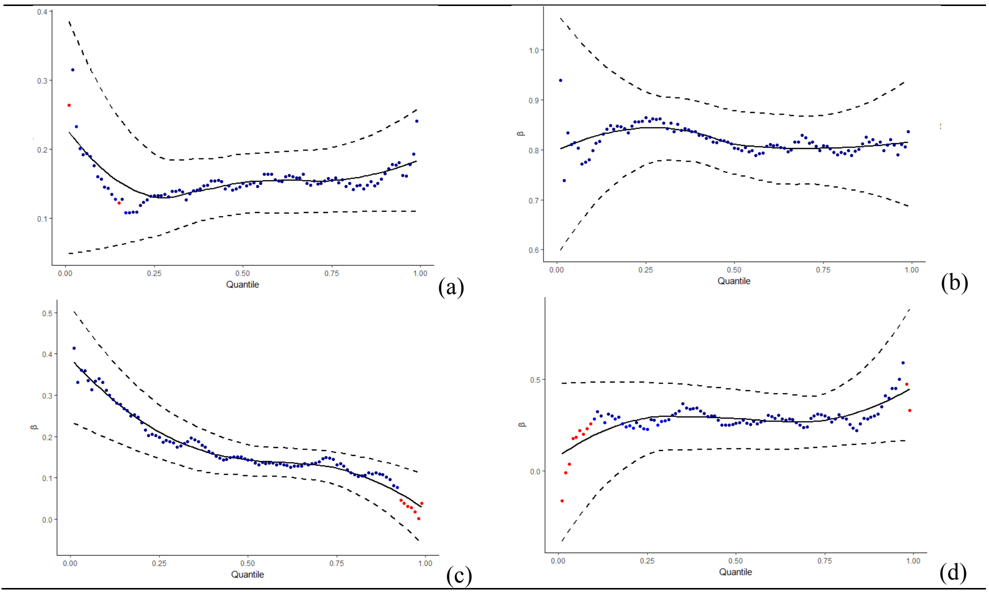
Interestingly, fixed capital has a stronger impact in the extremes of the distribution, presents a decreasing shape with a maximum in lowest quantile which turn to increase at the first quartile (i.e. low and high levels of fixed capital influence more economic performances). However,Subsidies shows major evidences in favour of the heterogeneity of the effects. This component shows a decreasing shape across all the distribution, with an inflection point in the neighbourhood of the median. Surprisingly, lower levels of subsidies have a greater impact on farm's performances (+1% of public funding contributes to an increase of 0.4%in added value), while for the upper tail decrease to less than 0.1 and switch to be not significant. Land follows an increasing distributional shape, but it is not significant across all the distribution.

Table 2: Spatial Quantile Regression Estimation

	Coeff	Z-value	P-Value	Quantile
K	0.16	3.82	0.00	
L	0.80	13.65	0.00	
G	-0.05	-0.89	0.37	0.1
S	0.31	6.61	0.00	
P	0.28	2.26	0.02	
K	0.15	7.19	0.00	
L	0.80	23.98	0.00	
G	0.05	2.55	0.01	0.5
S	0.14	7.79	0.00	
P	0.26	3.78	0.00	
K	0.17	5.55	0.00	
L	0.81	16.88	0.00	
G	0.10	2.95	0.00	0.9
S	0.10	3.66	0.00	
P	0.31	2.98	0.00	

Note: Estimates are reported in terms of elasticities, while the cut-off distance considered is 33 km.

Figure 1: Spatial Quantile Regression Estimation



Note: Figure 1 shows the estimates of the Spatial AR model for every quantile. Panel (a) reports estimates for variable K, (b) for L, (c) for S and (d) for ρ. The graph for the ground is not reported because of a lack of significance. Solid line represents the smoothed function of the estimates, while dashed lines are the confidence interval at 95%. Statistical significance is reported by different colours: Dark Blue= 0.01, Light Blue= 0.05, Red no significance

Lastly, evidences of significant spillover effects are found. Distributional shape of ρ (Figure 1-d) parameter shows a positive and significant effect on economic performances, even if both lower and upper tails are not meaningful. These results provide clear evidences in favour of the existence of spatial patterns on agricultural activities in Italian lagged regions. However, this parameter is not sufficient to estimate the intensity of the spillover effects. In this sense, we decompose the marginal impacts by following the traditional procedure presented in LeSage and Pace (2009).

Table 3: Marginal Impacts

Marginal Impact	K	L	G	S	*Quantile*
D	0.16***	0.80***	-0.05	0.31***	0.1
	[3.33]	[15.11]	[-1.00]	[7.55]	
I	0.06	0.31	-0.02	0.12	
	[1.56]	[1.64]	[-0.84]	[1.60]	
T	0.22**	1.12***	-0.07	0.44***	
	[3.05]	[5.22]	[-1.00]	[4.45]	
D	0.15***	0.81***	0.05°	0.14***	0.5
	[7.07]	[24.41]	[1.93]	[6.56]	
I	0.05*	0.28**	0.02	0.05**	
	[2.26]	[2.50]	[1.41]	[2.69]	
T	0.21***	1.08***	0.06°	0.19***	
	[5.43]	[9.46]	[1.85]	[6.85]	
D	0.17***	0.81***	0.10**	0.10***	0.9
	[5.87]	[17.41]	[2.97]	[4.06]	
I	0.07°	0.36*	0.04°	0.04°	
	[1.93]	[2.22]	[1.72]	[1.84]	
T	0.24***	1.18***	0.14**	0.14***	
	[4.13]	[7.01]	[2.75]	[3.43]	

Note: Table 3 presents the results of the decomposition in direct (D), indirect (I) and total effects (T). Q indicates the considered quantile. Estimates are considered in terms of elasticities, while z-values are in square brackets. The z-values and p-values are estimated by Bootstrap.

Statistical significance: *** <0.001, ** 0.01, * 0.05,°0.1

Spatial quantile regression requires an in-depth analysis for every quantile considered. Table 3 resume the decomposition of the marginal effects for the tails and the median of the conditional distribution. Direct and total effects estimates are positive and significant across all the conditional distribution for all the variables, while results on land are ambiguous and negligible. Nonetheless labour and fixed capital provide evidences of homogeneous effect on the outcome variable conditional to different level of the covariates, we provide evidences of heterogeneous effects for the subsidies.

In detail, the effect of the policies slightly declines for higher quantiles. The wider extension of significant positive effects at the lower quantiles suggests that there is an inverse relationship between subsidies and economic performances. Lower levels of subsidies are devoted to farmers which benefit of agricultural policies as an income maintenance instrument and for which, consequentially, economic performances are mainly affected. Looking at the indirect effects, fixed capital becomes less effective and seems to be not linked to neighbouring characteristics, while positive and significant spillover effects are found in terms of human and public capital. The indirect effects on labour can be explained in terms of favouring qualified labour mobility between neighbouring areas, while the impact on the subsidies is mainly related to structural, environmental and administrative conditions which are in deeply rooted in provincial and regional structure and which can be shared between neighbouring farms.

Conclusions

The heterogeneity arising in Italian agricultural sector can be deeply analysed by a spatial quantile regression model which highlights how both spatial and individual characteristics can influence the performance. Our analysis shows homogeneous effect of farm-specific factors (i.e. labour, fixed capital and land) on economic performance, while heterogeneous impacts of the policies are found, in particular for less performing farms. Evidences of positive and significant spillovers are limited to the inner part of the distribution. In this sense, this paper confirms the hypothesis that actual rural policies are designed as an income support instrument for the farmers.

On the estimation of high-dimensional regression models with binary covariates

Sulla stima dei modelli di regressione ad alta dimensionalità con covariate binarie

Valentina Mameli[1], Debora Slanzi[1,2] and Irene Poli[1,3]

Abstract In this paper we address the problem of estimating the parameters of high dimensional regression models characterized by binary covariates. We suggest a new procedure which combines particular clustering for the binary covariates and group penalized regression for estimating the model parameters. The good performance of the methodology is shown in a simulation study.

Abstract *Questo lavoro affronta il tema della stima di modelli di regressione ad alta dimensionalità con covariate binarie. In particolare, si propone un procedura di stima per questa classe di modelli che combina tecniche di cluster analisi e modelli di regressione penalizzata di gruppo. La metodologia proposta viene valutata con uno studio di simulazione.*

1 Introduction

In many scientific fields of research, recent advances in technology have allowed to gather data sets characterized by a very high number of variables. The sample size of these data can be small compared to the number of variables and only a small number of these variables can be relevant to the study. Moreover, in several contexts binary variables are present to express the presence or absence of particular

elements or features. For this structure of the problem we would like to provide a contribution in developing a procedure to select influential variables and estimate model parameters. Several different methodologies have been suggested in literature for variable selection in high-dimensional models, among these penalized regression models have gained popularity over the last few decades; see among others [4, 7, 1, 11, 6, 2]. Penalized procedures are designed with the aim of both selecting the most relevant variables and estimating the parameters of the models. In a general regression setting, models with continuous explanatory variables have been extensively studied, while models with binary explanatory variables have received much less attention.

The aim of this paper is to derive a new procedure to estimate high-dimensional models by combining the class of penalized regression models with binary variables clustering techniques. We propose to estimate penalized regressions based on the information obtained from the introduction of a grouping structure of covariates. More specifically, we propose a two-step procedure: in the first step, we group the covariates into non-overlapping clusters (or groups) using an approach able to deal with the binary nature of the covariates; in the second step, we select the most relevant clusters and covariates by using a penalized regression procedure in which the information obtained in the clustering phase is embedded.

The paper is organized as follows. In Section 2 we review some variable selection procedures, for individual, for group and for bi-level selection; we then present a new inferential procedure for high-dimensional regression models with binary covariates based on penalized regression models and clustering techniques. In Section 3 we conduct a simulation study to evaluate the performance of the new procedure.

2 Methodology

2.1 Model set-up

Le us consider the multiple linear regression model

$$y_i = X_i\beta + \varepsilon_i, \quad i = 1,\dots,n \tag{1}$$

where $X_i = (x_{i1},\dots,x_{ip})^T$ is a p-dimensional vector of explanatory variables (or covariates), y_i is the response value for the i-th observation, ε_i is the error term, n is the sample size and $\beta = (\beta_1,\dots,\beta_p)$ is the vector of parameters. The vector β is unknown and has to be inferred from the data. When the number of variables, p, is much larger than the sample size n the model is usually referred as a high-dimensional regression model. If only a small number of variables affects the response, the model results to be characterized by the *sparsity* condition [7]. To estimate the vector of regression coefficients β we consider penalized regression models and minimize the following function

$$Q(\beta) = \frac{1}{2n}(y - X\beta)^T (y - X\beta) + P(\beta|\lambda), \tag{2}$$

where $y = (y_1, \ldots, y_n)^T$ is the $n \times 1$ vector of response values and $X = (X_1, \ldots, X_n)^T$ is the $n \times p$ design matrix. The function $P(\cdot)$ is defined as a penalty on the regression coefficient parameters β and λ is a tuning parameter. The most used methods for choosing λ are cross-validation criteria or information criteria (see [9] among others). A number of penalized regression methods have been proposed in literature; see among others [6]. They include procedures for individual variable selection, group variable selection and bi-level variable selection. The Least Absolute Shrinkage Selection Operator (LASSO) proposed by [7] is one of the most famous procedure for individual variable selection. If the main interest is in selecting relevant groups of covariates and not individual ones, it is possible to take account of a grouping structure among the covariates as in group penalized regression procedures which include the group LASSO ([10]), the group Minimax Concave Penalty method [6] and the group Smoothly Clipped Absolute Deviation [6]. If, on the other hand, the focus is on selecting both the important groups of covariates as well as variables within these groups, bi-level selection procedures can be considered as the composite Minimax Concave Penalty ([1]), and the group exponential LASSO ([2]). These selection procedures have been introduced to overcome some limitations of the LASSO estimator and present a number of appealing properties in terms of both estimation accuracy as well as variable selection properties. Although a large amount of work has been done in the literature on the selection of continuous covariates in the high-dimensional framework, less attention has been given to the binary covariates case. To address the problem of estimating high-dimensional regression models with binary covariates we develop a methodology based on combining clustering techniques with penalized regression models. In this procedure a crucial step is the selection of binary variables groups to be embedded into the penalized regression model. The group selection can lead to a more effective variable selection and accurate predictions.

2.2 *Estimating the parameters of the clustering structure regression*

For a given clustering structure, the model (1) can be specified as

$$y = \sum_{k=1}^{K} \tilde{X}_k \tilde{\beta}_k + \varepsilon,$$

where $\tilde{X}_k$ is the $n \times d_k$ design matrix representing the d_k covariates belonging to the k-th cluster, $\tilde{\beta}_k = (\beta_{k1}, \ldots, \beta_{kd_k}) \in \mathbb{R}^{d_k}$ is the vector of regression coefficients of the k-th cluster and $\varepsilon = (\varepsilon_1, \ldots, \varepsilon_n)$ is the error vector. Let x_{ij} be the value of X_j at the i-th observation. Assume that $x_{ij} = 1$ if X_j is present in the i-th observation and $x_{ij} = 0$ otherwise, for $i = 1,\dots,n$ and $j = 1,\dots,p$. Let c_j denote a latent cluster label for X_j, with $c_j = k$ if X_j is allocated to the k-th cluster, $k = 1,\dots,K$. The scope of the clustering analysis in this context is to associate to each covariate X_j a unique label c_j with $j = 1,\dots,p$.

Among the clustering techniques the most suitable for binary data include the agglomerative hierarchical clustering methods with binary dissimilarity matrices, the Bayesian non-parametric approach for binary data and the K-modes. Our purpose is to exploit the use of clustering techniques to identify non-overlapping groups of covariates. In order to estimate the grouping structure, in this paper we consider the following clustering methods:

- The standard agglomerative hierarchical clustering algorithms produce a nested sequence of clusters, which initially considers each observation as a single cluster, then at each stage the two least dissimilar clusters are combined. The process is repeated until only one cluster will contain all the observations. The dissimilarity between clusters can be measured by linkage methods: average, complete and single. Moreover, among the main distance measures between objects proposed for binary data we consider the Jaccard and the Tanimoto distances; see [3].
- The Bayesian non-parametric approach, recently proposed by [8], assumes that the data x_{ij} are independent draws from a mixture of infinite Bernoulli distributions whose parameters are distributed according to a Beta distribution. Clustering of data is obtained by calculating the posterior probability of the latent clusters labels c_j for $j = 1,\dots,p$.
- The K-modes approach is a generalization of the K-means procedure suitable for categorical data; see [5]. This approach has two key differences with the classical K-means. First, it assumes that the representative point of the clusters (also known as centroid) is the modal value of a cluster. Second, the distance between objects is the Hamming distance. K-modes tries to find a partition of the objects into K groups by minimizing the distance between each observation and the group centroid.

We propose to estimate the model parameters by clustering the covariates according to a procedure above described and then introducing a group penalty in the estimating function (2). More specifically, the procedure involves the following two-steps:

1. cluster the covariates into non-overlapping groups by using a clustering technique suitable for binary-data;
2. regress the response variable y on the set of grouped covariates using a penalized regression procedure based on embedding the information gained from the preliminary clustering.

3 A simulation study

We conduct a simulation study to evaluate the performance of the clustering effects on the variable selection procedures. Among the several penalties that can be used here we focus on the composite Maximum Concave Penalty (cMCP), the group exponential LASSO (gel), the group Maximum Concave Penalty (gMCP), the group LASSO (gLASSO) and the group Smoothly Clipped Absolute Deviation (gSCAD). For each of these group penalties, we consider different clustering methods in order to introduce a grouping structure into the model. For the purpose of this analysis, we consider the hierarchical clustering with three linkage methods: complete, single, average links, and three dissimilarity measures: Tanimoto and Jaccard distances. Moreover, we consider the K-modes and the Bayesian non-parametric methods. We compared group penalized regression models with the LASSO model. The simulation is based on the linear regression model $y_i = X_i\beta + \varepsilon_i$, $i = 1,\dots,n$, where $\varepsilon_i \sim N(0,\sigma^2)$ as introduced in Equation 1. The standard deviation σ is assumed to be 1 and covariates were generated from a Bernoulli distribution. We consider the following setup: $p = 200$ covariates but just 4 of these covariates have non-zero coefficients. We randomly split the data into training and testing datasets. In this simulation the size of the data set is $n = 100$ and the size of the training set is 80. The number of clusters has been fixed to 10 for all the clustering methods considered. To evaluate the performance of the various group penalization methods combined with different clustering procedures, we calculate some measures of prediction accuracy and variable selection efficiency. In the simulation study, 1000 replicated data sets were generated from the model. For each of these datasets, we compute the Predictive Mean Square Error (PMSE), the Sensitivity (the ratio between the number of selected important variables and the number of important variables), and the Specificity (the ratio between the number of removed unimportant variables and the number of unimportant variables). The results of this simulation are presented in Tables 1 and 2. From Table 1 we can notice that all the penalized regression procedures considered yield satisfactory results in terms of PMSE for all the clustering techniques. In particular, the cMCP penalty provides almost the same good results regardless of the clustering algorithm considered. Moreover, we can notice the very good results achieved in terms of PMSE for the K-modes clustering and the Bayesian non parametric clustering for all penalties considered. Among group selection approaches, the gLASSO achieves the uppermost Sensitivity, especially when we consider the hierarchical approach with Tanimoto distance combined with average and single links. Both the bi-level selection penalties achieve low levels of Sensitivity, but high levels of Specificity, as we expected. In Table 2 we report the results for the LASSO model to allow a comparison with the results of group penalized regressions. We notice that LASSO shows good PMSE and Specificity values but a low value for Sensitivity. From this simulation study we can notice the good performance of this approach which embedded clusters of binary covariates in a group penalized regression model. Further simulation studies and analysis will be developed to evaluate conditions for better performances of this new approach.

Can a neighbour region influence poverty? A fuzzy and longitudinal approach

Può una regione confinante influenzare la povertà? Un approccio longitudinale e sfocato

Gianni Betti, Federico Crescenzi and Francesca Gagliardi

Abstract One of the most important goals of the 2030 UN Agenda for Sustainable Development is to *"…eradicate poverty, in all its forms and dimensions …"*. In order to give a comprehensive answer to such needs, in this paper we propose to adopt a longitudinal measure recently proposed by Verma *et al.* (2017), which is based on the fuzzy set approach to multidimensional poverty: the "Fuzzy At-persistent-risk-of-poverty rate"; then we propose to estimate this measure at regional level via small area estimation techniques, by introducing a spatial correlation model. In this way we are able to take into account whether a neighbour region can influence poverty in all its forms and dimensions, namely, the multidimensional dimension, the regional dimension and the longitudinal dimension.

Abstract Uno dei più importanti *goal* dell'Agenda 2030 per lo Sviluppo Sostenibile delle Nazioni Unite è *"…eradicate poverty, in all its forms and dimensions …"*. Con lo scopo di tentare di rispondere a questa necessità, nel presente lavoro proponiamo di utilizzare una misura longitudinale recentemente proposta da Verma *et al.* (2017), basata sull'approccio multidimensionale e sfocato per la misura della povertà: il cosiddetto "*Fuzzy At-persistent-risk-of-poverty rate*"; inoltre, proponiamo di stimare tale misura a livello regionale, tramite l'introduzione di un modello con correlazione spaziale tra gli errori. In questo modo prevediamo di catturare l'influenza che ha una regione confinante nella misura della povertà, in ogni sua dimensione, ovvero quella multidimensionale, quella regionale, ed infine quella longitudinale.

Key words: small area estimation, fuzzy longitudinal poverty, SILC, Spain.

1 Introduction

One of the most important goals of the 2030 UN Agenda for Sustainable Development is to *"…eradicate poverty, in all its forms and dimensions* …" (UN, 2015). This is particularly necessary after the global crisis started in 2008 and the failure of meeting the Millennium Development Goal of halving extreme poverty in the world by 2015.

The need of reducing poverty and launching anti-poverty programmes and policies has also been expressed by the European Union by the Europe 2020 Strategy (European Commission, 2010). This consists in a series of policy objectives called "headline targets", which should be reached by 2020. Among these targets, there is the reduction of the at-risk-of-poverty rate (ARPR, known in the literature as head count ratio, or FGT(0) in the family of Foster *et al*., 1984), and of the at-persistent-risk-of-poverty rate in a longitudinal context for monitoring poverty over time. Moreover, poverty measures are most useful to policy-makers and researchers when they are finely disaggregated, that is when they want to represent geographic units smaller than whole countries; this is exactly the purpose of DG Regional Policy of the European Commission, aiming to use sub-national/ regional level data (NUTS 2) for the social indicators used for monitoring the "headline targets" at the regional level.

In order to give a comprehensive answer to the needs reported above, in this paper we propose to adopt a longitudinal measure recently proposed by Verma *et al.* (2017), which is based on the fuzzy set approach to multidimensional poverty: the "Fuzzy At-persistent-risk-of-poverty rate"; then we propose to estimate this measure at regional level via small area estimation (SAE) techniques, by introducing a spatial correlation model. In this way we are able to take into account whether a neighbour region can influence poverty in all its forms and dimensions, namely, the multidimensional dimension, the regional dimension and the longitudinal dimension.

2 Longitudinal measures of fuzzy and multidimensional poverty

In this section we describe the construction of the fuzzy longitudinal poverty measures, which aim at estimating occasional, persistent or chronic concepts of poverty. In the fuzzy literature, these measures have been defined as: i) anytime, for those individuals belonging to fuzzy set poverty for at least one out four years; ii) continuous, for those belonging to all four years; moreover, we adopt a very recent definition proposed by Verma *et al.* (2017), namely iii) the "fuzzy at-persistent-risk-of-poverty", which refers to those individuals belonging to the fuzzy set in the most recent year, and to two or three years in the last three years: this measure is the fuzzy counterpart of the Eurostat "at-persistent-risk-of-poverty rate", one of the most important Laeken indicators.

From a mathematical point of view, let μ_t be the series of T = 4 membership functions over the four periods, we can define the anytime fuzzy measure as the fuzzy union over the periods, which consists in the maximum of the T values:

$$\mu_{any} = \max(\mu_1, \mu_2, \mu_3, \mu_4) \tag{1}$$

In the same way, the continuous fuzzy measure is defined as the fuzzy intersection over the periods, which consists in the minimum of the T values as:

$$\mu_{cont} = \min(\mu_1, \mu_2, \mu_3, \mu_4) \tag{2}$$

The definition of the fuzzy at-persistent-risk-of-poverty is much more complex, and we suggest to read Verma *et al.* (2017) for a full and detailed description.

3 Model based small area estimation

Sample sizes of surveys like EU-SILC, designed to be representative at national level, are frequently too low to get efficient estimates of indicators at small area level, like NUTS 2. In other words, it means that the measures calculated from such small sub-samples – termed in the related literature as “direct estimators” – have too large variances. Small area estimation theory is concerned with resolving these problems.

This classic EBLUP model proposed by Fay and Herriot (1979) can be extended by considering that the vector of errors follows a Simultaneously Autoregressive Process (SAR) with spatial autoregressive coefficient ρ and proximity matrix $\boldsymbol{W}$ (Cressie, 1993). In this way, the model with spatially correlated random effects is:

$$\hat{\boldsymbol{\theta}} = \boldsymbol{X\beta} + \boldsymbol{Z}(\boldsymbol{I} - \rho\boldsymbol{W})^{-1}\boldsymbol{u} + \boldsymbol{e}. \tag{3}$$

The estimator is unknown because it depends on some unknown parameters, such as ρ. By substituting them with consistent estimators, a two stage estimator is obtained which can be referred to as a Spatial EBLUP. (see Pratesi and Salvati, 2007, for further details).

In order to estimate the Spatial EBLUP models it is necessary to have the standard errors of the direct estimator $\hat{\theta}$. Since the poverty measures adopted in the present paper are quite complex (such as, for instance, the “fuzzy at-persistent-risk-of-poverty rate”), which are calculated on the basis of a very complex survey such as EU-SILC, we estimate their standard errors by means of the Jackknife Repeated Replication (JRR) in the version of Verma and Betti (2011)[1]..

[1] Verma and Betti (2011) demonstrate how a variant of the JRR method can fit better in case of “complex measures”; moreover, Betti *et al.* (2018) show that the JRR variant of Verma and Betti (2011) is particular adapt for estimating variance of fuzzy poverty measures.

4 Empirical analysis

The reference data for the present work are based on a subset of micro-data from the EU Statistics on Income and Living Conditions (EU-SILC) survey, which is the major source of comparative statistics on income and living conditions in Europe.

Generally, the EU-SILC national surveys are designed with focus on the production of reliable estimates at the national level. In fact, although EU-SILC survey has a very large sample in Spain (13,109 households and 34,756 individuals for 2011), the regional sub-samples are very heterogeneous in size, so that in some NUTS 2 regions estimates are not significant.

From the Spain EU-SILC 2011 Intermediate Quality Report (INE, 2012) we have a detailed description of the sample design that is important both for understanding whether regions form independent sampling domains, and for the construction of the 'computational' PSUs and strata, needed for the estimation of JRR standard errors.

Using such numerical data, here we present analysis of the direct estimates and their relative sampling errors for poverty and deprivation variables. The separate results for each of the 19 regions of Spain allow the input to the Fay and Herriot (FH) and the Spatial EBLUP models. The following two statistics are considered in turn in a longitudinal context: fuzzy monetary poverty rate (FM); and fuzzy supplementary deprivation rate (FS). For each one of these statistics, the longitudinal measures are those described in section 2: any-time poverty, continuous poverty, and at-persistent-of-risk rate.

From the results concerning standard errors of FM fuzzy at-persistent-risk-of-poverty rate, we can appreciate that both FH and SEBLUP are lower than the direct estimates. In general, we have a mean reduction of the standard error for FH of 18%, and for SEBLUP of 26%. The largest reduction standard errors are clearly found in regions with small sub-sample sizes, such as Melilla, Ceuta and Rioja.

However, for the main purpose of this paper, it is quite interesting to observe the larger gain in spatial EBLUP over FH; the geographical information of the w matrix of vicinity clearly supplies an evident added value, being clear that an increase in poverty in a neighbour region can affect the region under investigation as well.

From the results concerning standard errors of FS fuzzy at-persistent-risk-of-poverty rate, the reduction is smaller compared to the corresponding FM measure: 16% for FH and 13% for SEBLUP. In this case, the effect of the geographical information of the matrix of vicinity does not supply an added value.

Analyzing the FM anytime poverty rates, the highest values of are found in Extremadura, Castilla-La Mancha and Andalucia, while the lowest are in Navarra, Aragon and Baleares. The average gains in standard errors for FH and SEBLUB are very similar to the one found for FM at-persistent-risk-of-poverty rate. Again the largest reductions are found in the smallest regions of Melilla and Ceuta.

The measures of the FS anytime poverty rates show that the highest values are found in Galicia, Andalucia, Canarias and Murcia, while the lowest are in Melilla, Navarra, Aragon and Pais Vasco. Again the average gains in standard errors for FH and SEBLUB are very similar to the one found for FS at-persistent-risk-of-poverty rate. The largest reduction is found in the smallest region of Ceuta.

Table 1 reports the FM continuous poverty rates; the highest values of are in Extremadura, Ceuta, Castilla-La Mancha, Andalucia, Murcia and Rioja, the lowest are in Navarra, Pais Vasco, Asturias, Madrid and Melilla. In this case, the average gain in standard error is larger than ones found in all other measures, with mean reduction of about 23% for SEBLUP.

Table 1: FM continuous poverty rates

Region	Direct	se	SEBLUP	se	Gain
Galicia	7.91%	1.14%	8.10%	1.05%	91.59%
Asturias	5.11%	1.03%	5.70%	0.94%	90.98%

5 Concluding remarks and further considerations

In this paper we propose a series of mathematical procedures to properly estimate longitudinal poverty and deprivation at regional level. First of all, we consider direct estimates of poverty and deprivation measured by means of fuzzy sets theory, and in particular we take into account the new measure “fuzzy at-persistent-risk-of-poverty rate”, recently proposed by Verma *et al.* (2017); then we implant for the first time the procedure of Jacknife Repeated Replications in the version of Verma and Betti (2001) for estimating standard errors of such fuzzy direct estimates.

The primary result obtained is the extension of variance estimation to beyond measures of monetary longitudinal poverty, specifically to fuzzy formulation of those measures and, as a corollary, to multidimensional measures of longitudinal deprivation, which by their very nature are a matter of degree i.e. are fuzzy. To our knowledge, in the literature, no such extension has been published. Moreover, we propose to utilise SAE techniques, such as spatial EBLUP, to further reduce the variability of fuzzy poverty measures at regional level.

Overall, we can conclude that both FH and SEBLUP are able to reduce standard errors by 20-30% in average, with picks of 70% for regions where sample sizes are particular small. Moreover, the larger gain in spatial EBLUP over FH is evident only for FM longitudinal measures, while the gain is practically absent in FS ones, for which the geographical information of the w matrix of vicinity does not supply an added value. So, in conclusion, neighbour region can affect poverty only when we adopt a monetary measure, while it seems to unaffected in the case of a multidimensional or non-monetary measure: further research is necessary to understand reasons of such phenomenon.

Weight-based discrimination in the Italian Labor Market: how do ethnicity and gender interact?

L'influenza di genere ed etnia sulla discriminazione basata sul peso corporeo nel mercato del lavoro italiano

Giovanni Busetta, Maria Gabriella Campolo, and Demetrio Panarello[1]

Abstract Access to Italian job market is characterized by a strong degree of discrimination. In this study, we analyze three kinds of discrimination together: gender, race and weight, in order to investigate whether gender and race increase or decrease the impact of weight-based discrimination. To do so, we sent fictitious résumés including photos of either obese or thin applicants in response to online job offers. The results indicate that the strongest kind of discrimination is the racial one, and that discrimination based on weight appears to be stronger for women than men.
Abstract *L'accesso al mercato del lavoro italiano è caratterizzato da un alto grado di discriminazione. In questo studio, analizziamo congiuntamente tre tipologie di discriminazione: di genere, di razza e di peso, al fine di investigare se genere e razza producano un incremento o decremento dell'impatto della discriminazione basata sul peso. Per fare ciò, abbiamo inviato CV fittizi contenenti foto di candidati obesi e normopeso in risposta ad annunci di lavoro online. I risultati indicano che la discriminazione più forte è quella legata alla razza e che la discriminazione basata sul peso sembra essere maggiore per le donne che per gli uomini.*

Key words: Labor market discrimination, Field experiment, Net discrimination

1 Introduction

In the last decades, obesity became a relevant issue for most developed and developing countries [2]. Regarding Europe, OECD showed that obesity rates have doubled in most countries, including UK, Scandinavia and some southern European

countries [6]. Even if Italy is characterized by one of the slimmest adult population in Europe [7], the country is experiencing a strong increase in the portion of obese people, especially in between children age [5]. Thus, we consider that it will be a relevant and important problem to study for the next years. Moreover, as Italy has always been the country of fashion, a great attention has been devoted to physical appearance. Therefore, we think that weight discrimination must necessarily be a relevant topic, and we want to study discrimination against obese people in Italy.

Furthermore, we compare this kind of labor market discrimination with the other two most common causes of discrimination: against women, and against immigrants. In this respect, according to [8], the most frequent reasons for discrimination in the labor market are indeed age, sex, race and ethnicity, weight and height.

Comparing these three relevant forms of discrimination is then useful to evaluate whether discrimination based on weight has already become worrying. Surprisingly, considering that obesity is a major issue in every developed country, literature has devoted much less attention to the weight bias in the job market, compared to race and gender discrimination [1].

This paper has important policy implications because, as long as discrimination based on weight is rapidly increasing, overweight and obese people would need to be legally protected against it (see [3]).

The rest of the paper is organized as follows. The experimental design and data are presented in Section 2. Section 3 describes the model and shows the main results. Finally, we conclude our study in Section 4.

2 Experimental Design and Data

Our empirical experiment focuses on the impact of obesity in the first step of the hiring process. Therefore, we collected data through a field experiment carried out in Italy in the first semester of 2013. During that period, we sent fictitious résumés in response to 244 real online job postings published in the most important Italian job search websites that do not require registration. Thus, for each offer we prepared and sent 8 ad hoc constructed résumés (in total 1952), one for each fictitious identity that was previously generated accordingly, using fictitious names and addresses and adopting the European format and structure.

To avoid matching problems, we adapted the résumés to the skills required by the firms. For each job offer, we sent 8 equivalent résumés (with equivalent skills and work experience), changing only name, nationality and the photo attached: 4 résumés with different photos of thin applicants (Italian and immigrant woman and man), and 4 with photos of the same candidates modified to appear obese. The photos were manipulated using a software named Fatbooth, available on Apple App Store[2].

3 Methods and Results

Responses were classified as callbacks if the employer requested an applicant to contact them (not just for clarification)[3]. We then analyzed callback rates to see whether some fictitious applicants were discriminated.

We created several indexes measuring separately discrimination against: men, women, locals, immigrants, obese and non-obese candidates. Indexes range from 0 to 1, taking value 0 when no discrimination is observed (this is the case in which the firm replies to all the candidates) and 1 in cases of highest discrimination (none of the categories has been called back). All the values in between are scored 0.25, 0.50 and 0.75, depending on whether the firm decided to call back 3, 2, or 1 categories. In this way, we created several indexes to consider different kinds of discrimination.

Table 1 shows differences in discrimination against men and women, natives and immigrants, normal-weight and obese. They are calculated with respect to the discrimination indexes described above. In all cases, differences are statistically significant, and discrimination operates against women, immigrants and obese with respect to men, natives and non-obese. Results also show that discrimination based on both ethnicity and obesity are quantitatively higher than the one based on gender.

Table 1: Discrimination indexes – men, women, natives, immigrants, normal-weight, obese.

Discrimination against	Mean	Std. Err.	Difference in mean	p-value
Men	0.517	0.017	-0.075	***
Women	0.592	0.017		
Natives	0.419	0.018	-0.271	***
Immigrants	0.690	0.020		
Normal-weight	0.455	0.017	-0.158	***
Obese	0.613	0.018		

Note: *p<0.05; ** p<0.01; *** p<0.001

To make our results comparable with the main literature on the topic, we calculated correspondence tests which are considered a standard methodology [4], in order to use them as robustness check. The correspondence test allows us to calculate the percentage of net discrimination between normal weight individuals and obese in all the considered categories. The preliminary results of our experiment (Table 2, column 11) show that obese are discriminated in all subgroups, and these results are particularly relevant for immigrants. In this case, the concerning call back rate is equal to 0.56 and decreases to 0.46 if the immigrant is a woman. Table 2 also shows

[2] This software, working on the distances between mouth and chin, and enlarging the oval of the face, generates images of obese appearance.

[3] To minimize inconvenience to the employer, invitations were promptly declined since employers who contacted an applicant were contacted themselves by email.

the aggregated results of the correspondence test considering obese as minority group and normal weight as majority one.

Table 2: Correspondence test on weight-based discrimination, by sex and nationality.

	Jobs	No one invited	At least one invited	Equal treatment	Only normal weight invited	Only obese invited	Normal weight	Obese	Net discrimination		Relative call back rate
	1	2	3	4	5	6	7	8	9	10	11
									No.	%	
Woman	244	47	197	104	64	29	168	133	35	17.77	0.79
Man	244	26	218	130	60	28	190	158	32	14.68	0.83
Italian	244	20	224	134	54	36	188	170	18	8.04	0.90
Immigrant	244	93	151	60	75	16	135	76	59	39.07	0.56
Italian W	244	63	181	71	61	49	132	120	12	0.07	0.91
Immigr.W	244	139	105	25	64	16	89	41	48	0.46	0.46
Italian M	244	45	199	93	61	45	154	138	16	0.08	0.90
Immigr.M	244	124	120	40	57	23	97	63	34	0.28	0.65

Note: In the first column, we report the number of the total job offers. We performed a correspondence test on the answers obtained by the firms. In this respect, four are the possible outcomes: no one invited (second column); both invited (third column); only one applicant invited, normal weight or obese (fifth and sixth columns, respectively). In the following two columns, we reported the total number of normal weight and obese invited. Considering these results, we calculated net discrimination as the ratio between the difference in discrimination against obese (column 5) and the one against normal weight (column 6) over the number of jobs for which at least one candidate was invited. Difference in discrimination is reported in column 9, and the previous mentioned ratio is reported in column 10. Finally, we reported the relative callback rate as the ratio between the total of obese and normal weight invited.

The Net Discrimination Index (NDI) calculated shows that weight-based discrimination exists for all the considered subgroups, but it differs depending on the subgroup analyzed. Even if the difference is not high, NDI is higher for women than for men (almost 18% and 15%, respectively). Significant differences are found by comparing Italian (8%) and immigrant candidates (39%). Moreover, if we consider immigrant women, it increases to 46%. From these results, we can easily realize that weight-based discrimination is more relevant for immigrants than Italians. Moreover, in terms of gender gap, it is more pronounced within immigrants than within Italians.

Finally, we estimated a Probit model to analyze whether discrimination based on ethnic origin, weight and sex affect the opportunities of finding a job in the Italian labor market. In our equation model, the dependent variable Y is a dummy variable that takes value 1 if firm replies to the candidate and 0 otherwise (Call back).

$$Y_i = \beta_0 + \beta_1 Woman_i + \beta_2 Obese_i + \beta_3 Immigrant_i + \beta_4 Graduate_i + \beta_5 HighSchool_i + \beta_6 FrontOffice_i + \beta_7 HardWork_i + \beta_8 South_i + \varepsilon_i \qquad (1)$$

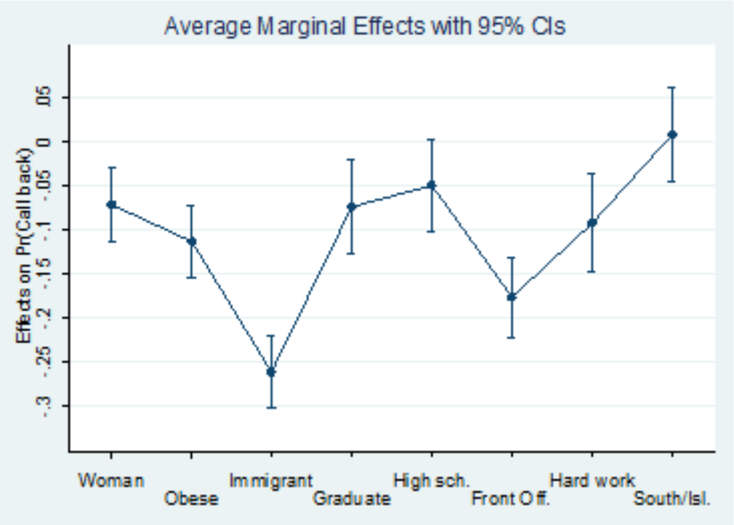
where Y is the latent variable reflecting the probability of the *i-th* subject of receiving a call back. On the right side of equation, with Greek letters we refer to parameters. β_0 is the constant term and ε is the disturbance term. The main explanatory variables are the sex of the candidate (*Woman*: 1=yes; 0=Man); a dummy variable that indicates if the candidate is obese (1=yes; 0=otherwise); a dummy variable that indicates the nationality of the candidate (1=immigrant; 0=Italian); the education level of the candidate, corresponding to the education required by the job opening, divided into three dummy variables (*Graduate*: 1=yes, 0=otherwise; *High School*: 1=yes, 0=otherwise; reference: No title); two dummy variables regarding the job characteristics of the offer (*Front Office:* 1=yes, 0=Back Office, *Hard Work*: 1=yes, 0=Soft work); finally, we consider the geographical area (North-Center=1; South and Islands=0).

Table 3: Probit estimation results.

	Coef.	Std. Err.	p value
Woman	-0.20	0.06	***
Obese	-0.32	0.06	***
Immigrant	-0.71	0.06	***
Graduate	-0.21	0.08	**
High School	-0.14	0.08	
Front Office	-0.49	0.07	***
Hard Work	-0.27	0.08	***
South and Islands	0.02	0.08	
Constant	0.76	0.09	***

Note: *p<0.05; ** p<0.01; *** p<0.001

Figure 1: Probit estimation results – marginal effects at mean



In general, the Probit estimation results (Table 3) show that the minority subgroups (Women, Obese and Immigrant) are more discriminated with respect to the majority ones. The probability of being called back decreases when the education level required by the job increases. Moreover, the probability of being called back is higher for candidates applying for back office and soft work jobs. In Figure 1, we report the marginal effects at mean of our Probit model.

4 Conclusions

In the present analysis, we analyzed weight-based discrimination in the first stage of the hiring process, comparing it with discrimination based on ethnicity and on gender. To do so, we sent fictitious résumés answering to 244 real online job postings published in the most important Italian job search websites that do not require registration. For each offer, we prepared and sent 8 ad hoc constructed résumés, one for each fictitious identity that was previously generated accordingly. In this respect, we compared Italians with immigrant candidates showing that, in the Italian labor market, immigrants are more discriminated than Italians (39% and 8%, respectively). Moreover, results show that weight-based discrimination exists for all the considered subgroups, but it differs depending on the subgroup analyzed. Indeed, it is higher for women than for men (almost 18% and 15%, respectively) and increases even more if women are immigrants (46%).

The Total Factor Productivity Index as a Ratio of Price Indexes.

L'indice della produttività totale dei fattori come rapporto di indici di prezzo.

Lisa Crosato and Biancamaria Zavanella

Abstract Ever since the seminal work by Robert Solow (1957), total factor productivity (TFP hereafter) has been associated with the movements in the production function caused by technical progress. This has largely influenced the choice of the index numbers involved in the productivity measurement. In fact, the methodology currently in use worldwide is based on the superlative Tornqvist index (Diewert, 1976). In this paper we observe the empirical evidence about TFP in a few countries and propose to re-define the TFP as the ratio of the price index of input to the price index of outputs, using the Sato-Vartia formula.

Abstract *La produttività totale dei fattori viene associata con i movimenti della funzione di produzione causati dal progresso tecnico a partire dal lavoro fondamentale di Robert Solow (1957). Questo ha ampiamente influenzato il modo di misurare la produttività e in particolare la scelta dei numeri indice coinvolti, tanto che la metodologia universalmente usata al momento è basata sull'indice superlativo di Tornqvist (Diewert, 1976). In questo lavoro partiamo dell'evidenza empirica sull'andamento della produttività totale dei fattori in alcuni paesi e ridefiniamo l'indice TFP come rapporto di indici di prezzo, usando la formula di Sato-Vartia.*

Key words: productivity, index numbers, Sato-Vartia, Tornqvist

1 Introduction

Productivity measures the extent to which an economic system transforms the available resources in goods and services. More specifically, we can define productivity as the ratio between the volume of output and of the input utilized to generate it or between the results achieved by the economic system of a region/country and the imputed factors (OECD, 2001). On the empirical side, for any production unit, the

Università di Milano-Bicocca - DEMS - Via Bicocca degli Arcimboldi, 8, 20126 Milano.
e-mail: lisa.crosato@unimib.it; biancamaria.zavanella@unimib.it

total factor productivity index is defined as an output quantity index divided by an input quantity index (Balk, 2010).

The interest in productivity measurement has been strong ever since the late thirties, starting from the introductory papers by Evans and Siegel (1942) and Magdoff (1939). Later on, the seminal work of Solow (1957), briefly followed by the quarrel with Pasinetti (1959) intertwined the total factor productivity (TFP) with technical progress.

The current methodology in use at official statistics offices for measuring Total Factor Productivity (TFP hereafter) derives from the Solow model rooted into a neoclassical framework and ends up in the ratio of two quantity indexes: the Tornqvist quantity input index and an implicit output quantity index derived through the output price index of Paasche (OECD, 2001). This way of constructing the TFP index, however, is not consistent with the axiomatic theory of index numbers and leads to puzzling empirical patterns.

This paper proposes to rethink the TFP index in terms of the ratio of the input price index to the output price index, by means of the Sato-Vartia formula. The underlying idea builds on the empirical evidence on the TFP changes, which for several countries show a fluctuating behaviour hardly consistent with the mechanisms driving technological progress. On the contrary, the relative changes between input and output prices are of a more volatile nature so that our representation could be more consistent with the observed pattern of TFP. Furthermore, the use of Sato-Vartia formulas is in line with the index numbers theory since they satisfy a few axiomatic tests failed by the Tornqvist and the implicit quantity indexes.

Among other factors besides technological progress shaping the pattern of TFP and causing noise, we can surely include the relative input/output cost or price behaviour. So a look at the TFP index on the index price side could maybe give a more consistent interpretation of this puzzling behaviour.

The remaining of the paper is organized as follows: section 2 sketches the definition of TFP index by means of Sato-Vartia input and output price indexes, Section 3 illustrates the empirical evidence for Italy, section 4 concludes.

2 Methodology

Our starting point is the current methodology outlined in the OECD manual, which builds on the Cobb-Douglas production function and then factorizes the parameter representing the tecnhical progress or TFP. Under the usual neoclassical hypotheses, output elasticities with respect to capital and labour match the shares of added value going to the same factors.

Through standard mathematical tools the TFP index can be derived as an output index divided by the Divisia index synthetising the real variation of production factors, weighted by the corresponding shares (Star and Hall, 1976). However, as it is well known, the Divisia index cannot be applied to real data because the index is continuous and the data are discrete, and since Diewert (1976) it has been approximated by the Tornqvist formula, chosen mainly on the basis of its relations to the possible functional forms for the production function. All this results in the definition of the TFP index as the ratio between an implicit quantity index for outputs (given by the nominal variation of value added over the Paasche price output index) and the Tornqvist index for input quantities. In formulas, let n be the number of possible outputs, L and K the labour and capital inputs respectively, V the value, p_{ti} the output prices and y_{ti} the output quantities for $i = 1, \ldots, n$, w_t the cost and L_t the quantity of labour, u_t the cost and K_t the quantity of capital. Then

$$u_t K_t + w_t L_t = \sum_{i=1}^{n} p_{it} y_{it}$$

indicates the aggregate value at time t so that the value index is given by

$$\frac{u_t K_t + w_t L_t}{u_{t-1} K_{t-1} + w_{t-1} L_{t-1}} = \frac{\sum_{i=1}^{n} p_{it} y_{it}}{\sum_{i=1}^{n} p_{it-1} y_{it-1}} =_{t-1} V_t \tag{1}$$

Now the value index can be decomposed into the product of a price Paasche index and a Laspeyres quantity index for output (${}_{t-1}P_t^{Po}$ and ${}_{t-1}Q_t^{Lo}$ respectively)

$$\frac{\sum_{i=1}^{n} p_{it} y_{it}}{\sum_{i=1}^{n} p_{it-1} y_{it-1}} =_{t-1} P_t^{Po} \cdot_{t-1} Q_t^{Lo} =_{t-1} V_t \tag{2}$$

According to the standard methodology of the OECD, the real variation of value added is then measured by the implicit quantity index

$$\sum_{i=1}^{n} p_{it} q_{it} / {}_{t-1}P_t^{Po} \tag{3}$$

and the TFP from $t-1$ to t is defined by

$${}_{t-1}V_t / {}_{t-1}P_t^{Po} =_{t-1} TFP_t \cdot {}_{t-1}Q_t^{TI} \tag{4}$$

with ${}_{t-1}Q_t^{TI}$ being the Tornqvist input quantity index.

However, the Tornqvist index does not satisfy the product test of index numbers and, as Balk (2010) points out, ”the implicit quantity index does not satisfy the Identity Test”. Therefore, the standard TFP index currently used results non consistent into the framework of axiomatic index number theory.

We propose to resort to the Sato-Vartia index instead, substituting it to the Tornqvist formula in (4)

$${}_{t-1}V_t / {}_{t-1}P_t^{Po} =_{t-1} TFP_t \cdot {}_{t-1}Q_t^{SVI} \tag{5}$$

Once again, (5) says that the TFP index is given by the ratio of the output quantity index to the input quantity index with the usual interpretation as a technical progress indicator and shitfting of the production function. Recalling the decomposition of the nominal variation of the value added through the Sato-Vartia index (see for instance Martini (2001))

$$\frac{\sum_{i=1}^{n} p_{it} y_{it}}{\sum_{i=1}^{n} p_{it-1} y_{it-1}} =_{t-1} P_t^{SVo}\,{}_{t-1}Q_t^{SVo} =_{t-1} V_t \tag{6}$$

we can express the TFP as

$$\begin{aligned} {}_{t-1}TFP_t &= {}_{t-1}Q_t^{Lo} / {}_{t-1}Q_t^{SVI} \\ &= \frac{{}_{t-1}V_t}{{}_{t-1}V_t} \frac{{}_{t-1}Q_t^{Lo}}{{}_{t-1}Q_t^{SVI}} \\ &= \frac{{}_{t-1}P_t^{SVI}}{{}_{t-1}P_t^{Po}} \end{aligned} \tag{7}$$

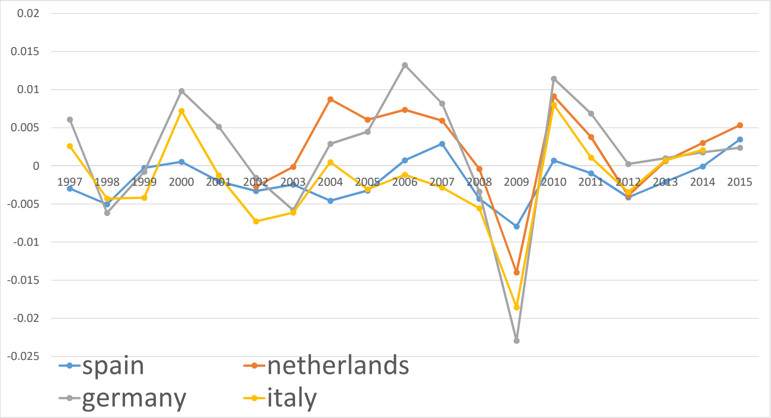
so that the TFP index can be represented, with no loss of information, as the ratio of the Sato-Vartia input cost index and the Paasche output price index. Furthermore, writing the TFP in this way we are explicitating that it is influenced by several different factors that maybe can contribute to justify the ups and downs of TFP detected empirically.

3 Empirical evidence

The empirical evidence we started working on in order to develop the idea underlying this work is based on data from the EUKLEMS database (www.euklems.net). Euklems collects several measures related to economic growth and productivity, at the industry level for all EU members from 1970 onwards and is the result of the homonymous project started in by the European Commission in order to provide quantitative input to evaluate competitiveness, economic growth and policy interventions.

Empirical evidence on log-changes in TFP over the last 18 years reveals a fluctuating behaviour that would indicate ups and downs in the technical progress hardly understandable (see Figure 1 for Italy, Germany, Spain and the Netherlands).

Fig. 1 Log-ratio of ${}_{t-1}TFP_t$. Source: Our elaborations on EU-KLEMS data for the indicated countries.



4 Conclusions

Changes in empirical TFP do not always show the increasing pattern one would associate to the accumulation of technical progress, but for some countries seem rather fluctuating around a null average value. This is not consistent with the technical-progress-ratio-of-quantity-indexes equation exploited worldwide to measure TFP, but could be explained by other factors, for instance by the index used in the deflation process.

Taken the added value deflation technicalities as given and known (due to the widespread use of the chained quantity Laspeyres index), to gain a different point of view we have turned our attention to the input quantity indexes at the denominator, calculated through the Tornqvist index.

In an axiomatic framework, the Tornqvist index has been questioned (Balk, 2010) because it does not satisfy the factor reversal test neither the cofactor identity. In this paper we propose the use of the Sato-Vartia index, which encompasses both problems if the data necessary to construct it are available, as in the EU-KLEMS database.

Although the numerical result of the TFP index is the same with either Tornqvist or Sato-Vartia formula, the choice of the representation in terms of quantity or price indexes is not a pettifogging matter, because the construction of the index influences its intepretation and evaluation in terms of economic policy. For instance TFP indexes, both at the aggregate or sectoral levels are widely used as regressors in empirical economics but, as it comes to the data, shocks in productivity are, for some countries, all but evident. Our contribution provides a possible re-evaluation of this behaviour and suggests TFP index or its changes to be carefully used as explanatory variables.

Monetary poverty indicators at local level: evaluating the impact of different poverty thresholds

Indicatori monetari di povertà a livello locale: studio dell'effetto di diverse soglie di povertà

Luigi Biggeri, Caterina Giusti and Stefano Marchetti[1]

Abstract The importance of poverty measures at sub-national level is widely attested, both for a detailed planning of policy actions, and for the citizens to evaluate their effects. However, there are relevant issues when computing sub-national poverty indicators that may impact their value: the definition of the poverty line for monetary poverty indicators, and the use of small area estimation methods when the sample size is not enough to obtain accurate estimates at local level. In this work, we estimate the poverty incidence at provincial level in Italy by using small area estimation methods, and we analyze the impact on the poverty incidence of different poverty lines, defined at national, regional and provincial level. The key results underline a strong impact on the poverty incidence when using sub-national poverty lines.

Abstract *Disporre di indicatori di povertà a livello locale è uno strumento indispensabile per i decisori politici, per poter pianificare opportune politiche di intervento, e per i cittadini, per poter valutare l'effetto delle politiche sul proprio territorio. La stima di indicatori di povertà monetaria relativi a livello locale pone due principali problemi metodologici: la definizione della linea di povertà e l'utilizzo di modelli di stima per piccole aree quando la ridotta numerosità campionaria a livello locale non consente di ottenere stime dirette accurate. Obiettivo di questo lavoro è confrontare l'incidenza della povertà nelle province italiane utilizzando linee di povertà alternative, definite a livello nazionale, regionale e provinciale, utilizzando modelli per piccole aree per le stime a livello provinciale.*

1 Introduction

The important role played by poverty measures at sub-national and local level in setting policy actions against poverty and social exclusion is widely attested. Local poverty indicators are relevant both for a detailed planning of the policies actions and for the citizens to evaluate their effect.

As it is well known, a common method used to measure the monetary poverty is based on income or consumption levels. Individuals or families are considered as poor if their income or consumption level falls below a minimum level (called poverty line, PL). The PL is usually defined at the national level. However, it is well known that in Italy there is a strong geographical heterogeneity in income and consumption levels (ISTAT 2013a, ISTAT 2013b). Then, we propose an analysis where the geographical heterogeneity is reduced by defining the PL at regional and provincial level. Moreover, it is important to underline that also the different price levels within the country can play a role in the definition of alternative PLs, as observed among others by Ayala et al. (2014) and Giusti et al. (2017). However, we do not treat this last issue in this work.

Here we refer to the household poverty incidence or Head Count Ratio (HCR), the simplest monetary poverty indicator usually elaborated by most of the National Statistical Offices. More in detail, we use consumption expenditures data from the Italian Household Budget Survey (HBS) 2012 to estimate the HCR for the 20 regions and the 110 provinces in Italy.

We first estimate the regional HCRs using two alternative PLs: the PL defined at national level and the PLs defined at regional level. The national PL for households of two components is defined by ISTAT as the mean per-capita consumption expenditure at national level. Then, this PL is adjusted for households with a different number of components by using the Carbonaro equivalence scale, which takes the following values: 0.6 for households with one component, 1.33 with three, 1.63 with four, 1.90 with five, 2.16 with six and 2.40 for households with seven or more components. We define the PLs at regional level in the same way but computing the mean per-capita consumption expenditure separately for each region.

Since we observe a high impact of the regional PL definition on the regional HCRs, we then extend the analysis at the provincial level. When computing the HCR at provincial level, the PL can be defined not only at national or regional level, but also at provincial level. The 2012 HBS sample size at provincial level, varying from zero to 1037, with a median value of 146, is for most of the provinces too small to obtain reliable estimates both of the HCRs and of the PLs at provincial level.

Therefore, we use a small area model to obtain more accurate estimates, as better explain in the next sections.

2 Estimating regional HCRs with different poverty lines

The PL used in the computation of the HCR with expenditures data depends on the level of the mean per-capita consumption expenditures that in Italy varies strongly among regions, with a percentage difference that reaches the 50% comparing Northern with Southern Italian Regions. Therefore, it is important to evaluate the impact of the use of sub-national poverty lines in measuring the poverty incidence.

Fig. 1 shows the estimates of the household HCRs for the 20 Italian regions by using the national PL and the regional PLs. The results clearly show that the variability of the spatial distribution of the HCRs is quite smaller when using the regional PLs rather than the national one. Moreover, the HCRs of north-east and north-west regions increase when using regional PLs, the HCRs of the central regions remain more or less the same, while the HCRs of the Southern regions strongly decrease. Thus, the use of different PLs has strong geographical implications in the evaluation of Italian households' poverty. On the other hand, the choice of the poverty definition and of the PL depends on the level of analysis and the kind of the policy to be implemented (Kangas and Ritakallio, 2007). However, for comparing relative monetary poverty at regional (local) level, it seems justified the use of region-specific PL (Mogstad et al., 2007).

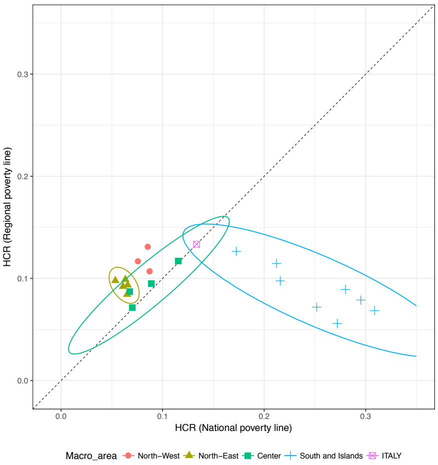

Figure 1: Estimates of the Head Count Ratio (HCR) for the 20 Italian regions with national versus regional poverty lines

3 Estimating the provincial HCR with different poverty lines

In this section we analyse the impact of three different thresholds on HCR estimates at provincial level in Italy. The HCR estimates at the province level are estimated using an area-level Fay-Herriot model (Fay and Herriot, 1979). This method uses aggregated auxiliary data to model direct estimates of the HCR to reduce their variability. As auxiliary variables at the province level we use the per-capita taxable income (information available from the “Agenzia delle entrate” database 2012) and the share of households who own their house (from the Population Census 2011). To save space we do not report here the model parameters, the model diagnostics and other details related to the estimation procedure. As a general result, the average decrease in variability of the HCR estimates is about 23.7% compared to the direct estimates.

We also estimate the provincial PLs by using a small area model, equal to the one used for provincial HCR estimates. Fig. 2 shows two plots: on the left the HCRs for the 110 Italian provinces based on the national PL versus the HCRs based on regional PLs, on the right the HCRs based on the national PL versus the HCRs based on provincial PLs. The two plots are similar: they show that when the PLs are estimated at more detailed geographical level we observe a strong decrease of the HCRs in the southern provinces, an increase for most of the north-east provinces, while the HCRs in central and north-west provinces increase in some provinces and decrease in others. Switching from regional to provincial PLs affect the HCRs more or less in the same way.

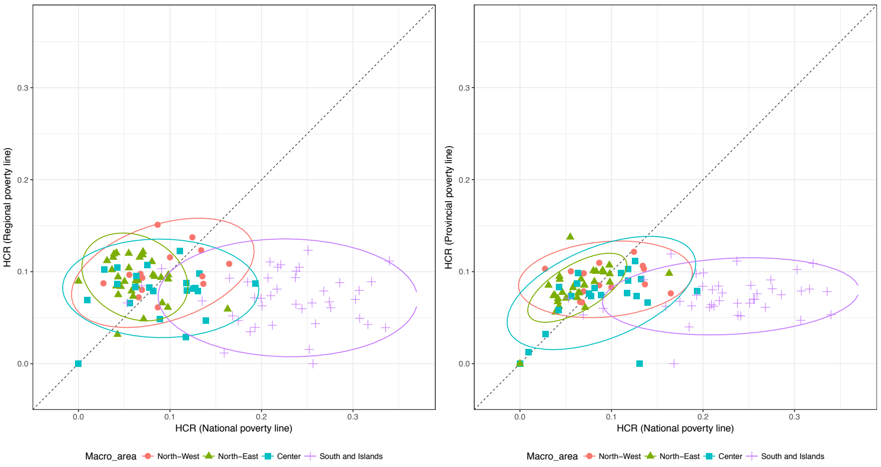

Figure 2: Estimates of the Head Count Ratio (HCR) for the 110 Italian provinces with national versus regional poverty lines (left) and with national versus provincial poverty lines (right).

Finally, Fig. 3 shows the HCRs based on regional vs. HCR based on provincial PLs. In this case it seems that the HCRs increase or decrease independently on the geographical level of estimation of the PLs. Moreover, the change in the values of the HCRs is very small compared to that observed when comparing results obtained using the national PL (Fig. 2).

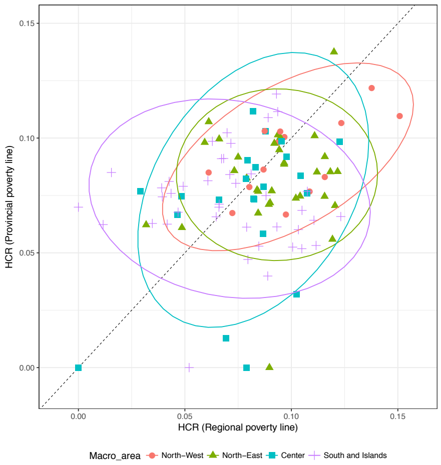

Figure 3: Estimates of the Head Count Ratio (HCR) for the 110 Italian provinces with regional versus provincial poverty lines

The main results presented in this section suggest that measuring the monetary poverty incidence at provincial level using national or local (regional or provincial) thresholds strongly change the picture of the phenomena. On the contrary, using provincial rather than regional PLs seems to not affect HCR estimates at the province level.

4 Concluding remarks

In this work we have presented alternative estimates of the HCR for Italian regions and provinces by using data on households' consumption expenditure. The aim was to evaluate the impact of subnational PLs on the HCRs. To estimate the HCRs and the PLs at provincial level we suggested the use of a small area model defined at the area level. Our results show that the choice of the PL is very relevant when the aim is to compare local relative poverty indicators.

The results can be extended in several directions, for example by also taking into consideration the different level of the prices in the regions and provinces, since also this aspect can highly impact the value of the HCRs. Moreover, to get a more complete picture of the poverty and living condition in the areas of interest, it would be important to complement the estimation of the HCRs with other monetary and non-monetary poverty indicators.

A gender inequality assessment by means of the Gini index decomposition

Una valutazione della disuguaglianza di genere attraverso la scomposizione dell'indice di Gini

Michele Costa

Abstract This paper proposes to measure and to evaluate gender gaps and gender inequalities by means of the decomposition of an inequality measure. A three-terms decomposition of the Gini index is applied, thus allowing to take into account also the role of overlapping between female and male subpopulations. An analysis of the income distribution of the Italian households shows how gender gaps represent a major source of inequality, without particular improvements over the last 20 years.
Abstract *In questo lavoro si propone di analizzare e di valutare i differenziali e la disuguaglianza di genere grazie alla scomposizione di una misura di disuguaglianza. Il ricorso ad una scomposizione dell'indice di Gini articolata su tre componenti permette di tenere conto anche della sovrapposizione tra le distribuzioni delle sottopopolazioni femminile e maschile. L'analisi della distribuzione del reddito familiare in Italia mostra che i differenziali di genere rappresentano un importante fattore di disuguaglianza, sostanzialmente stabile durante gli ultimi 20 anni.*

Key words: Gender gap, Gender income inequality, Inequality decomposition, Gini index

1 Introduction

Gender inequalities and gender gaps are a worldwide concern and represent the core of uncountable actions and policies developed by either governments and institutions. Gender inequalities are firstly a primary and fundamental issue of justice. Consequences of gender inequalities are frequently overlooked or underestimated, while it exists an interesting literature which analyzes the relation between gender inequality and welfare, pointing out gender gaps as a constraint for economic growth.

Michele Costa
Department of Economics, University of Bologna, e-mail: michele.costa@unibo.it

We assess the role of gender in income inequality by decomposing the Gini inequality ratio following the approach introduced by Dagum in 1997. First we evaluate the inequality within male and female subgroups, second we analyse the contribution to total inequality attributable to the differences between female and male subpopulations. The Dagum's Gini index decomposition also allows to evaluate the effect on overall inequality of the overlapping between female and male subpopulations, which represents a relevant element in gender inequality studies.

2 The Dagum's Gini index decomposition

The Gini index is one of the most important measure of inequality and, during its over 100 years of file, has experienced many different interpretations, expressions and formulas. For the case of a population disaggregated into k subgroups of size n_j, with $\sum_{j=0}^{k} n_j = n$, the Gini index G can be expressed as follows

$$G = \frac{1}{n\bar{y}^2} \sum_{j=1}^{k} \sum_{h=1}^{k} \sum_{i=1}^{n_j} \sum_{r=1}^{n_h} |y_{ji} - y_{hr}| \tag{1}$$

where $\bar{y}$ is the arithmetic mean of y in the overall population, y_{ji} is the value of y in the i-th unit of the j-th subgroup and, accordingly, y_{hr} is the value of y in the r-th unit of the h-th subgroup. For a detailed discussion of the Gini index see, e.g., [3],[7].

Among the many methods which allow to decompose the Gini index (see, e.g., [4],[8],[9]), we use the decomposition proposed by Dagum [5], where the differences $|y_{ji} - y_{hr}|$ in (1) are assigned to G_w, the component of inequality within subgroups, when $j = h$, to G_b, the component of inequality between subgroups, when $j \neq h$, $\bar{y}_j \geq \bar{y}_h$, $y_{ji} \geq y_{hr}$, and to G_t, the component of overlapping, when $j \neq h$, $\bar{y}_j \geq \bar{y}_h$, $y_{ji} < y_{hr}$.

The component of inequality within can be obtained quite esaily from the relation $G_w = \sum_{j=1}^{k} G_j p_j s_j$, where G_j is the Gini index of the j-th subgroup, while $p_j = n_j/n$ and $s_j = (n_j\bar{y}_j)/(n\bar{y})$ are the population share and the income share of the j-th subgroup, respectively.

For the other two components, G_b and G_t, which in the original version require some substantial computational effort, are available [1] simplified expressions, which are $G_b = G_b^* + 0.5(G - G_w - G_b^*)$ and $G_t = 0.5(G - G_w - G_b^*)$, where $G_b^* = \sum_{j=1}^{k-1} \sum_{h=1,j=k}^{k} \frac{p_{hj}^* - s_{hj}^*}{p_{hj}^* s_{jh}^* + p_{jh}^* s_{hj}^*} (p_j s_h + p_h s_j)$, $p_{hj}^* = p_h/(p_h + p_j)$ and $s_{hj}^* = s_h/(s_h + s_j)$.

In order to achieve a better understanding of the inequality structure, it is also possible to compare the decomposition obtained by using all n observations, that is $G_y = G_{wy} + G_{by} + G_{ty}$, to the decompositions obtained by referring only to subsamples of observations. In particular, it is useful to analyze the decompositions for the lower values of y, $G_{y|ymin} = G_{wy|ymin} + G_{by|ymin} + G_{ty|ymin}$ as well as for the higher values of y, $G_{y|ymax} = G_{wy|ymax} + G_{by|ymax} + G_{ty|ymax}$. When the structure of the decomposed indices $G_{y|ymin}$ and $G_{y|ymax}$ is similar, we get that the underlying inequality factor operates uniformly on y, while different structures indicate that particular regions of y are more affected by the inequality factor.

Following a similar approach, we can also evaluate the influence of a further inequality factor x by ranking y on the values of x and by comparing the decompositions of $G_{y|xmin}$ and $G_{y|xmax}$. Similar decompositions suggest that the x and the y are independent, while different decompositions indicate a relation between the two inequality factors.

A final element of interest refers to the evaluation of the inequality between, which is usually performed on the basis of the ratio G_w/G, where G acts as the maximum of G_b. The scenario $G_b = G$ implies $G_w = G_t = 0$: while $G_t = 0$, that is the absence of overlapping, doesn't present particular difficulties, the hypothesis $G_w = 0$, that is the equidistribution of y within each subgroup, represents a relevant departure from real situations. In order to achieve an evaluation of G_b more coherent with the observed data ([6], [2]), it is possible to keep $G_t = 0$ but to replace $G_w = 0$ with $G_w = G_{wmin}$, which is the minimum inequality within compatible with the observed data. In this case G_b is evaluated as $G_b/(G - G_{wmin})$.

3 The gender income inequality among Italian households

The Dagum's decomposition of the Gini index presented in Section 2 is extremely useful to analyze the relevance of gender in income inequality. The component G_w allows to evaluate how the income variability existing within the female and male subpopulations influence total inequality, while the contribution attributable to the differences between the female and male subpopulations is given by G_b and G_t. The meaning of G_b is straightforward, but as far as G_t it is useful to point out that high levels of overlapping indicate a small contribution of gender to income inequality, while low levels of overlapping suggest a stronger contribution.

The data used in this study are from the Survey on Households Income and Wealth of the Bank of Italy; the results illustrated in the following refer to the equivalent income obtained by means of the OCSE equivalence scale.Table 1 shows the p_i, s_i and G_i for the Italian households by gender of the head of the household: it is possible to observe some well known stylized facts of income inequality in Italy, that is the differences $(p_i - s_i)$. When $p_f = s_f$, the gender gap is equal to 0, while $p_f > s_f$ indicates the existence of a gender gap. The aggregate data of Table 1 suggest the presence of a gender gap, but also its reduction over time, since $(p_f - s_f)$ decreases from 3.8% in 1993, to 3.2% in 2004 and to 3% in 2014.

Moving from the aggregate and gross evaluation provided by $(p_f - s_f)$ to the more detailed and accurate information contained on the decomposed Gini index (Table 2), we obtain a different picture on gender income inequality. First, the importance of G_w on total inequality strongly decreases (from 62% in 1993 to 50% in 2014), thus indicating a weaker variability within the female and male subpopulations. Second, the overlapping between the female and male subpopulations in-

Table 1 Population share, income share and Gini index for the Italian households by gender of the head of the household

		1993			2004			2014	
	female	male	tot	female	male	tot	female	male	tot
p	0.275	0.725	1.000	0.388	0.612	1.000	0.471	0.529	1.00
s	0.237	0.763	1.000	0.356	0.644	1.000	0.441	0.559	1.00
G	0.319	0.334	0.333	0.307	0.336	0.327	0.311	0.324	0.320

creases: the importance of G_t rises from 13.5% in 1993 to 20.3% in 2014. A greater overlapping represents a positive signal for the reduction of the gender gap, since it suggests that the distributions of the subpopulations share a larger area. Third, the inequality between increases: the importance of G_b rises from 24.9% in 1993 to 29.7% in 2014. The relevance of the inequality between is fully understandable by comparing G_b to its maximum compatible with the observed data (last column of Table 2): in this case G_b represents 37.9% of total inequality in 1993, rising to 42.9% in 2014. Overall, the decrease of G_w is balanced by the increase of both G_b and G_t. While a greater G_t alleviates the role of gender as inequality factor, an increase of G_b leads to a stronger gender inequality from 1993 to 2014.

Table 2 Income inequality decomposition by gender of the head of the household

	Gw	Gb	Gt	Gw/G	Gb/G	Gt/G	Gb/(G-Gwmin)
1993	0.205	0.083	0.045	0.616	0.249	0.135	0.379
2004	0.175	0.092	0.060	0.535	0.281	0.183	0.407
2014	0.160	0.095	0.065	0.500	0.297	0.203	0.429

In order to better understand the results of Table 2, we focus on the tails of the distribution, taking into account the bottom and the top 20% of the income. Table 3 reports the p_i, s_i and G_i for the female and male subpopulations for the two cases and it is possible to observe some relevant differences.

By comparing the decomposed Gini indexes for the bottom and the top incomes (Table 4), we note that the two decompositions, initially quite different, are more or less similar in 2014. The importance of G_b shows a relevant increase, especially for the top incomes.

A further analysis of the gender income inequality refers to the study of specific population characteristics, such as educational level and geographical area of residence, chosen among the main inequality factors acknowledged by the literature. The Gini index decomposition is applied not to all n observations, but only to the subsample of households with the particular characteristic which we are analyzing. More specifically, we compare the female/male decompositions obtained on two subgroups related to two different values of the character under examination. When the two decompositions are substantially similar, the underlying factor is not rele-

vant for the interpretation of the gender inequality, while, on the contrary, different decompositions indicate an influence on gender inequality. Table 3 illustrates the p_i, s_i and G_i for two subgroups: for the educational level we compare the up-to-elementary-school group to the group with a university degree, for the geographical area the group living in the north to the group living in the south or islands.

The related decompositions of the Gini index for the analysis of the gender gap are shown in Table 4. The comparison between the decompositions suggests that the educational level influences the gender income inequality more than the geographical area. We also confirm the decrease of the importance of G_w, together with an increase of the relevance of G_t and G_b, especially for the more affluent subgroups.

4 Conclusions

The decomposition of an inequality index can be extremely useful into the study of the gender income inequality, where the decomposition refers to the female and male subpopulations. The analysis of the income distribution of the Italian house-

holds shows how gender gap explained 24.9% of total inequality in 1993, rising to 29.7% in 2014. The scenario is even worse when evaluating inequality attributable to the differences between female and male subpopulations without the traditional assumption of null inequality within: in this case gender gaps are accountable for 37.9% of total inequality in 1993, rising to 42.9% in 2014. Inequality decomposition also allows to evaluate the relation between gender and other inequality factors: educational level of the head of the household and geographical area of residence are taken into account, with the former showing a greater influence on gender income inequality.

Socio-Economic Statistics

The NEETs during the economic crisis in Italy, Young NEETs in Italy, Spain and Greece during the economic crisis

I giovani NEET negli anni della crisi economica in Italia, Spagna e Grecia

Giovanni De Luca, Paolo Mazzocchi, Claudio Quintano, Antonella Rocca

Abstract The recent economic crisis has further increased the socio-economic disparities across European countries. In particular, the levels of NEETS (young people Not in Employment, Education and Training) has resulted greater than before in European Mediterranean countries, more severely hit by the crisis. The aim of this paper is to analyze the peculiarities of NEETs in Italy, Spain and Greece in the years from 2007 to 2016 and verify if the introduction of the Youth Guarantee Schemes has contributed to decrease these high shares. To this aim, some econometric models have been applied to the Labour Force Survey data and Youth Guarantee Schemes effects have been tested using the Chow test.

Abstract *La recente crisi economica ha ulteriormente inasprito le differenze socio-economiche tra i paesi europei. In particolare, nei paesi del Sud Europa, maggiormente colpiti dalla crisi, si è assistito ad una crescita del livello dei giovani NEET (giovani che non lavorano, né studiano, né seguono corsi di formazione). Scopo di questo lavoro è analizzare le peculiarità di tale fenomeno in Italia, Spagna e Grecia negli anni dal 2007 al 2016 e verificare se l'introduzione del Fondo Garanzia Giovani ha prodotto una riduzione significativa dei livelli. A tale scopo, alcuni modelli econometrici sono stati applicati ai dati della Rilevazione continua sulle Forze Lavoro, mentre gli effetti del Fondo Garanzia Giovani sono stati verificati attraverso l'applicazione del test di Chow.*

Key words: NEETs, Youth unemployment rate, Early school leavers

1 Introduction

The late 2000s crisis and the increased complexity of the labour markets **have** exacerbated the social and economic inequalities almost *in* all European countries and *among* European countries. Countries whose economies already suffered of structural weakness were hit more hardly by the economic crisis than the most prosperous ones. In particular, the South of Europe is one of the regions in the world where the consequences of the crisis have become most salient. Furthermore, within each country the most vulnerable segments of population, such as young people and migrants, resulted more penalized in terms of job losses and worsening in their condition on the labour market.

In this paper the authors have analyzed and compared the changes occurred in the levels of NEETs (young people Not in Employment, Education and Training, aged 15-29 years) in the years of economic crisis, from 2007 to 2016, in Italy, Spain and Greece in a gender perspective, in order to highlight their main peculiarities. Furthermore, the authors have investigated if the overcoming of the deepest phase of economic crisis has led to significant reductions in the share of NEETs in light also of the recent labour market reforms. The reference is to the introduction of the Youth Guarantee Found, a recent European reform finalized to create opportunities to exit from the NEET status, ensuring that all young people receive a good-quality offer of job, apprenticeship, traineeship, or continued education (European Commission, 2017).

The structure of the paper is as follows: Section 2 introduces the framework of analysis; Section 3 shows the methodology while in Section 4 the main results and some conclusive considerations are reported.

2 The framework of analysis

During the economic crisis of the last decade, some European countries, such as Italy, Spain and Greece experienced one of the great recessions of the last century; contrariwise, other economies in Europe only slowed their growth (Germany and Poland, for example). Indeed, comparing the data in 2007 and 2016 – before and after that the economic crisis produced its effect (Eurostat on-line database, http://ec.europa.eu/eurostat/web/lfs/data/database) – while at EU-28 country level total unemployment (age class 25-74) registered only a slight increase, moving from 6.1% to 7.5%, in Italy, Spain and Greece, it suffered an increase of 5.1, 10.9 and 15 percentages points, respectively. The worsening was still greater and the gap higher for the youth unemployment rate, that in these years at EU-28 level increased only of 2.1% while for Italy, Spain and Greece, the increase was of 17.4, 26.3 and 24.6 percentage points respectively (passing from 20.4% to 37.8% in Italy, from 18.1% to 44.4% in Spain and from 22.7% to 47.3% in Greece). In the same period, in these countries also the share of NEETs remarkably increased. Indeed, while at European level it resulted almost stationary, passing from 11% in 2007 to 11.5% in 2016, in

Italy, Spain, and Greece it increased of 3.7, 4.5, and 2.6 percentage points respectively. Indeed, it moved from 16.1% to 19.8% in Italy, from 12.0% to 14.6% in Spain and from 11.3% to 15.8% in Greece. Therefore, while Spain, but especially Greece, resulted more penalized in terms of youth unemployment rates, Italy suffered the highest levels of NEETs.

Young people represent one of the most vulnerable segments of population, because of their less work experience, their weaker work contracts and of a labour market that primarily tends to protect older workers. Besides unemployment, other causes hide behind the high levels of NEETs and concern inactivity. While unemployment is mainly correlated with the economic cycle, inactivity represents an alarming social phenomenon, as it is linked to the exclusion of young people from education and training (Bell and Blanchflower, 2011) and from the labour market because these young people do not take any action, remaining outside the labour force. The permanence in the NEET status for a prolonged period produces serious consequences on the future life perspectives because it predisposes to long term unemployment and social exclusion (OECD, 2014; Balan, 2015). For these reasons, the European Commission, solicited by the European Parliament, implemented and financed the Youth Guarantee Fund, successfully already rolled out in Scandinavian countries (Escudero and Lopez Mourelo, 2015). It consists in a number of plans to target youth unemployment, including apprenticeships and traineeships programmes and support schemes for young business starters. Beneficiaries are all European regions with a youth unemployment rate higher than 25%. All Greek and Spanish regions were eligible for the Youth Employment initiative while in Italy the regions of Veneto and Trentino-Alto Adige should have been excluded; anyway, it was chosen to extend the scope to the Belluno, Rovigo and Venice provinces, because their youth unemployment rates were higher than 25% (www.garanziagiovani.gov.it). Even if the Youth Guarantee implementation plans were submitted in December 2013, they started to produce the first effects in the Spring of 2014. The introduction of these plans and the contextual overcoming of the deepest recession phase produced a reduction in both the unemployment and NEET rates everywhere. Therefore, in this paper, besides studying the peculiarities and determinants of NEETs across Italy, Greece and Spain, the authors aim at verifying if in the Spring of 2014 a structural break in the NEET trend occurred or not.

Data come from the Labour Force Survey (LFS), currently the main European reference source for comparable and multidimensional socio-economic statistics on employees and working conditions, waves from 2007 to 2016. The need to get an adequate number of observations and to detect changes occurred in short time intervals **have** motivated the construction (through ad hoc elaborations) of four-weekly time intervals. The LFS is in fact a continuous survey carried out during every week of the year. In order to account for the Youth Guarantee attendance, the analysis involves only young people from 15 to 24 years, the only implicated in these initiatives (in Spain the eligibility is extended to disables under-30s).

3 The statistical methodology

The analysis of the dynamics of the share of NEETs is based on a Seasonal Autoregressive Distributed Lag (SARDL) model, in which the dependent variable – the share of NEETs on the 15-24 years population – is studied according to some own lags (in order to consider the persistence of the NEET phenomenon over time and its seasonal component) and also to some independent variables (Almon, 1965). The model is given by

$$y_t = \mu + \sum_{k=1}^{p} \phi_k y_{t-k} + \sum_{K=1}^{P} \Phi_K y_{t-Ks} + \sum_{s=0}^{q} \beta_s x_{t-s} + \boldsymbol{\gamma}' \mathbf{z}_t + u_t$$

where y_t is the share of NEETs at time t, y_{t-k} are the lagged values; the second sum includes seasonal lags, x_{t-s} is the independent variable for which also some lags are considered and z_t is the r x 1 vector of additional not-delayed variables. Finally, ϕ_k, Φ_K, β_s and $\boldsymbol{\gamma}$ the corresponding parameters. These models are particularly easy to implement because the OLS estimates are appropriate.

In a second step, in order to study if the introduction of the Youth Guarantee Fund has produced a significant variation in the share of NEETs, we **have** define the dummy variable

$$g_t = \begin{cases} 0 & t \in T_b \\ 1 & t \in T_a \end{cases}$$

where T_b is the set of times before the introduction of the Youth Guarantee Fund and T_a is the set of times after. The Chow test has been used to compare the results of the model applied to all the data – defined as restricted model – with the results of the models separately run for the two periods (Chow, 1960). The unrestricted model can be then written as a two regime SARDL model,

$$y_t = \begin{cases} \mu_1 + \sum_{k=1}^{p} \phi_{1k} y_{t-k} + \sum_{K=1}^{P} \Phi_{1K} y_{t-Ks} + \sum_{s=0}^{q} \beta_{1s} x_{t-s} + \boldsymbol{\gamma}_1{}' \mathbf{z}_t + u_t & \text{if} \quad g_t = 0 \\ \mu_2 + \sum_{k=1}^{p} \phi_{2k}\, y_{t-k} + \sum_{K=1}^{P} \Phi_{2K} y_{t-Ks} + \sum_{s=0}^{q} \beta^{\bullet}_{2s} x_{t-s} + \boldsymbol{\gamma}_2{}' \mathbf{z}_t + u_t & \text{if} \quad g_t = 1 \end{cases} \}$$

The null hypothesis of the Chow test is the stability of the parameters across the two regimes, that is: H_0: $\theta_1 = \theta_2$ where θ_1 and θ_2 are the parameter vectors in the first and second regime, respectively. The Chow statistics is given by

$$F = \frac{(RRSS - URSS)/j}{URSS/(N_1 + N_2 - k)} \sim F_{j, N_1 + N_2 - k}$$

where RRSS is the restricted residuals sum of squares obtained estimating a unique model for all the period, while URSS denotes the unrestricted residuals sum of squares obtained as sum of the RSS of two models, the former considering the N_1 $\mathbf{N_1}$periods before the introduction of the Youth Guarantee Fund, the latter considering the N_2 $\mathbf{N_2}$periods after. Finally, j is the number of restrictions and k is the number of parameters of the unrestricted model.

Under the null hypothesis, the F-ratio follows the F distribution with j and (N_1+N_2-k) degrees of freedom in the numerator and denominator, respectively. However, the Chow test does not inform us whether the difference in the two models is due to the differences in the constant term, in a single coefficient, in all the coefficients of a variable regardless the lags, or finally in a specific subset of coefficients.

In particular, we are interested in checking if the Youth Guarantee Fund has involved a reduction in the constant term without any impact on the dependence structure with the other variable, which imply a decrease in the share of NEETs. In this case, the unrestricted model is

$$y_t = \mu_1(1 - g_t) + \mu_2 g_t + \sum_{k=1}^{p} \phi_k y_{t-k} + \sum_{K=1}^{P} \Phi_K y_{t-Ks} + \sum_{s=0}^{q} \beta_s x_{t-s} + \gamma' z_t + u_t$$

where μ_1 is the constant in the first regime, observed before the introduction of the Youth Guarantee Fund, and μ_2 is the constant of the second regime, characterized by its presence, and the hypothesis to test is H_0: $\mu_1 = \mu_2$.

When the Chow test is computed on a subset of coefficients, then the null hypothesis is: H_0: $\theta_{1V} = \theta_{2V}$, where θ_{1V} and θ_{2V} are the parameter vectors of the variable V in the first and second regime, respectively.

4 Results

Among both males and females, the incidence of NEETs has been higher in Italy, where, also in 2016, it was around the 20%[1]. Contrariwise, the unemployment rates, both with reference to the whole population and only to young people, were higher in Greece and Spain than in Italy. However, in Italy young people resulted more penalized on the labour market in comparison to the older people. The ratio between the youth and the total unemployment rates is indeed higher for Italy. While in Greece and Spain the high levels of NEETs result mainly linked to unemployment, Italy shows the higher share of inactive NEETs. Therefore, in Italy the causes of the NEET phenomenon are harder to find. According to education, Spain highlights the highest rates of early school leavers, but also of high-educated young people[2].

The SARDL models applied to the subsamples of young people identified in each country according to gender highlight the high persistence of the phenomenon over time and the strictly dependence from the unemployment rate (with the exception of Italian men), that for Spain and Italian women includes also some delays (Tab.1). According to education, the share of early school leavers is always significant, with the exception of Greek men. In Spain and for Italian and Greek women the annual moving average of early school leavers results significant too.

Finally, according to the Chow test, a significant change in the dynamics of NEET levels can be observed in Italy, where it is mainly due to the increase in the educational levels, and for Greek men, where, instead, it depends also on a structural break in the NEETs, unemployment and educational levels.

Therefore, since the introduction of the Youth Guarantee Fund some effects are evident, especially for young Italian people and for Greek men. Furthermore, even if

[1] The descriptive and graphical analyses are here not reported for sake of brevity, but they are available on request by authors.

[2] Anyway, results are affected by the differences in the education system of the 3 countries compared (education is compulsory until 15 years of age in Greece while in Spain and Italy until 16 years; tertiary education should be attained at 22 years of age in Spain and at 24 years of age in Greece and Italy).

in Italy the major contribution to this result comes from the reduction on the share of early school leavers, the lack of statistical significance for the test on the unemployment covariates should suggest that this Scheme has also produced a positive effect on the inactive NEET component. Therefore, in the Italian context, results suggest to deepen the analysis on the extent to which the reduction of early school leavers is linked to the Youth Guarantee Scheme or, otherwise, to the general increase in the levels of education.

Camel or dromedary? A study of the equilibrium distribution of income in the EU countries.

Cammello o dromedario? Un'analisi della distribuzione di equilibrio del reddito nei paesi dell'UE.

Crosato L., Ferretti C., Ganugi P.

Abstract We face here the problem of analysing the presence of bimodality of the equilibrium distribution of incomes in the EU countries, using EU-SILC data about 2012-2015. As a first step we visually inspect the kernel distribution and calculate the Sarle's bimodality coefficient. We evaluate also the relationship between bimodality and inequality. As a second step we propose to use some suitable stochastic models to analyse the shape (camel/dromedary) of the estimated the long-run income distribution. The chosen models are the classical Markov Chain and the Mover Stayer model.

Abstract *Questo lavoro affronta il problema di valutare la presenza o meno della bimodalità nella distribuzione di equilibrio dei redditi dei Paesi europei, per mezzo dei dati EU-SILC relativi agli anni 2012-2015. Come primo passo, analizziamo le stime kernel delle distribuzioni dei redditi e calcoliamo il coefficiente di bimodalità di Sarle. Come secondo passo, proponiamo di utilizzare alcuni processi stocastici per analizzare la forma (cammello/dromedario) della distribuzione dei redditi stimata sul lungo periodo. I modelli scelti sono la Catena di Markov classica e il modello Mover-Stayer.*

Key words: long-run income distribution, equilibrium, bimodality, bipolarization, inequality.

1 Introduction: Why is Bimodality relevant?

Investigating the presence of bimodality in the equilibrium distribution of income (i.e. the long-run distribution such that frequencies among income classes have achieved stability w.r.o. time) in EU countries is relevant both for political and theoretical reasons.

The political relevance of the topic depends directly from the fact that the achievement of the Welfare Systems after the Second World War in different decades within the European Countries has always found the decisive support in the Middle-Income Population. Given the crucial role of this part of Population in the formation of consensus, its eventual structural reduction in favor of Low and High Incomes introduces the premises of a breakdown in the consensus toward the same System and, in turn, toward the political parties which defend it. The intricacy of the problem is empowered by the fact that an eventual structural bimodality is entirely a different fact from a return to the XIX century Income Distribution with respectively predominant and scanty masses in the Low Incomes and in the tail of the distribution. On the contrary, bimodality involves “polarization” i.e. not only large mass for the working poors but also, even if far more curbed, for the rich employees.

The theoretical reason to study the eventual structural (long period) character of bimodality sources by the fact that just today in some European countries Income Distribution seems to be featured by a noticeable second mode (cfr. Fig. 1). It is then natural to work to ascertain if the same second peak is the result of temporary and now seemingly fading recession and so fated to be reabsorbed by a new period of (equalizing) growth.

Literature on bimodality of Incomes can be divided in two distinctive branches depending on the nature of the data. One of these two branches on Incomes has used the pro capita GDP at World or European level and has aimed to ascertain the eventual polarization of pro capita GDP in the World (Bourguignon and Morrisson, 2002; Pittau, 2005). The second branch of literature on Incomes uses Personal Income micro-data and aims to ascertain bimodality within the single country. Within this second field of research, the problem of measuring bimodality, or bipolarization, has been deepened among others by Chakravarty et al. (2007), Chakravarty and D'Ambrosio (2010), Lasso de la Vega et al. (201), Deutsch et al. (2013).

Our paper contributes to the second strand of the literature, building on the empirical evidence on the bimodality of income distribution in a few European Countries detected using the EU-SILC database. Our goal is to verify whether Income distributions display a “camel” or a “dromedary” shape and if they preserve such shape with respect of time and in the long-run period.

The paper is structured as follows: section 2 illustrates the data source and the bimodality of income distribution, section 3 applies the kernel density estimation and Sarle’s coefficient to evaluate the presence of bimodality and to have a look on its relationship with the Gini index, section 4 illustrates the expected results and section 5 concludes.

2 Data Description and evidence of bimodality in EU countries.

Our analysis is based on the data obtained from the European Union Statistics on Income and Living Conditions (EU-SILC) longitudinal study (see Krell et al., 2017, for a full description of the dataset and an analysis of the consistency of the data). EU-SILC has become the EU reference source for statistics on income distribution and social exclusion at European level and supplies, among other variables, the Net employee cash or near cash income (variable PY010N). According to the EU-SILC description, employee income is “the total remuneration, in cash or in kind, payable by an employer to an employee in return for work done by the latter during the income reference period”. The net income component is then given by the gross income component but for the tax at source, the social insurance contributions, or both, which are deducted (see the methodological guidelines and description of EU-SILC target variables).

We start by analyzing the net employee income for the last available year, i.e. 2015 income extracted from the longitudinal component of the database, because further on we will need to build transition matrices for the calculation of the equilibrium distribution. Figure 1 reports kernel densities estimates for the countries that, in 2012 and 2015 have at least 1,000 non-NAs and non-null observations for the variable at hand.

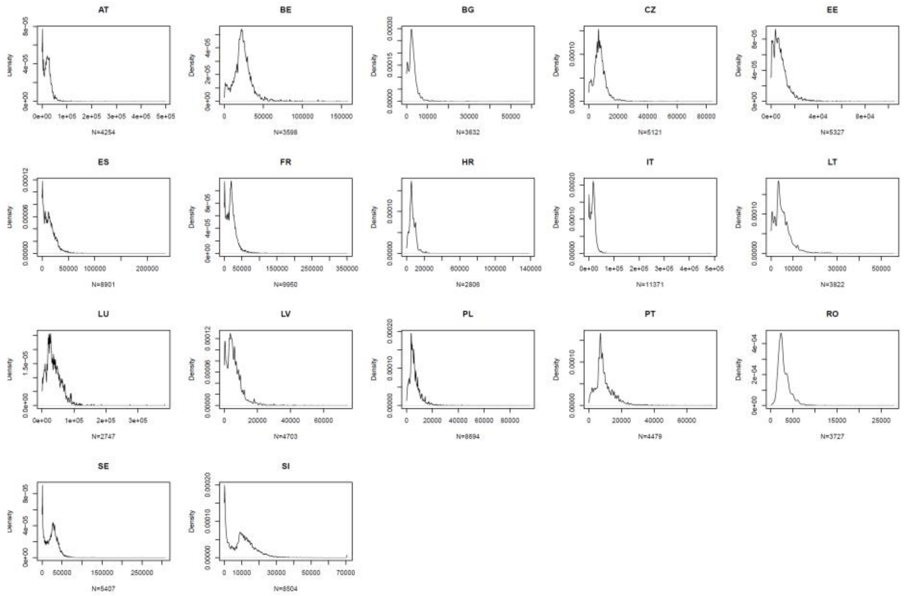

Figure 1: Kernel density estimates for 17 EU countries. Source: Author’s elaboration on EU-SILC LONGITUDINAL UDB 2015 – version 1 of March 2017. Variable PY10N, Net employee cash or near cash income greater than zero, countries with at least 1,000 non-null values only.

As can be seen, bimodality can be clearly detected in several countries. The presence of bimodality can be also evaluated through the Sarle’s bimodality coefficient (see

Ellison, 1987), whose corrected version for finite samples is given by the following formula:

$$b = \frac{g^2 + 1}{k + \frac{3(n-1)^2}{(n-2)(n-3)}}$$

where *n* is the sample dimension, *g* is the sample skewness and *k* is the sample excess kurtosis. In this case however the index neatly confirms bimodality only for Belgium, which is not consistent with the kernel densities of figure 1, suggesting the case for a further assessment of the extent to which bimodality takes place in the different countries.

The coefficient *b* seems positively related with the Gini index when considering the former communist countries (see figure 2), and, somewhat surprisingly, Belgium. The remaining countries instead show a not so clear relation.

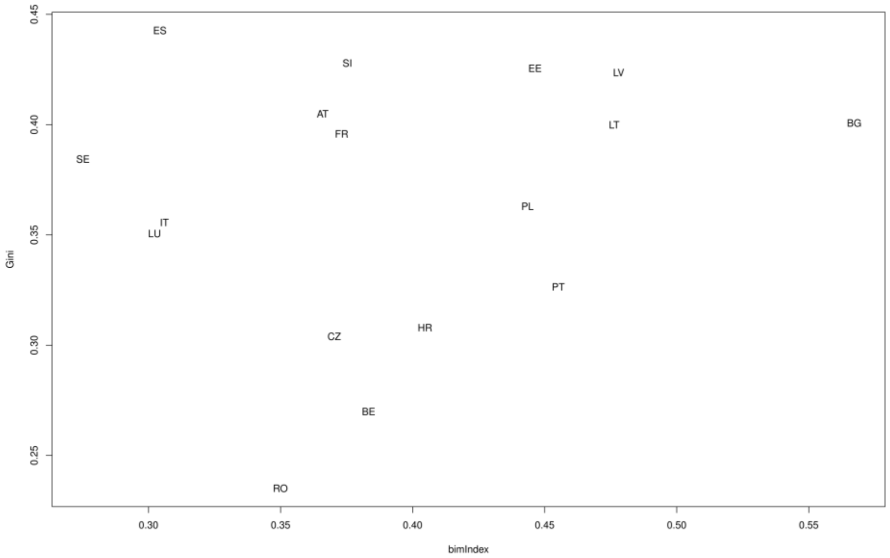

Figure 2: Scatterplot of the Gini concentration ratio (y-axis) versus the Sarle's bimodality index (x-axis) for 27 EU countries. Source: Author's elaboration on EU-SILC LONGITUDINAL UDB 2015 – version 1 of March 2017. Variable PY10N, Net employee cash or near cash income greater than zero, countries with at least 1,000 non-null values only.

3 Our proposal for evaluating the long-run two peaks distribution

Having ascertained the presence of bimodality in a relevant group of EU countries in the years 2012-2015, we tackle the problem to evaluate the long-run behavior of EU net incomes. We propose to estimate it using two stochastic models, Markov Chain

(MC) and Mover Stayer (MS) (see Anderson and Goodman, 1957, and Goodman, 1961). Both are based on the empirical yearly transition matrices, which summarize the probability to move among a set of suitably defined income classes. Such classes should be able to mirror the division among Low-, Middle- and High-Income individuals, as for example in Bourguignon (2002) or more recently in Xuehui and Shang-Jin (2017). The main difference is that the MS model supposes the existence of a bulk of individuals never moving from their starting state. In detail, let $S = diag\{s_i\}$ be the diagonal matrix where s_i denotes the probability that a EU citizen with a given income in 2012 is a Stayer and that consequently he/she will never leave from the corresponding income class. The MS global one-step transition matrix is given by the formula:

$$P = S + (I - S) * M,$$

where I is the identity matrix, and M is the transition matrix for the not-Stayers (Movers), which are supposed to move following a classical Markov Chain ruled exactly by M. Given the starting distribution p_0 (in this case coinciding with the percentage of citizens that in 2012 belongs to each income class), the long-run distribution is given by the equilibrium distribution π evaluated as:

$$\pi = p_0 * \left(\lim_{t\to+\infty} P^{(t)}\right),$$

where $P^{(t)}$ is the global t-steps transition matrix given by $P^{(t)} = S + (I - S) * M^{(t)},$ When $s_i = 0$ for every income class, the previous formula coincides with the classical MC equilibrium distribution. Parameters of both MC and MS can be estimated using the techniques proposed in Anderson and Goodman (1957) and Frydman et al. (1985).

4 Expected results

The long-run distribution gives a glance on what happen to the income distributions if the 2012-2015 economic conditions remain stable also in the future. We can expect only two possible results: 1) a camel or dromedary distribution maintains its starting shape, or 2) a camel/dromedary distribution tends respectively to lose/gain one “humpback”. If also the equilibrium distribution remains or becomes a two-peaks one, we can claim that bipolarization has become chronic in some EEC countries, and the income is neatly divided between Low- and High-Income individuals.

Bipolarization and Gini indices have to be calculated also on the equilibrium distributions and their values have to be compared to the values obtained on the initial income distributions p_0. It is in fact intriguing to ascertain if bipolarization involves also a rise in inequality. With the aim to obtain a more robust analysis we will calculated different bipolarization indices as proposed in Chakravarty et al. (2007), Chakravarty and D'Ambrosio (2010), Lasso de la Vega et al. (2010) and Deutsch et al. (2013).

5 Further research

Further research will regard mainly two aspects:

1) the estimation of the long-run distribution through more complex models, as for example a mixture of Markov Chains in which individuals are characterized by different speeds, such as in Frydman et al. (2002);

2) the modelization of the bimodal density distribution through an analytical bimodal density distribution as proposed in Ferretti et al. (2017).

Small Area Estimation of Inequality Measures

La stima per piccole aree di indicatori di disuguaglianza

Maria Rosaria Ferrante and Silvia Pacei

Abstract In order to estimate inequality measures at local level, small area estimation methods may be used to improve the reliability of estimates when the sample size is low. Small area models specified at area level, incorporate the design based estimates (direct estimates) as inputs, that are typically unbiased even though unreliable for small samples. Nevertheless, in the case of inequality measures, design based estimates are instead known to be biased for small sample sizes. In this work we focus on the search for a correction that can produce approximately unbiased direct estimators, taking into account the complexity of the survey design. We use data taken from the EU-SILC sample survey for Italy in 2013. Those modified estimators can then be used in small areas models.

Abstract *Allo scopo di stimare indicatori di disuguaglianza a livello locale, si possono impiegare metodi di stima per piccole aree per migliorare l'affidabilità delle stime quando la dimensione campionaria è piccola. I modelli per piccole aree specificati a livello di area, si basano su stimatori basati sul disegno (diretti), tipicamente corretti ma non affidabili per piccoli campioni. Gli stimatori degli indicatori di disuguaglianza sono invece distorti per piccoli campioni. L'obiettivo di questo lavoro è proporre una correzione che possa portare a stimatori diretti approssimativamente corretti, tenendo conto della complessità del disegno campionario. A questo scopo si usano i dati ottenuti per l'Italia dall'indagine* EU-SILC *del* 2013.

Key words: mean log deviation, complex sample survey, Fay-Herriot model.

1 Introduction

The increased interest for reliable information for restricted domain with reference to inequality measures is due to different reasons. One of the most relevant is to better plan policies to reduce inequality at local level. In this regards, an increasing gap in inequality and social exclusion among regions within the different EU member States has been observed in recent years. This issue is particularly relevant for Italy whose economic system is characterized by a strong territorial disparity.

Using data taken from the EU-SILC sample survey for Italy in 2013, we consider the estimation of inequality measures for the Italian provinces. Nevertheless the number of units sampled from many provinces is too low to provide reliable estimates using a “direct” estimator, that is an estimator calculated simply using the sample weights. This problem happens because EU-SILC survey is planned to provide reliable estimates for areas that are larger than those we are interested in.

To solve that problem we may resort to a small area estimation strategy. We consider area level models that incorporate the direct estimates as inputs. These estimates are typically obtained through unbiased estimators even though unreliable for small samples. Nevertheless, in the case of inequality measures, design based estimators are instead known to be biased for small sample sizes. The reason is that inequality measures can be written as ratios of random variables, both of which are estimated from the sample. They are thus biased in small sample, because the expected value of a ratio of random variables is not generally equal to the ratio of the expected values. The bias of the sample measure is $O\left(\frac{1}{n}\right)$, where n is the sample size.

In this work we focus on the search for a correction that can produce approximately unbiased direct estimators, taking into account the complexity of the survey design. Those modified estimators can then be used in small areas models.

We consider the class of generalized entropy (GE) measures, having the merit of satisfying the decomposability axiom, that allows to decompose the total inequality into the part due to inequality within areas and the part due to differences between areas. GE measures can be expressed as:

$$GE(\alpha) = \frac{1}{\alpha(\alpha-1)}\left[\frac{1}{n}\sum_{i=1}^{n}\left(\frac{y_j}{\bar{y}}\right)^{\alpha} - 1\right]; \quad j = 1, \dots, n; \quad \alpha \in [0, \infty) \qquad [1]$$

where $\bar{y}$ denotes the sample mean.

Specific special members of this family include Theil’s mean log deviation ($\alpha = 0$), Theil’s Index ($\alpha = 1$) and half the squared coefficient of variation ($\alpha = 2$). We start considering the mean log deviation for different reasons: *i*) it is used to study the “Inequality of opportunity” (Checchi and Peragine, 2010) with the purpose of assessing to what extent circumstances and efforts determine advantages; *ii*) it is particularly sensitive to changes in the tails of distribution, that are particular interesting in the case of income data; *iii*) it is found to be the less biased among the three indices mentioned (Breunig and Hutchinson, 2008).

2 Estimating the Theil's mean log deviation

We are interested in estimating the mean log deviation of the individual equivalized income, Y, for small areas indexed by i$= 1, \dots, m$. In the case of complex sample surveys, the direct estimator may be calculated using sample weights as follows:

$$ge(0)_i = \frac{1}{\hat{N}_i}\left[\sum_{j=1}^{n_i} w_j log\left(\frac{\bar{y}_i}{y_j}\right)\right]; \quad i = 1, \dots, m \qquad [2]$$

where $\bar{y}_i$ denotes the small domain sample mean calculated using sample weight, $\bar{y}_i = \frac{\sum_{j=1}^{n_i} w_j y_j}{\sum_{j=1}^{n_i} w_j}$, and $\widehat{N}_i = \sum_{j=1}^{n_i} w_j$.

In the literature a few papers consider the small sample bias issue for inequality measures (see Breunig, 2001, 2002; Giles, 2005; Breunig and Hutchinson, 2008) and propose a correction, but only in the simple random sample context. Breunig and Hutchinson (2008), for example, write the GE measures as functions of the population mean, μ, and some other population functions and then derive corrections for the GE measures, based on a second-order Taylor's series expansion of the sample estimates around the population values.

Regarding the mean log deviation, they obtain the following result for the approximate bias:

$$ABias\big(ge(0)\big) = -\frac{1}{2}\mu^{-2}Var(\hat{\mu}) \qquad [3]$$

They suggest to estimate [3] from sample data and then subtract it from $ge(0)$ to obtain a bias approximately corrected inequality value.

They also warn about the fact that the correction tends to increase the variability of the estimator, and that the overall reliability of estimates have to be considered.

Extension of this bias correction to the weighted estimator in equation [2] is not trivial. We consider an heuristic solution by substituting μ with the weighted sample mean and $Var(\hat{\mu})$ with the estimate obtained using the standard procedure used by Eurostat for a two-stage stratified sample (Eurostat, 2013). In particular, in EU-SILC survey carried out in Italy a stratified sample of municipalities is selected in the first stage and, in the second stage, a sample of households is randomly selected from the municipalities included in the first stage. The largest municipalities are always included in the sample (therefore they are called auto-representative or AR), while the other ones are selected according on a stratified sample where strata are defined by the administrative regions and the number of inhabitants (non auto-representative municipalities or NAR). The procedure used for estimating $Var(\hat{\mu})$ involves two different methods for AR and NAR municipalities. In our case, both estimates of μ and $Var(\hat{\mu})$ are calculated at small area level.

3 Simulation study

We carry out a simulation study to assess both the magnitude of the bias of the non-corrected estimator and the effectiveness of the correction adopted to reduce that small sample bias. To this purpose we consider the EU-SILC sample as target population and then repeatedly select random samples from it. We prefer to base our study on the EU-SILC dataset, rather than use data generated under some distribution model, to have a more realistic view of the small area estimation problem considered.

We consider as small areas the administrative regions and repeatedly select 1,000 two-stage stratified samples, mimicking the sample strategy adopted in the EU-SILC itself: in the first stage, AR municipalities are always included in the sample, while a stratified sample of NAR municipalities are selected; in the second stage, a simple random sample of households is selected from each municipality included in the first stage. We consider two overall sampling rates, 1.5 and 3%, to better understand the extent of the problem and the effectiveness of the solution with reference to different sample sizes. In our simulation setting the small area sample size ranges from a minimum of 6 to a maximum of 28 for the 1.5% sample, and almost twice for the 3% sample. $ge(0)$ and its bias corrected version, from now on $geCorr(0)$, are calculated considering the individuals, as usual. Individual equivalized income is, by definition, the same for all members of the same household.

$ge(0)$ and $geCorr(0)$ are compared in terms of bias and accuracy using the average absolute relative bias (AARB) and the average absolute relative error (AARE):

$$AARB = \frac{1}{m}\sum_{i=1}^{m}\left|\frac{1}{1000}\sum_{r=1}^{1000}(est_{ri}/GE(0)_i - 1)\right| \qquad [4.a]$$

$$AARE = \frac{1}{m}\sum_{i=1}^{m}\frac{1}{1000}\sum_{r=1}^{1000}|est_{ri}/GE(0)_i - 1| \qquad [4.b]$$

where est_{ri} denotes the value of an estimator (alternatively $ge(0)$ or $geCorr(0)$) obtained for the r.th simulated sample and i.th small area, and $GE(0)_i$ is the true small area mean log deviation.

Percentage values of indicators in [4.a] and [4.b] are reported in Table 1. Results show that the correction considered greatly reduces the bias of the non-corrected estimator, although the corrected estimates remain a little biased on average. On the other hand, with respect to the concern about the reduction of the overall reliability of the estimates due to the correction, we find instead a negligible increase in the accuracy indicator.

Table 1: Percentage performance measures based on the simulation study

	1.5% sample		***3% sample***	
	$ge(0)$	$geCorr(0)$	$ge(0)$	$geCorr(0)$
AARB%	15.9	4.0	7.9	2.6
AARE%	51.8	52.3	37.8	38.2

Testing the Learning-by-Exporting at Micro-Level in light of influence of “Statistical Issues” and Macroeconomic Factors

Verifica dell’ipotesi Learning-by-Exporting a livello micro alla luce dell’influenza delle “questioni statistiche” e dei fattori macroeconomici

Maria Rosaria Ferrante and Marzia Freo

Abstract This study aims at testing the Learning-by-Exporting (LBE) on the TFP from the perspective of the evaluation literature. The focus is posed on the distribution of the outcome, the pre-entry selection bias is addressed, and both “statistical issues” and the influence of macroeconomic factors are accounted for. Basing upon a panel of Italian manufacturing firms, we design an experiment by aligning and pooling cohorts of starter, incumbent exporter and domestic firms and we further address the panel drop out. Main findings are that internationalisation has an impact on firms’ TFP, which is larger for best performing firms. Then it is shown that estimates of LBE impact are biased when i) the heterogeneous influence of macro-factors across groups and cohorts, and ii) the drop out of some firms from the panel are not accounted for.

Abstract *Il presente contributo indaga l’effetto del Learning-by-Exporting (LBE) nella prospettiva degli studi di valutazione. L’attenzione è posta alla distribuzione dell’outcome, e si tengono sotto controllo i meccanismi di auto-selezione, le questioni statistiche e l’influenza dei fattori macro-economici. Sulla base dell’analisi di un panel di imprese manifatturiere italiane (1998-2007), attraverso un elaborato disegno di ricerca, si verifica che l’internazionalizzazione ha un impatto sulla PTF delle imprese, specialmente sulle migliori. che le stime dell'impatto del LBE sono distorte se non si tiene conto i) *dell'influenza eterogenea dei fattori macro e della caduta e uscita di alcune imprese dal panel.*

Key words: Learning-by-Exporting, TFP, Panel Attrition, Macroeconomic Factors.

1 Introduction

During last years, many empirical studies have investigated the hypothesis that firms experience an increase in productivity during the period following their entrance into international markets (the Learning-By-Exporting or LBE hypothesis) and have displayed evidences for different countries with "mixed" conclusions ([4]). To investigate the mechanisms through which LBE may be explained and to identify a number of stylised facts for policy conclusions two meta-analyses have been run ([3], [5]) which highlight the roles played by issues related to sampling and methodological heterogeneity, on one side, and to different country-level macroeconomic environments, on the other side.

This study is a further contribution which aims to test the presence of the LBE effect on productivity growth, taking into account for meta-analysis's findings and going back to the firm-level. With respect to the most of previous micro-level studies, we design an ad-hoc research process which, besides micro-level factors, allows us to explicitly recognize macro-effect and the commonly called "sampling issues".

Differences between exporters and non-exporters are analysed from the perspective of the evaluation literature, by using counterfactual methods, and enlarging the focus to cover the whole probability distribution of the LBE effects looking at differences on various quantiles.

As far as the "sampling issues" are concerned, we test the LBE effect using a ten year panel data of Italian manufacturing firms observed during the period 1998-2007, and examine six cohorts of firms which started to export from 2000 to 2005. This data allows us to investigate firms behaviour during the pre- and post-entry periods. It is confirmed that the number of firms that may be observed to enter and remain in the international market for some years is quite low, and that the panel data suffer from attrition. Both these sampling issues have frequently emerged within the applied literature ([2]) but, at the best of our knowledge, they have never been jointly afforded.

Coming to the macroeconomic factors, their heterogeneity across domestic and international markets and over time is explicitly recognised. This is made possible by the length of the available panel that allows one to track the performance of firms over time and permits the observation and the control of cyclical movements. At the best of our knowledge in the literature on the evaluation of the LBE effect, the influence of the cycle is not considered at the micro-level.

In summary, in this study, we design a manifold research experiment in order to address these further sources of heterogeneity, concerning sampling and macroeconomic factors, and to obtain reliable statistical results on the LBE effect.

2 The Research Design

The detection of the LBE is managed as an empirical evaluation problem by comparing the TFP evolution of the treated group of firms starting to export to two untreated control groups which are respectively formed by domestic firms and by incumbent exporter firms. Exploiting the ten-year panel data, we define the treated "starters exporter" firms all firms observed to export for at least three years after having not exported for the two previous years. Performance of the treated groups is compared to two alternative control groups: the incumbent exporter firms which are always observed to export and the domestic firms which are observed selling their products only to domestic market, during all but one year. In order to take into account for the attrition bias due to drop-out, the study furtherly singles out groups of incumbent and domestic firms which from one year onwards exit from the panel (named "exiter") according this pattern: exiter firms are continuously present in the panel during the first five year and in some year after drop out. This allows us to run the analysis on the data both when they are balanced and when they are unbalanced. It is worth noting that many further firms in the panel have been considered not eligible for this study because they have not a well-defined pattern concerning the export status.

Since the number of export starters size for each cohort is small, to obtain a group of starters large enough to allow a reliable statistical analysis, we decide to align the sequences of firm-observations at the year in which each firm begins to export, which we fix as the time of treatment $j=0$ and to pool firms that belong to the six cohorts. In this way we obtain a group of 478 export starters and we consider the time to treatment variable in terms of the advance or delay to the treatment time (from $j=-2$ to $j=2$, where $j=0$ represents the treatment time). Note that the definition of the starters group leads us to observe a two-year-long period before the treatment ($j=-2,-1$) and a three-year-long period after the treatment ($j=0,1,2$). Moreover after the alignment, observations which share the same value of time-to-treatment variable are generated in different years and therefore they are affected by different level of macroeconomic variables.

Insofar, to detect the LBE effect on TFP, the six singled-out cohorts of starters are compared to the corresponding cohorts of domestic or incumbent firms. Then , the alignment and pooling of the cohorts of starters also requires that five-year-long sequences nested within longer sequence of incumbents and domestics are aligned and pooled. This action involves some caution to avoid deteriorating the comparisons in terms of the relative weights of the observations and in terms of the membership to specific target groups and years. In fact, the comparison is based on five-year-long sequences, and while starters have always five-year-long sequences, domestics and incumbents, due to their definition, exhibit longer sequences. In order to avoid domestic or incumbent firms being over-represented with respect to starter firms, we apply the following procedure for each comparison of the starter exporter to domestic (or incumbent) firms:

1. for each firm sequence among domestic (or incumbent), we extract all the five-year long sub-sequences; we align the sub-sequences at time to treatment j=0 and append to each sub-sequence the inclusion probability defined as the inverse of the number of sub-sequences which may be extracted by each firm sequence;
2. we sample five-year long sub-sequences according to their inclusion probabilities;
3. we pool the sampled sub-sequences to form the control group and we run analysis over the treated and the control groups.

This three-steps aligning-sampling-pooling procedure is repeated 100 times with a bootstrap.

3 The Evaluation Model

Based on the previously reported considerations, to properly measure the premium actually due to entry into the international market, we shall account for: 1) the pre-entry selection bias on TFP levels, 2) the bias due to drop out, and 3) the differential effect of the macroeconomic factors.

To estimate the LBE effect on the whole TFP distribution, we adopt the quantile decomposition methodology (QD, hereinafter) ([1]). According to QD, in the first step two conditional quantile models are used to establish the relationships between the productivity and covariates of the firms in two different groups along the entire distribution. In the second step, the conditional distributions implied by the estimated quantile model for firms in a certain group are applied to the observed covariate distribution of firms in the other state such that a counterfactual unconditional TFP distribution is estimated. Finally, the observed differences among the TFP distributions across the groups are decomposed into a component explained by the differences in the composition of covariates and a component explained by different returns to covariates (coefficients). In this way, it becomes possible to compute the impact of each of the components on the overall outcome distribution. The differences among distributions are evaluated at different quantiles. The component due to the covariates can be interpreted as the effect induced by the heterogeneity in characteristics, that is, by the self-selection mechanism on observables. The component due to the coefficients can be interpreted as the net export productivity premium.

To detect the post-entry TFP premium, we will estimate the net premium of starter firms, by comparing the dynamics of the productivity of the starter firms after entrance into international markets to the dynamics of the productivity of domestic and incumbents firms. These results are attainable by running QD over the bootstrapped samples drawn first over the balanced dataset and then over unbalanced dataset. These two cases may represent two bounds of values which premiums may attain. In fact, on one side, the measured TFP premium computed over always-present firms is likely to be underestimated because of the observed positive selection of domestic and incumbent always present firms. On the other side, the TFP premium that refers to Unbalanced dataset, which is enlarged to cover drop out observations, is likely overestimated because the premiums of the exiter firms are deteriorated by the crisis pattern.

With the aim of adjusting the TFP of exiters for drop out selection, we modify the QD approach by resorting to the Heckman selection model and to the two-stages Heckman estimator.

We adopt as the outcome variable the TFP change in years after the entrance. Concerning the specifications of conditional models adopted for estimating the net TFP premium, the specified covariates represent the observable characteristics for which outcome is controlled. This specification is chosen to further reduce, at least partially, the bias induced by the selection process on unobservable characteristics, while the QD mainly controls for the selection on the observables characteristics.

The general specification used for the quantile conditional model regresses the yearly rate of growth of TFP at time-to-treatment j=-1,0,1 over the set of structural firm characteristics that are supposed to explain the self-selection mechanism (industrial groupings dummies, macro-area dummies, TFP level, size in term logarithm of number of employees, and per capita wage at fixed time to treatment j=-2). Including the TFP pre-entry level allows us to control for unobserved pre-entry heterogeneity. To control for cyclical effects, the specification of the equation includes a vector d of five-year dummies This allows controlling for heterogeneity across cohorts and groups differently affected by the diminishing pull of export demand, as the TFP export premium is partially affected by macro-effects, which act differently across groups and cohorts. In the conditional model over unbalanced data as further term is added the inverse Mills' ratio which adjusts for drop out selection.

4 Main Results and Conclusions

LBE effects have been estimated as differentials in TFP rates of growth in favour of starter firms against either domestic or incumbents, respectively over balanced and unbalanced data and by adjusting unbalanced data for the drop out.

Estimates over balanced data show differential growth of TFP in favour of starter firms which are suddenly positive for the best-performing firms while they become positive two years after the entry for the slower-performing firms.

When the TFP premium growth rates are estimated over unbalanced data similar findings emerge, with the peculiarity that premiums are always higher with respect to those computed over balanced data and they are remarkably higher when considered versus domestics. They also are in general statistically significant.

The acceleration of premium growth during the third year is still higher when it is adjusted for drop out selection, even if not significant, because it discounts the higher standard errors of two-step estimators influencing the test results. Also in estimates adjusted for drop out it appears that the initial sunk costs of internationalization could produce lower growth for starter firms during the year of entrance, but during the post-entry periods, these premiums evolve faster. Also in this case, the premiums become positive earlier for the best-performing starter firms, which accelerate versus domestics just after entrance and versus incumbents one year after entrance.

In summary, according to expectations, if post-entry effects had not intervened, the net premiums of starters would have experienced a growth of the same strength of incumbents' or domestics' premiums, resulting in a null differential growth. Thus, starter exporting firms, after an initial deceleration, increase their TFPs more than incumbents and domestic firms. During the period after the entrance, the best-performing starters accelerate compared with domestics and the following period compared with incumbents. Two periods later, even the lesser- and medium-performing starter firms grow faster than the incumbents and even more than the domestics. Moreover, premiums become higher when the comparisons are enlarged to always present and exiter firms and are still higher when they are adjusted for drop-out. These results are evidence of LBE effects that intervene sometime after firms begin to export. Insofar, we are able to show, that neglecting these statistical and economical aspects could lead to hidden the LBE effect or to obtain biased estimation of the effect itself.

Concerning previous research questions, we find support to the LBE effect during the post-entry period. In particular, firms starting to export are in general observed to increase their TFP faster than domestic and incumbent firms two years after their entrance into international markets, and also before when they are best performing firms, that is they are at the top section of TFP's growth distribution. We also find that LBE effects would have been lower or even absent if we had not accounted for the macroeconomic cycle and the drop-out selection.

The mobility and the job success of the Sicilian graduates

La mobilità e il successo lavorativo dei laureati magistrali siciliani

Ornella Giambalvo and Antonella Plaia and Sara Binassi

Abstract The paper focuses on the job success of Sicilians Graduates comparing people who remain in Sicily for work reasons (Stayers) and who moves from Sicily to another Italian region or abroad (Movers) during 2016. Data referred to the *Almalaurea Consortium* annual survey collecting data of first and second level graduates interviewed at one, three or five years from graduation. We model the probability to be a successful graduate by means of a logistic regression model considering job and curriculum characteristics. The results show that many factors influence the job success, with some differences between graduates intervíwed 1 or 5 years after graduation, but it is clear that to be a Mover increases significantly the probability to be successful graduate.

Abstract *Il lavoro vuole analizzare il successo lavorativo dei giovani laureati siciliani che dopo un anno o dopo cinque anni dalla laurea lavorano. Nello specifico si analizzano le differenze fra le caratteristiche dei laureati Movers (quelli che lasciano la Sicilia) e Stayers (quelli che rimangono nella regione di studio) attraverso l'adozione di un modello logit che prende in considerazione variabili legate alle caratteristiche del lavoro e al curriculum universitario. I risultati mostrano che molti fattori influenzano il successo nel lavoro, con differenze tra gli intervistati a 1 e a 5 anni, ma è chiaro che essere un Mover aumenta significativamente la probabilità di essere un laureato di successo.*

of the academic curricula) also caused the increasing spirit of competition among the universities. Every year, before the student's enrolment, Censis Institute, other research Institutions and other organizations (including Media), produce university rankings. Each of these takes into account several aspects referred to the university's organization, reputation and student benefits or referred to the student's actual characteristics. Some of them consider also the graduates employment rate one or three years after graduation. The Lisbon Strategy stressed the importance of the quality of employment regarding especially young people and young graduates. The strategic context for European cooperation in the education field estimates that the value of the graduates employment rate, for young people (20-34 years old) would be 82% in 2020. In 2016, the EU-28 employment rate of recent graduates (based on graduates – aged 20–34 – who had completed their education or training between one and three years prior to the survey) was 78.2%, ranging from highs of 90.2% in Germany and 96.6% in Malta to lows of 49.2% in Greece (52.9% in Italy). During the crisis period this employment rate followed a decreasing trend (-14% from 2008 to 2013) while in EU28 the decreasing trend was -6%. In Italy the economic crisis continues to produce its negative effects in employment and unemployment rates, particularly referring to young people (15-29 years old) and graduates: in 2016 the first rate reaches 49.5% whereas the second is 22.4%. Furthermore, the graduates employment rate varies according to the territorial differences: in 2016 it reaches the 43.4% in the Southern regions *vs.* the 65.9% in the Northern ones. Moreover, in the last fifteen years, students' enrolment has decreased significantly, while students' migration from the South to the Northern or the Central regions has increased [2]. This phenomenon creates further inequalities in within the country and a cultural and socio-economic loss for the South.

Based on the above results the paper focuses on the analysis of the job success of Sicilians Graduates between who remains in Sicily for work reasons (Stayers) or otherwise moves from Sicily to another region in Italy or abroad (Movers). Data referred to the *Almalaurea Consortium* annual survey collecting data of first and second level graduates interviewed at one, three or five years from graduation. We focus our attention to the second-level graduates interviewed after one and five years. In particular we consider the differences in job success according to some job characteristics and graduates' curriculum between Stayers and Movers. Who are the graduates that migrate and who are the students that stay? Is the migration of Sicilian graduates a consequence of personal and family dynamics? How do students that migrate from the South perform compared to students that stay? Who find a better job and when? This paper attempts to gives some responses to these important questions.

2 Data and variables

The 2016 AlmaLaurea survey on graduates' employment conditions [1] involved more than 16,000 first- and second-level graduates in 2015 enrolled in the universities of Sicily interviewed one year after graduation and 7,288 second-level graduates in 2011, interviewed five years after graduation. Since a high share of first-level graduates who comes from the universities of Sicily, continues their education with a master's degree (58% versus 56% of the overall population of first-level graduates), here we analyse the employment performance of second-level degree, focusing on one and five years after graduation. One year after graduation, the share of Sicilians graduates of 2015 employed who remain in Sicily for work reasons is 71%. Most of all women, with a degree in medicine, architecture, humanities and economic-statistics. The 29% decides to move, for work reasons, outside the region, most of all women, mostly from engineering and economic-statistics. Movers seem to be younger at graduation than Stayers and they are more regular in complying with the expected duration of the degree program. The graduation mark is slightly better for Movers than Stayers. In evaluating the characteristics of the work carried out, such as, for example, the type of work activity, remuneration and the correspondence between university studies and work carried out, it should be noted that, among the Stayers employed, a part of them entered the labour market already during the Master studies, or even before (33 against 13% of Movers). A further 9% changed their jobs after the conclusion of their studies, a value slightly lower than that for the Movers, equal to 14%. Finally, 58% entered the labour market only at the end of the Master degree (73% among Movers employed). One year after obtaining the title, self-employment concerns 14% of Stayers employed (the share is decidedly higher than the percentage of Movers, 6%). Almost in line between Stayers and Movers is the share of employed on permanent contracts (including the contract with increasing protection): 29% on Stayers compared to 32% on Movers. Stayers employed claim to receive a lower than Movers average salary.However, regardless of the type of work performed, part-time activities concern the 48% of those employed in Sicily against 18% of those who moves from the region. A year after the title, Stayers employed is effective or very effective (an indicator which combines a formal request title for the exercise of one's own work and use, in the work carried out, of the skills learned during the university) for more than half of the graduates workers (58% against 56% of Movers). Five years after graduation, the percentage of Sicilians graduates of 2011 employed who remain in Sicily for work reasons is 65%. Self-employment reaches 37% of Stayers employed (the share is decidedly higher than the percentage of Movers, 12%). The share of employed on permanent contracts rises among Movers: 53% compared to 40% on Stayers. Large part of the Stayers declare to carry out their activities in the private sector (73% against 63% of the Movers). More in detail they work within the services (88%; 5 percentage points more than the Movers). The industry sector, on the other hand, absorbs 9% of the Stayers and 16% of the Movers. Stayers employed claim to receive, also at five years after graduation, a lower average salary than Movers: the net monthly salary in fact, it is equal to 1,126 euros for Stayers, compared to 1,479 euros for the Movers (part-time activities concern the 26% of Stayers against 13% of Movers). Stayers employed is effective or very effective for more than half of the graduates workers (68% against 63% of Movers). Finally, in terms of job satisfaction, the gap is still positive for Movers.

3 First Results and some comments

As described in the previous sections, in this paper we want to compare the *job success* of what we called *Movers* vs *Stayers*. We define a Successful Graduate a person with a monthly neat earnings over the average (conditioning on his degree subject grouping and the type of degree) who uses greatly the skills acquired through the degree course. Conversely, an unsuccessful graduates, is a person with a monthly net earnings below the average (conditioning on his degree subject grouping and the type of degree) who uses limitedly or in no way the skills acquired through the degree course. We model the probability to be a successful graduate by means of a logit model [3] with the following covariates (chosen according to previous literature evidence [1]): the subject grouping of the degree, the graduation mark, the gender, the duration of studies, the age at graduation, the type of degree (single cycle vs second-level degree), the job sector of activity, part-time vs full-time job, satisfaction for the current job, together with some socio-economic characteristics of the graduate's family, such as parents' education level. Moreover, the interactions between Parents' education level and Migration, Gender and Migration, Parents' education level and gender have been considered. Tables 1 (graduates in 2015 interviewed after 1 year) and 2 (graduates in 2011 interviewed after 5 year) show the results with all the significant covariates and interactions.

According to Table 1, all the degree subjects show a probability of being a successful graduate lower than a graduate in Medicine; Males show a higher probability than female; a graduation delay below the average corresponds to a higher probability, even if these results are not coherent with the significance of the Age at graduation (we need to investigate further this aspect); the probability increases if at least one parent is graduated; Movers show a higher probability than Stayers; the probability increases if, during studies, graduates were resident in a province different from the University one; graduates have a higher probability to be a successful one if he/she did not work at graduation.

It's interesting to notice that, if we limit our analysis to only those students that did not work at graduation (table not shown), the *Graduation mark* and both the *Graduation delay* and the *Age at graduation* are no more significant (and this in someway explains the apparently discordant effect of these two variables shown in Table 1), nor they are all the previous significant interactions.

Considering 2011 graduates interviewed after 5 years (Table 2), coming from the universities of Catania and Palermo increases (with respect to Messina) the probability to be a successful graduate; only some of the degree subjects show a probability of being a successful graduate significantly lower than a graduate in medicine; Males show a higher probability than female; a graduation delay below the average corresponds to a higher probability, even if, again, this results is not coherent with the significance of the Age at graduation; Movers show a higher probability than Stayers; the probability decreases if the graduate works in a private or not-for-profit company or is part-time, while it increases with the satisfaction for the job.

Finally, focusing again on Movers and Stayers, it is evident that, even if we cannot say that "Being a Movers" is the first factor to be a successful graduate, the

Statistical Analysis of Energy Markets

Forecasting Value-at-Risk for Model Risk Analysis in Energy Markets

Angelica Gianfreda and Giacomo Scandolo

Abstract We consider the assessment of mis-specification risk when forecasting Value-at-Risk on a daily horizon. In particular, we focus on Energy Markets (electricity, oil, gas), where the impact of model risk may be relevant. Within an AR-GARCH framework to capture known features of volatility, we consider nine competing distributions for the standardized innovations and we apply a recently proposed measure of model risk to quantify the amount of model uncertainty in the procedure. Our approach is made more robust by discarding, on a daily basis, the worst performing models by using a set of weights built upon the Bayesian Information Criterion. The analysis covers the period 2001-2015, allowing for an in-depth assessment of the dynamics of model risk.

Key words: Building Weights, Risk Management, Electricity, Natural Gas, Brent Crude Oil

1 Introduction

In the financial literature, it has been recognized that the choice of the underlying probabilistic model for the risk factors can have a significant impact on a risk forecast. The hazard of producing a poor risk assessment due to the choice of an unsuited model is usually termed *model risk*. A distinction is usually made between two aspects of model risk: *estimation risk* and *mis-specification risk*. The former one refers to the uncertainty arising from parameters estimation, once a parametric family of distributions has been chosen. Instead, the latter one refers to the choice of

Giacomo Scandolo
University of Firenze, Via delle Pandette 9, Firenze e-mail: giacomo.scandolo@unifi.it

the parametric family itself. Given that quantifying and managing mis-specification risk is more difficult and it has been investigated to a lesser extent[1], we aim at focussing on this issue considering energy markets over almost fifteen years of data (from 2001 to 2015), so that we are able to assess model risk on a long-run basis and depict its historical evolution.

2 Methodology

Given a financial portfolio, the Value-at-Risk $\mathrm{VaR}_{\alpha,t+1}$, from day t to day $t+1$ at level α, is implicitly defined through the equality $P(L_{t+1} > \mathrm{VaR}_{\alpha,t+1}) = \alpha$, where $L_{t+1} = V_t - V_{t+1}$ is the loss from day t to day $t+1$ (here, V_t and V_{t+1} are the portfolio market values at days t and $t+1$). We consider the values $\alpha = 1\%$ and 5%, typical for market risk.

The assessment of VaR naturally depends on a probabilistic model. Henceforth, at any given date, competing models will produce competing VaR forecasts and model risk arises when these forecasts are dispersed. Several measures of model risk have been proposed in the literature. Here, we consider the Relative Measure of Model Risk (henceforth, RMMR) as defined in Barrieu and Scandolo (2015). Let VaR_i be the forecast of $\mathrm{VaR}_{\alpha,t+1}$ under model i, and VaR^* the forecast under a *reference* model; then, the RMMR is defined as the number

$$\mathrm{RMMR} = \frac{\max_i \mathrm{VaR}_i - \mathrm{VaR}^*}{\max_i \mathrm{VaR}_i - \min_i \mathrm{VaR}_i} \tag{1}$$

It easily turns out that this number lies in the interval $[0,1]$ (provided the reference model is among the competing models), and it is insensitive to the amount invested in the portfolio. We observe that the closer is RMMR to 1, the lower is VaR^* with respect to the other competing forecasts and therefore the higher is the amount of model risk involved.

In this work, we consider three portfolios, each of them investing in one of the following energy-related assets: Brent crude oil (*Oil*), ICE UK natural gas (*Gas*), and day–ahead auction prices for electricity observed on the European Energy Exchange (EEX) for delivery in the German/Austrian zones (*Electricity*). The oil and gas series always displayed positive prices, while several occurrences of negative prices were observed for electricity. Therefore, for the former two portfolios we set $L_t = -(e^{X_t} - 1)$, where X_t is the daily log-return observed at day t; for the electricity portfolio, we simply set $L_t = -X_t$, where X_t is the daily price change. In each case, we model the series (X_t) through an AR(5)–GARCH(1,1) process. Specifically, we have $X_t = \mu_t + \sigma_t Z_t$, where $\mu_t = \overline{\mu} + \sum_{i=1}^{5} \phi_i X_{t-i}$ is the conditional mean following an AR(5) process, and $\sigma_t^2 = \omega + \alpha(X_{t-1} - \mu_{t-1})^2 + \beta\sigma_{t-1}^2$ is the conditional variance following a GARCH(1,1) model. The IID innovation series (Z_t) can follow any of 9 competing standard distributions, which are: *normal* (NORM) and *skew*

[1] See for instance Cont (2006) and Daníelsson et al. (2016); among others.

normal (SNORM); *Student-t* (STD) and *skew Student-t* (SSTD); *Generalized Error Distribution* (GED) and *skew GED* (SGED); *Johnson's S_U family* (JSU); *Normal Inverse Gaussian* (NIG); *Generalized Hyperbolic family* (GHYP). Notice that some of these models are nested[2] and some of them allow for extra-parameters that give control on asymmetry and/or tail behaviour.

For any fixed distribution for the innovations, the parameters of the AR-GARCH model are estimated day-by-day by ML using a rolling window of 256 past daily data. This allows us to obtain a forecast VaR_i $(i = 1, \ldots, 9)$ of the daily Value-at-Risk under all competing models. Once a reference model is fixed throughout (NORM, for instance), the final output is a daily series of model risk measures.

As a result of the rolling estimation process, we obtain the maximized log-likelihood $\widehat{\ell_i}$ $(i = 1, \ldots, 9)$ for each day and competing model, and then the series of Bayesian Information Criterion, defined as $BIC_i = -2\widehat{\ell_i} + \log(n)p_i$, where n is the length of the dataset ($n = 256$ in our analysis) and p_i is the number of parameters in model i. [3] We observe that BIC is a measure of fitting ability (the lower is BIC, the better is the fitting) which penalizes for over-parametrization, and we use these values in two ways. First, on a daily basis we can rank the 9 models according to their fitting ability. In particular, at each day we single out the *daily best* model, as the one with the lowest BIC value; we then employ this model as the reference one in the computation of RMMR. Second, we can attach to each model a *percentage weight*, defined as

$$w_i = \frac{a_i^2}{\sum_{j=1}^{K} a_j^2}, \tag{2}$$

where

$$a_i = \frac{\max_j BIC_j - BIC_i}{\max_j BIC_j - \min_j BIC_j}.$$

Notice that w_i is decreasing in BIC_i: higher fitting ability is therefore associated with higher weights. We use these weights to discard, on a daily basis, the worst fitting models; specifically, after ranking the models with increasing weights, we retain models until the cumulative weight 0.95 is reached. We think this step is crucial in obtaining a measure of model risk that does not strictly depend on the initial choice of the competing models. As a consequence, RMMR do not necessarily lie in the interval $[0,1]$ if the reference model is among the discarded ones. Finally, we use the weights to obtain an average forecast, naturally defined as $\text{VaR}_{\text{avg}} = \sum_i w_i \text{VaR}_i$, which can be used as a possible reference model throughout (here, discarded models are left out of the average and weights are therefore properly normalized).

[2] For instance, NORM is a particular case of SNORM.

[3] For instance, $p_i = 10$ for the STD model: 6 parameters for the AR process, 3 for the GARCH process and 1 for the STD distribution.

3 Empirical results

As anticipated, for each day we obtain various measures of model risk, by considering as reference model either one specific distribution, or the daily best, or the average forecast $\mathrm{VaR}_{\mathrm{avg}}$. We always discard the worst fitting models, as explained above (on average, 2 or 3 models are discarded each day). We repeat the entire procedure for VaR at $\alpha = 1\%$ and $\alpha = 5\%$ and for all three portfolios of individual assets (oil, gas and electricity). All time series have been collected from Datastream, from 01/01/2001 to 31/12/2015, and are quoted on a basis of 5 days per week, for a total of 3914 observations. We used the R-package `rugarch`. Some of the RMMR series and related empirical findings are shown next.

The ”overall best” model for each of the three assets is identified by looking at the majority of days in which it is found to be the best fitting model. Overall best models (and in parenthesis the ”overall worst” models, being the best daily models in the fewest number of days) are: STD (GHYP) for oil, GED (GHYP) for gas, and STD (SNORM) for electricity. We observe that the Normal model is not the overall worst model for any of the three assets because the use of BIC penalizes models with many parameters.

In Table 1 we show some descriptive statistics of the RMMR (for $\alpha = 1\%$) for some choices of the reference model. We emphasize that while the overall best/worst models are fixed throughout for any given asset, the daily best model may change on a daily base. As explained before, weights are computed for each model: they are used for discarding the worst fitting models and to compute the average forecast $\mathrm{VaR}_{\mathrm{avg}}$.

Reference model		Oil	Gas	Ele
Normal	mean	1.04	0.54	0.64
	std. dev.	0.52	0.74	0.91
	max	5.95	4.75	5.04
Overall best	mean	0.52	0.64	0.77
	std. dev.	0.32	0.33	0.44
	max	2.28	3.44	8.25
Overall worst	mean	1.59	1.31	0.73
	std. dev.	0.46	0.44	0.50
	max	5.99	5.55	9.41
Daily best	mean	0.31	0.20	0.29
	std. dev.	0.30	0.28	0.34
	max	1.00	1.00	1.00
Average forecast	mean	0.48	0.49	0.44
	std. dev.	0.11	0.13	0.14
	max	0.87	0.88	0.95

Table 1 Some descriptive statistics for RMMR ($\alpha = 1\%$).

Looking at the mean levels, we see that the daily best models provide on average the lowest amount of model risk. The overall best gives less model risk than the overall worst for Oil and Gas; a bit surprisingly, this is not the case for Electricity. The model risk associated to the average VaR is stable around 0.5. Looking at the maximum levels we see that the RMMR sometime reach levels around 10, which signal a huge amount of model risk.

Figure 1 shows the daily dynamics of RMMR for Gas during 2002 (with $\alpha = 1\%$), when using the overall best (GED) and overall worst (GHYP) as reference models. We can see that, even though RMMR with respect to GHYP is consistently higher than for GED, the two series are highly volatile (as confirmed by the standard deviations in Table 1). Therefore, to ease the presentation, we used rolling means of the RMMR computed on a 256-day basis, and we show the dynamics of the RMMR ($\alpha = 1\%$) for two portfolios in Figure 2 (gas and oil shows similar RMMR dynamics). Finally, we also compare the RMMRs for both $\alpha = 1\%$ and $\alpha = 5\%$, showing[4] that the amount of model risk depends on α

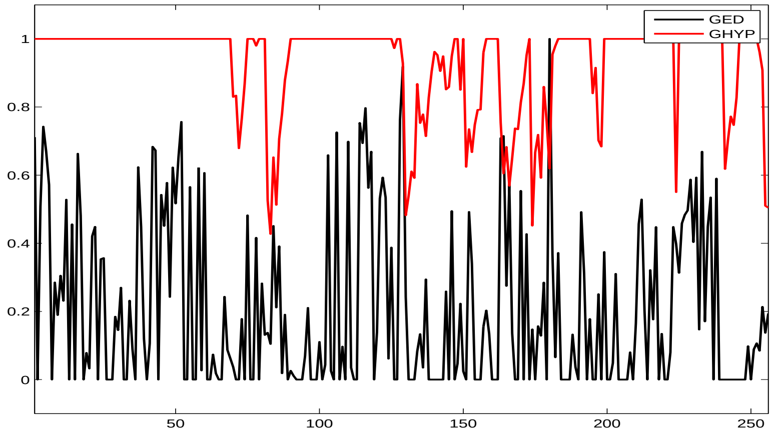

Fig. 1 Dynamics of RMMR for $\text{VaR}_{1\%}$ for Gas in 2002, using the overall best (GED) and the overall worst (GHYP) as reference models.

4 Conclusions

Quantifying and managing mis-specification risk has been less investigated so far, hence we have provided for the first time the empirical assessment of mis-specification risk when studying energy assets. Relaxing the assumption of normality and using a wide range of alternative distributions, we have quantified model risk under the well-established setting of GARCH models. Our empirical results emphasize that the distributional assumptions made in price modelling can produce a relevant discrepancy in risk figures and then trigger substantial model risk. In general, we find that better models tend to produce less model risk. Although not

[4] This figure is omitted for lack of space.

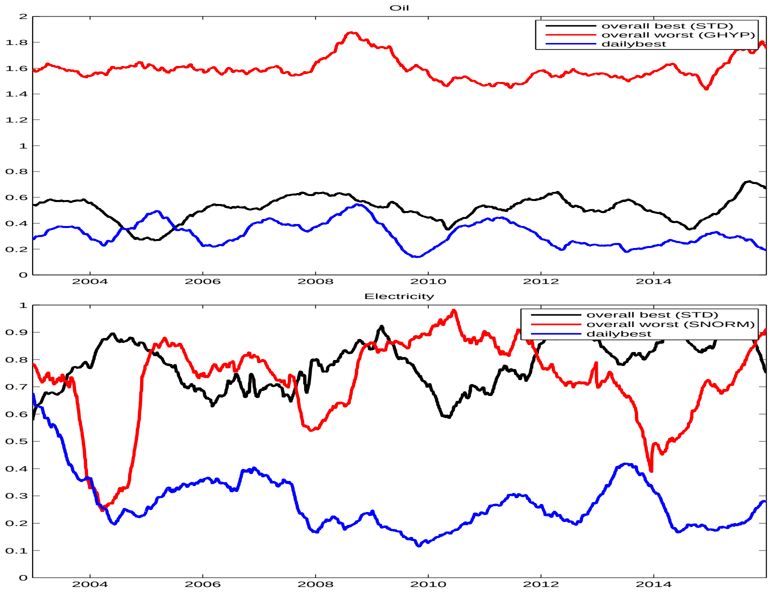

Fig. 2 Dynamics of rolling mean RMMR for $\alpha = 1\%$ using the overall best, the overall worst, and the daily best as reference models for Oil (top panel) and Electricity (bottom panel).

completely surprising, this pattern is quite evident across different assets and levels of VaR.

It is worth highlighting that our analysis intentionally addresses the choice of the innovations distribution, which is one among a number of possible sources of model risk affecting the final VaR figures. Future research may indeed address the misspecification risk due to the choice of the number of lags in the ARMA-GARCH structure or even due to the choice among different types of specification for the conditional mean/volatility.

Prediction interval of electricity prices by robust nonlinear models

Lisa Crosato, Luigi Grossi and Fany Nan.

Abstract It is well known that volatility of electricity prices estimated through GARCH-type models can be strongly affected by the presence of extreme observations. Although the presence of spikes is a well-known stylized effect observed on electricity markets, their presence has been often neglected and robust estimators have been rarely applied. In this paper we try to fill this gap introducing a robust procedure to the study of the dynamics of electricity prices. The conditional mean of de-trended and seasonally adjusted prices is modeled though a robust estimator of SETAR processes based on a polynomial weighting function (Grossi and Nan, 2015), while a robust GARCH is used for the conditional variance. The robust GARCH estimator relies on the extension of the forward search by Crosato and Grossi (2017). The robust SETAR-GARCH model is applied to the Italian electricity markets using data in the period spanning from 2013 to 2015. The purpose of this application is therefore twice: first, it is possible to enhance the prediction from point to intervals with associated probability levels, second, we set up a procedure to detect possible extreme prices which are commonly observed in electricity markets.

1 Introduction

In this paper we introduce a doubly robust approach to modelling the volatility of electricity spot prices, minimizing the misleading effects of the extreme jumps that characterize this particular kind of data on the predictions. The purpose of this paper is twice: first, it is possible to enhance the prediction from point to intervals with associated probability levels, second, we can detect possible extreme prices which are commonly observed in electricity markets. Although many papers have applied quite sophisticated time series models to prices and demand time series of electricity and gas very few have considered the strong influence of jumps on estimates and the need to move to robust estimators (Nowotarski et al.; 2013). Thus, the big differences between our paper and the previous literature related to jumps

in electricity prices are twofold: 1) we don't detect extreme observations and we don't focus on the prediction of jumps; 2) We apply robust estimators which are not strongly influenced by the jumps. In this way we improve the prediction of normal prices which represent the majority of data. Our approach could then be integrated with other methods dealing with jumps forecasting.

Our methodology is applied separately to the hourly time series of Italian electricity price data from January 1st, 2013 to December 31th, 2015. In the first step, we apply a threshold autoregressive model (SETARX) to the time series of logarithmic prices. In the second step the weighted forward search estimator (WFSE) for GARCH(1,1) models is applied to the residuals extracted from the first step in order to estimate and forecast volatility. The weighted forward search is a modification of the Forward Search intending to correct the effects of extreme observations on the estimates of GARCH(1,1) models. Differently from the original Forward Search, at each step of the search estimation involves all observations which are weighted according to their degree of outlyingness.

2 A robust SETAR model for electricity prices

It is well-known that the series of electricity prices have long-run behaviour and annual dynamics, which change according with the load period. A common characteristic of price time series is the weekly periodic component (of period 7), suggested by the spectra that show three peaks at the frequencies $1/7$, $2/7$ and $3/7$, and a very persistent autocorrelation function.

We assume that the dynamics of log prices can be represented by a nonstationary level component L_{tj}, accounting for level changes and/or long-term behaviour, and a residual stationary component p_{tj}, formally:

$$\log P_{tj} = L_{tj} + p_{tj}. \tag{1}$$

To estimate L_{tj} we use the wavelets approach (Lisi and Nan, 2014). We consider the Daubechies least asymmetric wavelet family, LA(8), and the coefficients were estimated *via* the maximal overlap discrete wavelet transform (MODWT) method (for details, see Percival and Walden, 2000).

The detrended prices p_t, will then be modeled by a two-regime Self-Exciting Threshold AutoRegressive model SETAR(7,1) which is specified as

$$p_t = \{ \mathbf{x}_t \beta_1 + \varepsilon_t, \quad \text{if} \quad p_{t-1} \leq \gamma \mathbf{x}_t \beta_2 + \varepsilon_t \quad \text{if} \quad y_{t-1} > \gamma \tag{2}$$

for $t = 1,...,N$, where p_{t-1} is the threshold variable and γ is the threshold value. The relation between p_{t-1} and γ states if p_t is observed in regime 1 or 2. $\beta_{\mathbf{j}}$ is the parameter vector for regime $j = 1,2$ containing 7 coefficients to account for weekly periodicity. $\mathbf{x_t}$ is the t-th row of the $(N \times 7)$ matrix $\mathbf{X}$ comprising 7 lagged variables of p_t (and eventually a constant). Errors ε_t are assumed to follow an $\mathrm{iid}(0, \sigma_\varepsilon)$ distribution.

Parameters can be estimated by sequential conditional least squares. In the case of robust two-regime SETAR model, for a fixed threshold γ the GM estimate of the autoregressive parameters can be obtained by applying the iterative weighted least squares:

$$\hat{\beta}_j^{(n+1)} = \left(\mathbf{X}_j' \mathbf{W}^{(n)} \mathbf{X}_j\right)^{-1} \mathbf{X}_j' \mathbf{W}^{(n)} \mathbf{p}_j \tag{3}$$

where $\hat{\beta}_j^{(n+1)}$ is the GM estimate for the parameter vector in regime $j = 1,2$ after the n-th iteration from an initial estimate $\hat{\beta}_j^{(0)}$, and $\mathbf{W}^{(n)}$ is a weight diagonal matrix, those elements depend on a weighting function $w(\hat{\beta}_j^{(n)}, \hat{\sigma}_{\varepsilon,j}^{(n)})$ bounded between 0 and 1. The threshold γ can be estimate by minimizing the objective function $\rho(r_t)$ over the set Γ of allowable threshold values. Weights are calculated as

$$w(\hat{\beta}_j, \hat{\sigma}_{\varepsilon,j}) = \psi\left(\frac{y_t - m_{y,j}}{C_y \hat{\sigma}_{y,j}}\right) \psi\left(\frac{y_t - \mathbf{x}_t \hat{\beta}_j}{C_\varepsilon \hat{\sigma}_{\varepsilon,j}}\right)$$

where ψ is the polynomial weight function (Maronna et al., 2006) and $m_{y,j}$ is a robust estimate of the location parameter (sample median) in the j-th regime. $\hat{\sigma}_{y,j}$ and $\hat{\sigma}_{\varepsilon,j}$ are robust estimates of the scale parameters σ_y and σ_ε respectively, obtained by the median absolute deviation multiplied by 1.483. C_y and C_ε are tuning constants fixed at 6.0 and 3.9 respectively.

3 Robust volatility estimation through the forward search

Now we apply the weighted forward search (WFS) estimator to derive robust prediction intervals for the volatility of electricity prices, starting from the residuals of the SETAR model estimated in section 1. Let ε_t denote an observed time series of heteroscedastic residuals. For electricity prices $\varepsilon_t = p_t - \hat{p}_t$ where $\hat{p}_t$ is the price fitted by the robust SETAR model. We proceed now by estimating a standard GARCH(1,1) model on residuals ε_t, so that $\varepsilon_t | F_{t-1} \sim N\left(0, \sigma_t^2\right)$ and

$$\sigma_t^2 = \alpha_0 + \alpha_1 \varepsilon_{t-1}^2 + \beta \sigma_{t-1}^2 \tag{4}$$

with $\alpha_0 > 0, \alpha_1 \geq 0, \beta \geq 0, \alpha_1 + \beta < 1$.

The WFS (see Crosato and Grossi, 2017, for details) starts with the selection of a small subset of observations showing the minimum median of squared residuals. Then, at each step of the search, MLE estimation is carried out on all observations weighted to account for their degree of outlyingness so that the estimation pattern along the search is not influenced by the presence of spikes. All units, a part of the first b, are ranked according to their squared standardized residuals with respect to the model estimated at the previous step of the search. Proceeding along the search, an increasing number of units are given weight 1 while the remaining are downweigthed by the corresponding value of the complementary cumulative distribution function of the squared standardized residuals defined on the whole sample. The weights range from approximately 0 to 1 so that outliers will be heavily downweighted until the end of the search while the closer the weight to 1 the stronger is the degree of agreement of the observation with the estimated GARCH. This way the temporal structure of the time series is respected, filling the time gaps created by the forward search ordering but on the same time observations are ordered consistently with the GARCH model estimated until the last steps when all observations enter with their original value.

A plus of the WFS approach is that outliers are identified automatically through a test reducing the arbitrariness in declaring a given observation as outlier. Once outliers have been identified the forward plots of coefficient estimates are cut automatically and WFS GARCH estimates are obtained.

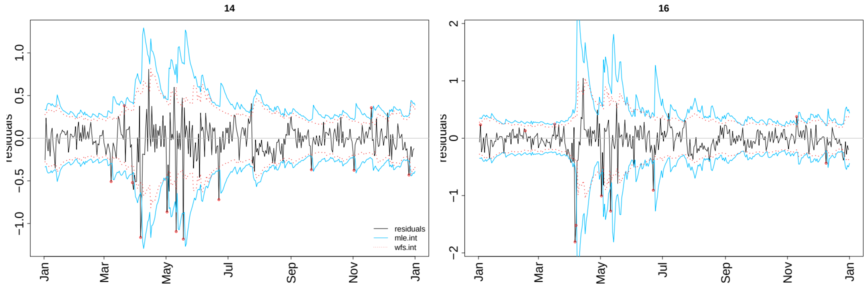

Fig. 1 Forecasted conditional confidence intervals of volatility for hourly electricity prices in Italy (hour 14 and 16, January to December 2015) obtained by MLE (light blue) and WFS (dotted red).

The outliers identified through the WFS test vary from a minimum of 29 (hour 21) to a maximum of 59 (hours 8 and 9). A few outliers characterize many hours of the same day, as is the case of the 21st and 27th of April, 2013 for 14 hours as well as mot days of June 2013. Spikes in 2014 characterize mainly the months of February, March and April. Outliers for 2015, hours 14 and 16, are highlighted by red circles in figure 1.

Using the MLE and WFS estimated coefficients and applying equation (4) for the conditional variance recursively, we then obtain the forecasted price volatility and the corresponding 95 percent confidence intervals (see figure 1). As can be seen, the WFS intervals (dotted red) are tighter around the realized volatility than the MLE ones (light blue). The gain in prediction is evident in the aftermath of a spike or a drop, for instance in April and May. Note that the correction provided by the WFS works also for smallest jumps, as in July and December.

Bias Reduction in a Matching Estimation of Treatment Effect

Sulla Riduzione della Distorsione nella Stima Matching dell'Effetto del Trattamento

Maria Gabriella Campolo, Antonino Di Pino and Edoardo Otranto

Abstract The traditional matching methods for the estimation of the treatment parameters are often affected by selectivity bias due to the endogenous joint influence of latent factors on the assignment to treatment and on the outcome, especially in a cross-sectional framework. In this study, we show that the influence of unobserved factors involves a cross-correlation between the endogenous components of the propensity scores and causal effects. A correction for the effects of this correlation on matching results leads to a reduction of bias. A Monte Carlo experiment supports this finding.

Abstract *I tradizionali stimatori matching dei parametri del trattamento spesso producono stime affette da selettività dovuta all'influenza endogena di fattori latenti, specialmente nelle analisi cross-section. In questo studio, mostriamo che l'influenza di fattori non osservabili mette in correlazione la propensione a sottoporsi al trattamento e gli effetti causali prodotti da quest'ultimo. La correzione delle stime matching per gli effetti di questa correlazione consente di ridurre la distorsione dovuta alla selettività. Questo risultato è supportato dalle evidenze di una serie di esperimenti Monte Carlo.*

1 Introduction

A typical assumption of models for treatment effects is based on the hypothesis that the decision of a subject to receive a certain treatment depends on the difference in the outcomes potentially gained by the subject under the two alternative regimes of treatment and control, respectively (see, e.g., Winship and Morgan, 1999). Starting from this assumption, the decision of a subject to undergo the treatment is endogenous with respect to the potential outcome. The non-random selection of the units into the treatment regime, due to the endogeneity of treatment, involves that important unobserved covariates influence jointly the propensity of a subject to undergo the treatment and the outcomes. As a consequence, matching estimation of the treatment effect, based on the comparison of treated and untreated units with the same propensity score, is biased (e.g. Austin, 2011).

In this context, a natural solution, as the detection of new statistically significant covariates in the treatment choice equation, could not reduce the bias; in fact, Heckman and Navarro-Lozano (2004) show that this is the case when these variables are not exogenous with respect to the outcome.

In this study, we try to circumvent the problem of misspecification of the selection equation in matching methods based on propensity score, assuming that the potentially omitted endogenous factors can be represented by a stochastic component correlated with the causal effects of the treatment. This implies that the causal effect of each subject is correlated with the causal effect of another subject with similar propensity score; moreover, the stochastic component is autocorrelated, as causal effects relative to similar propensity scores will be more similar. In order to assess this endogenous relationship, we model the causal effects adopting a sort of state-space model (see, for example, Harvey, 1990), where a common latent factor is detected in correspondence of the endogenous stochastic component of the propensity score sorted in an ascending (or descending) order. State-space models are generally adopted for time series; the extension to this framework is simple, substituting the ordering of the observations in terms of dating with the order in terms of increasing propensity score. The predictions of these components are used as correction terms in the matching procedure. The estimation method proposed, called State-Space Corrected Matching (*SSCM*), is based on the Kalman filter (see Harvey, 1990) and possesses the nice characteristic of not imposing conditions of identification of the probability to undergo the treatment as in the randomized experiments.

We verify the performance of this method comparing its bias with respect to the bias occurring with traditional propensity score matching (cf., among others, Rosenbaum and Rubin, 1983) by Monte Carlo experiments. In the Monte Carlo experiment we generate data in a cross-sectional context, adopting a two-regime model whose data generation process (*DGP*) is affected by endogeneity. Applying our correction method, we obtain a marked reduction of bias in the estimated average treatment effect for the treated (*ATT*) in comparison with the traditional Propensity Score Matching estimator (*PSME*, Rosenbaum and Rubin, 1983).

In next Section we describe this new procedure, whereas in Section 3 we show the results of the Monte Carlo experiments comparing the performance of *SSCM* estimation method and traditional *PSME* in terms of prediction of the *ATT* parameter.

2 The Model

In this paper we insert several novelties with respect to the present literature. The most relevant is the individuation of an autoregressive process that characterizes, jointly, individual propensity scores and causal effects. As a consequence, another important novelty is given by the correction term based on the estimation of a State-Space model in which the endogenous component common to causal effects and propensity scores is specified by a "measurement" equation and a "transition" equation, respectively. In addition, in our model it is not necessary to reproduce conditions of identification of the probability to undergo the treatment such as in a randomized experiment.

In this analysis, we start to consider the potential outcome gained by choosing one of the two treatment status as a relevant (endogenous) determinant of the decision undergoing the treatment. In particular, we specify the model assuming that the difference between the potential (expected) outcomes, y_{1i} and y_{0i}, obtainable, respectively, under the regimes T_i =1 (if the subject belongs to the treatment group) and T_i=0 (if the subject belongs to the comparison group), determines, at least in part, the choice of the regime.

We specify a Probit (or Logit) model, where the (latent) propensity to undergo the treatment of the *i-th* subject, T^*_i, depends linearly on the covariates in **Z**:

$$T*_i = \mathbf{z}'_i \boldsymbol{\beta} + v_i \tag{1}$$

where $\mathbf{z}'_i$ is the *i*-th row of the matrix **Z**, $\boldsymbol{\beta}$ is a vector of unknown coefficients and v_i is a zero-mean random disturbance with unit variance. If $T^*_i > 0$, $T_i = 1$ (the subject is undergone to treatment), otherwise $T_i = 0$ (the subject is not undergone to treatment).

Assuming that the assignment to treatment is endogenous, T^*_i will depend on the causal effect $\Delta_i = y_{1i} - y_{0i}$.

Formally, we can explain autocorrelation and endogeneity specifying our model similarly to a generalized Roy model (e.g., Carneiro et al., 2003). In doing this, we add to the above selection equation (Eq. 1) two equations that specify the outcome of treated and untreated subjects, as follows:

$$y_{1i} = \mu_{1i} + u_{1i} \qquad \text{if } T_i = 1; \tag{2a}$$

$$y_{0i} = \mu_{0i} + u_{0i} \qquad \text{if } T_i = 0; \tag{2b}$$

In Eqs. (2a) and (2b) μ_{1i} and μ_{0i} are the expected outcomes, respectively, of treated and untreated subjects, depending on the decision to undergo the treatment (T = 1) or not (T = 0). The error terms u_{1i} and u_{0i} are normally distributed with zero mean and variances equal to σ^2_1 and σ^2_0 respectively. The covariances σ_{1v} and σ_{0v} of the disturbances of both outcome equations, u_{1i} and u_{0i}, with the disturbances of the selection equation (1), v_i, can be different from zero as a consequence of endogeneity. The covariances σ_{1v} and σ_{0v} are measurements of the endogeneity of the propensity to undergo the treatment, T^*_I with respect to the outcome gained under T =1 and T = 0.

Correlation between outcomes and propensity scores, as well as the autocorrelation of the causal effects, may be specified starting from the definition of causal effects, Δ_i. Hence, subtracting Eq. (2b) from Eq. (2a), we obtain:

$$\Delta_i = y_{1i} - y_{0i} = \mu_{1i} - \mu_{0i} + (u_{1i} - u_{0i}) \tag{3}$$

Imposing a linear relationships between the error terms of the outcome equations and the selection equation, we have:

$$u_{1i} = \sigma_{1v} v_i + \varepsilon_{1i} \tag{4a}$$

$$u_{0i} = \sigma_{0v} v_i + \varepsilon_{0i} \tag{4b}$$

where ε_{1i} and ε_{0i} are i.i.d. disturbance with zero mean. By substituting (4a) and (4b) into Eq. (3):

$$\Delta_i = y_{1i} - y_0 = \mu_{1i} - \mu_0 + (\sigma_{1v} - \sigma_{0\text{v}})v_i + (\varepsilon_{1i} - \varepsilon_{0i}) \tag{5}$$

Putting $\mu_{1i} - \mu_{0\text{i}} = \mu_i$; $(\sigma_{1v} - \sigma_{0\text{v}})v_i = \sigma\, v_i$ and $(\varepsilon_{1i} - \varepsilon_{0i}) = \varepsilon_i$, Eq. (5) can be written as a *measurement equation* of a state-space model, as follows (cf., among others, Harvey, 1990):

$$\Delta_\text{i} - \mu_i = \sigma\, v_i + \varepsilon_\text{i} \tag{6}$$

In Eq. (6), ε_i is a vector of n×1 disturbance terms uncorrelated across i. The variable v_i can be considered as the state variable whose elements are not observable, but are assumed to be generated by a first-order Markov process, such as the following transition "equation":

$$v_i = \rho v_{i-1} + \eta_\text{i} \tag{7}$$

The dependent variable of Eq. (6), $\Delta_\text{i} - \mu_i$, may be considered as the stochastic component of the causal effect Δ_i, endogenous with respect to the decision to undergo to treatment. Starting from this result, the selectivity effect due to the endogeneity of the decision to undergo the treatment may be corrected by estimating σv_i in Eq. (6), and using the predicted values, $\sigma\hat{v}_i$, as a correction term in the matching estimation of the causal effects. In doing this, a preliminary estimation of causal effects Δ_i is obtained at a first stage by applying a propensity score matching procedure. Then, at a second stage, matching is replicated using the corrected outcomes y_{1i} - $\sigma\hat{v}_i$ so as to obtain the corrected causal effects Δ_i -$\sigma\hat{v}_i$ $= \hat{\mu}_i$. We call this estimator the State-Space Corrected Matching (*SSCM*) estimator.

3 Monte Carlo Experiment

We propose a Monte Carlo experiment to compare the performance of the *SSCM* procedure with that of the *PSME* in terms of bias reduction under both the conditions of heterogeneous and homogeneous covariates between regimes. For this purpose, we generate 500 data sets of 2,000 units from the Two-Regime model above in Eqs. (1), (2a) and (2b). The exogenous covariates Z are generated in order to reproduce the very frequent condition of heterogeneity in observed covariates between treatment and comparison group, and the condition of homogeneity in the observed covariates between regimes. We consider two different *DGPs*, with and without endogeneity, so as to fix two distinct set of population parameters under the condition of endogeneity and exogeneity, respectively.

Table 1 summarizes the estimated *ATT* values obtained by embedding different endogeneity conditions into the *DGP*. Computing the bias with respect to the population *ATT* value (set equal to 5), the *SSCM* estimator performs better than the *PSME* procedure. The bias resulting from the application of *SSCM* is markedly smaller than the one resulting from *PSME*.

Table 1: Simulation Results. Estimated ATT parameters. Population *ATT* value = 5. Generated sample size: n = 2000. No of reps. 500. Simulated endogeneity by setting σ_{1v} and σ_{0v}.

		SSCM			*PSME*	
Endogeneity	***ATT***	*95% CI*		***ATT***	*95% CI*	
σ_{1v} 5.4; σ_{0v} 2.4	4.974	*4.930*	*5.018*	7.996	*7.970*	*8.022*
σ_{1v} 5.4; σ_{0v} -2.4	4.320	*4.279*	*4.362*	6.814	*6.782*	*6.846*
σ_{1v} 5.4; σ_{0v} 0.8	4.983	*4.939*	*5.027*	7.571	*7.534*	*7.607*
σ_{1v} 5.4; σ_{0v} -0.8	4.729	*4.688*	*4.770*	7.572	*7.536*	*7.608*
	% BIAS*	*St.Dev.*	*t***	***% BIAS****	*St.Dev.*	*t***
σ_{1v} 5.4; σ_{0v} 2.4	-0.51%	*0.022*	222.160	59.92%	*0.013*	*607.170*
σ_{1v} 5.4; σ_{0v} -2.4	-13.59%	*0.021*	205.720	36.28%	*0.016*	*414.280*
σ_{1v} 5.4; σ_{0v} 0.8	-0.35%	*0.022*	222.480	51.41%	*0.018*	*410.660*
σ_{1v} 5.4; σ_{0v} -0.8	-5.42%	*0.021*	225.710	51.45%	*0.018*	*412.000*

Note: * % of Bias [(Est. ATT-5)/5]%; ** t-ratio: ATT/St.Dev.)

We can observe, in particular, that, if we reproduce the “more common” endogeneity conditions (characterized by covariances, σ_{1v} and σ_{0v}, with the same sign) in the *DGP*, the confidence intervals obtained by the *SSCM* estimates include the population *AT*T value. In the less frequent case, in which the propensity to undergo the treatment is endogenously affected in the two regimes with opposite sign, confidence intervals of the *SSCM* estimates do not include the population parameter. However, the percentage of bias of *SSCM* estimation does not exceed 15% in absolute value.

4 Conclusion

The aim of this study is to improve the propensity-score matching approach so that estimation results do not overly suffer from the influence of the endogeneity of treatment. We show that, applying a state-space model, we can estimate the endogenous component of the causal effects, so as to use the result of this estimate as a correction term. In particular, the results of the Monte Carlo experiments here reported confirm that, simulating endogeneity of the selection into treatment in a Two-Regime model, the predicted components of causal effects can be successfully used, at a second stage of the estimation procedure, to correct the matches outcomes.

As the results of our Monte Carlo analysis show, this method allows us to reduce the selectivity bias in matching without imposing, to the data or the model, any restriction usually adopted to reproduce a condition comparable to the randomization. At this stage of our research, we have deepened the characteristics of the SSCM estimator only through Monte Carlo experiments. However the inferential properties must still be investigated. This will be the next aim of this research.

Statistical Inference and Testing Procedures

Comparison of exact and approximate simultaneous confidence regions in nonlinear regression models

Confronto tra la regione di confidenza esatta ed approssimata nei modelli di regressione nonlineari

Claudia Furlan and Cinzia Mortarino

Abstract Accuracy measures for parameter estimates represent a tricky issue in nonlinear models. Practitioners often use the separate marginal confidence intervals for each parameter. However, these can be extremely misleading due to the curvature of the parameter space of the nonlinear model. For low parameter dimensions, routines for evaluating approximate simultaneous confidence regions are available in the most common software programs, but the degree of accuracy also depends on the intrinsic nonlinearity of the model. In this paper, the accuracy of the marginal confidence intervals, Hartley's exact simultaneous confidence region (sCR), and the most widespread approximate sCR are compared via both real data and simulations, for discrete time diffusion models in the class of nonlinear regression models.
Abstract *Nei modelli non lineari non è scontato riuscire ad ottenere misure di accuratezza delle stime. Nella pratica spesso si usano gli intervalli di confidenza marginali per ogni parametro, ma questa procedura può portare a risultati inaffidabili a causa della curvatura dello spazio parametrico tipico dei modelli non lineari. Nei più comuni software si può trovare implementato il calcolo della regione di confidenza simultanea approssimata per un numero ridotto di parametri, ma il livello di copertura esatto dipende dal grado di non linearità intrinseca del modello. In questo lavoro, nell'ambito dei modelli di regressione non lineari e in particolare per i modelli di diffusione a tempo discreto, si confrontano fra loro i livelli di copertura degli intervalli di confidenza marginali, della regione di confidenza simultanea (sCR) esatta di Hartley e della sCR approssimata più utilizzata.*

Key words: nonlinear models, simultaneous confidence region, Hartley's simultaneous confidence region, Bass model

1 Introduction

Nonlinear models are the natural modelling framework for many real-world phenomena. Unlike linear models, accuracy measures for parameter estimates, such as confidence intervals or confidence regions, may represent a difficult task due to the intrinsic curvature of the parameter space. A common mistake is relying on

Claudia Furlan e-mail: furlan@stat.unipd.it · Cinzia Mortarino e-mail: mortarino@stat.unipd.it
Department of Statistical Sciences, University of Padova, Italy.

marginal confidence intervals, whose use can be misleading. Simultaneous confidence regions are usually available in the most commonly used software programs, only in the approximate form at least for low parameter dimensions.

The problem of constructing exact confidence regions for the parameters of nonlinear models has received little attention in the past (Lee et al, 2002), since this is computationally intensive. Given the complexity of obtaining an exact simultaneous confidence region (sCR), a few approximations have been proposed (Seber and Wild, 1989) under the normality assumption of homoscedastic errors. For instance, the so-called ‘approximate’ sCR is derived by approximating the nonlinear model via a linear Taylor expansion, thereby taking advantage of the asymptotic normality of the estimator. Thus, the approximate confidence levels of the ‘approximate’ sCR are valid asymptotically. This approximation is computationally more attractive, since it corresponds to hyperellipsoids.

Under the normality assumption of homoscedastic errors, Hartley (1964) proposed an exact sCR based on inverting an exact test. However, the power of the exact test, and thus the coverage probability of the corresponding sCR, depends on the choice of the idempotent projection matrix. More recently, Demidenko (2017) studied the exact statistical properties in small samples.

Among the nonlinear regression models, in this paper, we focus on two of the most widespread discrete time diffusion models of products and technologies; these are the Bass model (BM) and the Generalized Bass model (GBM) which have three and six parameters, respectively. We analyze two case studies based on real data, namely Algerian natural gas production and Austrian solar thermal capacity. In this paper we derive and compare Hartley (1964)’s exact sCR with Guseo (1983)’s projection matrix with the ‘approximate’ sCR, in terms of accuracy, via simulation studies. The simulation studies are performed to explore the effect of increasing the parameter dimension with different model structures. Specifically, the BM is considered in a constrained version and in its full form (two and three parameters respectively), while the GBM is considered with two different intervention functions (six parameters in both versions). The simulation studies are performed for lifecycles with the same diffusion characteristics as those of the two case studies.

2 Diffusion models

Let us denote with n the number of observations used to fit the model and with y the n-dimensional vector obtained by stacking the observed y_i values, $i = 1,2,\dots,n$. Similarly, $f(\vartheta;t)$ will denote the vector $f(\vartheta;t) = \{f(\vartheta;t_1), f(\vartheta;t_2),\dots, f(\vartheta;t_n)\}'$.

For a general nonlinear regression model,

$$y_i = f(\vartheta;t_i) + \varepsilon_i, \quad \vartheta \in \mathbb{R}^k, \quad i = 1,2,\dots,n, \tag{1}$$

where $\mathfrak{C}(\Theta) \subset \mathbb{R}^k$ is the exact sCR with confidence level $1-\alpha$.

In the application of diffusion models, the starting point is given by an observed time series reporting sales data or consumption/production of a technological innovation. In this work, we consider the BM and GBM (Bass et al, 1994). Let $z(t)$ be the cumulative data, at time t, and $w(t)$ an intervention function. The GBM is:

$$z(t) = m\frac{1 - e^{-(p+q)\int_0^t w(\tau)d\tau}}{1 + \frac{q}{p}e^{-(p+q)\int_0^t w(\tau)d\tau}}, \tag{2}$$

where m is the market potential, p is the innovation coefficient, q is the imitation coefficient, and $w(t)$ can be any integrable function. Below, we examine the model arising when $w(t)$ is specified by the so-called *exponential* shock (Guseo and Dalla Valle, 2005),

$$w(t) = 1 + c_1 e^{b_1(t-a_1)} I_{t \geq a_1}, \tag{3}$$

which allows us to describe the diffusion of a product for which, at time a_1, we observe a rapid and reversible ($b_1 < 0$) shock with intensity c_1; and when $w(t)$ is specified by the so-called *rectangular* shock,

$$w(t) = 1 + c_1 I_{a_1 \leq t \leq b_1}, \tag{4}$$

which allows us to describe the diffusion of a product for which we observe a constant shock with intensity c_1, in the time interval $[a_1, b_1]$. We will denote the GBM of Eq. (2) with $w(t)$ as in (3) by GBM$_{exp}$, and with $w(t)$ as in (4) by GBM$_{rect}$. These structures are a special case of model (1), where $f(\vartheta;t)$ is represented by $z(t)$ in Eq. (2), with $w(t)$ specified as in (3) or (4). The cumulative time series data (y) can easily be used to jointly estimate all the parameters (m, p, q, a_1, b_1, c_1) of the model using nonlinear least squares. Finally, the BM is the special case of the GBM, when $w(t) = 1$, $t \in \mathbb{R}^+$.

3 Exact and approximate inference

Hartley (1964) proposed a method for evaluating an exact sCR. This method gives the possibility of verifying whether any point in the parameter space Θ belongs to the exact $(1-\alpha)$ level sCR. Hartley (1964)'s exact sCR is

$$\mathfrak{C}(\Theta) = \left\{ \vartheta : \frac{[y - f(\vartheta;t)]' P [y - f(\vartheta;t)]}{[y - f(\vartheta;t)]'[I_n - P][y - f(\vartheta;t)]} \leq \frac{k}{n-k} F_{1-\alpha}(k, n-k) \right\}, \tag{5}$$

where $F_{1-\alpha}(k, n-k)$ is the $1-\alpha$ percentile of a Snedecor's F distribution with k and $n-k$ degrees of freedom. The confidence level is exact if ε's components can be assumed to be independent and distributed according to a Gaussian distribution. In this work, we assume error homoscedasticity with variance σ^2, and we use the projection matrix proposed by Guseo (1983), $P = F(F'F)^{-1}F'$, where F denotes the $n \times k$ matrix obtained by deriving the vector $f(\vartheta;t)$ with respect to the k-dimensional vector ϑ, $F = \frac{\partial f(\vartheta;t)}{\partial \vartheta}$. This assumption about P leads to the exact sCR that is used in this work:

$$\mathfrak{C}(\Theta) = \left\{ \vartheta : \frac{[y - f(\vartheta;t)]' F(F'F)^{-1}F' [y - f(\vartheta;t)]}{[y - f(\vartheta;t)]'[I_n - F(F'F)^{-1}F'][y - f(\vartheta;t)]} \leq \frac{k}{n-k} F_{1-\alpha}(k, n-k) \right\}. \tag{6}$$

The so-called ‘approximate’ sCR, denoted here by $\mathfrak{I}(\Theta)$, is derived by approximating the nonlinear model by a linear Taylor expansion, taking advantage of the asymptotic normality of the estimator. The ‘approximate’ sCR, $\mathfrak{I}(\Theta) \subset \mathbb{R}^k$, is

$$\mathfrak{I}(\Theta) = \left\{ \vartheta : (\vartheta - \hat{\vartheta})' \hat{F}' \hat{F} (\vartheta - \hat{\vartheta}) \leq k s^2 F_{1-\alpha}(k, n-k) \right\}, \tag{7}$$

where $\hat{F} = F(\hat{\vartheta})$, and s^2 is the sample variance. As the linear approximation is valid asymptotically, $\mathfrak{I}(\Theta)$ will have the correct confidence level of $1-\alpha$, asymptotically.

To evaluate $\mathfrak{C}(\Theta)$ and $\mathfrak{I}(\Theta)$, we derived the expression of the components of F for the GBM$_{exp}$, GBM$_{rect}$, and BM, but we omit them here for brevity.

4 Real data analysis

One field that is currently under the public eye is the diffusion of renewable and nonrenewable energy systems. One energy system of each type was chosen in this study, namely Algerian natural gas production, in billion cubic metres (BCM), with annual data from 1970 to 2004 ($n = 35$, source: www.bp.com), and Austrian thermal solar capacity, in MW$_{th}$, with annual data from 1982 to 2008 ($n = 27$, source: www.estif.org). The data are shown in Figure 1.

We compare the $\mathfrak{C}(\Theta)$ of Eq. (6) and $\mathfrak{I}(\Theta)$ of Eq. (7) in both time series, for increasing parameter dimensions. To accomplish this, we have selected three nested models: the constrained BM (with m fixed, thus $k = 2$), the BM ($k = 3$), and GBM ($k = 6$). In this paper, we decide to show $\mathfrak{I}(\Theta)$ and $\mathfrak{C}(\Theta)$ only for the BM $k = 3$. To do that, we used a grid of 12,190,801 points. Each point in the grid has been subsequently tested to assess inclusion in $\mathfrak{C}(\Theta)$ or $\mathfrak{I}(\Theta)$, via conditions (6) and (7), respectively, with $1-\alpha = 0.95$. For the natural gas production, the proportion of common points with respect to $\mathfrak{C}(\Theta)$ is 0.706, while it is 0.7 for $\mathfrak{I}(\Theta)$. For the solar thermal capacity, the proportion of common points with respect to $\mathfrak{C}(\Theta)$ is 0.442, while it is 0.512 for $\mathfrak{I}(\Theta)$. The degree of overlap is smaller in both energy systems compared with what we found with $k = 2$. The representation of these points, for both time series, is shown in Figure 2, together with the representation of a grid covering the parallelepiped generated by combining the marginal confidence intervals of level 0.95, evaluated separately with the Bonferroni method for the three parameters. For both time series, the difference between $\mathfrak{C}(\Theta)$ and $\mathfrak{I}(\Theta)$ is larger than that observed for the case with $k = 2$. In particular, for the solar thermal capacity, the discrepancy between $\mathfrak{I}(\Theta)$ and $\mathfrak{C}(\Theta)$ is much bigger, and the shape of $\mathfrak{C}(\Theta)$ is far from being ellipsoidal.

Moving to the case with $k = 6$, we fitted the GBM$_{exp}$ to the natural gas production and the GBM$_{rect}$ to the solar thermal capacity. Only the fitted values when $k = 6$ are plotted in Figure 1, since the GBMs were found to be the best models, according to the F-test for nested models. For the natural gas production, the proportion of common points with respect to $\mathfrak{C}(\Theta)$ is 0.060, while it is 0.103 for $\mathfrak{I}(\Theta)$. For the solar thermal capacity, the proportion of common points with respect to $\mathfrak{C}(\Theta)$ is 0.333, while it is 0.984 for $\mathfrak{I}(\Theta)$. The degree of overlap is drastically low, denoting a high curvature of the space $f(\vartheta;t)$. Especially in this final case, $\mathfrak{I}(\Theta)$ appears to be extremely small with respect to $\mathfrak{C}(\Theta)$, thereby excluding many values that belong to $\mathfrak{C}(\Theta)$.

5 Simulation study

In this section, $\mathfrak{C}(\Theta)$ and $\mathfrak{I}(\Theta)$ are compared in terms of coverage probability, for the models used in Section 4: the constrained BM, BM, and GBM. For each model, we generated N=1,000 simulated time series, using estimates as true values. Moreover, the length of simulated time series corresponds to the number of real data ($n = 35$ for the natural gas production and $n = 27$ for the solar thermal capacity). In this way, the simulation study investigates the coverage probability of $\mathfrak{C}(\Theta)$ and $\mathfrak{I}(\Theta)$, with data with diffusion characteristics, intervention functions, and stage of the lifecycle corresponding to those of the time series considered in Section 4.

Given each simulated time series, $j = 1,\dots,N$, we evaluated parameter estimates and both sCRs, $\mathfrak{C}(\Theta)_j$ and $\mathfrak{I}(\Theta)_j$. We then tested whether the true values of the parameters used to generate the N time series were included in $\mathfrak{C}(\Theta)_j$ or $\mathfrak{I}(\Theta)_j$. The proportion of $\mathfrak{C}(\Theta)_j$ and $\mathfrak{I}(\Theta)_j$ containing the true values represents the coverage probability. The coverage probabilities of $\mathfrak{I}(\Theta)$ and $\mathfrak{C}(\Theta)$ for the constrained BM ($k = 2$), BM ($k = 3$), and GBM ($k = 6$) are plotted in Figure 3: the difference between $\mathfrak{C}(\Theta)$ and $\mathfrak{I}(\Theta)$ increases with the model complexity, and it is negligible for $k = 2$ for both energy systems. It emerges that the coverage probability of $\mathfrak{C}(\Theta)$ also decreases as the variability $(\sigma/m)^2$ increases, but its decay is less severe than what happens with $\mathfrak{I}(\Theta)$. This is especially true for $k = 6$. In summary, for both the case studies, the degree of overlap of $\mathfrak{C}(\Theta)$ and $\mathfrak{I}(\Theta)$ decreased as k increased, denoting that the parameter space curvature increased with k, as well as that the shape of $\mathfrak{C}(\Theta)$ was progressively farther from being ellipsoidal. We could conclude that $\mathfrak{I}(\Theta)$ can be satisfactorily used with a low parameter dimension, or with a moderate parameter dimension only if the variability is limited. The validity of this result is limited to data with diffusion characteristics similar to those used in this paper. Further research is required to generalize the effect of the lifecycle stage on the coverage probability.

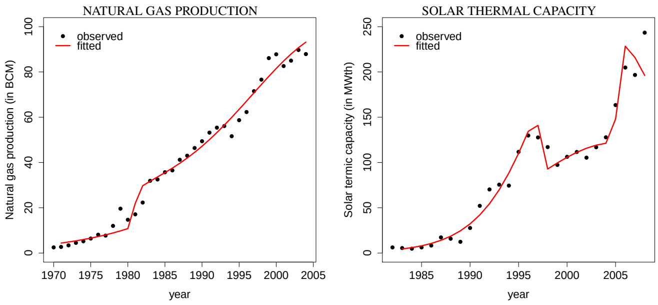

Fig. 1 The lines denote the fitted values (GBM$_{exp}$ and GBM$_{rect}$, respectively).

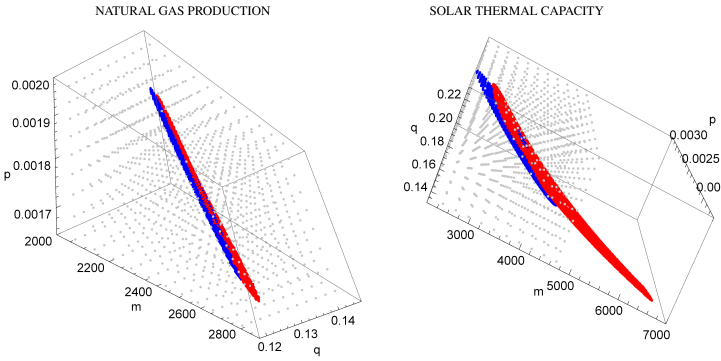

Fig. 2 BM ($k = 3$, $1 - \alpha = 0.95$). $\mathfrak{C}(\Theta)$ is in red and $\mathfrak{I}(\Theta)$ in blue. Grey points represent sCIs.

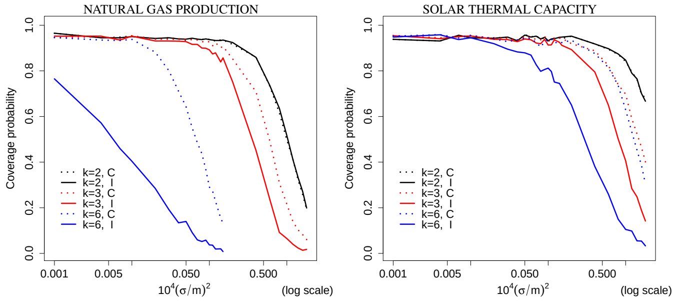

Fig. 3 Coverage probability of $\mathfrak{C}(\Theta)$ and $\mathfrak{I}(\Theta)$. Values of $(\sigma/m)^2$ are in the log scale.

Tail analysis of a distribution by means of an inequality curve

Analisi della coda di una distribuzione attraverso una curva di concentrazione

E. Taufer, F. Santi, G. Espa and M. M. Dickson

Abstract The Zenga (1984) inequality curve $\lambda(p)$ is constant in p for Type I Pareto distributions. We show that this property holds exactly only for the Pareto distribution and, asymptotically, for distributions with power tail with index α, with $\alpha > 1$. Exploiting these properties one can develop powerful tools to analyze and estimate the tail of a distribution. An estimator for α is discussed. Inference is based on an estimator of $\lambda(p)$ which utilizes all sample information for all values of p. The properties of the proposed estimation strategy is analyzed theoretically and by means of simulations.

Abstract *La curva di concentrazione $\lambda(p)$ di Zenga (1984) è costante in p per le distribuzioni di Pareto di tipo I. Questa proprietà vale esattamente solo per la distribuzione di Pareto e, asintoticamente, per le distribuzioni con indice di coda $-\alpha$, con $\alpha > 1$. Sfruttando queste proprietà si possono sviluppare metodi molto efficaci per analizzare e stimare la coda di una distribuzione. Si discute uno stimatore per α. L'inferenza si basa su uno stimatore di $\lambda(p)$. Le proprietà della strategia di stima proposta sono analizzate teoricamente e mediante simulazioni*

1 Introduction

Consider an iid random sample $X_1, X_2, \dots, X_n$ drawn from a random variable with distribution function F satisfying

$$\bar{F}(x) = x^{-\alpha} L(x), \tag{1}$$

where $\bar{F} = 1 - F$, and $L(x)$ is a slowly varying function, that is $L(tx)/L(x) \to 1$ as $x \to \infty$, for any $t > 0$. We will say that $\bar{F}$ is regularly varying (RV) at infinity with index $-\alpha$, denoted as $\bar{F} \in RV_{-\alpha}$. The parameter $\alpha > 0$ is usually referred to as *tail index*; alternatively, in the extreme value (EV) literature it is typical to refer to the EV index $\gamma > 0$ with $\alpha = 1/\gamma$ (see e.g. [10]).

The paper proposes an estimator of the tail index α which relies on Zenga inequality curve $\lambda(p)$, $p \in (0,1)$ [12]. The curve $\lambda(p)$ has the property of being constant for Type I Pareto distributions and, as it will be shown, this property holds for distributions satisfying (1). See [1], [12] , [13] for a general introduction and analysis of $\lambda(p)$.

Probably the most well-known estimator of the tail index is the Hill [6] estimator, which exploits the k upper order statistics. The Hill estimator may suffer from high bias and is heavily dependent on the choice of k (see e.g. [2]). It has been thoroughly studied and several generalization have appeared in the literature. For recent review of estimation procedures for the tail index of a distribution see [3].

The approach to estimation proposed here, directly connected to the inequality curve $\lambda(p)$ has a nice graphical interpretation and could be used to develop graphical tools for tail analysis. Another graph-based method is to be found in [9], which exploits properties of the QQ-plot; while a recent approach based on the asymptotic properties of the partition function, a moment statistic generally employed in the analysis of multi-fractality, has been introduced by [5]; see also [8] which analyzes the real part of the characteristic function at the origin.

2 The curve $\lambda(p)$ and estimation strategy

Let X be a positive random variable with finite mean μ, distribution function F, and probability density f. The inequality curve $\lambda(p)$ is defined as:

$$\lambda(p) = 1 - \frac{\log(1 - Q(F^{-1}(p)))}{\log(1-p)}, \quad 0 < p < 1, \tag{2}$$

where $F^{-1}(p) = \inf\{x\colon F(x) \geq p\}$ is the generalized inverse of F and $Q(x) = \int_0^x t f(t) dt/\mu$ is the first incomplete moment. Q can be defined as a function of p via the Lorenz curve

$$L(p) = Q(F^{-1}(p)) = \frac{1}{\mu} \int_0^p F^{-1}(t) dt. \tag{3}$$

For a Type I Pareto distribution [7, 573 ff.] with

$$F(x) = 1 - (x/x_0)^{-\alpha}, \quad x \geq x_0 \tag{4}$$

it holds that $\lambda(p) = 1/\alpha$, i.e. $\lambda(p)$ is constant in p. This is actually an if-and-only-if result, as we formalize in the following lemma:

Lemma 1. *The curve* $\lambda(p)$ *defined in* (2) *is constant in* p *if, and only if,* F *satisfies* (4).

The following result can also be stated, asymptotically for the case where $\bar{F}$ satisfies (1) as it is stated in the next lemma. For this purpose write

$$\lambda(x) = 1 - \frac{\log(1 - Q(x))}{\log(1 - F(x))}, \tag{5}$$

Lemma 2. *If* $\bar{F}$ *satisfies* (1)*, then* $\lim_{x\to\infty} \lambda(x) = 1/\alpha$.

A tail property of Pareto type I distribution is worth of being noted. Let X be a random variable distributed according to (4) – that is, $X \sim \text{Pareto}(\alpha, x_0)$ –, the following property holds for any $x_1 > x_2 > x_0$:

$$\mathbb{P}[X > x_1 | X > x_2] = \left(\frac{x_1}{x_2}\right)^{-\alpha},$$

hence, the truncated random variable $(X|X > x_2)$ is distributed as $\text{Pareto}(\alpha, x_2)$.

The implications of this property are twofold. Firstly, the truncated random variable is still distributed according to (4), thus Lemma 1 still applies. Secondly, the tail index α is the same both for original and for truncated random variable, thus function $\lambda(p)$ can be used for the estimation of α regardless of the truncation threshold x_2.

The same property we have just outlined holds asymptotically for distribution functions satisfying (1).

Figure 1 reports the empirical curve $\hat{\lambda}(p)$ as a function of p for a Pareto distribution defined by (4) with $\alpha = 2$ and $x_0 = 1$, denoted with $\text{Pareto}(2, 1)$ and a Fréchet distribution with $F(x) = \exp(-x^{-\alpha})$ for $x \geq 0$ and $\alpha = 2$, denoted by Fréchet(2) at different truncation thresholds. Note the remarkably regular behavior or the curves and the closeness to the theoretical form for the Fréchet case already for low levels of truncation.

In this paper the above properties are exploited for devising an estimation method of the tail index α for distributions of class (1).

Let $X_{(1)}, \ldots, X_{(n)}$ be the order statistics of the sample, $\mathbb{I}_{(A)}$ the indicator function of the event A. To estimate $\lambda(p)$, define the preliminary estimates

$$F_n(x) = \frac{1}{n}\sum_{i=1}^{n} \mathbb{I}_{(X_i \leq x)} \qquad Q_n(x) = \frac{\sum_{i=1}^{n} X_i \mathbb{I}_{(X_i \leq x)}}{\sum_{i=1}^{n} X_i} \tag{6}$$

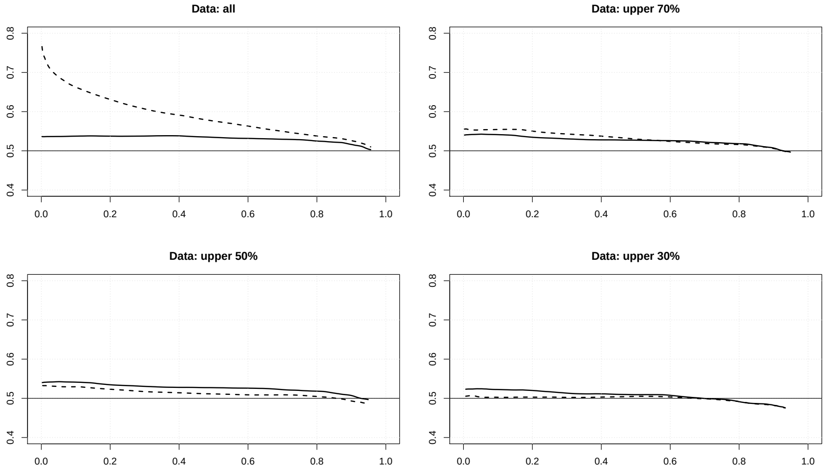

Fig. 1 Plot of $\hat{\lambda}(p)$ and p for Pareto$(2,1)$ (solid line) and Fréchet(2) (dashed line) at various levels of truncation. Sample size $n = 500$. Horizontal line at $1/\alpha = 0.5$

Under the Glivenko-Cantelli theorem (see e.g. [11]) it holds that $F_n(x) \to F(x)$ almost surely and uniformly in $0 < x < \infty$; under the assumption that $E(X) < \infty$, it holds that $Q_n(x) \to Q(x)$ almost surely and uniformly in $0 < x < \infty$. F_n and Q_n are both step functions with jumps at $X_{(1)}, \dots, X_{(n)}$. The jumps of F_n are of size $1/n$ while the jumps of Q_n are of size $X_{(i)}/T$ where $T = \sum_{i=1}^{n} X_{(i)}$. Define the empirical counterpart of L as follows:

$$L_n(p) = Q_n(F_n^{-1}(p)) = \frac{\sum_{j=1}^{i} X_{(j)}}{T}, \quad \frac{i}{n} \le p < \frac{i+1}{n}, \quad i = 1, 2, \dots, n-1, \tag{7}$$

where $F_n^{-1}(p) = \inf\{x : F_n(x) \ge p\}$. To estimate α define

$$\hat{\lambda}_i = 1 - \frac{\log(1 - L_n(p_i))}{\log(1 - p_i)}, \quad p_i = \frac{i}{n}, \quad i = 1, 2, \dots n - \lfloor \sqrt{n} \rfloor. \tag{8}$$

and let $\hat{\alpha} = 1/\bar{\lambda}$ where $\bar{\lambda}$ is the mean of the $\hat{\lambda}_i$'s. The choice of $i = 1, \dots, n - \lfloor \sqrt{n} \rfloor$ guarantees that $\hat{\lambda}_i$ is consistent for λ_i for each $p_i = i/n$ as $n \to \infty$.

3 Simulations

To evaluate the performance of $\hat{\alpha}$, some numerical comparisons are carried out with respect to some reduced bias competitors optimized with respect to the choice of k, the number of largest order statistics used in estimation, as discussed in [4]. The class of moment of order p estimators [4], which reduce to the Hill estimator when $p = 0$ is considered; in the tables they are indicated as $Mop(p)$.

As far as the estimator $\hat{\alpha}$ is concerned, different levels of truncation of the data are considered. In the tables $Ze(q)$ indicates the estimator $\hat{\alpha}$ with q indicating the fraction of upper order statistics used in estimation.

For the comparisons, the Pareto and the Fréchet distributions, as defined in the previous section, are used. Random numbers for the Pareto distribution are simply generated in `R` using the function `runif()` and inversion of F; random numbers from the Fréchet are simulated using the function `rfrechet()` from the library `evd` with shape parameter set equal to α.

Tables 1 and 2 contain the results of simulations. For each sample size $n = 100, 200$, 500, 1000, 2000, $M = 1000$ Monte-Carlo replicates were generated. Computations have been carried out with `R` version 3.3.1 and each experiment, i.e. given a chosen distribution and a chosen n, has been initialized using `set.seed(1)`.

n	*Hill*	$Mop(0.5)$	$Mop(1)$	$Ze(1)$	$Ze(0.7)$	$Ze(0.5)$	$Ze(0.3)$
100	3.41	1.01	1.02	6.44	5.93	5.46	4.68
200	3.97	1.01	1.02	8.67	8.11	7.38	6.53
500	1.99	1.00	0.99	5.33	4.84	4.58	4.07
1000	2.75	1.00	1.00	8.31	7.64	7.11	6.49
2000	1.10	1.00	0.99	3.67	3.48	3.18	2.84

Table 1 Hill estimator: RMSE. Other estimators: relative RMSE *wrt* to the Hill estimator. Pareto$(2,1)$ distribution. Results based on 1000 replications.

n	*Hill*	$Mop(0.5)$	$Mop(1)$	$Ze(1)$	$Ze(0.7)$	$Ze(0.5)$	$Ze(0.3)$
100	0.72	0.99	0.97	1.19	1.41	1.34	1.11
200	0.62	0.99	0.96	1.01	1.26	1.29	1.13
500	0.50	0.98	0.94	0.81	1.07	1.15	1.09
1000	0.44	1.00	0.93	0.71	0.93	1.06	1.06
2000	0.37	1.00	0.91	0.61	0.82	0.94	1.00

Table 2 Hill estimator: RMSE. Other estimators: relative RMSE *wrt* to the Hill estimator. Fréchet(2) distribution. Results based on 1000 replications.

From the tables one can note that the performance of $\hat{\alpha}$ is brilliant for the Pareto and slightly better of Mop estimators for the Fréchet. Truncation seems to have only a small effect on the performance of the estimator.

Nonparametric penalized likelihood for density estimation

Stima della densità non-parametrica basata su verosimiglianza penalizzata

Federico Ferraccioli, Laura M. Sangalli and Livio Finos

Abstract In this work we consider a nonparametric likelihood approach to multivariate density estimation with a regularization based on the Laplace operator. The complexity of the estimation problem is tackled by means of a finite element formulation, that allows great flexibility and computational tractability. The model is suitable for any type of bounded planar domain and can be generalized to the non-Euclidean settings. Within this framework, we as well discuss a new approach to clustering based on the concept of diffusion in a potential field, and a permutation-based procedure for one and two samples hypothesis testing.

Abstract *In questo lavoro viene considerato un metodo di stima della densità tramite verosimiglianza non parametrica con un termine di regolarizzazione basato sull'operatore di Laplace. Il problema di stima è risolto attraverso l'uso di una formulazione ad elementi finiti, che assicura elevata flessibilità e trattabilità computazionale. Il modello è adatto per qualsivoglia tipo di dominio planare chiuso e può essere generalizzato al caso non Euclideo. Si propone un approccio al clustering basato sul concetto di diffusione, insieme ad una procedura di test di ipotesi per uno e due campioni basata su permutazione.*

1 Introduction

The problem of density estimation plays a central role in statistics. It is a fundamental tool for the visualization of structure in exploratory data analysis, and it may be used as intermediate procedure in classification and custering problems. The last decades have seen enormous amount of research focused on kernel density estimation [10]. Simplicity of use and elegant analytic results are the key features of the success of the kernel approach. However, bandwidth selection remains a crucial problem for this method. Moreover, despite recent progress on the asymptotic convergence of the errors, good finite sample performance is by no means guaranteed and many practical challenges remain. The problem get even worse in the multidimensional setting, where the specification of a symmetric, positive definite bandwith matrix is needed, although it's common practice to use diagonal matrices.

Beside the class of kernel density estimators, many other smoothing methods for density estimation have been proposed. All these estimators are based on the idea of reducing the complexity of the problem with some type of approximations or some form of constraint on the space of solutions. In the former case, the approximation is given by basis expasion such as wavelets [4] or splines [9]. In the latter case, the two most prominent approaches are based on regularization of the likelihood functional [8] or shape constraints on the density, e.g. log-concavity [3]. The latter is a parameter-free method but at the cost of a severe restriction on model flexibility. Regularized likelihood methods are extremely flexible but because of the computational complexity they never reached popularity.

In this work we present a new nonparametric likelihood approach to density estimation. The model is based on a finite element formulation and can deal with data distributed over non-regular planar domains. We also briefly discuss a density based clustering method and a permutation based procedure for goodness of fit and for two-samples hypothesis testing.

2 Methodology

2.1 Classical approach

The problem of nonparametric maximum likelihood estimation, in the univariate case, has been considered for the first time in [6]. Let $X_1, \dots, X_n$ i.i.d. observations with distribution function F and density f on a bounded domain $\Omega \in \mathbb{R}$. Without further assumptions, the maximum likelihood estimator for f is not well defined. The likelihood function is unbounded above and the maximization procedure returns the trivial solution of sum of delta functions at the observations. Unlike classical parametric likelihood estimation, where the parameter space is finite, the estimator belongs to an infinite class of functions and some type of regularization becomes necessary to obtain a non-degenerate solution. The basic approach is to maximize a score ω, depending on f and on the observations, defined by

$$\omega = \omega(f) = L - \alpha R(f)\,, \tag{1}$$

where $L = \sum_i \log f(x_i)$ is the log-likelihood, $R(f)$ is the roughness penalty, and the parameter $\alpha > 0$ controls the amount of smoothness. The authors consider, as measure of the roughness or complexity, the functional $R(f) = ||(\sqrt{f})^{(1)}||_2^2$, where the square root permits to avoid the positive contraints on the density. Further developments of this model are presented in [8], where the author considers a regularization functional of the form $R(f) = ||(\log f)^{(3)}||_2^2$. In this case the limiting estimate, as α tends to infinity, is the normal density with the same mean and variance as the data. Note that in this case the positive constraint is avoided by means of the logarithm transformation. Although both models could be generalized to the multivariate setting, consistency results and implementation are given only in the univariate case.

2.2 Model and estimation procedure

In this work we propose a generalization to the estimation of density defined over bounded planar domains. Suppose we observe $X_1, \dots, X_n$ i.i.d. observations drawn from a distribution F on a bounded planar domain $\Omega \in \mathbb{R}^2$. Instead of considering the density f, let us define the log density $g = \log f$, where g is a real function on Ω. This transformation is particularly convenient from the theoretical as well as the practical point of view.
We are interested in a penalized maximum likelihood estimation for g. As previously stated, some types of regularization are necessary, in order to restrict the class of possible solutions. More formally, we consider the estimator that is a solution of the optimization problem

$$\text{minimize} \quad -\frac{1}{n}\sum_{i=1}^{n} g(X_i) + \int_{\Omega} \exp(g(x))\,dx + \lambda R(g) \tag{2}$$

$$\text{subject to} \quad g \in \mathscr{H}^2(\Omega)\,, \tag{3}$$

where $\mathscr{H}^2(\Omega)$ is Sobolev space of functions with continuous weak derivatives up to the second order. As pointed out by [8], the second term of the functional ensures the unitary contraint on the density. We consider here the penalization functional $R(f) = \int_{\Omega} (\Delta \log f)^2\, dx$, where Δ is the Laplace operator. The Laplacian is a measure of local curvature that is invariant with respect to Euclidean transformations of spatial coordinates, and therefore ensures that the concept of smoothness does not depend on the orientation of the coordinate system.
A more complex prior knowledge concerning the domain, which can be translated into a partial differential operator, could be incorporated in the regularization term. We shall consider linear second order elliptic operators of the form

$$Lg = -\mathrm{div}(K\nabla g) + b\nabla g + cf \tag{4}$$

The diffusion term $-\mathrm{div}(K\nabla g)$ induces a smoothing with a preferential direction that corresponds to the first eigenvector of the diffusion tensor K. The degree of anisotropy is controlled by the ratio between its first and second eigenvalue. The transport term $b\nabla g$ induces a smoothing only in the direction specified by the transport vector b. Finally, the reaction term cf has instead a shrinkage effect towards a uniform density on the domain.

Likewise in [7] and [1], the estimation problem is tackled by means of finite element method (FEM), a methodology mainly developed and used in engineering applications, to solve partial differential equations. The strategy of finite element analysis is very similar in spirit to that of univariate splines, and consists of partitioning the problem domain into small disjoint sub-domains and defining polynomial functions on each of these sub-domains in such a way that the union of these pieces closely approximates the solution. Convenient domain partitions are given for instance by triangular meshes. The simplified problem is made computationally tractable by the choice of the basis functions for the space of piecewise polynomials on the domain partition. Each piece of the partition, equipped with the basis functions defined over it, is named a finite element.

Unlike kernel density estimation, the proposed approach admits a likelihood formulation and it's well defined on any domain Ω, without necessity for boundary correction. The absence of constraints on f allows the estimation of extremely complex structures, a fundamental feature in research areas such as density based clustering. Based on the proposed method, we shall in particular discuss a clustering procedure stimulated by Morse theory [2]. We shall also introduce one and two-sample nonparametric tests, based on a permutation approach.

3 Simulation study

Let us consider a complex domain, defined by the closed annulus $ann(a;r,R) = \{x \in \mathbb{R}^2 : r \leq ||x-a|| \leq R\}$, where a is the center and (r,R) the internal and external radii. In our case we consider the annulus centered at the origin, with internal radius 3 and external radius 5. The distribution we have defined on the annulus is the joint probability $\theta \sim \mathrm{Unif}(0,2\pi)$ and a truncated Gaussian distribution in the interval $[1,1]$ with zero mean and standard deviation $\sigma = 0.3$. The Gaussian defines a random distance from the circle with center the origin and radius 4, in the direction normal to the perimeter. This domain includes complex characteristics such as nonlinear boundaries and holes. Despite the presence of complex domains in real data, none of the standard methods in density estimation is appropriate for these problems.

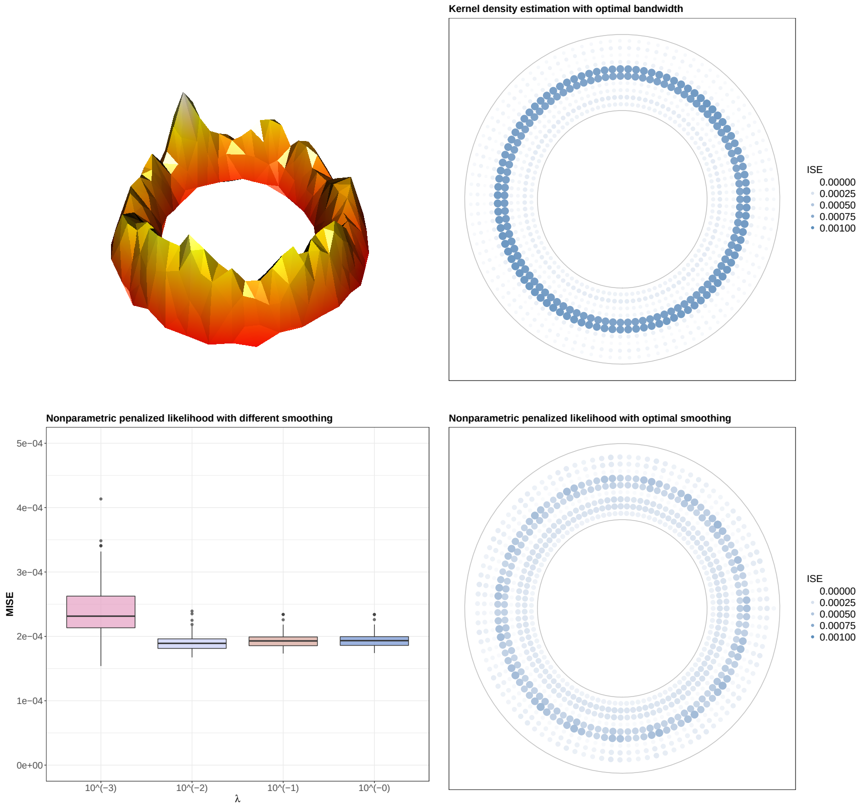

Fig. 1 On the left, an example of estimated density (top) and the distrubution of the MISE of 1000 simulation for different values of the smoothing parameters (bottom). On the right, the MSE surface of 1000 simulation for the nonparametric likelihood (top) and the KDE estimator (bottom), respectively.

4 Model extensions and conclusions

The proposed model performs well with respect to the state of the art of density estimators, while reducing the number of parameters to be selected. The estimator is also well defined on every bounded planar domain. The model can be generalized to non-euclidean setting, e.g. manifolds [5], and a time dependency can be included. These two features are extremely important in applications such as the study of brain activity, where the distribution of the signals over an highly convoluted domain, the cerebral cortex, changes over time. To the best of the authors knowledge, none of the existing methods is appropriate for this type of problems. Clustering procedures and two-samples testing based on the proposed estimator are also presented. Future works will consider convergence of the estimators, consistency in the multivariate case and time-dependent generalizations.

Rethinking the Kolmogorov-Smirnov Test of Goodness of Fit in a Compositional Way

Il test di bontá di adattamento di Kolmogorov-Smirnov ripensato in chiave composizionale

G.S. Monti, G. Mateu-Figueras, M. I. Ortego, V. Pawlowsky-Glahn and J. J. Egozcue

Abstract The Kolmogorov Smirnov test (KS) is a well known test used to asses how a set of observations is significantly different from the probability model specified under the null hypothesis. The KS test statistic quantifies the distance between the empirical distribution function and the hypothetical one. The modification introduced in Monti et al. (2017) consists of computing the mentioned distances as Aitchison distances. In this contribution, we suggest a further modification of the latter test and investigate, by simulation, the asymptotic distribution of the proposed test statistic, checking the appropriateness of a Generalized Extreme Value (GEV) Distribution. The properties of the asymptotic distribution are studied via Monte Carlo simulations.

Abstract *Il test di Kolmogorov Smirnov (KS) é tra i piú noti test di bontá di adattamento di un modello ai dati. Il test KS é una funzione della distanza tra la distribuzione empirica dei dati e quella ipotizzata sotto l'ipotesi nulla. La modifica del test proposta in Monti et al. (2017) consiste nell'impiego della distanza di Aitchison come misura di tale scostamento. In questo contributo proponiamo una leggera modifica di quest'ultima statistica test, per la quale, attraverso simulazioni Monte Carlo, studieremo la distribuzione asintotica valutando l'accuratezza di una distribuzione generalizzata per valori estremi (GEV).*

1 Modified Kolmogorov-Smirnov Test

Consider a random sample, denoted $\mathbf{x} = (x_1, \ldots, x_i, \ldots, x_n)$, coming from a continuous variable X. Let the hypothesized CDF be $F(x|\theta)$, where θ is the vector of parameters of F. We formulate the hypothesis $H_0 : \; X \sim F(\cdot|\theta)$, against the alternative that the random variable does not follow the claimed distribution.

The Kolmogorov-Smirnov (KS) test (Kolmogorov, 1933) consists of rejecting H_0 when the statistic

$$D_{KS} = \sup_{x \in \mathbb{R}} |F_n(x) - F(x)|\,,$$

exceeds a critical value — which depends on the sample size n and on the significance level α — where, for all x, $F_n(x) = \frac{1}{n}\{\text{the number of } X_i\text{'s which are} \leq x\}$ is the empirical distribution function (EDF) of the sample. D_{KS} can be computed calculating first

$$D_{KS}^{+} = \max_{i=1,\ldots,n} \left\{ \frac{i}{n} - F(X_{(i)}) \right\} \quad \text{and} \quad D_{KS}^{-} = \max_{i=1,\ldots,n} \left\{ F(X_{(i)}) - \frac{(i-1)}{n} \right\}, \qquad (1)$$

where $X_{(i)}$ is the ith order statistic; then the KS test statistic is $D_{KS} = \max\left\{D_{KS}^{+}, D_{KS}^{-}\right\}$. The distribution of this statistic is known, even for finite samples (Darling, 1957), and tables are available.

Here we consider a slight variation of the modified KS test statistic, denoted D_a, which has been defined and discussed previously (Monti et al., 2017). D_a consists in replacing the absolute difference between the sample and the hypothetical CDF, with the Aitchison distance (Aitchison, 1983) between two part compositions

$$\begin{aligned} \mathbf{Z}_\ell(i) &= \left(\frac{i}{n+1}, 1 - \frac{i}{n+1}\right) = \left(\frac{i}{n+1}, \frac{n+1-i}{n+1}\right), \\ \mathbf{Z}_u(i) &= \left(\frac{i-1}{n+1}, 1 - \frac{i-1}{n+1}\right) = \left(\frac{i-1}{n+1}, \frac{n+2-i}{n+1}\right), \\ \mathbf{Z}_0(i) &= \left(F(x_{(i)}), 1 - F(x_{(i)})\right), \end{aligned}$$

that is $D_a = \max\left\{D_a^{+}, D_a^{-}\right\}$, where

$$D_a^{+} = \max_{i=1,\ldots,n} \left\{ \mathrm{d}_a\Big(\mathbf{Z}_\ell(i), \mathbf{Z}_0(i))\Big) \right\}, \quad D_a^{-} = \max_{i=1,\ldots,n} \left\{ \mathrm{d}_a\Big(\mathbf{Z}_0(i), \mathbf{Z}_u(i)\Big) \right\}. \qquad (2)$$

Whereas in the previous version we considered the ratios $\frac{i}{n}$ in formula (2), in this version we adopt the median rank or the Weibull plotting position which are slightly more accurate than mean ranks.

D_a is motivated by the fact that probabilities, like for instance $i/(n+1)$ and $F(x_{(i)})$ as well as $(i/(n+1), 1 - i/(n+1))$ and $(F(x_{(i)}), 1 - F(x_{(i)}))$, can be considered as two part compositions, and then the Aitchison distance (Aitchison, 1983; Aitchison et al., 2001) can be adopted as a natural similarity measure. We recall that for 2-part compositions, $\mathbf{p}_1 = (p_1, 1 - p_1)$ and $\mathbf{p}_2 = (p_2, 1 - p_2)$, the Aitchison square distance between them is

$$\mathrm{d}_a^2(\mathbf{p}_1,\mathbf{p}_2) = \left(\frac{1}{\sqrt{2}} \ln \frac{p_1}{1-p_1} - \frac{1}{\sqrt{2}} \ln \frac{p_2}{1-p_2} \right)^2 .$$

It has been shown that D_a, as a test statistic, is invariant under a reversion of the orientation of the axis of the data (Monti et al., 2017).

Supported by a large number of Monte Carlo simulations, in Section 2 it will be shown that D_a follows reasonably well a Generalized Extreme Value Distribution (GEVD) for maxima and its location and scale parameters depend approximately on the sample size.

Recall that a random variable Z has a GEVD if its probability function can be written as

$$F_Z(z|\mu,\sigma,\xi) = \exp\left[-\left(1+\xi\left(\frac{z-\mu}{\sigma}\right)\right)^{-1/\xi} \right] , \; 1+\frac{\xi}{\sigma}(z-\mu) > 0 \, , \qquad (3)$$

where $\mu \in \mathbb{R}$ is a location parameter, $\sigma > 0$ is a scale parameter, and $\xi \in \mathbb{R}$ is a shape parameter. The values of the shape parameter ξ define the three families of asymptotic distribution: type II for $\xi > 0$, type III for $\xi < 0$ and Gumbel in the limiting case $\xi = 0$ in this parameterization (Fisher and Tippett, 1928; Embrechts et al., 1997).

2 Simulation results

In order to assess the accuracy of the GEV model to the D_a statistic defined in (2), we have conducted an intensive Monte Carlo (MC) simulation.

For each reference model – Normal, Uniform, Gamma, Beta, Exponential and lognormal with random parameters, i.e. we consider only the all-parameters-known case – and for each sample size – 1,000 different sample size values, ranging from 5 to 50,000 – we have simulated 1,000 random samples. For each simulated sample we have computed the D_a statistic in order to test the goodness of fit of the theoretical distribution. All the computations were carried out using the R statistical software program (R Core Team, 2017).

For each reference model and for each fixed sample size we have estimated the parameters of the Gumbel distribution, a subfamily of the GEV for $\xi = 0$, and of the GEV model for the $1,000$ D_a values by maximum likelihood method.

Two linear regression models and three linear regression models of the 1,000 MC estimates of the Gumbel, μ (location) and σ (scale), and GEV parameters, μ (location), σ (scale) and ξ (shape), were estimated as a function of the log-size of the sample. The regression outputs are summarized in Table 1, which reports estimates, standards errors and p-values.

Table 1 Regression output for the different linear regression models.

Likelihood ratio tests have been used to compare the two nested models for all simulation settings, and the proportions of simulated p-values less than 0.05 are reported in Table 2.

Looking at the simulations results we can deduce that the D_a statistic follows a Gumbel distribution, whose location parameter μ is related to the logarithm of the

Reference Model	#p-values < 0.05/1000
Normal	0.046
Uniform	0.048
Gamma	0.049
Beta	0.052
Exp	0.067
lognormal	0.048

Table 2 Proportions of simulated p-values less than 0.05 for comparisons of Gumbel and GEV models via asymptotic likelihood ratio tests for each reference distribution.

sample size by a linear relationship. Furthermore, the estimated parameter values are stable with rather small variations among models.

To complete the work, a further Monte Carlo investigation was made on the size (type I error) and on the power of the test. 2,000 samples of fixed size $n = 10, 50, 100, 200, 500, 1000, 1500, 2000, 5000, 10000$, were drawn from each of several distributions. Figure 1 reports six different plots. In the first column the probability of rejecting the null hypothesis using the D_a statistic considering three underlying distributions are reported. The second column reports the probability of rejecting hypothesis $H_0 : X \sim N(1,4)$ against $H_1 : X \sim T(2)$ using the D_a statistic (case (a)); $H_0 : X \sim Ga(2,3)$ against $H_1 : X \sim Exp(2)$ (case (b)) and $H_0 : X \sim Unif(0,1)$ against $H_1 : X \sim Exp(2)$ (case (c)).

Stochastic Dominance for Generalized Parametric Families

Dominanza Stocastica per Famiglie Parametriche Generalizzate

Tommaso Lando and Lucio Bertoli-Barsotti

Abstract The T-X family is a recent method for generating distributions by composing probability distributions and quantile functions. Such an approach makes it possible to obtain a large number of flexible families of parametric distributions, new or already existing, most of which are typically used to model phenomena in different areas, such as economics and finance. We present a general method to derive sufficient conditions for the second-order stochastic dominance, within T-X families of distributions.

Abstract *La famiglia T-X permette di generare distribuzioni di probabilità tramite la composizione di funzioni di ripartizione e funzioni quantile. Tale approccio permette di ottenere un gran numero di famiglie parametriche molto flessibili, nuove o già esistenti, gran parte delle quali sono utilizzate per descrivere fenomeni di tipo economico, finanziario, e non solo. Si presenta un metodo generale che permette di ricavare condizioni sufficienti per la dominanza del secondo ordine all'interno di famiglie T-X di distribuzioni.*

Key words: stochastic dominance, T-X family, generalized distributions

1. Introduction

[1] Tommaso Lando, Università degli studi di Bergamo; email: tommaso.lando@unibg.it

Lucio Bertoli-Barsotti, Università degli studi di Bergamo; email: lucio.bertoli-barsotti@unibg.it

Generalized parametric distributions have a wide range of application in several different scientific fields, due to the flexibility offered by a quite high number of parameters. Ranking generalized distribution with respect to a dominance relation represents a major issue in different areas, such as economics and finance (see e.g. Wilfling 1996, Kleiber and Kotz, 2003). On the other hand, it is generally difficult to rank generalized models with stochastic dominance rules, because their functional forms are generally not easily tractable.

In this framework, the so-called T-X family, recently introduced by Alzatreeh et al. (2013), provides an interesting method for generating distributions by composing a "baseline" distribution with a quantile function and finally a "transformer" distribution (see Aljarrah et al. 2014). This approach can be used to generate new or already existing families of distributions. It can be shown (Lando and Bertoli-Barsotti) that, by studying the composition of the T-X family, it is possible to derive sufficient conditions for the first order stochastic dominance (FSD) and the second order stochastic dominance (SSD). In particular, under some circumstances, a pair of T-X models still preserve the SSD order if the corresponding baseline and transformer distributions are ranked by FSD and SSD, respectively.

2. Preliminaries

In this paper, we refer only to continuous random variables (RVs). We denote with CDF the cumulative distribution function and with PDF the probability density function. Therefore, a RV U has CDF F_U and PDF f_U. We recall the basic definitions of the first order stochastic dominance (FSD) and the SSD.

Definition 1. We say that U_1 FSD dominates U_2 and write $U_1 \geq_1 U_2$ iff

$$F_{U_1}(u) \leq F_{U_2}(u), \forall u \in \mathbb{R}$$

Definition 2. We say that U_1 SSD dominates U_2 and write $U_1 \geq_2 U_2$ iff

$$\int_{-\infty}^{u} F_{U_1}(t)dt \leq \int_{-\infty}^{u} F_{U_2}(t)dt, \forall u \in \mathbb{R}$$

It is clear that FSD holds iff CDFs do not cross. Moreover, SSD can be related to the number of crossings between CDFs or PDFs. In particular, when the integral conditions of Def. 2 is difficult to verify for some parametric distributions, we may use an alternative method for deriving sufficient conditions for SSD, which requires CDFs to cross (at most) once (see Hanoch and Lèvi, 1969). Moreover, when it is not possible to verify the crossing condition on CDFs (e.g. when a closed form expression for the CDF is not available), we can rely on some closely related results, which involve densities. In particular, it is sufficient to prove that PDFs cross at most twice (Shaked 1982; see also Ramos et al. 2000, for some related conditions for non-negative RVs). Let us denote with $S^{-}(h)$ the number of sign changes of a function h. We summarize some important results in the theorem below.

Theorem 1.

Let Z_1 and Z_2 have finite means.

1) If $S^{-}(F_{U_1} - F_{U_2}) = 1$ and the sign sequence is $-,+$, then $U_1 \geq_2 U_2$ iff $E(U_1) \geq E(U_2)$.
2) Let $S^{-}(f_{U_1} - f_{U_2}) = 2$ with sign sequence $-,+,-$ Then, $U_1 \geq_2 U_2$ iff $E(U_1) \geq E(U_2)$.
3) Let U_1, U_2 be non-negative RVs and let $f_{U_1}(z)/f_{U_2}(z)$ be unimodal, where the mode is a supremum. Then, $E(U_1) \geq E(U_2)$ implies $U_1 \geq_2 U_2$.

The T-X{Y} method, originally introduced by Alzaatreh et al. (2013) and then studied by also Aljarrah et al. (2014), is based on the composition of the CDFs of two RVs, X and T, with the quantile function (QF) of a third RV Y. Given three RVs X, Y and T, where Y and T must have the same support, a new RV Z is defined by means of its CDF

$$F_Z(z) = F_T{}^{\circ}Q_Y{}^{\circ}F_X(z) = \int_{-\infty}^{Q_Y(F_X(z))} dF_T(t), \tag{1}$$

where Q_Y is the QF of Y. The corresponding PDF is

$$f_Z(z) = \left\{\frac{d}{dz} Q_Y{}^{\circ}F_X(z)\right\} f_T\{Q_Y{}^{\circ}F_X(z)\} = \frac{f_X(z)}{f_Y\{Q_Y{}^{\circ}F_X(z)\}} f_T\{Q_Y{}^{\circ}F_X(z)\}, \tag{2}$$

where f_X, f_Y, f_T are the PDFs of X, Y, T, respectively (Aljarrah et al. 2014). In this formula, F_T plays the role of the generator distribution (transformer) and F_X represents a baseline distribution (transformed).

Many continuous RVs have closed-form expressions for the QF, than can be used as the RV Y in (1), to generate T-X{Y} families. For instance, the original paper of Alzaatreh et al. (2013) focuses on the T-X{exponential} family, which is obtained by taking Q_Y to be the QF of an exponential RV with scale parameter equal to 1, i.e.:

$$Q_Y(p) = -\ln(1-p). \tag{3}$$

The T-X{Y} family makes it possible to generate a large number of new families of distributions, as well as many existing parametric models of noticeable practical relevance because of their several applications, such as: the generalized beta of the first and the second kind, and the generalized gamma distributions (McDonald 1984).

3. Sufficient conditions for SSD

Because many existing parametric distributions belong to the T-X family, we are concerned with finding the sufficient conditions for ranking distributions of such family with FSD and SSD (in particular). It can be shown (Lando ans Bertoli-Barsotti) T-X families obtained by composition of CDFs and QFs ranked by FSD or SSD preserve some kind of order.

In this study, we are interested in studying dominance relations among pairs of distributions within the same T-X family. Put otherwise, we compare pairs of distributions with CDF given by (1), but with different parameters. In particular, we assume that X and T, taken individually, are parametric families of distributions, say,

$$F_X(x) = F_X(x, \boldsymbol{\pi}), F_T(t) = F_T(t, \boldsymbol{\lambda}), \tag{3}$$

Thus, the new distribution defined by (1) depends on the parameters of F_X and F_T:

$$F_Z(z) = F_Z(z, \boldsymbol{\pi}, \boldsymbol{\lambda}). \tag{4}$$

We aim at comparing the RVs Z_1 and Z_2, where, for $i = 1,2$:

$$F_{Z_i}(z) = F_Z(z, \boldsymbol{\pi}_i, \boldsymbol{\lambda}_i) = F_{T_i}{}^\circ Q_{\mathrm{Y}}{}^\circ F_{X_i}(z), \tag{5}$$

with $F_{X_i}(x) = F_X(x, \boldsymbol{\pi}_i)$ and $F_{T_i}(t) = F_{T_i}(t, \boldsymbol{\lambda}_i)$.

Theorem 3. Let $F_{Z_i}(z) = F_{T_i}{}^\circ Q_Y{}^\circ F_{X_i}(z)$, for $i = 1,2$. Let Z_1 and Z_2 have finite means, and let $Q_Y{}^\circ F_{X_2}$ be convex . If $X_1 \geq_1 X_2$, and $T_1 \geq_2 T_2$ with $S^-(F_{T_1} - F_{T_2}) \leq 1$, then $Z_1 \geq_2 Z_2$.

Proof. This theorem has been proved by Lando and Bertoli-Barsotti (submitted manuscript).

It can be shown that there is a wide class of distributions that can be ranked using the sufficient condition of Theorem 2, although, in some cases, the proposed method is not applicable, because, for some T-X families, $Q_Y{}^\circ F_{X_2}$ is not convex.

Theorem 2 establishes that a strong dominance (FSD) between baseline distributions and a weak dominance (SSD) between generators may be sufficient for the weak dominance among the T-X family. Now, it is also worth noting that, for $Q_{\mathrm{Y}}{}^\circ F_{X_2}$ convex, $X_1 \geq_2 X_2$, with single-crossing CDFs, and $T_1 \geq_1 T_2$ do not imply $Z_1 \geq_2 Z_2$. This can be shown with a counter-example. A fortiori, $X_1 \geq_2 X_2$ and $T_1 \geq_2 T_2$ do not imply $Z_1 \geq_2 Z_2$ as well. Therefore, if we wish to rank Z_1, Z_2 by SSD with this method, it is generally required that the baseline distributions are ranked by FSD.

4. Conclusions

This study is aimed at deriving sufficient conditions for stochastic dominance within the T-X family of distributions. This approach can be extended to other types of dominance. In particular, we shall analyse the interesting case of the Lorenz order, which is especially relevant in the field of economics.

Statistical Models for Ordinal Data

A comparative study of benchmarking procedures for interrater and intrarater agreement studies

Valutazione comparativa di procedure di benchmarking per l'analisi dell'accordo inter e intra valutatore

Amalia Vanacore[1] and Maria Sole Pellegrino[2]

Abstract Decision making processes typically rely on subjective evaluations provided by human raters. In the absence of a gold standard against which check evaluation trueness, the magnitude of inter/intra-rater agreement coefficients is commonly interpreted as a measure of the rater's evaluative performance. In this study some benchmarking procedures for characterizing the extent of agreement are discussed and compared via a Monte Carlo simulation.

Abstract *In numerosi contesti, le decisioni strategiche sono affidate a valutazioni soggettive, fornite da valutatori umani, per le quali non esiste un gold standard che permetta di valutarne la veridicita'. L'affidabilita' del valutatore viene quindi spesso misurata in termini di precisione attraverso coefficienti di accordo inter- e intra-valutatore, che risultanto utili se interpretabili. Nel lavoro proponiamo uno studio Monte Carlo per analizzare e confrontare le prestazioni di alcune procedure di benchmarking.*

Key words: rater agreement, kappa-type coefficient, benchmarking procedures, Monte Carlo simulation

1 Introduction

Agreement coefficients are widely adopted for assessing the precision of subjective evaluations provided by human raters to support strategic and operational decisions in several fields (e.g. manufacturing and service industries, food, healthcare and risk management). Specifically, the agreement between the evaluations provided on the same sample of items by two or more raters (i.e. inter-rater agreement) or by

[2] Dept. of Industrial Engineering, University of Naples "Federico II", p.le Tecchio 80, 80125 Naples; e-mail: mariasole.pellegrino@unina.it

the same rater in two or more occasions (i.e. intra-rater agreement) is commonly measured using a kappa-type agreement coefficient.

In order to qualify the extent of agreement as good or poor the computed coefficient is compared against an arbitrary benchmark scale. However, the magnitude of an agreement coefficient may strongly depend on some experimental factors such as number of rated items, rating scale dimension, trait prevalence and marginal probabilities [13, 9]. Thus, interpretation based on the straightforward benchmarking should be treated with caution especially for comparison across studies when experimental conditions are not the same.

A proper characterization of the extent of rater agreement should rely upon a benchmarking procedure that allows to identify a suitable neighborhood of the true value of rater agreement by taking into account sampling uncertainty. The most simple and intuitive way to accomplish this task is by building a confidence interval of the agreement coefficient and comparing its lower bound against an adopted benchmark scale. A different approach is the one recently proposed by Gwet [9] which, under the assumption of asymptotically normal distribution, evaluates the likelihood that the estimated agreement coefficient belongs to each benchmark category.

The above benchmarking approaches will be in the following discussed and their performances will be evaluated and compared in terms of weighted misclassification rate via a Monte Carlo simulation study.

The remainder of the paper is organized as follows: in Section 2 two well-known paradox-resistant kappa-type agreement coefficients are discussed; the commonly adopted benchmark scales and some characterization procedures based on parametric and non-parametric approaches to benchmarking are presented and discussed in Section 3; in Section 4 the simulation design is described and the main simulation results are fully discussed; finally, conclusions are summarized in Section 5.

2 Paradox-resistant agreement coefficients

The kappa-type agreement coefficients are rescaled measures of the observed agreement corrected with the probability of agreement expected by chance. The most common kappa-type coefficient is that proposed by Cohen [5]. Despite its popularity, it is affected by two paradoxes [4]: the degree to which raters disagree (bias problem) and the marginal distribution of the evaluations independently provided by each rater (prevalence problem). A solution to face the above paradoxes is to adopt the uniform distribution for chance measurements, which given a certain rating scale can be defended as representing the maximally non-informative measurement system [6].

Specifically, let n be the number of items rated by two raters on an ordinal k-point rating scale (with $k > 2$), n_{ij} the number of items classified into i^{th} category by the first rater and into j^{th} category by the second rater and w_{ij} the corresponding symmetrical weight, introduced in order to consider that, on an ordinal rating scale, disagreement on two distant categories is more serious than disagreement on neighboring categories. The weighted version of the uniform kappa, often referred to as Brennan-Prediger coefficient [9], is formulated as:

$$\widehat{BP}_w = \frac{p_{a_w} - p_{a|c}^{BP_w}}{1 - p_{a|c}^{BP_w}} \tag{1}$$

where p_{a_w}, the weighted observed proportion of agreement, and $p_{a|c}^{BP_w}$, the weighted proportion of agreement expected under the assumption of uniform chance measurements, are respectively given by:

$$p_{a_w} = \sum_{i=1}^{k}\sum_{j=1}^{k} w_{ij}\frac{n_{ij}}{n}; \quad p_{a|c}^{BP_w} = \frac{T_w}{k^2} \tag{2}$$

being T_w the sum over all weight values w_{ij}.

Another well-known paradox-resistant agreement coefficient alternative to Cohen's Kappa is the AC_1 coefficient proposed by Gwet [8], whose weighted version AC_2 [9] is formulated as:

$$\widehat{AC}_2 = \frac{p_{a_w} - p_{a|c}^{AC_2}}{1 - p_{a|c}^{AC_2}} \tag{3}$$

where the probability of chance agreement $p_{a|c}^{AC_2}$ is given by:

$$p_{a|c}^{AC_2} = \frac{T_w}{k(k-1)} \cdot \sum_{i=1}^{k} \pi_i(1-\pi_i) \tag{4}$$

Specifically, $p_{a|c}^{AC_2}$ is defined as the probability of the simultaneous occurrence of two events, one rater provides random rating (R) and the two raters agree (G):

$$p_{a|c}^{AC_2} = P(G \cap R) = P(G|R) \cdot P(R) \tag{5}$$

where $P(G|R) = T_w/k^2$ and $P(R)$ is approximated with a normalized measure of randomness defined by the ratio of the observed variance to the variance expected under the assumption of totally random ratings:

$$P(R) = \frac{\sum_{i=1}^{k} p_i(1-p_i)}{(k-1)/k} \tag{6}$$

with p_i denoting the propensity that a rater assigns score i to an item which is estimated by $p_i = (n_{i\cdot} + n_{\cdot i})/2n$ being $n_{i\cdot}$ (resp. $n_{\cdot i}$) the total number of items classified into i^{th} category by the first (resp. second) rater.

3 Benchmarking procedures for characterizing the extent of agreement

After computing an agreement coefficient, a common question is ”how good is the extent of agreement?” As a general rule kappa values greater than 0.6 are generally considered acceptable [10]. In order to provide an aid to qualify the magnitude of kappa-type coefficients, a number of benchmark scales have been proposed mainly in social and medical sciences over the years. The scale proposed by Landis and Koch [11] is by far the most widely adopted benchmark scale; it consists of six ranges of values corresponding to as many categories of agreement: poor, slight, fair, moderate, substantial and almost perfect agreement for coefficient values ranging between -1 and 0, 0 and 0.2, 0.21 and 0.4, 0.41 and 0.6, 0.61 and 0.8 and 0.81 and 1.0, respectively. This scale was then simplified by Fleiss [7] and Altman [1], with three and five ranges, respectively, and by Shrout [12] who collapsed the first three ranges of values into two agreement categories.

Despite its popularity, the straightforward benchmarking can be misleading because it does not associate the interpretation of the extent of agreement with a degree of uncertainty and it does not allow to compare the extent of agreement across different studies, unless they are carried out under the same experimental conditions. In order to have a fair characterization of the extent of rater agreement, it is necessary to associate a degree of uncertainty to the interpretation of the coefficient.

Under asymptotic conditions, the magnitude of the kappa type coefficient can be related to the notion of extent of agreement by benchmarking the lower bound of its asymptotic $(1-2\alpha)\%$ confidence interval (CI). Recently, Gwet [9] proposed a parametric benchmarking procedure based on Interval Membership Probability (IMP) that is the probability that the coefficient falls into each benchmark category.

Under non-asymptotic conditions, two non-parametric CIs based on bootstrap resampling are the percentile (p) CI and, for severely skewed distribution, the Bias-Corrected and Accelerated (BCa) CI [2]. Being free from distributional assumptions, the benchmarking procedure based on bootstrap CIs fits also the cases of moderate and small sample sizes.

4 Simulation study

The above-discussed benchmarking procedures have been applied to characterize the extent of both BP_w and AC_2 across 72 different settings. Their statistical properties have been investigated via a Monte Carlo simulation study developed considering two raters classifying $n = 10, 30, 50, 100$ items into one of $k = 2, 5, 7$ possible ordinal rating categories. The data have been simulated by sampling $r = 2000$ Monte Carlo data sets from a multinomial distribution with parameters n and $\mathbf{p} = (\pi_{11}, \ldots, \pi_{ij}, \ldots, \pi_{ik})$; the π_{ij} values have been set so as to obtain six true population values of agreement (viz. 0.4, 0.5, 0.6, 0.7, 0.8, 0.9), assuming a linear weighting scheme [3].

The performances of the benchmarking procedures under comparison have been evaluated in terms of weighted misclassification rate (hereafter, $\mathbf{M}_{\mathrm{w}}$). Specifically, let $\{X_h; r\}$ be a Monte Carlo data set containing r benchmarks X_h obtained for a population value taken as reference for a specific agreement category ω. $\mathbf{M}_{\mathrm{w}}$ is evaluated as the weighted proportion of misclassified X_h:

$$\mathbf{M}_{\mathrm{w}} = \frac{1}{r} \sum_{\omega=1,\Omega} w_{\omega\omega'} \cdot I\left[X_{h|\omega} \in \omega'\right]; \quad \omega' \neq \omega \tag{7}$$

where $I[\cdot]$ is an indicator taking value 1 if the argument is true and 0 otherwise and $w_{\omega\omega'}$ is a linear misclassification weight adopted to account that on an ordinal benchmarking scale some misclassifications are more serious than others. The best and worst values of $\mathbf{M}_{\mathrm{w}}$ obtained across the analysed benchmarking procedures for BP_w and AC_2 are reported in Table 1 for each combination of n and k values. Specifically, while the benchmarking procedure based on bootstrap CIs are suitable for all the analysed sample sizes, the parametric procedures work only under asymptotic conditions being thus applied only to large samples of $n \geq 50$; therefore the parametric and non-parametric procedures are compared each other only for $n \geq 50$.

Table 1 Best and worst $\mathbf{M}_{\mathrm{w}}$ across the four benchmarking procedures (Standard: Parametric CI; $\underline{\text{Underlined}}$: IMP; *Italics*: p CI; **Bold**: BCa CI) for BP_w and AC_2 for different n and k values

(a) Best $\mathbf{M}_{\mathrm{w}}$ for BP_w

	$n=10$	$n=30$	$n=50$	$n=100$
$k=2$	*0.102*	**0.096**	*0.068*	$\underline{0.049}$
$k=5$	**0.123**	*0.081*	0.056	0.034
$k=7$	**0.087**	*0.066*	0.048	0.027

(b) Worst $\mathbf{M}_{\mathrm{w}}$ for BP_w

	$n=10$	$n=30$	$n=50$	$n=100$
$k=2$	**0.160**	*0.118*	$\underline{0.080}$	*0.058*
$k=5$	*0.131*	**0.088**	$\underline{0.072}$	$\underline{0.051}$
$k=7$	*0.089*	0.072	$\underline{0.060}$	$\underline{0.044}$

(c) Best $\mathbf{M}_{\mathrm{w}}$ for AC_2

	$n=10$	$n=30$	$n=50$	$n=100$
$k=2$	*0.159*	*0.098*	*0.072*	0.046
$k=5$	*0.111*	*0.073*	0.051	0.030
$k=7$	*0.085*	**0.031**	0.044	*0.026*

(d) Worst $\mathbf{M}_{\mathrm{w}}$ for AC_2

	$n=10$	$n=30$	$n=50$	$n=100$
$k=2$	**0.193**	**0.099**	**0.084**	**0.055**
$k=5$	**0.130**	**0.092**	**0.066**	$\underline{0.046}$
$k=7$	**0.092**	*0.058*	**0.056**	$\underline{0.042}$

For small and moderate samples (i.e. $n \leq 30$), $\mathbf{M}_{\mathrm{w}}$ slightly differs across non-parametric benchmarking procedures and agreement coefficients: specifically, the highest difference in $\mathbf{M}_{\mathrm{w}}$ is 9%, observed for $n = 10$ and $k = 2$. Moreover, for increasing sample sizes, $\mathbf{M}_{\mathrm{w}}$ becomes quite indistinguishable across procedures and coefficients with a difference always no more than 2%. It is worthwhile to pinpoint that the differences in $\mathbf{M}_{\mathrm{w}}$ across non-parametric benchmarking procedures and agreement coefficients get smaller as n increases because of the decreasing skewness in the distributions of the coefficients: if the distribution is symmetric, the BCa and *p* CIs agree.

5 Conclusions

The results of the Monte Carlo simulation suggest that for small samples the non-parametric benchmarking procedures based on bootstrap resampling have satisfactory and comparable properties in terms of weighted misclassification rate. Moreover, with $n \geq 30$ the performances of the procedures based on bootstrap CIs differ from each other at most for 2%, therefore benchmarking the lower bound of the percentile bootstrap confidence interval could be suggested — because of its less computational burden — for characterizing the extent of rater agreement, both for BP_w and AC_2. For large samples, the performances are indistinguishable across all benchmarking procedures, thus benchmarking the lower bound of the parametric confidence interval would be preferred being the easiest method to implement.

Measuring the multiple facets of tolerance using survey data.

Misurare le molteplici attitudini alla tolleranza usando dati di survey.

Caterina Liberati and Riccarda Longaretti and Alessandra Michelangeli

Abstract In recent studies, there has been a growing interest toward tolerance and its implications in social and economic systems. So far, the openness of people to homosexuals or to foreign-born people has been considered the best indicator of tolerant attitudes. In this paper, we consider tolerance as a multi-faced phenomenon involving several different social domains. The aim is to provide some recommendations on how to develop a multidimensional index for tolerance in the case of survey's items measured by Likert-scale. Our discussion relies on a case study about a student survey carried out at Milan-Bicocca University

Abstract *In studi recenti, c'è stato un crescente interesse verso la tolleranza e le sue implicazioni nei sistemi sociali ed economici. Finora, l'apertura delle persone agli omosessuali o alle persone nate all'estero è stata considerata il miglior indicatore di atteggiamenti tolleranti. In questo lavoro, consideriamo la tolleranza come un fenomeno dalle molteplici sfaccettature che coinvolge diversi domini sociali. Presentiamo alcune raccomandazioni da tenere in considerazione quando si sviluppa un indice composito per valutare il livello di tolleranza in caso di items di un questionario misurati con una scala Likert. La nostra discussione si basa su un caso studio su un'indagine studentesca svolta all'Università Milano-Bicocca.*

Key words: Tolerance Measure; Multidimensional Index; Ordinal data; Survey

1 Introduction

Most studies about tolerance focus on individuals' attitudes towards homosexual people, ethnic minorities and migrants. In these works, the analysis is usually based on surveys with questions such as "*Would you like to have homosexuals as your neighbors?*" or "*Would you like to have people of a different race as your neighbors?*"[1] They are simple yes/no questions, formally known as polar questions, that give a clear-cut understanding of people attitudes. The fraction of respondents giving a positive answer is the measure of tolerance (see, for example ref. [1]). References [3] and [4] argue that openness to homosexuals is the best available indicator of tolerant attitudes.

In this paper, we adopt a wider perspective and look at tolerance as a multi-faced phenomenon involving several different social domains, so that attitudes towards homosexuals and foreign-born people are only a partial aspect of this phenomenon. We provide some recommendations of statistical nature on how to develop a multidimensional index when ordinal data are used. This is the case of surveys with Likert scale type questions that, usually, uses statements such as "*Please rate the extent to which you agree/disagree with the following*" and the response scales use anchors such as 1 = Strongly Disagree, 2 = Disagree, 3 = Neutral, 4 = Agree, 5 = Strongly Agree, etc. One of the advantages of Likert scale survey questions is that they allow to measure attitudes and opinions with a greater degree of nuance than a simple yes/no question.

Our attempt assesses different domains of the social environment and at the same time raises considerations about how to merge all the aspects together. We rely our analysis on a survey administered to a sample of students at University of Milan-Bicocca. The multidimensional approach aggregates different dimensions of tolerance into an index. The aggregation procedure requires an explicit choice on construction of variables and weighting of dimensions. We discuss these aspects considering a student survey carried out at the University of Milan-Bicocca.

The paper is organized as follows: Section 2 describes the data and in Section 3 we make preliminary considerations about a synthetic measure of tolerance.

2 Data

To study tolerance, we use a survey addressed to university students on religiosity and inter-religious dialogue. The survey has been developed by the University of Milan-Bicocca, and it is part of a framework agreement signed by 30 Italian Universities and 25 Research Centers. The objective of the study is to investigate the relationship between "Gender and Religions" among university students. Its purpose is to survey the opinion of university students about different topics, such as

[1] Both questions are from the World Value Survey [6].

inter-religious dialogue, women/religion relationship, multicultural society, homosexuality. Questions, measured by 7-points Likert scale [2], are listed in Table 1.

Table 1 Questionnaire themes

Social Domain	**Item topic**
Inter-religious dialogue	Inter-religious dialogue mitigates conflicts in the Italian society Same freedom of religious practice for all religions in Italy Same freedom of religious practice for all religions in Italy
Women/religion relationship	Women priests into Catholic Church Women can pray together with Muslim men Women rabbis into Jewish religion
Death/religion relationship	Voluntary interruption of pregnancy Eutanasia is socially acceptable
Multicultural society	The marriage between people of different religions The marriage between people of different ethnic communities Italian society is enriched by foreign people
Homosexuality	All States should legally recognize same-sex marriage. All States should legally recognize the child adoption by same-sex couples.

Because of the sensitivity of topics surveyed and in order to preserve the privacy of respondents, the questionnaire has been administered via Pencil And Paper Interview (PAPI) without saving any identification details. The sample interviewed is composed of 3,386 bachelor and master students from different fields: humanistic studies, legal, political, economic and statistical sciences .

The gender distribution is very unbalanced showing a severe prevalence of females (73.10%) respect to males (25.90%). However, we observe the same proportion for the students' population at the university of Milano-Bicocca. Also nationality and residence show an unimodal frequency distribution, with a maximum in correspondence of labels "Italian" (81.13%) and "Milan metropolitan area" (41.04%), respectively.

3 Measuring Tolerance: considerations for a quantitative synthesis

As mentioned in the Introduction, the main challenge of this work is to point out some issues arising when tolerance is analyzed from a multidimensional perspective.

First, the metric of variables included in the aggregation procedure should be homogeneous. Combining data measured by different scales or mixed data types

[2] The answers ranged between 1 = Strongly Disagree to 7=Strongly Agree.

means transforming one or more variables, to allow for statistical or thematic analysis on all information available [2].

Second, the functional form used to aggregate items should take into account the type of relationship between items. For example, a linear additive form assumes that items are independent. It should be verified that they are actually independent and, if so, this would be a necessary and sufficient condition for a proper composite indicator [5]. On the other hand, the additive aggregation function permits the assessment of the marginal contribution of each variable separately, therefore it would be optimal if a measure of tolerance could be defined into an algebraic sum of alternative domains. If items are correlated, then a geometric functional form should be preferred the linear one.

Third, the aggregation procedure should take into account the variability in the distribution of each item. Items with a uniform distribution across individuals should have a lower weight than items characterized by a dominant rating-value. Indeed a uniform distribution implies a strong heterogeneity in the subjects' responses.

In conclusion, an ideal composite index should be able to deal with all the issues listed above or, in alternative, should be the result of a compromise between different requirements.

Modified profile likelihood in models for clustered data with missing values

Verosimiglianza profilo modificata in modelli per dati raggruppati con valori mancanti

Claudia Di Caterina and Nicola Sartori

Abstract Clustered data are frequently subject to missing values, especially those collected from longitudinal studies. The main focus of the analysts is usually not on the clustering variables, hence the group-specific parameters are treated as nuisance. If a fixed effects formulation is preferred and the total number of clusters is large relative to the single-group sizes, classical frequentist techniques are often misleading. We propose here to combine multiple imputation and the modified profile likelihood function to obtain accurate inferences on a parameter of interest under models with incidental parameters for incomplete grouped observations. Such solution is examined via simulation studies which shed light on the convenience for the imputation model to take into account the clustered structure of the data.

Abstract *Nei dati raggruppati si registrano abitualmente valori mancanti, soprattutto in quelli raccolti per studi longitudinali. L'attenzione degli analisti di solito non è rivolta alle variabili di raggruppamento, dunque i parametri specifici dei vari cluster sono considerati di disturbo. Se si preferisce adottare una formulazione ad effetti fissi ed il numero totale di gruppi è grande rispetto alle singole dimensioni di questi, le classiche tecniche frequentiste risultano spesso inadeguate. Qui proponiamo di combinare l'imputazione multipla e la verosimiglianza profilo modificata per ottenere un'inferenza accurata sul parametro d'interesse in modelli con parametri incidentali per osservazioni incomplete organizzate in cluster. Tale soluzione viene esaminata attraverso studi di simulazione che fanno luce sull'opportunità che il modello di imputazione tenga conto della struttura raggruppata dei dati.*

1 Introduction

Clustered, stratified or grouped data are either cross-sectional or longitudinal observations that can be arranged in groups. Missing values are ubiquitous in quantitative research analysis, particularly in clustered data resulting from clinical trials or panel surveys. Depending on the pattern and mechanism of missingness, a variety of techniques for handling inference in the presence of incomplete datasets can be used (see, e.g., Little and Rubin, 2002). When observations are organized in many groups of small to moderate size, statistical models which capture the unobserved heterogeneity across clusters via group-specific nuisance parameters are likely to suffer from the incidental parameters problem (Neyman and Scott, 1948). Such specifications are referred to as fixed effects models, in opposition to the random effects models which require to assume a distribution for the group features and their incorrelation with the covariates in the model.

Here we focus our attention on clustered observations characterized by both aspects, and propose a twofold strategy. On the one hand, tackling the incompleteness of the data by means of multiple imputation, and on the other, dealing with the incidental parameters assumed by the model through the modified profile likelihood function. More details on the two approaches can be found in Sections 2 and 3, respectively. Section 4 shows simulation results that help to investigate how the considered inferential tools should be combined in order to draw reliable conclusions on the parameter of interest.

2 Multiple imputation

The basic rationale behind multiple imputation (MI) is to exploit the distribution of the observed data in order to estimate a set of plausible values for the unobserved data. In particular, m multiply imputed datasets are created by substituting the missing observations in the original sample with draws from the posterior predictive distribution of the unobserved data conditional on the observed data. These completed datasets are then separately analyzed and the m results are pooled into overall estimates and standard errors using Rubin's rules (Rubin, 1987).

Various methods can be adopted to generating imputations (Little and Rubin, 2002, Section 10.2). Among those drawing from pragmatic conditional distributions when more variables are incomplete, multiple imputation by chained equations (MICE) (van Buuren and Oudshoorn, 1999) provides considerable flexibility in customizing imputation models for different data characteristics (Ji et al., 2018). For a thorough overview of the standard procedure and a helpful guidance for practice in case of data missing at random (MAR), we refer to White et al. (2011).

A well-known matter in MI inference is uncongeniality (Meng, 1994), which occurs when the imputer's model class and the ultimate analyst's model class are incompatible. Recently, Xie and Meng (2017) have pointed out many open problems connected with this topic. The general prescription is to include in the imputation model all variables that are related to the missing data, so that to make the MAR assumption more plausible. This should reduce the need to make special adjustments for mechanisms that are not MAR (van Buuren and Oudshoorn, 1999). With specific reference to models for clustered observations with incidental parameters, a typical question concerns whether and how accounting for the groups when imputing the missing values. White et al. (2011) suggest to disregard the clustering in this phase, if this is not of direct interest. Results in Andridge (2011) also highlight the inadequate inferential performance due to the inclusion of the fixed effects in the imputation model, contrary to what happens with random effects. On the opposite, Reiter et al. (2006) conclude that completely ignoring the sampling design during MI can be a risky practice. Further evidence is surely needed in this area.

3 Modified profile likelihood

In fixed effects models for clustered data where the number of groups is much larger than the single group sizes, the incidental parameters problem descends from the magnitude of the bias of the profile score function (McCullagh and Tibshirani, 1990). Correcting for the presence of the nuisance components, Barndorff-Nielsen (1980, 1983) proposed to rely on the modified profile likelihood (MPL) for making adequate inference on the parameter of interest. In fact, its superiority with respect to the ordinary profile likelihood (PL) within the two-index asymptotic setting can be proved for independent clustered sample units (Sartori, 2003).

For observations y_{it} subdivided in N groups of sizes T_i, suppose the model

$$Y_{it} \sim f(y_{it};x_{it},\psi,\lambda_i)\,, \qquad i=1,\dots,N, \quad t=1,\dots,T_i, \tag{1}$$

where x_{it} is a p-dimensional vector of covariates. The global parameter is $\theta = (\psi,\lambda)$, where $\psi \in \Psi \subseteq \mathrm{I\!R}^k$ denotes the component of interest and $\lambda = (\lambda_1,\dots,\lambda_N) \in \Lambda$ indicates the vector with incidental parameters. Note that, here and henceforth, to avoid clutter the transpose symbol acting on vectors is omitted. Moreover, we assume $T_i = T$ and $\dim(\lambda_i) = 1$ $(i=1,\dots,N)$ for the sake of notational simplicity. With independent groups, the log-likelihood function about θ can be expressed by

$$l(\theta) = \sum_{i=1}^{N} l^i(\theta) = \sum_{i=1}^{N} l^i(\psi,\lambda_i)\,,$$

with $l^i(\psi,\lambda_i) = \sum_{t=1}^{T} \log p(y_{it};x_{it},\psi,\lambda_i)$. Let us define the full maximum likelihood (ML) estimate for model (1) as $\hat\theta = (\hat\psi,\hat\lambda) = \arg\max_\theta l(\theta)$. Standard inference on the parameter of interest is typically based on the profile log-likelihood

$$l_P(\psi) = \sum_{i=1}^{N} l^i\big(\psi,\hat\lambda_{i\psi}\big) = \sum_{i=1}^{N} l_P^i(\psi)\,,$$

where $\hat{\lambda}_{i\psi}$ is the constrained ML estimate of λ_i for fixed ψ obtained, under usual regularity conditions, by equating to zero the score $l_{\lambda_i}(\theta) = \partial l^i(\psi,\lambda_i)/\partial\lambda_i$ and solving for λ_i $(i = 1,\dots,N)$. Given $\hat{\lambda}_\psi = (\hat{\lambda}_{1\psi},\dots,\hat{\lambda}_{N\psi})$, the full constrained ML estimate for fixed ψ is denoted by $\hat{\theta}_\psi = (\psi,\hat{\lambda}_\psi)$.

The general expression taken by the logarithmic version of the MPL is $l_M(\psi) = l_P(\psi) + M(\psi)$, and one computationally convenient formulation of $M(\psi)$ is owed to Severini (1998). Specifically, using the additive form $M(\psi) = \sum_{i=1}^N M_i(\psi)$, the ith summand in Severini's modification term equals

$$M_i(\psi) = \frac{1}{2}\log j_{\lambda_i\lambda_i}(\hat{\theta}_\psi) - \log I_{\lambda_i\lambda_i}(\hat{\theta};\hat{\theta}_\psi), \qquad i = 1,\dots,N.$$

In the above equation, we have $j_{\lambda_i\lambda_i}(\theta) = -\partial^2 l^i(\psi,\lambda_i)/(\partial\lambda_i\partial\lambda_i)$ and $I_{\lambda_i\lambda_i}(\hat{\theta};\hat{\theta}_\psi) = E_{\theta_0}\{l_{\lambda_i}(\theta_0)l_{\lambda_i}(\theta_1)\}\big|_{\theta_0=\hat{\theta},\theta_1=\hat{\theta}_\psi}$ indicating the scalar expected value calculated with regard to $\hat{\theta}$ of the product of partial scores evaluated at two different points in the parameter space.

4 Simulation studies

Monte Carlo experiments based on 1000 iterations can be run to study the effectiveness of the approach which incorporates MI and MPL inferences. The cluster size and number of groups considered are $T = 6$ and $N = 50,100,250$, respectively. For each couple (T,N), $p = 2$ covariates are randomly generated. The first, x_{1it}, is sampled from a Bernoulli(0.5) distribution. The second, x_{2it}, is drawn from the $N(0,1)$ random variable. We then simulate the binary clustered outcomes as independent realizations of $Y_{it} \sim Bern(\pi_{it})$ $(i = 1,\dots,N, t = 1,\dots,T)$. In particular $\pi_{it} = e^{\lambda_i+\beta x_{it}}/(1+e^{\lambda_i+\beta x_{it}})$, where $x_{it} = (x_{1it},x_{2it})$, $\beta = (\beta_1,\beta_2) = (1,1)$ and each λ_i is independently generated from the standard normal distribution. Here our interest is confined to datasets with completely observed response and MAR predictors, yet the same methodology could be applied in different contexts of incompleteness. Missing entries are thus created by deleting x_{1it} with probability ω_{1it} and x_{2it} with probability ω_{2it}. According to the dependence of the missingness on the stratification, two main scenarios may be distinguished. In case of missingness unrelated to the groups (setting I), we suppose $\omega_{1it} = e^{-2+y_{it}}/(1+e^{-2+y_{it}})$ and $\omega_{2it} = e^{0.5-y_{it}}/(1+e^{0.5-y_{it}})$. When instead the clustered structure plays a role in the probability of observing a covariate (setting II), we use $\omega_{1it} = e^{\lambda_i-2+0.2y_{it}}/(1+e^{\lambda_i-2+y_{it}})$ and $\omega_{2it} = e^{\lambda_i-y_{it}}/(1+e^{\lambda_i-y_{it}})$. Such values are chosen in order for the fraction of missing data in the datasets to be around 35%. The procedure starts by obtaining $m = 5$ complete samples through MICE, using a logistic regression for imputing x_{1it} and a Bayesian linear regression for x_{2it}, as implemented by the R package `mice` (van Buuren and Groothuis-Oudshoorn, 2010). In both imputation models, the dummy variables indicating the groups are either included or not. Inference on each completed dataset is then conducted using PL and MPL for the parame-

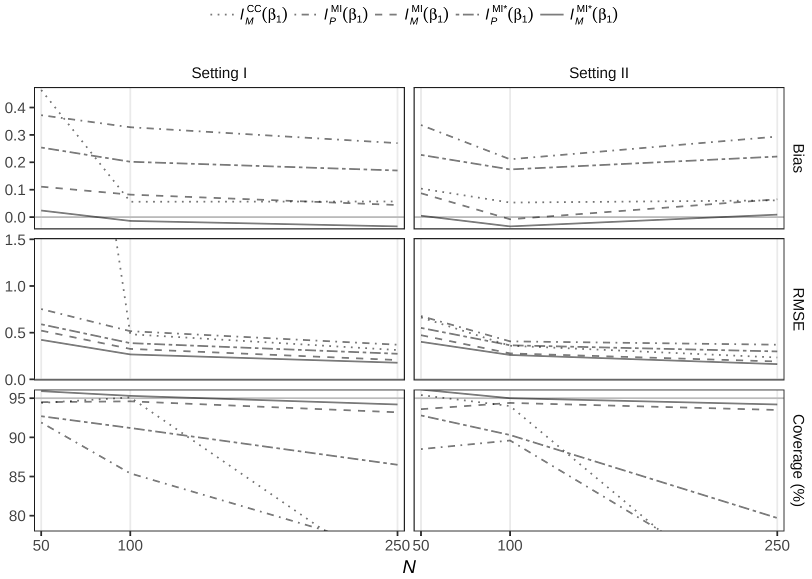

Fig. 1 Comparison between inferences on β_1 obtained via complete-case analysis $\left(l_M^{\text{CC}}\right)$ and multiple imputation, either taking the groups into consideration when imputing the missing values $\left(l_P^{\text{MI}}, l_M^{\text{MI}}\right)$ or not $\left(l_P^{\text{MI}^*}, l_M^{\text{MI}^*}\right)$. Results based on 1000 clustered datasets simulated with $T = 6$ observations per group and $N = 50, 100, 250$ number of groups.

ter of interest β in the logistic regression with outcomes y_{it}, using the R package `panelMPL` (Bellio and Sartori, 2015). Rubin's rules are finally applied to pool together estimates and variances derived by the two likelihood functions. A complete-case analysis, which disregards units with missing values, is also carried out via both methods. Due to space constraints, just partial results of the experiments referred to β_1 are shown in Figure 1. Therein, empirical bias and root mean squared error (RMSE) of the various estimators can be compared, along with coverage of 95% Wald confidence intervals. Note that the performance of the complete-case PL is not reported, as it was found to be poorer than any other method in all scenarios. The output indicates that the solution combining MI and MPL outperforms the complete-case analysis, in terms of point and interval estimation. In addition, it seems that to neglect the clustering while imputing the unobserved covariates is recommendable, whether the incompleteness depends on the specific group features or not. One plausible reason is the incidental parameters problem observed under the imputation model. An improved fit of the latter might be achieved, for instance, by adopting bias reduction (Firth, 1993). This can be the subject of future research, as well as developments of the present work that consider other values for T and different patterns and mechanisms of missingness in the data.

Worthiness Based Social Scaling

Giulio D'Epifanio

Abstract

The construction of a set of scales is delineated, for evaluating the performance of social agents (e.g. providers of services as hospitals, schools, etc.) conditionally on "reference states" $x := X \in \{x_1, \ldots, x_R\}$ of the governed individuals. Each scale is associated to an index which uses conditional "worthiness increases" $\omega_{l|x}$, between the levels of an ordinal outcome indicator $Y := l \in (0, 1, .., L)$. This indicator was been defined on a scheduled, by the policy-maker (PM), chain of hierarchically ordered goals. The "worthiness increases" are interpreted by modeling interrelated latent evolutionary processes, on the scheduled goal chain, up to hyperparameters γ which are driven by conditions x. Then, to standardize the set of scales on a given "reference behavior", a pseudo-Bayesian (see [1]) method is used which elicits value γ^* by minimizing "residual from updating" (see [4]). It norms the model specifications on the "reference data" of the (chosen a priori) "standard agent". Finally, adhering to general requirements in rational choices from the decision theory, a standardized worthiness-based index can be implemented, which takes into input the agents actual data.

Key words: performance index, ordinal scaling, worthiness

1 Indexing worthiness

The performance of any social agent u is associated to the "social behavior", described by the set of distributions (e.g. see table 1) $p_{|x}[u] := (p_{0|x}, p_{1|x}, \cdots, p_{L|x})[u]$, which were realized on the set of the individuals that u governs, upon the levels of

x4	1	20	236	24	1
x5	0	6	198	100	13

Table 2 Example. Reference data of the standard-agent A_0

Suppose that the PM has specified a certain chain of, increasingly challenging, binary-outcome goals

$$O_0 \preceq O_1 \preceq O_2 \preceq \ldots \preceq O_l \preceq \ldots \preceq \ldots \preceq O_{L-1} \preceq O_L := O_{Full}, \tag{1}$$

which are hierarchically (i.e. Guttman like) ordered. Then, the (nominally recoded on $\{0, 1, \ldots, L\}$) ordinal outcome indicator Y is defined so that the event occurrence "$Y \geq l$" identifies the achieving of the l-th scheduled goal $O_l := (Y \geq l)$, $l := 0, \ldots, L$. Therefore, the pursued "full purpose" could be realized at different degree of achieving, from the "tautological" (i.e. alway achieved) goal $O_0 := (Y \geq 0)$ toward the final goal O_L. Let $\mathscr{P}^*$denote the population of the (real or perhaps virtual) individuals which are governed by the reference agent *(*e.g. a recognized "best practice" for standardization*)* A_0 (e.g. see table 2). Then, the criterion of intrinsic worthiness (see [3]) may be interpreted[1] on a goal-based probabilistic setup as follows.

For any actual individual i, having achieved goal O_{l-1} on chain of goals (1), the higher "the risk of failing the next goal O_l", referring such a risk on the population $\mathscr{P}^*$, the greater the "increase of worthiness", due to the performance of the agent which governs i "as if" i was in $\mathscr{P}^*$, whenever it actually achieves goal O_l.

[1] Consider hierarchical chain of goals *(1)*. Given that a certain goal O_{l-1} has been achieved, the greater the resistance, with reference to the evaluation framework, to also achieve the next pursued goal O_l*,* by continuing to improve, the greater the increment of value due to the intrinsic worthiness of who, effectively, is able to achieve it.

Thus, the $\mathscr{P}^*-$standardized, conditionally on status $x := X \in \{x_1, \dots, x_R\}$, worthiness increase between any two adjacent levels of $Y := l \in (0, 1, .., L)$ is provided[2] (for $l := 1, .., L$) by:

$$\omega^*_{l|x} := \Delta_{l-1} Val_{|x} := Val_{|x}(O_l) - Val_{|x}(O_{l-1}) =$$
$$= \varphi_l\left(\frac{Pr\{Y = l-1|x;\, \mathscr{P}^*\}}{Pr\{Y \geq l-1|x;\, \mathscr{P}^*\}}\right) = \varphi_l\left(\frac{p_{l-1|x}}{p_{l-1|x} + p_{l|x} + \cdots + p_{L|x}}\right) \geq 0 \qquad (2)$$

Here, continuous monotone functions $\varphi_l(.)$ (e.g. set here the identity) of the conditional probability rates may be chosen (see [3]) for specifying some characteristics (e.g. the additivity) of the scale. Formally re-interpreting "worthiness increases" as "utility increases", functionals of the "rank dependent expected utility", adhering to requirements of rational choices (e.g. see [2], pp. 559), leads to the following instance of conditional-expectation-based index[3]:

$$u :\longmapsto W[p_x[u];\, \omega^*_x, x] := \sum_{l:=1}^{L} \varphi_l\left(\frac{Pr\{Y = l-1\,|\,x;\, \mathscr{P}^*\}}{Pr\{Y \geq l-1\,|\,x;\, \mathscr{P}^*\}}\right) \cdot (1 - F_{Y|x}[p[u]](l)) \qquad (3)$$

Here, $F_{Y|x}[p]$ denotes the cumulative distribution such that $F_{Y|x}[p](l) = p_{0|x} + p_{1|x} + \cdots + p_{(l-1)|x}$. Thus, through $x \in \{x_1, \dots, x_R\}$, it may be defined the global evaluation index: $u \longmapsto \sum_{r:=1}^{R} q_r \cdot W[p_{x_r}([u];\, \omega_{x_r}(\mathscr{P}^*)]$. It uses the actual agents data (e.g. see table 1)), standardized on the reference-agent's data (e.g. see table 2). Here, $q_r \geq 0$ ($\sum_{l:=1}^{R} q_r = 1$) weights[4] the reference domain for the status x_r.

2 Eliciting standardized worthiness increases

To justify differences in "worthiness increases" (2), through reference conditions $x := X \in \{x_1, \dots, x_R\}$, the PM may adopt some "reference evaluation criterion" and working assumptions formally specified by means of a structural probabilistic model (4)-(7). Here[5], the conditional rates (1-ν_{rl}) (which enter "worthiness increases"

[2] It is the worthiness credit which is gained by any social agent in improving the condition of a "*standard individual*", in the reference condition $x \in \{x_1, \dots, x_R\}$, from the current level $(l-1)$ to the next l on the scale of Y which was constructed on goal chain (1).

[3] for any agent u, given x, it takes into input the distribution realized (e.g. see table 1), by the individuals that u governs in condition x, on the standardized worthiness-quantified levels of Y.

[4] these weights should represent the political relevancy of the "social reference domains" to the main aim of the PM.

[5] On the stratum of the n_r individuals in the condition x_r, the manifest outcome $(Y_{r0}, \dots, Y_{rL})$ is distributed as a multinomial (eq.4) where the expectation-parameters $\psi_r := (\psi_{r0}, \psi_{r1}, \dots, \psi_{rL})$ are normed, within the container Dirichlet model (eq. 5), on a set of constraints on the latent evolutionary processes undertaken the levels of outcome scale Y (eqs (6)-(7)).

(2)) are represented as latent parameters of interrelated evolutionary-processes behind the goals chain (1), which are driven by manifest conditions x up to hyper-parameters[6] $\gamma := (\mu_0, \delta, \beta^X)$ to be regulated. Then, the methodological question arises in automatic eliciting of values γ^* so that "worthiness increases" $\omega_{l|x}(\mathscr{P}^*; \gamma^*)$ enter evaluation indexes (3). To norm the model on the reference-agent's data table (2), recalling a "minimum information principle"[7], hyper-parameters γ may be regulated (e.g. see [5],[4]) to that value γ^* such that the *"residual from updating"*[8]$\| \; Vec\,(\, E(\Psi \mid y,x;\gamma,w) - E(\Psi \mid x;\gamma,\, w)\,) \; \|$ is minimized subject to specifications of constraints (6)-(7).

$$Y_r{:=}\{Y_{r0},...,Y_{rL}\}|\psi_r \overset{ind.}{\sim}{}_{r:=1,...,R} Mult(y_{r0},...,y_{rL};\psi_{r0},\psi_{r1},...,\psi_{rL},n_r) \tag{4}$$

$$\psi_r{:=}(\psi_{r0},\psi_{r1},...,\psi_{rL})|m_r,a_r \overset{ind.}{\sim}{}_{r:=1,...,R} Dirichlet(\psi_{r0},...,\psi_{rL};m_r,a_r) \tag{5}$$

$$m_r{:=}(m_{r0},\, m_{r1},...,m_{rL}),\, 0{<}m_{rl}{:=}E[\psi_{rl}]{<}1,\, \textstyle\sum_{s:=0}^{L} m_{rs}{=}1, \quad a_r{:=}w_r, w_r{>}0$$

$$v_{r1}{:=}\frac{m_{r0}}{m_{r0}+m_{r1}}=\frac{e^{\eta_{r1}}}{1+e^{\eta_{r1}}}\,, \tag{6}$$

$$v_{rl}{:=}\frac{m_{r0}+...+m_{r(l-1)}}{m_{r0}+m_{r1}+...+m_{rl}}=\frac{e^{\eta_{irl}}}{1+e^{\eta_{rl}}}\,,$$

$$\cdots$$

$$v_{rL}{:=}\frac{m_{r0}+...+m_{r(L-1)}}{m_{r0}+m_{r1}+...+m_{rL}}=\frac{e^{\eta_{rL}}}{1+e^{\eta_{rL}}}\,,$$

$$\eta_{rl}{=}\mu_0{+}\textstyle\sum_{s:=1}^{L} \delta_l{\cdot}I_{(s=l)}{+}\sum_{w:=2}^{R} \beta^X_{w(l-1)}{\cdot}I_{(X(r)=w)} \tag{7}$$

$$reference\,condition\,r{:=}1,...,R{:=}5;\; scale\,level\,transitions\,l{:=}1,...,L{:=}4$$

Direct Individual Differences Scaling for Evaluation of Research Quality

DINDSCAL per la Valutazione della qualità della Ricerca

Gallo M., Trendafilov N., and Simonacci V.

Abstract *The eValuation of Research Quality (VQR) is one of the most important assessment processes achieved by the National Agency for the Evaluation of Universities and Research Institutes. Its main task is to provide information on the status of the Italian research system by assessing the performance of universities in various scientific areas. The basic evaluation criteria were defined by panels of experts according to the specific characteristics of each subject area and through a synthetic statement on the products submitted by researchers. With the aim of studying this phenomenon in depth, DINDSCAL (Direct Individual Differences Scaling) model is proposed for a compositional analysis of VQR dataset.*

Abstract *La Valutazione della Qualità della Ricerca (VQR) è uno dei processi di valutazione più importanti realizzati dall'Agenzia Nazionale di Valutazione del Sistema Universitario. Il suo compito principale è fornire informazioni sullo stato del sistema di ricerca italiano valutando le prestazioni delle universitın varie aree scientifiche. I criteri di valutazione di base sono stati definiti da gruppi di esperti in base alle caratteristiche specifiche di ciascuna area tematica e attraverso una dichiarazione sintetica sui prodotti presentati dai ricercatori. Con l'obiettivo di studiare approfonditamente tale fenomeno, il modello DINDSCAL è proposto per l'analisi composizionale dei dati VQR.*

1 Introduction

The National Agency for the Evaluation of the University and Research Systems (ANVUR), in the framework of an evaluation project (VQR), collected research outputs from 96 Italian universities, including 18 research Institutes. Sixteen panel of experts in evaluation (GEV), one for each scientific area of research, classified the products in specific merit classes. According to Ministerial Decree no. 458 dated 27 June 2015, common guidelines were defined for all GEVs. A new approach based on DINDSCAL (Direct Individual Differences Scaling [2]) model and compositional analysis is proposed in this work to extract information regarding the criteria used by the GEV, if the dimension of structure and the geographic location influence the quality of research outputs. In literature the INDSCAL (Individual Differences Scaling) model is used to study the individual differences in three-way data by doubly centered set of matrices of squared dissimilarity measures between a range of stimuli [1]. A direct approach as DINDSCAL is here preferred, in order to directly analyse simultaneous slices of squared dissimilarity matrices organized as compositional data.
The new approach is shortly described in Sect. 2. Sect. 3 summarizes the analysis of the VQR data.

2 Theory

2.1 Compositional data

Let $\underline{V}$ $(n \times p \times m)$ be a three-way array where each row v_{ik} $(i = 1,\cdots,n, k = 1,\cdots,m)$ is a compositional vector of p parts observed after the kth treatment (or occasion). From a geometrical point of view the sample space for all vectors v_{ik} is the simplex. There is a rich literature for CoDa proprieties and how is possible to handle them in simplex space (for a detailed review and references see [3]).
Here the CoDa are transformed in centred log-ratio (clr) in order to move from simplex to real space [4]. Let $\underline{L}$ $(n \times p \times m)$ be a three-way array with the CoDa in logarithm scale $[l_{ijk} = log(v_{ijk})]$. The clr-coordinates for each frontal slice of $\underline{X}$ are defined $X_k = L_kJ_p$, where L_k is a $n \times p$ matrix and J_p is a $p \times p$ centring matrix, $J_p = I_p - \frac{1}{p}E_p$ with I is an identity matrix and E is a matrix of ones. Thus, when the columns of X_k are centred, $X_k = J_nL_kJ_p$, the metric multidimensional scaling (MDS) for each X_k is given by the following identity:

$$-\frac{1}{2}J_n(D_k \odot D_k)J_n = X_kX_k^\top, \tag{1}$$

where '$\odot$' denotes the usual elementwize (Hadamard) matrix product and D_k is a $n \times n$ symmetric matrix containing zero on main diagonal and the dissimilarity measure between the n compositions collected at the kth occasion.

As well as recalled, the measures in D_k are Aitchison distances. Thus, they have all properties necessary for a meaningful interpretation of compositional results. Moreover, the identity (1) shows that $-\frac{1}{2}J_n(D_k \odot D_k)J_n$ is positive semi-definite.
With the aim to a simultaneous metric of m symmetric slices D_k, the INDSCAL model decomposes the each slice as

$$-\frac{1}{2}J_n(D_k \odot D_k)J_n = Q\Lambda_k Q^\top + \Delta_k, \tag{2}$$

where Q is $n \times r$ assumed of full column rank, Λ_k diagonal matrix and Δ_k is $n \times n$ matrix, containing the errors of the model fit. In other words all slices share a common loading matrix Q and differ each other only by the (non-negative) diagonal elements of Λ_k called idiosyncratic saliences.
Unfortunately, in (2) the parameter set of all $n \times r$ matrices Q with full column rank is a non-compact Stiefel manifold. To solve this drawback an approach called direct INDSCAL was proposed by [2].

2.2 DINDSCAL problem

Following the approach proposed by [5], it is easy to show that the squared Aitchison distances are given by the following identity:

$$D_k \odot D_k = (I_n \odot X_k X_k^\top)E_n + E_n(I_n \odot X_k X_k^\top) - 2X_k X_k^\top \quad k = 1, ..., m. \tag{3}$$

Thus, the DINDSCAL fitting problem for CoDa is concerned with the following equality constrained optimization problem:

$$\min_{Q,\Lambda_k} \sum_{k=1}^{m} \|D_k \odot D_k - (I_n \odot Q\Lambda_k^2 Q^\top)E_n - E_n(I_n \odot Q\Lambda_k^2 Q^\top) + 2Q\Lambda_k^2 Q^\top\| \ , \tag{4}$$

subject to $(Q, \Lambda_1, \Lambda_2, \ldots, \Lambda_m) \in \mathscr{O}_0(n,r) \times \mathscr{D}(r)^m$, where $\mathscr{D}(r)^m = \underbrace{\mathscr{D}(r) \times \ldots \times \mathscr{D}(r)}_{m}$, and $\mathscr{D}(r)$ denotes the set of all $r \times r$ diagonal matrices. $\mathscr{O}_0(n,r)$ denotes the set of all $n \times r$ orthonormal matrices with zero column-sums, i.e.: $\mathrm{O}_0(n,r) := \{Q \in \Re^{n \times r} | \ Q^\top Q = I_r$ and $E_n Q = 0_n\}$. It is easy to observe that the additional constraint of clr-transformation zero column- rows sums, i.e. $E_n X_k = 0_n$ and $X_k E_p = 0_p$ does not introduce new constrains. Thus the problem of minima defined in (4) can be solved by a non-linear conjugate gradient algorithm, which leads to globally convergent algorithms.
For a formal introduction to the method and its numerical integration see [6], while all information about the gradient dynamical system for the DINDSCAL problem is given in [2].

3 Case study

The research outputs submitted from each university was calculated considering the number of university staff members. Each product was classified in a specific merit classes, that is, Excellent, Good, Fair, Acceptable, and Limited. Products classified as not eligible are assigned to a specific merit class. According to the kind of research outputs (articles, monographs, book chapters, etc.) bibliometric algorithm or peer-review methodology were used to evaluate the 117,079 research outputs submitted in the 16 MIUR scientific areas.
The data are preprocessed according to the procedure described in Sect. 2.1, DINDSCAL is able to find some important differences between two groups of scientific areas and between the scientific structures with different size. In short, there is a tangible contraposition between large-size scientific structures, especially those localized in the Centre of Italy, and the others. Moreover, the medium size structures localized in the Centre and in the South of Italy are characterized only by specific scientific area.

A test for variable importance

Sulla scelta di variabili esplicative rilevanti

Rosaria Simone

Abstract Statistical literature is being more and more concerned with debates about hypothesis testing and p-values supporting the significance of a given variable specification. Specifically, if on one hand statistical foundations about significance are not arguable, scholars should be able to distinguish between significance and variable importance. This is a matter of serious concern in questionnaire analysis to derive respondents' profiles and develop targeted marketing strategies, for instance. To this aim, this contribution proposes a hypothesis system that considers the normalized dissimilarity measure to assess the importance of explanatory variables in the setting of mixture models for ordinal data to account for uncertainty of choice.
Abstract *Un dibattito sempre più presente nella letteratura statistica moderna riguarda lo studio della effettiva importanza di covariate significative rispetto ai risultati dei classici test di ipotesi e tecniche di selezione del modello. Se l'applicazione delle procedure standard non è in discussione, d'altra parte la distinzione tra variabili significative e variabili rilevanti assume un ruolo fondamentale ai fini decisionali. Tale problematica è di particolare rilievo nell'dei dati provenienti da questionari, ad esempio per la profilazione dei consumatori al fine di individuare specifiche strategie di marketing. In questo contesto, un sistema di ipotesi basato su una misura di dissimilarità viene proposto per testare la rilevanza di variabili esplicative nel caso di una classe di misture per dati ordinali.*

Key words: Dissimilarity, Variable Selection and Importance, CUB mixture models, Rating Data

Rosaria Simone

1 Motivations

The opening lines of [3] invite readers to critically use p-values in the era of big data:

> There is growing frustration with the concept of the p-value. Besides having an ambiguous interpretation, the p-value can be made as small as desired by increasing the sample size, n. The p-value is outdated and does not make sense with big data: Everything becomes statistically significant.

The purpose of this contribution is to investigate such concern and propose a methodology for variable selection in the setting of statistical models for rating data. Our discussion stems from a well consolidated idea to measure separation of probability distributions relying on the concept of Gini's *Transvariation* [5] which has been applied in several circumstances (see [1], for instance). Departing from the identity: $\min(a,b) = \frac{1}{2}\big(a+b-|a-b|\big)$, an inverse indicator of how far apart two (discrete) probability distributions $\mathbf{p} = (p_1,\dots,p_m)'$, $\mathbf{q} = (q_1,\dots,q_m)'$ are, is given by:

$$\sum_{r=1}^{m} \min(p_r,q_r) = 1 - \frac{1}{2}\sum_{r=1}^{m} |p_r - q_r|. \tag{1}$$

This is a measure of their overlapping. For instance, consider the conditional distributions of a discrete response given a dichotomous factor (dashed lines joining mass probabilities are chosen to enhance visualization in Figure 1). Albeit statistically significant differences are found, the discrimination of response patterns becomes more meaningful from left to right as the overlapping gets smaller.

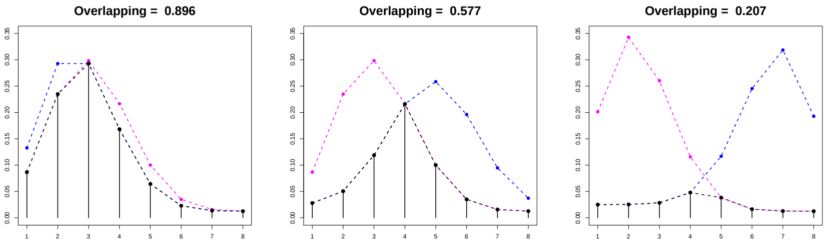

Fig. 1 Visualization of overlapping between discrete probability distributions

As an application of how this measure could work in discriminating significant covariates for a given ordinal response, here the focus will be on CUB models [2]. The original paradigm is the weighted combination of a (shifted) Binomial distribution $g_r(\xi_i)$ for the *feeling* component and a (discrete) Uniform for the *uncertainty* component, meant as the fuzziness derived from the discretization of the continuous latent perception. For a sample $(R_1,\dots,R_n)$ of ordinal responses, say on the support $\{1,\dots,m\}$ for a given $m>3$, a CUB regression model is specified via:

$$Pr(R_i = r|\boldsymbol{y}_i, \boldsymbol{w}_i) = \pi_i\, g_r(\xi_i) + (1-\pi_i)\frac{1}{m}, \qquad (2)$$

where feeling ξ_i and uncertainty π_i parameters are linked to values of subjects' covariates $\boldsymbol{w}_i, \boldsymbol{y}_i$ by a logit link:

$$logit(\xi_i) = \boldsymbol{w}_i\,\boldsymbol{\gamma}, \qquad logit(\pi_i) = \boldsymbol{y}_i\,\boldsymbol{\beta}.$$

This full model specification is customarily abbreviated as CUB (p,q), where $\boldsymbol{\gamma}^{'} = (\gamma_0,\dots,\gamma_q)^{'}, \boldsymbol{\beta}^{'} = (\beta_0,\dots,\beta_p)^{'}$ are the estimable parameters: when $p = q = 0$, then model fitting assumes constant feeling ξ and uncertainty π parameters. Estimation of CUB models relies on likelihood methods and, specifically, on the implementation of the Expectation-Maximization algorithm. Fit improvements yielded by the specification of covariates can be tested via a Likelihood Ratio Test if models are nested: in general, the significance of an explanatory variable can be checked via standard Wald test. In the following, let D be a dichotomous variable included in the model specification to explain patterns of responses in terms of feeling and/or uncertainty, so that $\boldsymbol{\theta}_0 = (\pi_0, \xi_0)$, $\boldsymbol{\theta}_1 = (\pi_1, \xi_1)$ are the parameters of the conditional CUB distributions $\big(R_i|D_i = 0\big) \sim$ CUB (π_0, ξ_0) and $\big(R_i|D_i = 1\big) \sim$ CUB (π_1, ξ_1). If D implies statistically significant differences in model parameters, then two subgroups of respondents are identified and one should establish if the resulting clustering is actually relevant. This issue is particularly common when the sample size n is large. Here we wish to discuss a system of hypothesis:

H_0 : D should not be retained in the model (D is not important)

versus

H_1 : D should be retained in the model (D is important).

Thus, significant differences in model parameters will be investigated in order to disclose to which extent the clustering variable is actually relevant and should be retained in the model.

2 A test for variable importance

In order to test if the inclusion of a significant factor leads to relevant improvement of the fit, the (normalized) dissimilarity measure [6, 8]:

$$Diss(\boldsymbol{p},\boldsymbol{q}) = \frac{1}{2}\sum_{r=1}^{m} |p_r - q_r| \ \in (0,1) \qquad (3)$$

stems quite naturally from the motivating discussion. If $\boldsymbol{p},\boldsymbol{q}$ are two probability distributions, it assesses the proportion of cases in which the two distributions differ. Thus, if a CUB $(1,1)$ is fitted to the data with a dichotomous factor D for both components:

$$logit(\pi_i) = \beta_0 + \beta_1 D_i, \qquad logit(\xi_i) = \gamma_0 + \gamma_1 D_i,$$

and, accordingly, two clusters are identified, the dissimilarity between the estimated conditional response probabilities of $R_i|D=0$, $R_i|D=1$ indicates how far apart the groups $D=0$ and $D=1$ are in terms of the corresponding estimated CUB $(0,0)$ probability distributions. Similar considerations hold if the dichotomous variable D is specified only for one of the components.

3 A simulation experiment

The validation of the proposed approach to test variable importance will be run with a Monte Carlo experiment. For illustrative purposes, we shall consider the simplest case of a dichotomous variable D, with levels 0,1 (for instance, males and females, smokers and non smokers, etc.), able to discriminate feeling, by assuming heterogeneity constant among subjects. Thus, in the end we shall have two separate groups of respondents, corresponding to feeling parameters ξ_0 and ξ_1 if $D=0$ or $D=1$, respectively. We derive the empirical critical values c_α under the null $H_0 : \xi_0 = 0.30,\ \xi_1 = 0.35$ by generating a sample of data in which a dummy covariate is significant but the difference in parameter values is very small, thus it may raise doubts about importance of the implied classification. To this aim, we sample 1000 times from the null distribution for varying $\pi \in (0.2, 0.4, 0.6, 0.8)$, different numbers of categories and sample sizes for the two groups.

Empirical critical values for the dissimilarity statistics corresponding to nominal level $\alpha = 0.05$ are summarized in Table 1: lower and upper bounds (l_b and u_b, resp.) of 80% bootstrap confidence intervals (1000 replicates) are also reported as an instance of a measure of uncertainty of the test statistics. Thus, at level α, a value of dissimilarity between the implied conditional distributions lower than the corresponding critical value indicates that D has a weak importance for the purpose of discrimination of response patterns and its specification in the model could be matter of discussion.

As a by product of the simulation experiment, new evidence is found to support the specification of uncertainty for ordinal data models: indeed, critical values decrease for higher values of heterogeneity (that is, larger weights for the Uniform distribution), indicating that this component has a not-negligible effect in the analysis of variable importance. In order to enhance the purpose of the test, an additional simulation experiment has been planned: for each run and for the chosen parameter values, a sample has been generated with a significant dummy variable splitting the observations into two groups of sizes n_0 and n_1 respectively. Then the dissimilarity test has been applied to check for variable importance according to the proposal. Results are summarized in Table 2 and highlight that, especially for large samples,

The proposed variable-importance test has shown perfect agreement with the corresponding one using the (symmetrized) Kullback-Leibler divergence (here not reported for the sake of brevity), but it is more advantageous since the dissimilarity measure is a proper (normalized) distance and it is able to foster interpretation and visualization of results. Similar conclusions are found when considering $\xi_0 = 0.1$ or $\xi_1 = 0.5$ for the feeling under the null (it is not necessary to test for values $\xi > 0.5$

since CUB distributions are reversible) and for increasing differences between ξ_0 and ξ_1. Dually, the proposed test can be run in case the clustering covariate is tested to explain heterogeneity for samples with homogeneous feeling or both components.

4 On-going developments

The proposed testing procedure for variable importance prescribes that, once a dichotomous factor is specified in the model to explain the response (in terms of feeling and uncertainty in case one assumes the CUB paradigm), then the dissimilarity between the estimated conditional distributions can reveal its discrimination ability in an effective and insightful way. The topics here investigated are being subject to more in-depth analysis stemming from real case-studies; further studies are tailored to the application of the approach to other classes of models, as well as to the study of properties of the dissimilarity estimator -also known as Duncan segregation index in other contexts- in the vein of [4, 10]. Notice that the same approach can be exploited to design a proper test of significance for difference in parameter values:

$$H_0 : \boldsymbol{\theta}_0 = \boldsymbol{\theta}_1 \quad versus \quad H_1 : \boldsymbol{\theta}_0 \neq \boldsymbol{\theta}_1$$

with test statistics based on the dissimilarity between the conditional distributions. From some preliminary investigations in this perspective one obtains a test that is as powerful as the corresponding one using the Kullback-Leibler divergence to assess distances between distributions. This approach has been investigated in [7, 9] to design a homogeneity test in case of continuous populations and small sample sizes.

Statistical Models New Proposals

Decomposing Large Networks: An Approach Based on the MCA based Community Detection

La decomposizione di networks di grosse dimensioni: un approccio basato sull'identificazione di comunitá via MCA

Carlo Drago

Abstract The emergence of the big data has called for considering new methodologies to analyze big networks. In these particular contexts there are many cases in which it is important to take into account not only the single node but groups of nodes which can have the same or similar functions on a defined network. On large networks it is important to represent them in a meaningful way. Interval data seems an adequate representation which can be used to represent these networks. The specific contribution of this work it is to show the way in which is possible to rank the different structural characteristics of the different robust communities represented by the network. The rank applied to the structural characteristics allows the understanding also of the relevant core of the network

Abstract *L'emergere dei big data ha richiesto di considerare nuove metodologie per analizzare le grandi reti. In questi contesti ci sono molti casi in cui è importante prendere in considerazione non solo il singolo nodo ma gruppi di nodi che possono avere le stesse funzioni o funzioni simili su una rete definita. I dati ad intervallo sembrano una rappresentazione adeguata che può essere utilizzata per rappresentare queste reti. Il contributo specifico di questo lavoro è mostrare il modo in cui sia possibile classificare le diverse caratteristiche strutturali delle diverse comunità robuste rappresentate dalla rete. Il rango applicato alle caratteristiche strutturali consente di comprendere il nucleo principale della rete*

1 Big Data and Networks

The emergence of the big data has demanded the consideration of new methodologies to analyze big networks. In particular the growth in size of the social networks has called for a new relevant role for the different platforms which have given various new services. At the same time the data related to the different attributes on the network is growing exponentially. In this way it is usually difficult to handle and analyze networks and it is necessary to define an approach which can be useful to deal with these types of networks. Furthermore in these contexts there are many cases in which it is important to take into account not only the single node but also the group of nodes which can have the same functions on a defined network. One strategy is to decompose the networks and to represent it in a manageable way [14]. The different groups of nodes need to be considered as kinds of compartments on the networks and they can have a similar function or role on the networks as a whole [6]. It could be important to consider the groups of the nodes as a relevant entity and it is relevant to analyze the different relationships between the different entities. The challenge is to represent the network by considering their more relevant parts. The approach proposed considers symbolic data [1]. So the proposal is to consider a specific representation for the community or the specific aggregated data and then consider the community also as an entire entity.

2 The Analysis of the Community Structure

The different communities are groups of nodes which tend to be strongly connected to each other and they tend to be loosely connected with nodes of other communities [6]. The identification of the community structure is very important in order to detect groups of nodes which can be part of the same functional structure of the same network. The communities are the relevant elements on the construction of a network. In this sense we consider each different network as based on the communities which can be identified on the network. The first step is to identify the different communities which can be considered inside the network and then represent them. There are various different methodologies with the aim of detecting the different communities inside a network [9]. Each different method can have a different performance [11, 10]. In particular different algorithms can have different biases for the separate network structures and so we have to compare the results we obtain using different community algorithms. In this regard the global optimum as set of nodes of the considered objective can be really discrepant than the one returned by each method [10]. The use of a single methodology can as the Louvain method can be robustified by considering other methods and synthesize the eventually different results obtained. It is useful to consider approaches which can take into account an ensamble of different algorithms or approaches in order to synthesize the results obtained [4]. So we obtain a robust community structure via multiple correspondence analysis (MCA) and we validate them using the Rand Index. At this point it is necessary to represent the different communities in such a way which cannot lead to the loss of relevant information from the original data. The computed Rand Index gives us information on the capacity of the resulting representation to ”capture” the initial results of the different community detection on the network.

3 From the Communities to their Representation

Each different community, can be represented as a different interval data [3]. Differently it is possible to consider the entire network as a symbolic data [7]. In this sense we are able to obtain different interval data for each community. The procedure used is comprised of three steps: identifying the different communities from a network using an approach of community detection [9] (eventually using an MCA approach), and then from the different member community we can obtain the interval data. Following [3] each different community is based on all the single nodes of the network. From the interval data considered it is possible to measure the different attributes which are relevant in order to represent the entire community. Each measure is related to structural characteristics or attributes of the same node. We can have the attribute or structural characteristics for the entire community in addition to the attribute of those of the single n nodes. Then we have the single interval measure for the community based on those of the nodes which are members of the community:

$$X^a = (x_1, x_2, \dots, x_n) \tag{1}$$

Where x is a measure for the nodes belonging to a community X^a (for instance the different betweenness or the degree). The interval data for the single community is:

$$X^{I,a} = [\overline{x}, \underline{x}] \tag{2}$$

Where $\overline{x}$ represents the upper bound of the measure belonging to the community and the $\underline{x}$ the lower bound. At this point we can consider the descriptors of the different communities as intervals [8]. In this way we can consider both the single different observations, but also the different communities by considering the intervals of their measures. It is possible to compare the different communities by their attributes (the upper and the lower bound) but also the centers and the radii [12]. We have the center:

$$X^{I,a}_{center} = \frac{1}{2}(\underline{x} + \overline{x}) \tag{3}$$

we can also consider the range between the upper and the lower bound

$$X^{I,a}_{range} = (\underline{x} - \overline{x}) \tag{4}$$

and the radii

$$X^{I,a}_{radius} = \frac{1}{2}(\underline{x} + \overline{x}) \tag{5}$$

These descriptors allow to take into account the different communities and to compare them.

4 Ranking the Different Representations

At this point it is necessary to identify the different rankings of the representations. In this sense we have to explicitly consider the different intervals and their attributes. In particular each interval can be characterized by their attributes as the lower bound and the upper bound. Starting from their descriptors it is possible to compare the different attributes or structural indicators for each community considered. Following [12] we consider the ranking for the different intervals obtained. The comparison can be conducted by considering the different attributes of the intervals (the upper and the lower bounds, the range and the radii). An application of ranking of the different attributes of the different communities is to detect the centre of the network based on the different communities. In this sense we are interested not in single nodes but in considering the communities as the initial point of the analysis. The ranking of centrality, for instance, is computed by considering the different communities, and at the same time those selected are considered on the final network selected by their structural characteristics. At this point, it is possible to consider the ranking also by taking into account only a number of different communities. The aim is to detect the central part of the network for some relevant structural characteristics. We obtain a stylized structure of the network considering the most relevant communities. The validation phase is performed by observing a graph in which are visualized the changes on some indicators (betweenness and degree for instance). We consider the changes on the center values for each community. A radar plot [13] is a tool to analyze and compare the different measures on the ranking: it could be used as a diagnostic tool in the choice. The final network structure is based on considering only these communities.

5 Simulation Study and Application on Real Data

It is possible to consider different simulated networks in order to evaluate the procedure proposed. In order to test the algorithms then we consider various types of networks and we consider the approach for each different network. In particular we simulate different networks of different typology and different size and then we apply the approach (Barabasi Game, Erdos Renyi and also Forest Fire [2]). We are able to show the community structure by detecting the different communities using the MCA-based community algorithm procedure [4]. Then we represent them as interval data and we compute two descriptors as upper and lower bound for each community. Finally we are able to compute also the center and the radius. The statistical methods considered on the different intervals based on the communities are on [8]. The package RSDA on R allows the performing of different computations based on interval data [15]. We visualize the ranking of the different communities obtained by considering the appropriate methods and we can visualize them by using a radar plot. A radar plot visualizes each attribute of the community and structural indicator expressed as interval. At the same time we can choose the number of communities by observing the change on the relevant center parameters in the different communities (on betweenness and degree in our case). So we are able to visualize the most central communities by considering the highest ranked communities by their betweenness and the degree. At the same time the radar plot is actually showing the ranking considering also the other structural characteristics represented as interval data for each specific data. Finally by choosing the first ranked communities we are able to identify the stylized structure of the network starting from their specific initial structure. In this sense we start from the entire structure and then we are able to rank the different communities by considering the different attributes. Finally we select the first communities and we obtain the most central communities from the network. In the case of application on real data we consider the network of the Zachary karate club [16]. Here we are able to observe and select (see the figure 6) the most relevant part of the network by selection of the most central communities. These communities identify the ”core of the network” rather than other peripherical network structures.

6 Conclusions

The procedure considered determines the different communities of the network and detects the most central different representations by considering some structural indicators as the betweenness or the Freeman degree. Other attributes of the different communities can be considered. The approach followed in this paper is to consider the different communities, representing them as interval data and then ranking them. It is important to emphasize that the analysis is community-based and it is robust allowing to enclosing the results of many community detection algorithms.

On Bayesian high-dimensional regression with binary predictors: a simulation study

La regressione Bayesiana con previsori binari in contesti ad alta dimensionalità: uno studio di simulazione

Debora Slanzi, Valentina Mameli and Irene Poli

Abstract Aim of this work is to develop a comparative analysis to evaluate the performances of several Bayesian regression approaches in the high-dimensional context where the number of observations is very small with respect to the number of predictors. Moreover in this study we assume that the predictors can be expressed only as binary variables coding the presence or the absence of a particular characteristic of the system. This binary structure is very present in many real studies, in particular in laboratory experimentation.
Abstract *Lo scopo di questo lavoro è quello di sviluppare un'analisi comparativa per valutare il comportamento di alcuni metodi inferenziali di regressione Bayesiana in contesti di alta dimensonalità dove il numero di osservazioni è molto piccolo rispetto al numero dei predittori assunti per il modello. Lo studio considera solo predittori espressi in forma di variabili binarie in grado di codificare la presenza e l'assenza di una particolare caratteristica del sistema. Questa struttura del problema presente in molti studi di fenomeni reali e in particolare in ambito sperimentale.*

1 Introduction

Bayesian regression models have been widely studied and adopted in the statistical literature [14, 10]. Many studies regard the development of efficient and effective priors to select the set of relevant variables and derive accurate posterior predictive distributions [6, 4]. Moreover in the context of high-dimensionality, when there are many predictors, sparsity is assumed and many parameters can be set to values very close to zero without affecting the fit of the model [11, 9]. The Bayesian penalized regression techniques for the analysis of high-dimensional data include, among others, the Bayesian Lasso [8, 7], the normal-gamma regression [5], the horse-shoe regression [1] and the Bayesian ridge regression [3, 12]. Generally the setup of the regression considers the standard multiple linear model assuming independent Normal error terms. Moreover it is usual to standardize both the response and the covariates to have zero mean and variance equals to one. While there are several studies conducted to compare the performances of the models when the predictors are continuous, these approaches are not very suited when the predictors are binary variables. This situation frequently occurs in many experimental fields, as for example in biochemical studies where the presence and absence of a component determines the results of the experimentation and affects the success of the study. In this paper we focus on this particular situation, and we conduct a simulation study to compare the performance of several high-dimensional Bayesian regression models when the predictors are expressed as binary variables.

The paper is organized as follows. In Section 2 we present the Bayesian multivariate regression model and we introduce the prior distributions considered in the analysis. Section 3 describes the characteristics of the simulation study and presents the results of the comparison by means of indicators of goodness of fitting and prediction. Finally in Section 4 we derive some concluding remarks.

2 Bayesian regression

Let consider the standard multiple linear regression model which assumes that a vector of responses $y = (y_1, y_2, \dots, y_n)$ can be represented as

$$y = \alpha\mathbf{1} + \mathbf{X}\beta + \varepsilon$$

where the vector of errors $\varepsilon = (\varepsilon_1, \dots, \varepsilon_n)^T$ are independent with $p(\varepsilon_i) = N(\varepsilon_i|0, \sigma^2)$ and $\mathbf{X}$ is an $n \times p$ matrix of predictor variables. The scalar α is the intercept, $\mathbf{1}$ a $n \times 1$ unit vector and the vector β represents the regression coefficients. In this work we adopt the Bayesian inferential approach which involves a choice of the prior distribution of the $(p \times 1)$-dimensional vector of regression coefficients β. Many approaches are proposed in literature to derive effective and efficient prior distributions with different characteristics. Among them, the sparsity inducting priors are commonly applied in the setting of high-dimensionality, where most of the predictors are assumed to be unassociated with the responses. The hierarchical representation of the full Bayesian regression model as proposed by [8], introduces the distributions of the parameters and the hyperparameters as follows:

$$\begin{aligned} y|\alpha,\mathbf{X},\beta,\sigma^2 &\sim N_n(\alpha\mathbf{1}+\mathbf{X}\beta,\sigma^2\mathbf{I}_n), \\ \beta_j|\lambda_j^2,\sigma^2 &\sim N(0,\lambda_j^2\sigma^2), \\ \sigma^2 &\sim \pi(\sigma^2)d\sigma^2, \\ \lambda_j^2 &\sim \pi(\lambda_j^2)d\lambda_j^2. \end{aligned}$$

Different priors for σ^2 lead to different regression structures in terms of error distribution, while the hyperparameters $\lambda_1,\lambda_2,\dots,\lambda_p$ are used to model the sparsity characteristics and control the amount of shrinkage in the coefficient estimates [11]. Usually σ^2 follows an improper prior distribution proportional to $1/\sigma^2$, while the distribution assumed for $\lambda_1,\lambda_2,\dots,\lambda_p$ leads to different prior distributions for the regression coefficients β. Therefore, depending on the particular choices for the local shrinkage hyperparameters $\lambda_1,\lambda_2,\dots,\lambda_p$ we can consider some of the most frequently used Bayesian regression models:

- *Bayesian Lasso regression*: the hyperparameters $\lambda_1,\lambda_2,\dots,\lambda_p$ follow a joint exponential prior distribution which depends on further hyperparameters. Generally, this assumption is simplified by assuming that $\lambda_j^2 \sim Exp(1)$, $i = 1,\dots,p$ [8, 7];
- *Horseshoe regression*: the prior distribution for the local shrinkage hyperparameters $\lambda_1,\lambda_2,\dots,\lambda_p$ is the zero-mean half-Cauchy distribution [1];
- *Normal-Gamma regression*: the hyperparameters $\lambda_1,\lambda_2,\dots,\lambda_p$ follow a Gamma distribution where both shape and scale parameters have an associated prior distribution. Then the marginal distribution of β_j is generally affected by these choices in a way that smaller value of shape parameter of the Gamma distribution is associated with larger amount of shrinkage for the betas [5];
- *Bayesian Ridge regression*: it can be obtained by assuming $\lambda_1^2 = \lambda_2^2 = \dots = \lambda_p^2 = \lambda^2$ [3].

3 A comparative simulation study

We conduct a comparative simulation study to evaluate the performance of the Bayesian regression models under different prior distributions: Bayesian Lasso, the Bayesian horse-shoe regression, the Bayesian normal-gamma regression and the Bayesian ridge. The study has been conducted considering only binary variable predictors. The statistical analyses were performed using the R-project free software environment for statistical computing. In particular, we use the R-package `monomvn` to fit the regression models [13].

3.1 Experimental setting

The simulation is based on the linear regression model $y_i = X_i\beta + \varepsilon_i$, $i = 1,\dots,n$, where $\varepsilon_i \sim N(0,1)$. Predictors are generated independently from a Bernoulli distribution with probability of success 0.1 to represent sparsity condition[1]. The simulation considers an increasing number of predictors, p =200, 500, 1000, 1500, 2000, 3000. The number of non-zero regression coefficients is assumed to be $p^\star = 10$ with values $\{-1,1\}$.

From this data generative process, we simulate $N = 2000$ observations (the full dataset) and we randomly select n =100, 200 and 500 sample points (corresponding to the 5%, 10% and 25% of the full space) as training set to estimate the models. The remaining data are considered as test set on which to evaluate the performance of the various Bayesian methods. Each simulation is repeated 50 MonteCarlo runs to evaluate the robustness of the approaches and we compute the Predictive Mean Square Error (PMSE) and the Sensitivity (the ratio between the number of selected important variables and the number of actual important variables) as defined in [2]. In particular, values of Sensitivity close to 1 means that the approach is able to select the relevant information for the regression.

3.2 Comparative results

The results for increasing number of predictors are presented, i.e. p= 200, 500, 1000, 1500, 2000, 3000. Note that for n=200, we did not run simulations for p=200, and for n=500 we did not run simulations for p=200 and 500. In Table 1 we report the evaluation of the prediction capacity by means of PMSE for the different regression models. We can see that with regard to the predictive power of the models, they perform almost in the same way producing accurate predictions in particular when the number of covariates don't exceed too much the number of observations. This predictive power tends to decrease when the ratio between the number of observations and variables tends to decrease. We notice that there is the same trend for all the different approaches, however, the Bayesian Ridge regression presents the poorest performance for all the different values of n here considered. A different situation emerges if we consider the sensitivity measure by which the power of selecting important variables of the simulation is expressed. In Figure 1 we show how this measure evolves through the increasing values of p assuming different values of n. We notice that again the approaches show a very similar performance, but the Bayesian Ridge regression presents values of Sensitivity higher than the other regressions. Therefore, comparing the different indicators of performance of these regressions we see that they all have a good prediction accuracy but the Bayesian Ridge regression presents an higher capacity (Sensitivity) to detect the relevant vari-

[1] We plan to develop the simulation also for other usual values of probability of success representing sparsity condition.

Table 1 Predictive Mean Square Errors for regression: BL=Bayesian Lasso; HS= Horseshoe regression; NG= Normal-Gamma regression; BR= Bayesian Ridge (standard errors of MonteCarlo runs in parentheses).

n	p	BL	HS	NG	BR
100	200	1.52 (0.10)	1.55 (0.14)	1.52 (0.10)	1.81 (0.15)

ables of the system. The results of this simulation can be helpful when choosing the structure of the regression model to adopt in a particular study.

4 Concluding remarks

In this work we have developed a comparative analysis to study the performance of several Bayesian regressions with binary predictors in terms of predictive accuracy and variables selection. Further analyses will be conducted to strengthen these preliminary results and to identify the relation between n and p in deriving reliable inferential results in particular when binary predictors are present in the model.

On the estimation of epidemiological parameters from serological survey data using Bayesian mixture modelling

Sulla stima di parametri epidemiologici da dati da indagini sierologiche tramite l'uso di modelli di mistura bayesiani

Emanuele Del Fava, Piero Manfredi, and Ziv Shkedy1

Abstract In the context of serological surveys for the estimation of important epidemiological functions, mixture models offer an alternative and more accurate approach than the conventional one based on the diagnostic assay's cut-off points. In this work, we propose an innovative Bayesian mixture model for the estimation of flexible models for the age-specific seroprevalence and force of infection (or incidence rate). In order to account for the possible waning of immunity by age, we propose a Bayesian variable selection approach to determine the best age-specific model for the mean and the variance of the seropositive subpopulation. Our methodology is applied to a sample of antibody titres to varicella from Italy. Our results confirm that mixture models are a flexible and highly customisable tool, adapt to be systematically used in serological surveys.

Abstract *Nel contesto delle indagini sierologiche per la stima di importanti parametri epidemiologici, i modelli di mistura rappresentano un approccio alternativo e più accurato di quello basato sull'uso dei valori critici associati ai test diagnostici. In questo lavoro, proponiamo un innovativo modello di mistura bayesiano, finalizzato alla stima di modelli flessibili per la sieroprevalenza e la forza dell'infezione (o tasso d'incidenza) dipendenti dall'età. Allo scopo di modellare il possibile declino degli anticorpi con l'età, proponiamo un metodo di selezione bayesiana di variabili per determinare il miglior modello, dipendente dall'età, per la media e la varianza della sottopopolazione dei sieropositivi. La nostra metodologia è applicata ad un campione di titoli anticorpali contro la*

Introduction

Serological surveys, which are usually employed to quantify the antibody titre against a specific antigen, are among the most direct and informative techniques that are available to investigate the dynamics of the level of immunity protection in a certain population [12]. Despite that, the data resulting from these surveys remain somehow unexploited, for various reasons. One of them is that the assessment of the immunity profile in a population, the so-called seroprevalence of prevalence of immune individuals, is still often performed by dichotomisation of individual antibody titres measured by the diagnostic serological assay. This means that all the information contained in the individual antibody titre, such as the strength and the individual heterogeneity of the immunological response, is lost, as it is replaced by a binary variable giving the infection status, namely, whether the subject is seronegative or seropositive (showing evidence of past infection or vaccination). Moreover, the use of fixed cut-offs in serological surveys may be sub-optimal as the method is prone to misclassification or inconclusive classification [2, 10]. Conversely, mixture models are showing to be a more appropriate tool for the classification of serological antibody titres and for the estimation of age-specific epidemiological parameters, both from the statistical and the epidemiological point of view, in the case of infections in the pre-vaccination and post-vaccination state [3, 4, 14, 15].

The objective of this work is to provide an example of how to accurately estimating flexible models for the age-specific seroprevalence and force of infection (FOI) for varicella, using Bayesian mixture models for the classification of antibody titres and Bayesian variable selection for estimating the parameters associated with the seropositive subpopulation while accounting for possible immunity waning by age.

Data and Methods

Data on antibody titres for varicella zoster virus (VZV) in Italy were collected between 2003 and 2004 at national level [8]. Serological tests for VZV-specific IgG were performed using a commercial enzyme linked immunosorbent assay (ELISA), according to the manufacturer's guidelines. A sample of 2517 subjects, from 1 to 79 years of age, was collected. For each subject, the antibody titre (evaluated quantitatively as an antibody concentration and expressed as an optical density (OD) measured in mUI/mL) and the age were collected for the analysis. Children under 10 years old were oversampled.

We use Bayesian mixture models [5] in order to estimate the age-specific seroprevalence and the age-specific FOI directly from VZV antibody titres. We consider the population to be at demographic and epidemiological equilibrium. Since data were collected in a pre-vaccination period, we can safely assume that each serological sample is drawn from a population consisting of just two subpopulations, one for the seronegative and one for the seropositive individuals. We then assume that the individual antibody titre, after a logarithmic transformation, i.e. $\mathrm{Y_i} = \log_{10}(\mathrm{OD_i} + 1)$, is distributed as a mixture of two skew-normal distributions, with mixture weights depending on the age a of the individuals,

$$Y_i(a) = \left(1 - \pi_i(a)\right)SN(Y_i|\mu_1, \sigma_1^2, \gamma_1) + \pi_i(a)SN(Y_i|\mu_{2i}(a), \sigma_{2i}^2(a), \gamma_2)$$

where μ_k, σ_k^2, γ_k, $k = 1,2$ denote the mean, the variance, and the skewness parameters of the two mixture components, respectively. The mean and the variance of the seronegative component (μ_1, σ_1^2) are assumed to be age-independent, while those for the seropositive component (μ_2, σ_2^2) are allowed to vary by age, in order to account for possible waning of the antibody titre. The skew-normal distribution generalises the normal distribution by allowing for skewness through a specific parameter, γ_k, which we assume to be independent of age [1, 7]. A positive (negative) value of γ_k implies a distribution skewed to the right (left), thus a distribution with an excess of extremely high (low) antibody titres. The mixture weight of the immune component, $\pi(a)$, represents the age-specific seroprevalence, which is the expected proportion of immune individuals at exact age a in the given population [6]. Model estimation and inference are carried out by using Bayesian Markov Chain Monte Carlo (MCMC) methods.

For the parameters $\theta^{SP}(a) = (\mu^{SP}(a), \tau^{SP}(a))$, where τ is the precision, i.e., the reciprocal of the variance σ^2, we specify an age-specific piecewise-constant model, where the parameter θ^{SP} is constant within each of the T considered age groups $(a_{[t-1]}, a_{[t]})$:

$$\theta^{SP}(a) = \theta_1^{SP} + \sum_{t=2}^{T} \theta_{[t]}^{SP}\,, a \in \left(a_{[t-1]}, a_{[t]}\right).$$

Since we do not have any a priori knowledge about the direction of the changes across age of θ^{SP}, we use an unrestricted model, i.e. the age-dependent parameters $\theta_{[t]}^{SP}$ may either increase or decrease with respect to the preceding value $\theta_{[t-1]}^{SP}$. Since it would be too computer-intensive to fit all possible models and then select the best one using a selection criterion, we propose a Bayesian Variable Selection (BVS) approach to estimate the posterior probability of each possible model, and, in particular, the one for the model with the constant parameter [9, 11, 13].

As regards the seroprevalence $\boldsymbol{\pi(a)}$, we specify a Beta prior distribution for each age group $\boldsymbol{j}$, namely, $\boldsymbol{\pi}_{[j]} \sim \boldsymbol{Beta}(\boldsymbol{\alpha}_{[j]}, \boldsymbol{\beta}_{[j]})$, under the monotonically non-decreasing constraint $\boldsymbol{\pi}_{[j-1]} \leq \boldsymbol{\pi}_{[j]} \leq \boldsymbol{\pi}_{[j+1]}$, with the hyperparameters $\boldsymbol{\alpha}_{[j]}$ and $\boldsymbol{\beta}_{[j]}$ being given weakly-informative non-negative prior distributions. The order constraint is necessary to obtain a nonnegative estimate of the FOI. The ensuing posterior distribution of the age-specific seroprevalence is still distributed as a Beta, namely, $\boldsymbol{Beta}(\boldsymbol{Y}_{[j]} + \boldsymbol{\alpha}_{[j]}, \boldsymbol{n}_{[j]} - \boldsymbol{Y}_{[j]} + \boldsymbol{\beta}_{[j]})$, under the same order constraint. Given the estimate of the seroprevalence, the FOI is successively estimated by $\boldsymbol{\pi}'_{[j]}/(\boldsymbol{1} - \boldsymbol{\pi}_{[j]})$, where the first derivative of the prevalence at the numerator is approximated by $\left(\boldsymbol{4\pi}_{[j+1]} - \boldsymbol{3\pi}_{[j]} - \boldsymbol{\pi}_{[j+2]}\right)/\boldsymbol{2}$ and then smoothed.

Results

The VZV antibody titres data show a clear polarised distribution between the seronegative and the seropositive individuals (Figure 1A), with the seronegative cases being concentrated among children and, to a lesser extent, young adults. There is evidence for waning of the antibody protection after 40 years, as implied by the decrease in the mean of the seropositive component, with a posterior probability of 0.47 for this model (Figure 1A). There is also some evidence for a two-step waning model, showing a decrease in the 10-20 age group and again after 40 years of age, with a posterior probability of 0.38. Conversely, for what concerns the variance of the component, we do not reject the null hypothesis of the null model, as its posterior probability is 0.25. The negative estimates of the skewness for both components ($\gamma^{SN} = -1.81, \gamma^{SP} = -2.59$) imply an excess of high-value antibody titres.

The estimate of the seroprevalence (Figure 1B) shows a steep linear increase in the first ten years of age, up to around 80 % (much lower than in other European countries), followed by a slower increase in the following years. This pattern is reflected by the estimated age-specific FOI (Figure 1C), which peaks between 5 and 10 years (during primary school) and then declines to a plateau.

Table 1: Mean and standard deviation of the seronegative (SN) and the seropositive (SP) components of the skew-normal mixture model fitted to VZV data.

Age group	$\boldsymbol{\mu^{SN}}$	$\boldsymbol{\sigma^{SN}}$	$\boldsymbol{\mu^{SP}(a)}$	$\boldsymbol{\sigma^{SP}(a)}$
1-10	1.40 (1.37, 1.43)	0.34 (0.31, 0.37)	3.52 (3.44, 3.58)	0.62 (0.56, 0.70)
10-20	-	-	3.47 (3.42, 3.54)	0.63 (0.58, 0.71)
20-40	-	-	3.47 (3.40, 3.54)	0.63 (0.58, 0.71)
40+	-	-	3.33 (3.27, 3.39)	0.63 (0.58, 0.71)

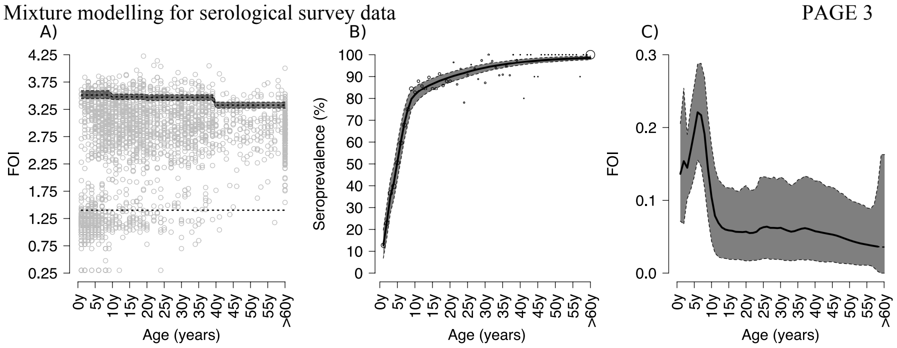

Figure 1: Fit of the mixture model to VZV data for Italy: A) scatter plot by age of antibody titres with over imposed the constant mean of the seronegative component and the age-dependent mean of the seropositive component (with 95% credible interval); B) age-specific seroprevalence with 95% credible interval; C) age-specific FOI with 95% credible interval.

Conclusions

In this work, we employed Bayesian mixture models to estimate key epidemiological parameters, such as the seroprevalence and the force of infection directly from antibody levels. Contrarily to the fixed cut-off approach, which leads to the estimation of these parameters based on binary infection status data, the mixture model adapts directly to the antibody data, without losing the information contained therein. Rather, the method allows for both the classification of individuals among different serological groups (by giving each subject an age-dependent probability of belonging to a specific group), also of those cases that would be classified as inconclusive under the fixed cut-off approach, and the estimation of the epidemiological parameters of interest. Moreover, the employment of a Bayesian MCMC approach allows to derive credible intervals around all the model parameters.

The model is also customisable enough to include a model conditional on age for the mixture parameters. The use of the BVS approach is computationally feasible and allows to show the support for all possible models in terms of posterior probability, even though one must pay attention to the variables under consideration, as the computational time dramatically increases with their number.

For all these reasons, we believe that the mixture modelling approach represents a flexible and highly customisable approach that should be seriously considered as the optimal way of analysing serological survey data. As a consequence, we claim that more attention should be devoted to the design of the serological surveys, both for what concerns the determination of the sample size by age and the measurement of the antibody titres.

An evaluation of KL-optimum designs to discriminate between rival copula models

Una valutazione della capacità del disegno KL-ottimo di discriminare tra modelli copula rivali

Laura Deldossi, Silvia Angela Osmetti, Chiara Tommasi

Abstract The problem of model discrimination has prompted a great amount of research over last years. According to the specific characteristics of the rival models (nested, non-nested, linear or not) different optimum criteria have been proposed to select design points with the aim to discriminate between rival models. Ds-, T- and KL-criteria are the most known. Up to our knowledge, in the literature there is not any study to evaluate the performance of these discrimination criteria. In this work, via a simulation study and focusing on rival copula models, we analyze the performance of the KL-optimum design applying the likelihood ratio test for non-nested models.

Abstract *Nel corso degli ultimi anni il problema di discriminare tra modelli rivali ha prodotto una grande quantità di ricerche. A seconda della tipologia di modelli rivali (annidati, non annidati, lineari o non lineari), diversi criteri sono stati proposti con l'obiettivo di selezionare il disegno ottimo per la discriminazione. Tra i più noti ricordiamo i criteri Ds-, T- e KL-. Per quanto ci consta, in letteratura non esistono studi relativi alla valutazione della loro effettiva capacità discriminatoria. In questo lavoro, attraverso uno studio di simulazione in cui abbiamo applicato il test del rapporto di verosimiglianza per modelli non annidati, abbiamo analizzato le prestazioni del disegno KL-ottimo per discriminare tra modelli bivariati la cui struttura di dipendenza è descritta attraverso una funzione copula.*

1 Introduction

A major limitation associated with the design of an experiment is that the optimality of a design depends on a priori true model that is not known in advance. Actually, very often, the experimenter has not just one but several possible models for describing a phenomenon. Thus, his/her first goal is to collect data in order to discriminate among rival models. The problem of model discrimination has prompted a great amount of research over last years. To discriminate between nested models (linear or not) [1] propose the D_s-criterion where the models are embedded in a more general one and the design aims at estimating the additional parameters as precisely as possible. A criterion to obtain optimal designs for discriminating between two homoscedastic models for normally distributed observations is T-optimality, which was introduced by [2]. A criterion based on the popular Kullback-Leibler (KL) distance is proposed by [6] for any non-normal assumption.

About discrimination between copula models, [9] apply the D_s-criterion which can be used only for nested models; for this reason, they need to introduce the mixture copula model (which includes the rival copulae as special cases). In this paper, instead, we consider the KL-optimality criterion proposed by [6] which compares directly the competing models without using any other auxiliary reference model. Specifically, we consider a bivariate model with two possible dependence structures: Clayton and Gumbel copulae (the competing models). Since, up to our knowledge, there are no studies to evaluate the performance of a discrimination criterion, in this work we analyze the performance of the KL-optimum design through a simulation study where we apply a version of Cox's test. For comparison purposes, we also describe the performance of the Uniform design, which is very often adopted in real case studies.

The paper is organized as follows. In Section 2 the bivariate copula model is introduced and the main definitions are given. The KL-optimality criterion is introduced in Section 3. Section 4 concerns the simulation study to evaluate the performance of the KL-optimum design.

2 Bivariate Copula-Based Model

Let (Y_1,Y_2) be a bivariate response variable with marginal distributions $F_{Y_1}(y_1;\alpha)$ and $F_{Y_2}(y_2;\beta)$, which depend on the unknown parameter vectors α and β, respectively. If there is an association between Y_1 and Y_2, it is necessary to define a joint model for (Y_1,Y_2).

A bivariate copula is a function $C: I^2 \to I$, with $I^2=[0,1]\times[0,1]$ and $I=[0,1]$, that, with an appropriate extension of the domain in R^2, satisfies all the properties of a cumulative distribution function (cdf). In particular, it is the cdf of a bivariate random variable (U_1,U_2), with uniform marginal distributions in $[0,1]$:

$$C(u_1,u_2;\theta_C) = P(U_1 \le u_1, U_2 \le u_2;\theta_C), \quad 0 \le u_1 \le 1 \quad 0 \le u_2 \le 1, \tag{1}$$

where $\theta_C \in \Theta_C$ is a parameter measuring the dependence between U_1 and U_2.

The importance of copulae in statistical modelling stems from Sklar's theorem [7], which states that a joint distribution can be expressed in terms of marginal distributions and a function $C(\cdot,\cdot;\theta_C)$ that binds them together. In more detail, according to Sklar's theorem, if $F_{Y_1,Y_2}(y_1,y_2;\delta,\theta_C)$ is the joint cdf of (Y_1,Y_2), where $\delta = (\alpha,\beta)$, then there exists a copula function $C\colon I^2 \to I$ such that

$$F_{Y_1,Y_2}(y_1,y_2;\delta,\theta_C) = C\{F_{Y_1}(y_1;\alpha),F_{Y_2}(y_2;\beta);\theta_C\}, \quad y_1,y_2 \in \mathbb{R}. \qquad (2)$$

If $F_{Y_1}(y_1;\alpha)$ and $F_{Y_2}(y_2;\beta)$ are continuous functions then the copula $C(\cdot,\cdot;\theta_C)$ is unique. Conversely, if $C(\cdot,\cdot;\theta_C)$ is a copula function and $F_{Y_1}(y_1;\alpha)$ and $F_{Y_2}(y_2;\beta)$ are marginal cdfs, then $F_{Y_1,Y_2}(y_1,y_2;\delta,\theta_C)$ given in (2) is a joint cdf.

From (2) we have that a copula captures the dependence structure between the marginal probabilities. This idea allows researchers to consider marginal distributions and the dependence between them as two separate but related issues. For each copula there exists a relationship between the parameter θ_C and Kendall's τ coefficient (see [7] pp. 158-170) and between θ_C and the lower and upper tail dependence parameters λ_l and λ_u (which measure the association in the tails of the joint distribution; see [7] pp. 214-216). Several bivariate copulae have been proposed in the literature (see for instance [7]). In this paper we consider only Clayton and Gumbel copulae, which are recalled in Table 1. Both these copulae allow only for positive association between variables ($\tau \geq 0$) but they exhibit strong *left* and strong *right* tail dependence, respectively.

3 KL-Optimality Criterion

An approximate design ξ is a discrete probability measure on a compact experimental domain $\mathscr{X}$; $\xi(x)$ represents (at least approximatively) the proportion of observations to be taken at the experimental condition x. An optimal design maximizes a concave functional of ξ, which is called optimality criterion and reflects an inferential goal.

Let (Cl,G) denote Clayton and Gumbel copulae, respectively and let (θ_{Cl},θ_G) be the corresponding dependence parameters. From now on, we assume that nominal values for δ, θ_{Cl} and θ_G are available; hence, we compute locally optimum designs. In order to discriminate between the two rival copulae, we propose to use

Table 1 Copula functions and related association parameters

Copula	$C(u_1,u_2;\theta)$	$\theta \in \Theta$	$\tau = \tau(\theta)$
Clayton	$(u_1^{-\theta} + u_2^{-\theta} - 1)^{-1/\theta}$	$\theta \in (0,\infty)$	$\tau = \theta/(\theta+2)$
Gumbel	$\exp\left(-\left[\{-\ln(u_1)\}^{\theta} + \{-\ln(u_2)\}^{\theta}\right]^{1/\theta}\right)$	$\theta \in [1,\infty)$	$\tau = 1 - 1/\theta$

the following geometric mean of KL-efficiencies:

$$\Phi_{KL}(\xi;\delta,\theta_{Cl},\theta_G) = \left\{\mathrm{Eff}_{G,Cl}(\xi;\theta_{Cl})\right\}^{\gamma}\cdot\left\{\mathrm{Eff}_{Cl,G}(\xi;\theta_G)\right\}^{1-\gamma} \quad 0\le\gamma\le 1,$$

where γ is a suitably chosen weight which balances the belief in the two competing copulae;

$$\mathrm{Eff}_{i,j}(\xi;\theta_j) = \frac{I_{i,j}(\xi;\theta_j)}{I_{i,j}(\xi^*_{i,j};\theta_j)}, \quad \xi^*_{ij} = \arg\max_{\xi} I_{i,j}(\xi;\theta_j), \quad i,j = Cl,G \tag{3}$$

and

$$I_{i,j}(\xi;\theta_j) = \inf_{\theta_i} \sum_{x\in\mathscr{X}} \mathscr{I}\left\{f^{j}_{y_1y_2}(x;\delta,\theta_j), f^{i}_{y_1y_2}(x;\delta,\theta_i)\right\}\,\xi(x), \tag{4}$$

is the KL-criterion proposed by [6]. Here $\mathscr{I}\left\{f^{j}_{y_1y_2}(x;\delta,\theta_j), f^{i}_{y_1y_2}(x;\delta,\theta_i)\right\}$ denotes the Kullback-Leibler divergence between the true density function $f^{j}_{y_1y_2}(x;\delta,\theta_j)$ and the rival one $f^{i}_{y_1y_2}(x;\delta,\theta_i)$, with $i,j = Cl,G$.

4 Evaluation of the performance of the KL-optimum design: an example with bivariate binary logistic model

In order to assess the ability of the KL-optimum design to discriminate between two competing copula models we employ a version of Cox's test (see [3] and [4]).

Given δ, τ and a design ξ, let (y_{1i}, y_{2i}) for $i = 1,2,...n$ be a sample of outcomes from one of the two rival models. For a specific Scenario δ and for a specific value of Kendall's τ coefficient, we generate M samples of size n, at a design ξ. Then, we check how many times the likelihood ratio test provides an evidence in favour of each model. Following [8] we have to test both the following systems of hypotheses:

$$A)\ \begin{cases} H_{Cl}:\ \mathscr{F}_{Cl} = \{f^{Cl}_{y_1y_2}(x;\delta,\theta_{Cl}),\ \theta_{Cl}\in\Theta_{Cl}\} \\ H_G:\ \mathscr{F}_G = \{f^{G}_{y_1y_2}(x;\delta,\theta_G),\ \theta_G\in\Theta_G\} \end{cases}$$

$$B)\ \begin{cases} H_G:\ \mathscr{F}_G = \{f^{G}_{y_1y_2}(x;\delta,\theta_G),\ \theta_G\in\Theta_G\} \\ H_{Cl}:\ \mathscr{F}_{Cl} = \{f^{Cl}_{y_1y_2}(x;\delta,\theta_{Cl}),\ \theta_{Cl}\in\Theta_{Cl}\} \end{cases}$$

From now on, we omit the argument x and δ for ease of notation. As test statistics, we consider the log-likelihood ratios:

$$T_{ClG} = L_{Cl}(\widehat{\theta}_{Cl}) - L_G(\widehat{\theta}_G) \quad \text{and} \quad T_{GCl} = L_G(\widehat{\theta}_G) - L_{Cl}(\widehat{\theta}_{Cl}), \tag{5}$$

where $L_{Cl}(\theta_{Cl})$ and $L_G(\theta_G)$ are the log-likelihood functions under H_{Cl} and H_G, respectively, and $\widehat{\theta}_{Cl}$ and $\widehat{\theta}_G$ are the corresponding maximum likelihood estimators.

Let p_{ClG} and p_{GCl} be the p-values of T_{ClG} and T_{GCl}, respectively. Whenever $p_{ClG} > p_{GCl}$ (or $p_{GCl} > p_{ClG}$) we accept Clayton (or Gumbel) model.

In the case of non-nested models the log-likelihood ratio is not (asymptotically) distributed as a Chi-squared random variable (see for instance [4, 8]). Hence, we implement a Monte Carlo procedure to approximate the sample distribution of T_{ClG} and T_{GCl} and to compute the corresponding p-values, $\hat{p}_{ClG}$ and $\hat{p}_{GCl}$ under H_{Cl} and H_G, respectively. Differently, [3, 4] proposed the asymptotic distribution of the log-likelihood ratio suitably standardized.

Consider now an example in dose finding study. Let (Y_1, Y_2) be a binary response variable where both Y_1 and Y_2 take values in $\{0, 1\}$ (1 denotes occurrence and 0 denotes no occurrence). We consider (see [5]) the following logistic models for the marginal success probabilities of efficacy and toxicity:

$$\pi_1(x;\alpha) = P(Y_1 = 1|x;\alpha) = \frac{e^{\alpha_0+\alpha_1 x+\alpha_2 x^2}}{1+e^{\alpha_0+\alpha_1 x+\alpha_2 x^2}}, \quad \alpha = (\alpha_0, \alpha_1, \alpha_2),$$
$$\pi_2(x;\beta) = P(Y_2 = 1|x;\beta) = \frac{e^{\beta_0+\beta_1 x}}{1+e^{\beta_0+\beta_1 x}}, \quad \beta = (\beta_0, \beta_1),$$

where $x \in \mathscr{X} = [-1, 1]$ denotes the standardized dose of a drug.

If $C(\cdot,\cdot;\theta_C)$ is a copula function which models the dependence between $\pi_1(x;\alpha)$ and $\pi_2(x;\beta)$, then the joint probability of $(Y_1$,$Y_2)$ at the dose x is

$$p^C_{11}(x;\delta,\theta_C) = P(Y_1 = 1, Y_2 = 1|x;\delta,\theta_C) = C\{\pi_1(x;\alpha), \pi_2(x;\beta);\theta_C\}. \qquad (6)$$

Given $\delta = (1, 1.5, -3, 2.5, 5)$ and $\tau = 0.8$, we perform two Monte Carlo simulations, based on the generation of $M = 5000$ samples of size n from model (6) using (in the data generating model) the Clayton copula with $\theta_{Cl} = 8$ and the Gumbel copula with $\theta_G = 5$, respectively ($\theta_{Cl} = 8$ and $\theta_G = 5$ correspond to the same value of the association parameter $\tau = 0.8$). The doses and the proportions of observations to be taken at each dose are given by the KL-optimum design, which is reported in the first column of Table 2.

Table 2 KL-optimal design ξ_{KL} for $(\theta_{Cl};\theta_G) = (8;5)$ and Uniform design ξ_{Unif}

ξ_{KL}	ξ_{Unif}
$\left\{\begin{array}{cc} -0.793 & -0.050 \\ 0.470 & 0.530 \end{array}\right\}$	$\left\{\begin{array}{ccccc} -1 & -0.5 & 0 & 0.5 & 1 \\ 0.2 & 0.2 & 0.2 & 0.2 & 0.2 \end{array}\right\}$

We apply the likelihood test and compute the Monte Carlo p-values of T_{GCl} and T_{ClG}: p^m_{ClG} and p^m_{ClG} for $m = 1, \ldots, M$. We calculate the percentages of correct selection of the true model, i.e. the percentage of times that $p^m_{ClG} > p^m_{GCl}$ for $m = 1, \ldots, M$, when the data are generated from the Clayton copula, and the percentage of times that $p^m_{GCl} > p^m_{ClG}$ for $m = 1, \ldots, M$, when the data are generated from the Gumbel copula. The results are reported in the third and the fourth columns of Table 3.

We can observe that using the KL-optimum design the percentage of correct decision is around 72% from $n = 100$ and it exceed 90% from $n = 500$. Furthermore, the percentage of wrong decision decreases substantially as n increases. Taking into

Table 3 Monte Carlo simulation of the likelihood ratio test ($M = 5000$): data generated from Clayton and Gumbel copulae for $\tau = 0.8$ at the KL-optimum design ξ_{KL} (columns 3-4) and at the Uniform design ξ_{Unif} (columns 5-6)

n	**Test decision**	ξ_{KL} **True copula model (%)**		ξ_{Unif} **True copula model (%)**	
		Clayton	Gumbel	Clayton	Gumbel
100	Correct decision	72	71.88	60.54	32.64
	Wrong decision	28	28.12	39.46	67.36
200	Correct decision	82.28	84.04	67.50	43.12
	Wrong decision	17.72	15.96	32.50	56.88
500	Correct decision	95.56	95.4	81.20	63.38
	Wrong decision	4.44	4.6	18.80	36.62
1000	Correct decision	99.5	99.2	92.84	81.14
	Wrong decision	0.5	0.8	7.16	18.86

account that the competing models differ only for the tail dependence, the obtained results are excellent. Finally, for comparison purposes, we analyze the performance of the Uniform design defined in the second column of Table 2. The corresponding percentages of correct decision and wrong decision are listed in the fifth and sixth columns of Table 3. We can observe that the percentage of correct selections obtained with the KL-optimum design is substantially better than those corresponding to the uniform design, especially for $n < 500$.

Variational Approximations for Frequentist and Bayesian Inference

Approssimazioni Variazionali per Inferenza Frequentista e Bayesiana

Luca Maestrini and Matt P. Wand

Abstract Variational approximations are a flexible instrument for deterministic approximate inference in complex statistical models. We illustrate the concept of variational approximation from both frequentist and Bayesian perspectives, providing methodological examples that take advantage of the classical concepts of exponential families.

1 Introduction

Variational approximations is a class of techniques for deterministic approximations which is now part of mainstream computer science and machine learning methodology. Applications cover a wide area of elaborate problems such as those arising in speech recognition, graphical models, document retrieval or genetic linkage analysis [2]. These methods are also widening their presence in statistics as a response to the increasing complexity of models in modern statistical applications [4].

We describe the concept of variational approximation referring to a Bayesian model. In keeping with the statistics literature on variational approximations, let p

be the generic symbol for a density function, denote with $\mathbf{y}$ the observed data, $\theta \in \Theta$ the parameters to be inferred and let q be an arbitrary density function over Θ.

The logarithm of the marginal likelihood satisfies

$$\begin{aligned}\log p(\mathbf{y}) &= \int q(\theta)\log\left\{\frac{p(\mathbf{y},\theta)}{q(\theta)}\right\}d\theta + \int q(\theta)\log\left\{\frac{q(\theta)}{p(\theta|\mathbf{y})}\right\}d\theta \\ &\geq \int q(\theta)\log\left\{\frac{p(\mathbf{y},\theta)}{q(\theta)}\right\}d\theta, \qquad (1)\end{aligned}$$

giving a lower bound $\underline{p}(\mathbf{y};q)$ on the marginal likelihood such that

$$p(\mathbf{y}) \geq \underline{p}(\mathbf{y};q) \equiv \exp\int q(\theta)\log\left\{\frac{p(\mathbf{y},\theta)}{q(\theta)}\right\}d\theta. \qquad (2)$$

Maximization of $\underline{p}(\mathbf{y};q)$ is equivalent to minimization of the Kullback–Leibler divergence between $q(\theta)$ and $p(\theta|\mathbf{y})$. The key idea of variational approximations is to approximate the posterior density $p(\theta|\mathbf{y})$, or the likelihood function itself in the frequentist case, by a $q(\theta)$ for which $\underline{p}(\mathbf{y};q)$ is more tractable than $p(\mathbf{y})$ and obtain approximate estimates through lower bound maximization. Tractability is achieved by restricting $q(\theta)$ to a more manageable class of densities. Common restrictions for the approximating density are:

a. $q(\theta)$ is a member of a parametric family of density functions;
b. $q(\theta)$ factorizes into $\prod_{i=1}^{M} q_i(\theta_i)$, for some partition $\{\theta_1,\ldots,\theta_M\}$ of θ.

We apply restrictions (a) and (b) to describe frequentist and Bayesian methodologies respectively which are known as Gaussian variational approximation and variational message passing.

2 Gaussian Variational Approximation

Frequentist models that stand to benefit from variational approximations are those for which the likelihood specification involves conditioning on a vector of latent variables $\mathbf{u}$. Given a log-likelihood of the model parameter vector θ

$$\ell(\theta) \equiv \log p(\mathbf{y};\theta) = \log\int p(\mathbf{y}|\mathbf{u};\theta)\,p(\mathbf{u};\theta)\,d\mathbf{u},$$

interest is in obtaining $\hat{\theta} = \underset{\theta}{\operatorname{argmax}}\,\ell(\theta)$, maximum likelihood estimate of θ.

In practice, $\ell(\theta)$ may not be available in closed form because of analytically intractable integration. In such circumstances and depending on the forms of $p(\mathbf{y}|\mathbf{u};\theta)$ and $p(\mathbf{u};\theta)$, variational approximations can provide a more amenable approximation. However, nontrivial frequentist examples where an explicit solution arises by applying a product density methodology as in (b) are not known.

Suppose instead to restrict q to a parametric family of densities $\{q(\mathbf{u};\xi) : \xi \in \boldsymbol{\Xi}\}$, similarly to (a). Then, similarly to (1) we can define the log-likelihood lower bound

$$\underline{\ell}(\theta,\xi;q) \equiv \int q(\mathbf{u};\xi)\log\left\{\frac{p(\mathbf{y},\mathbf{u};\theta)}{q(\mathbf{u};\xi)}\right\}d\mathbf{u}$$

and a new maximization problem

$$\left(\hat{\underline{\theta}},\hat{\underline{\xi}}\right) = \underset{\theta,\xi}{\operatorname{argmax}}\underline{\ell}(\theta,\xi;q),$$

with $\hat{\underline{\theta}}$ variational approximation to the maximum likelihood estimator. Furthermore, standard error estimates can be obtained by plugging in $\hat{\underline{\theta}}$ for θ and $\hat{\underline{\xi}}$ for ξ in the variational approximate Fisher information matrix arising from replacement of $\ell(\theta)$ by $\underline{\ell}(\theta,\xi;q)$.

In *Gaussian variational approximations* (GVA), $q(\mathbf{u};\xi)$ is assumed to be a multivariate normal density [5]. We investigate the application of GVA to generalized linear mixed models (GLMMs) for semiparametric regression.

Consider GLMMs within one-parameter exponential family

$$\mathbf{y}|\mathbf{u} \sim \exp\left\{\mathbf{y}^{\mathrm{T}}(\mathbf{X}\beta+\mathbf{Zu}) - \mathbf{1}^{\mathrm{T}}b(\mathbf{X}\beta+\mathbf{Zu}) + \mathbf{1}^{\mathrm{T}}c(\mathbf{y})\right\}, \quad \mathbf{u} \sim N(\mathbf{0},\mathbf{G})$$

where $\mathbf{X}$ and $\mathbf{Z}$ are general design matrices. Matrix $\mathbf{G}$ models random effect covariance, while $\mathbf{Z}$ can include, for instance, spline basis functions. The functions b and c characterize members of the exponential family.

Setting $q(\mathbf{u};\xi)$ to be the $N(\mu,\boldsymbol{\Lambda})$ we can derive variational lower bound

$$\begin{aligned}\underline{\ell}(\beta,\mathbf{G},\mu,\boldsymbol{\Lambda}) = {} & \tfrac{n}{2} + \mathbf{y}^{\mathrm{T}}(\mathbf{X}\beta+\mathbf{Z}\mu) - \mathbf{1}^{\mathrm{T}}B\left(\mathbf{X}\beta+\mathbf{Z}\mu, \mathrm{dg}\left(\mathbf{Z}\boldsymbol{\Lambda}\mathbf{Z}^{\mathrm{T}}\right)\right) + \mathbf{1}^{\mathrm{T}}c(\mathbf{y}) \\ & -\tfrac{1}{2}\left\{\mu^{\mathrm{T}}\mathbf{G}^{-1}\mu + \mathrm{tr}\left(\mathbf{G}^{-1}\boldsymbol{\Lambda}\right)\right\} + \tfrac{1}{2}\log\left|\mathbf{G}^{-1}\boldsymbol{\Lambda}\right|, \qquad (3)\end{aligned}$$

where n is the number of rows in $\mathbf{y}$, $B\left(\mu,\sigma^2\right) \equiv \int_{-\infty}^{\infty} b(\mu+\sigma x)\,\phi(x)\,dx$, $\phi(x)$ is the $N(0,1)$ density function and, for a square matrix $\mathbf{A}$, $\mathrm{dg}(\mathbf{A})$ is the column vector containing the diagonal entries of $\mathbf{A}$. For vector arguments, function B is applied in element-wise fashion. Inference and prediction on nonparametric, additive or general semiparametric models in GLMM form follow directly from the lower bound optimization.

3 Variational Message Passing

In Bayesian inference, a mean field variational approximation $q^*(\theta)$ is the maximizer of expression (2) subject to a product density restriction as in (b).

It can be shown that the optimal q-density functions satisfy

$$q^*(\theta_i) \propto E_{q(\theta\backslash\theta_i)}\{p(\theta_i|\mathbf{y},\theta\backslash\theta_i)\}, \quad 1 \le i \le M, \qquad (4)$$

where $\theta \backslash \theta_i$ denotes the entries of θ with θ_i omitted. Expression (4) gives rise to an iterative scheme for obtaining the parameters of the optimal density functions $q^*(\theta_i)$ which is known as mean field variational Bayes. *Variational message passing* (VMP) arrives at the same approximation via message passing on an appropriate factor graph. Among the several variants of VMP in the literature, we consider the factor graph fragment approach introduced in [8] and based on [3], whose major advantage is that calculations only need to be done once for a certain distribution family and can be easily adapted to accommodate more complex model structures. The use of conjugates exponential families streamlines the algebraic and computational effort in deriving messages between factor graph components at the base of VMP algorithms. A listing of such a procedure can be found in Sect. 2.5 of [8].

This framework gives rise to a class of VMP algorithms to approximate fitting and inference for a wide range of common and non-standard likelihoods.

4 Illustrations

The next two illustrative examples are applications in frequentist and Bayesian settings that witness the flexibility of variational approximations. The former provides approximate estimates for a simulated Poisson spline regression model, the latter concerns a skew t response regression model on real data.

4.1 GVA for Poisson Spline Regression

We simulate 500 observations from a Poisson process as a function of a $\text{Uniform}(0,1)$ covariate and estimate a Poisson semiparametric regression model with canonical link using O'Sullivan penalized splines [6] on 50 interior knots via GVA.

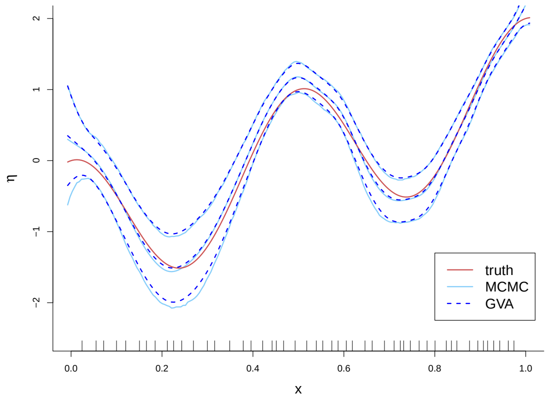

Fig. 1 Data generating process for the Poisson semiparametric regression. 95% MCMC credible intervals and GVA confidence bands are compared to the true η function that generates data according to a $\text{Poisson}(e^{\eta})$ distribution. Knot positions are also displayed.

Let $\hat{\boldsymbol{\Lambda}}_{\text{GVA}}$ be the estimate of $\boldsymbol{\Lambda}$ obtained maximizing the Gaussian variational lower bound (3) adapted to the current model. Given $\text{H}_{\mu\mu}\underline{\ell}$ Hessian matrix of $\underline{\ell}(\beta, \mathbf{G}, \mu, \boldsymbol{\Lambda})$ with respect to μ, one can prove that $\hat{\boldsymbol{\Lambda}}_{\text{GVA}} = \left(-\text{H}_{\mu\mu}\underline{\ell}\right)^{-1}$. We use this result and the estimates obtained through the lower bound optimization to derive the plot in Fig. 1, which concerns the true generating process. For a rough performance evaluation we plot GVA results as in (2) with those from Markov chain Monte Carlo (MCMC) samples obtained using the `R` package `rstan` [7] setting priors $N\left(0, 10^5\right)$ on β and Half-Cauchy$\left(10^5\right)$ on the scale parameter appearing from defining $\mathbf{G} \equiv \sigma^2\mathbf{I}$. GVA seems to adequately approximate the MCMC process prediction and credible intervals.

4.2 VMP for Skew t Regression

We illustrate the parameter estimation of a skew t regression model via VMP.

Consider the dataset examined in [1] with the linear model

$$y_i = \beta_0 + \beta_1 \text{CRSP}_i + \varepsilon_i, \quad \varepsilon_i \sim \text{Skew-t}\left(0, \sigma^2, \lambda, \nu\right), \quad 1 \leq i \leq 60$$

with λ parameter of symmetry and $\nu > 0$ degrees of freedom. The variables y_i and CRSP_i denote the Martin Marietta company excess rate and the return excess index for the New York Stock Exchange respectively. We adopt the skew t distribution described in [1] and write it in terms of standard normal and inverse χ^2 auxiliary variables to limit the complexity of algebraic derivations and numerical integration appearing in the derivation of a VMP algorithm. We choose a product density restriction on $q\left(\theta\right)$ which is a compromise between approximation performances and algebraic complexity. We approximate the parameter posterior densities with VMP

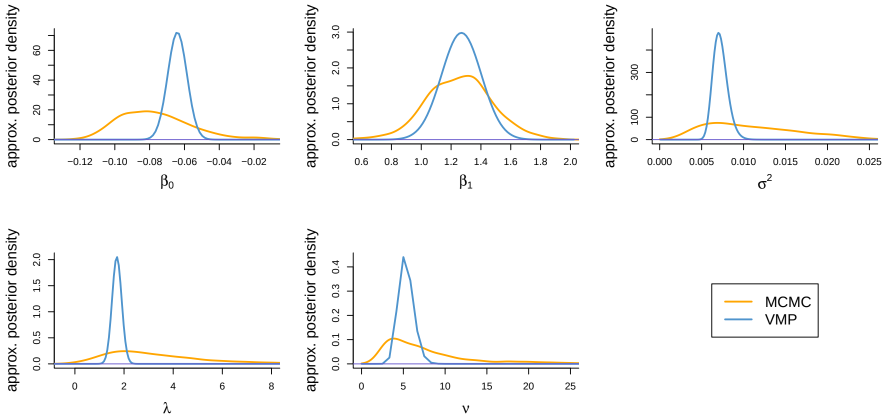

Fig. 2 Martin Marietta data: posterior density plots via MCMC and VMP.

and compare them to MCMC density estimation via `rstan`. The hyperparameters for β are fixed to $\mu_\beta = \mathbf{0}$ and $\boldsymbol{\Sigma}_\beta = 10^5\mathbf{I}$ over a prior $N\left(\mu_\beta, \boldsymbol{\Sigma}_\beta\right)$ while those on the shape parameters are Inverse-$\chi^2(0.01, 0.01)$ on the squared scale, $N\left(0, 10^5\right)$ on λ and $\Gamma\left(1, 0.01\right)$ on ν. Posterior density plots are shown in Fig. 2. VMP curves apparently underestimate the variance of MCMC posterior densities but locate around their modes.

Node-specific effects in latent space modelling of multidimensional networks

Effetti nodo-specifici nell'analisi a spazi latenti di reti multidimensionali

Silvia D'Angelo and Marco Alfò and Thomas Brendan Murphy

Abstract Social network analysis is a growing and popular field in statistics since the second half of the last century. Although single networks have been largely studied and a variety of models has been developed for their analysis, multidimensional networks are still a young and quite unexplored subject. In most cases, the attention has been focused on the specific case of dynamic networks. The aim of the present work is to provide an extension of latent space models for network analysis to the case of multidimensional networks. We also introduce node-specific effects (sender and receiver effects), typical to the single network literature, to allow for a more flexible representation of the multidimensional network. Finally, a real data application will be presented.
Abstract A partire dalla metà dello scorso secolo, l'analisi delle reti sociali è un campo popolare e in pieno sviluppo in statistica. Sebbene le reti singole siano state ampiamente studiate e siano disponibili una larga varietà di modelli per la loro analisi, l'estensione al caso di reti multidimensionali è ad oggi poco esplorata. Nella maggior parte dei casi, l'attenzione è stata rivolta al caso particolare delle reti dinamiche. In questo lavoro presenteremo un'estensione dei modelli a spazi latenti alle reti multidimensionali. Inoltre, introdurremo effetti nodo-specifici (sender e receiver), tipici in letteratura nel caso di reti singole, per descrivere un modello flessibile di reti multidimensionalli. Infine, verrà presentata un'applicazione a dati reali.

1 Introduction

Social network analysis is a well known and vibrant branch of statistics. As network structures arise in many different contests, network analysis has seen application in a broad variety of fields.

In general, a network is defined by a set of units (the nodes) among which a relation can be established. In the most simple case, the relation to be recorded between a pair of nodes (a dyad), is either present or not present. If it is present, the dyad is said to be linked by an edge. A large variety of models for the analysis of single networks (where a single relation is recorded) has been proposed in the literature (see [7] for a review) and has paved the way for the analysis of more complex network structures, such as multidimensional networks. Recent works on multidimensional networks are those of Gollini and Murphy [1], D'Angelo et al. [6], Salter-Townshend and McCormick [8], Durante et al. [9] and Sewell and Chen [10]. In the present work, we illustrate a model to describe the ties observed in a multidimensional network by means of underlying similarities among the nodes and node-specific characteristics. Section 2 describes the proposed model, while section 3 presents an application of the model to the well known Vickers data [3].

2 The model

Let us define a multidimensional network (or multiplex) as a collection of K networks (or views), defined on the same node set N. Each network defines a different relation among the nodes in N. That is, the edge set $E^{(k)}$, $k = 1, \dots, K$ may be different in each view. A multidimensional network can be represented by means of graph theory as a collection of graphs (G), defined on a constant node set N:

$$G = \left(N, \left\{E^{(k)}; k = 1, \dots, K\right\}\right),$$

where a single network is $G^{(k)} = \left(N, E^{(k)}\right)$, $k = 1, \dots, K$. If the multiplex collects binary relations, that is whether something is verified or it is not, the realization of G will be denoted by a collection of adjacency matrices

$$\mathbf{Y} = \left\{y^{(1)}, \dots, y^{(k)}, \dots, y^{(K)}\right\}, \quad k = 1, \dots, K,$$

with n the number of observed nodes. The general entry of the k^{th} matrix will be $y_{ij}^{(k)} = 1$ if the relation k is present between nodes i and j and $y_{ij}^{(k)} = 0$ otherwise. Our aim is at describing the association structure underlying the multidimensional network and at estimating edge probabilities.

A first approach in the context of latent space models for networks, has been introduced by Hoff and Raftery [2]. This class of model assumes that the probability of an edge between two nodes depends on how similar they are;

this similarity refers to their distance in a so called latent (or social) space. The coordinates of the nodes in this space (and therefore the distances) are unknown and the aim is at recovering them to depict the similarities among the nodes and reconstruct the edge probabilities. This class of model was partially extended to the context of multidimensional networks by Gollini and Murphy [1] and D'Angelo et al. [6].

As we are modelling binary adjacency matrices, it is reasonable to model edge probabilities with a logistic regression (as in [6]):

$$Pr\left[y_{ij}^{(k)} = 1 \mid d(z_i,z_j), \alpha^{(k)}, \beta^{(k)}\right] = \frac{\exp\left\{f\left(\alpha^{(k)}, \beta^{(k)}, d(z_i,z_j)\right)\right\}}{1+\exp\left\{f\left(\alpha^{(k)}, \beta^{(k)}, d(z_i,z_j)\right)\right\}} \tag{1}$$

where z_i and z_j are the latent coordinates of nodes i and j and $d(\cdot)$ is the squared Euclidean distance. As the aim is at recovering the similarities among the nodes, the latent space is supposed to be common to all the networks. The sets of parameters $\boldsymbol{\alpha} = \left(\alpha^{(1)}, \dots, \alpha^{(K)}\right)$ and $\boldsymbol{\beta} = \left(\beta^{(1)}, \dots, \beta^{(K)}\right)$ help to distinguish network connectivity and, in general, link probabilities in the different networks.

We may define a more flexible specification of the edge probabilities by introducing node-specific parameters, to account for the direction of the edge in direct multiplex:

$$Pr\left[y_{ij}^{(k)} = 1 \mid d(z_i,z_j), \alpha^{(k)}, \beta^{(k)}, \theta_i^{(k)}, \gamma_j^{(k)}\right] = \frac{\exp\left\{f\left(\alpha^{(k)}, \beta^{(k)}, d(z_i,z_j), \theta_i^{(k)}, \gamma_j^{(k)}\right)\right\}}{1+\exp\left\{f\left(\alpha^{(k)}, \beta^{(k)}, d(z_i,z_j), \theta_i^{(k)}, \gamma_j^{(k)}\right)\right\}} \tag{2}$$

The set of parameters $\boldsymbol{\Gamma} = \left(\boldsymbol{\Gamma}^{(1)}, \dots, \boldsymbol{\Gamma}^{(K)}\right)$, where $\boldsymbol{\Gamma}^{(k)} = \left(\gamma_1^{(k)}, \dots, \gamma_j^{(k)}, \dots, \gamma_n^{(k)}\right)$ and $\boldsymbol{\Theta} = \left(\boldsymbol{\Theta}^{(1)}, \dots, \boldsymbol{\Theta}^{(K)}\right)$, where $\boldsymbol{\Theta}^{(k)} = \left(\theta_1^{(k)}, \dots, \theta_i^{(k)}, \dots, \theta_n^{(k)}\right)$ describe, respectively, receiver and sender effects (see for example Krivitsky et al. [5]). Within each view, sender and receiver parameters are assumed to have a multiplicative effect on the intercept parameter $\alpha^{(k)}$ and to be bounded in $[-1,1]$.

Estimation of the proposed model parameters is carried out by employing a hierarchical Bayesian framework, using a Metropolis within Gibbs algorithm.

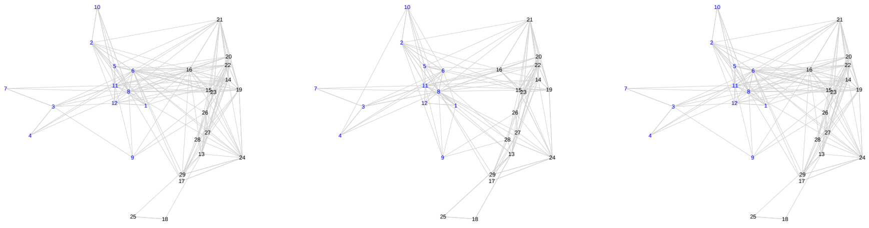
3 Application

The model proposed in section 2 has been applied to a benchmark dataset, the Vickers data [3], see for example [4]. In this case three different kind of relations among 29 students have been collected. In particular, the three corresponding networks describe:

1. if student i gets on with student j,
2. if student i is best friend with student j,
3. if student i works with student j.

None of the networks is sparse and the observed densities are, respectively, 0.445, 0.223 and 0.244. The observed out-degree (the number of ties a node sends) and in-degree (the amount of ties a node attracts) distributions in the three networks show that only a few nodes interact with most of the others, while the majority of them is less active.

Figure 1 shows the estimated latent positions of the students. The nodes have been coloured according to students gender, with blue and black numbers representing, respectively, males and females. A group structure seems to emerge in the latent space, with reference to the gender. This is confirmed by the heatmap in figure 2, which represents the estimated distances among the nodes and exhibits a clear block structure. Indeed, it seems that male students interact more with other male students, while females prefer the company of other females, exception made for a small group of nodes. These are three boys (5, 8, 11) and two girls (16, 21), all lying in the centre of the latent space. These five serve as a bridge between the two groups in the class. Figure 3 shows the estimated sender (and receiver) effects, together with the observed out-degrees (and in-degrees), for each network. The estimated coefficients are in line with what observed in the data, showing that the proposed model is a good candidate in representing the Vickers multiplex.



(a) (b) (c)

Fig. 1: Estimated latent coordinates for the nodes and observed edges. The relations represented are: get on well (figure *a*), best friend (figure *b*) and work with (figure *c*). Black numbers correspond to female students and blue numbers to males.

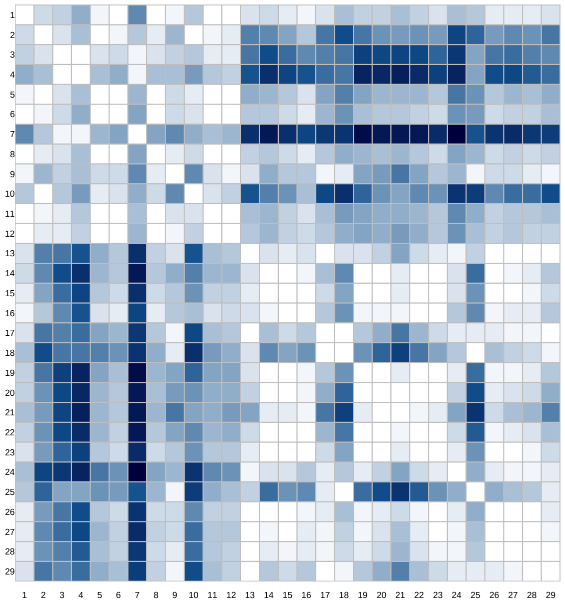


Fig. 2: Estimated distances between the nodes in the latent space. Nodes $1-12$ are male students, while nodes $13-29$ are females.

Fig. 3: Estimated sender effects vs. observed out-degrees (figure *a*) and estimated receiver effects vs observed in-degrees (figure *b*) in the Vickers seventh grade networks.

4 Discussion

In this work we have proposed a novel approach to model multidimensional networks that builds both on latent space model for networks and on two typical instruments of social networks analysis: sender and receiver effects. A single latent space is employed to model the similarities between the nodes and node-specific parameters are introduced to model the possible presence of heterogeneity across the multiple networks. This approach allows a flexible reconstruction of the edge probabilities and could serve as an alternative to modelling each network of the multiplex via its own latent space [1]. Indeed, the use of sender and receiver effects prevents from choosing the dimensions of the latent spaces, which could be a relevant issue in some contexts. Unidimensional node-specific parameters would capture network-specific behaviours while the common latent space would represent the overall relationships between the actors in the multiplex. Also, a single latent space allows a straightforward visualization of the multiplex, a useful feature, especially when the number of views is high.

Statistics for Consumer Research

A panel data analysis of Italian hotels

Un'analisi di dati panel di hotel italiani

Antonio Giusti, Laura Grassini, Alessandro Viviani[1]

Abstract The present paper aims at presenting a study on the performance of the hotel industry in Italy, by analysing a panel of firms (ATECO 55.1) in the years 2008-2015. After an analysis of price and operating cost changes at the aggregate level (paragraph 2), a quantile regression is applied on microdata for modelling total production (sales). The model tries to distinguish the contribution of the quantity and quality of labor.

Abstract *Il lavoro propone un'analisi della performance dell'industria alberghiera in Italia, analizzando un panel di hotel (ATECO 55.1) negli anni 2008-2015. Dopo un confronto fra costi e prezzi a livello aggregato (paragrafo 2), il lavoro procede con l'applicazione della regressione quantile sui microdati, per modellare l'andamento della produzione in funzione dei fattori produttivi. Particolare attenzione è rivolta al fattore lavoro*.

Key words: hotel industry, operating costs, production, panel data.

1. Introduction

Hotels have a variety of internet distribution channels in selling rooms but the cost of using those intermediaries is considerable. Online Travel Agencies (OTA) and opinion aggregator websites have deeply changed the structure of the hospitality industry with consequences in the mechanisms of economic value creation (Toh, Raven, DeKay, (2011); Santoro, (2015)). It follows that an interesting issue can be the analysis of hotel operating costs and productivity. In this respect, even though the most used metrics in hotel industry refer to the number of rooms (room occupancy

Alessandro Viviani, Dipartimento di Statistica, informatica, applicazioni, Università degli Studi di Firenze, email: viviani@disia.unifi.it.

rate, revenue per available room, etc.), the presence of an intensive rivalry among firms generates high pressure to increase efficiency and productivity, so that traditional accounting measures are used, as well (Sainaghi, (2011); Sainaghi, Phillips, Zavarrone, (2017)).

As far as productivity and efficiency are concerned, current research at micro level encounters difficulties in selecting input and output, in their measurement and modelling and, namely, many empirical analyses are carried out on primary survey data of limited size (Sainaghi, Phillips, Zavarrone, (2017)). However, there are also applications of traditional growth accounting for hotel and restaurant industries (Smeral, (2009)).

The present work develops an analysis of accounting data of a panel of Italian hotels in the years 2008-2015. Two main issues are addressed: 1) whether the cost changes of inputs are recovered by output price changes; 2) an evaluation of the contribution of production factors, by the estimation of a function explaining total production (sales) through the regression quantile approach. A special attention is given to labor, as we have tried to distinguish between labor quantity and quality. In fact, human resources are a key factor in the service sector and in the accommodation industry in particular. Moreover, the increasing number of services offered by hotels (suites, dining and banquet facilities, etc.) often requires skills that are far away from the hotel core competencies (Hemmington, and King, 2000; Gonzalez-Rivera, 2005). In many cases, outsourcing is an effective way to overcome those problems.

Data are derived from Aida database, and refer to more than 3000 Italian hotels. Unfortunately, Aida database does not provide information about hotel category (number of stars) or number of rooms.

The paper is structured as follows. Section 2 presents the analysis of process and costs at the aggregate level. Section 3 describes the results of the model estimation.

2. Operating costs, operating margin and productivity

The operating-revenue to operating-cost ratio (*RVC*) and global productivity (*GP*) at time *t* are defined respectively as (Bosch-Badia, (2010)):

$$RVC_t = \frac{RV_t}{OC_t} = \frac{Operating\ revenue\ at\ current\ prices}{Operating\ costs\ at\ current\ prices}$$

$$GP_{t,0} = \frac{Operating\ revenue\ at\ constant\ prices}{Operating\ costs\ at\ constant\ prices}$$

Let be $opc_{t,0}$ the synthetic price index of outputs and $ipc_{t,0}$ as the synthetic price index of inputs, at base 0. The ratio between these two price indexes is:

$$pch_{t,0} = \frac{opc_{t,0}}{ipc_{t,0}} \quad \text{so that} \quad RV_t = GP_t\ pch_{t,0}$$

Finally, considering m_t as the operating margin:

$$m_t = \frac{RV_t - OC_t}{RV_t} = 1 - \frac{1}{GP_{t,0}\ pch_{t,0}}$$

and $T_t = RV_t/A_t$ as the asset turnover (A_t is total assets), we derive ROA (Return

On Assets) as:

$$ROA_t = T_t\left(1 - \frac{1}{GP_{t,0}\ \ pch_{t,0}}\right) = T_t\ k_t$$

where k_t represents the conversion coefficient of turnover into ROA.

Operating revenue is total sales; operating costs are: intermediate costs (materials, services etc.), labour costs and other costs (including capital depreciation). All current figures are also expressed at 2008 constant prices. Details of the deflation operations are given. The price index of output (*opc*) is computed by the ratio between current and constant price values of total production for the sector 55 (ATECO 2007). The labour cost index is provided by National Statistical Institute (ISTAT) that also releases price indices for capital depreciation. The implicit price index of intermediate costs is derived from column totals of the use-matrix (ATECO 55), by comparing values at constant and current purchase prices (*use table method*). However, as use-supply tables are available until 2013, we have provided an alternative price index (*method 2*), by applying the weights from the use-table (column values at current prices) to the price indexes of sectorial total (instead of intermediate) production (for 2014 and 2015, weights from the 2013 use-table are employed). As can be argued from Table 1 and Figure 1, the time pattern 2008-2013 of the two alternative index numbers is nearly similar but not their level. As the price index derived from the use-table is more consistent with our analysis, we have estimated 2014 and 2015 values assuming the same growth rate of the price indexes from *method 2* (Figure 1).

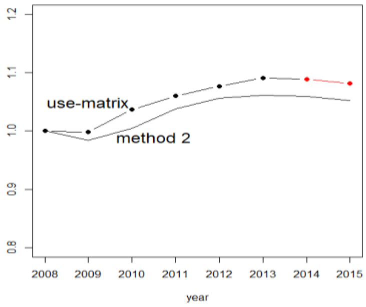

Figure 1 Price indexes for intermediate costs (base year 2008; estimates: red)

Operating costs at 2008 prices are computed by adding up the three cost components expressed at 2008 prices. Finally, the implicit price index of operating costs (*ipc*) is derived by the ratio between operating costs at current prices and operating costs at 2008 prices. Table 1 shows all price indexes and *pch*, which is the ratio between *opc* and *ipc.* The values of *pch*, after a weak increase in 2009, are systematically lower than one, showing that the change of input costs is not compensated by an adequate change in the price of services, although a weak recovery seems to occur in 2015. Figure 2 shows the time pattern of the actual conversion coefficient k_t and the value corresponding to $pch_{t,0}$=1. In 2015, the gap is not recovered yet, despite a positive trend of hotel arrivals (+15%) and nights spent (+4.5%) between 2008 and 2015.

Table 1 Index numbers of costs and prices (base year 2008)

Year	Intermediate costs (*use table*)	Intermediate costs (*method 2*)	Labour costs	Capital depreciation	Operating costs (*ipc*)	Production (*opc*)	*opc/ipc* (*pch*)
2008	1	1	1	1	1	1	1
2009	0.998	0.984	1.025	1.016	1.009	1.014	1.005

3. Results of the quantile regression

The analysis at the micro level, proceeds with the estimation of a function explaining total production, where: total sales *Y* is output and the stock of fixed assets (*K*), labor costs (*L*) and intermediate costs (*C*) are inputs. Data are expressed in thousand Euros at constant 2008 prices. Also the "annual number of nights spent in hotels and similar accommodation facilities" (*N*) is included as it reflects the trend-cycle of the sector in Italy. Furthermore, we have decomposed labor costs into two terms: (1) number of workers, as a measure of labor quantity (*W*); (2) average cost per worker, as a proxy of labor quality (*Cw*), where $L=W\times Cw$. The model (Model 1) with fixed effects is:

$$lnY_{it} = \beta_0 + \sum_{j=1}^{n-1} I_j\, \alpha_j + \beta_1 lnK_{it} + \beta_2 lnW_{it} + \beta_3 lnCw_{it} + \beta_4 lnC_{it} + \beta_5 lnN_t + u_{it}$$

where *i* is the single unit (*i*=1,…, 3058), *t*=2008,…,2015 is time, α_j is the individual fixed effect, I_i is a 0-1 dummy variable assuming 1 for $j=i$, and u_{it} is the error component.

The model is estimated through the quantile regression (QR). Each QR parameter β expresses the change in a specific quantile of the response variable produced by one unit change in the regressor, with the other model covariates taken constant. With QR, we can observe how some quantiles of $logY$ may be more affected by certain predictors, than other quantiles. The presence of a large number of individual fixed effects can significantly inflate the variability of parameter estimators. Regularization and shrinkage of such effects are applied, by using the R *rqpd* library, with standard errors estimated by bootstrapping methods (Koenker, 2004).

Figure 3 illustrates the parameter estimates for the 9 quantiles, and related 95% confidence intervals, while Table 2 shows the estimated values of parameter for some quantiles. Figure 3 and Table 2 are quite revealing in several ways. Almost all parameter values are highly significant (excluding the intercept for the 0.1 quantile) and vary across quantiles. Only the *lnC* coefficient (β_4, not plotted) shows a stable pattern around 0.65.

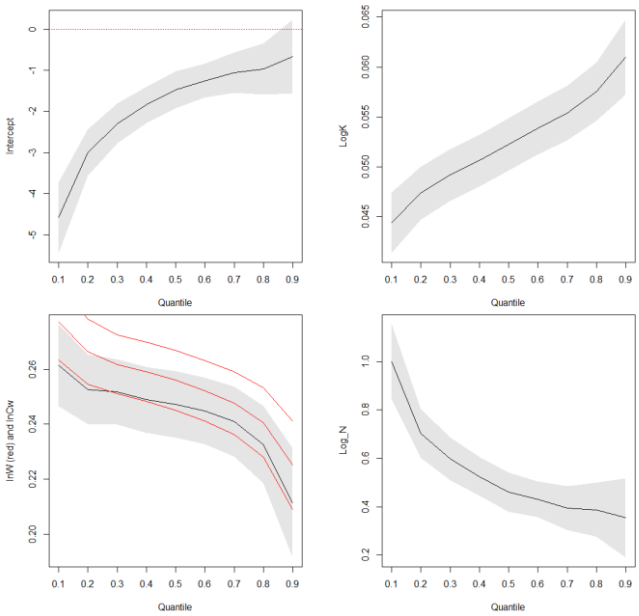

Figure 3 Estimated parameters and 95% confidence intervals

The effect of the variable expressing cycle-trend (*lnN*) is significant with a decreasing pattern over quantiles. It means that aggregate tourist demand affects to a greater extent smaller hotels (lower quantiles of sales), that reveal to be more sensitive to market dynamics.

As the size of the firm grows, the role of capital is increasingly greater whilst the opposite occurs for labor, because both related parameters (β_2 and β_3) exhibit the same decreasing pattern across quantiles. The alternative model (Model 2), with the sole variable *lnL* (in place of *lnW* and *lnCw*) produces similar results (Table 2). Larger firms result less sensitive to labor costs, probably because high skill services are outsourced, or shared within the hotel chain. Finally, if we consider the coefficients attached to the production factors, quasi-constant returns to scale emerge at each quantile.

The most important limitation of the work lies in the fact that information about the quality level of the hotel is not considered. A natural progression of this work is to provide data about hotel category and, possibly, number of rooms, even though it probably will determine a reduction of the dataset size.

A Bayesian Mixed Multinomial Logit Model for Partially Microsimulated Data on Labor Supply

Un Modello Bayesiano Logit Multinomiale Misto per Dati Parzialmente Microsimulati sull'Offerta di Lavoro

Cinzia Carota and Consuelo R. Nava

Abstract We focus on the determinants of labor choices in the presence of partially microsimulated data and discrete choice sets not identical for all agents under examination. The independence of irrelevant alternative assumption is thus discussed and the variability of the available choice set is taken into account. By comparing a Bayesian mixed multinomial logit model to a model without random effects, we show how the above described scenario affects labor choices made by single females and females within couples when the same discrete choice set is assigned to both individuals in each couple and the partner's choice is known.

Abstract *Si studiano le determinanti delle scelte di lavoro in presenza di dati parzialmente microsimulati e di insiemi discreti di scelte non identici per tutti gli agenti in esame. Viene pertanto discussa l'assunzione di indipendenza dalle alternative irrilevanti e viene tenuta in conto la variabilità dell'insieme delle scelte disponibili. Attraverso un modello bayesiano logit multinomiale a effetti misti comparato a uno privo di effetti aleatori, si mostra come questo scenario impatta sull'analisi delle scelte lavorative delle donne single oppure inserite in una coppia in cui ambedue gli individui sono esposti allo stesso insieme di scelte ed è nota la scelta del partner.*

Key words: Bayesian mixed multinomial logit model, independence of the irrelevant alternatives assumption, labour supply, random discrete choice set.

1 Introduction

Investigating the determinants of individual choices via random utility models (RUMs) [13, 15] is nowadays a common practice. RUMs describe the agent preference scheme in terms of the utility assigned to each discrete choice option, in a set of mutually exclusive alternatives (choice set). RUMs define a mapping from observed individual and/or choice characteristics into preferences with challenging theoretical and empirical statistical implications. The latter are investigated in various research fields, among which psychology and economics are by far the most important.

Recently, also policy evaluations take advantage of RUMs [3]. Instead of mere comparisons between events before and after a policy implementation, suitable RUMs are combined with microsimulation methods to anticipate, simulate and estimate the effects of socio-economic interventions. Such methods can simulate changes caused not only by hypothetical policies, but also by individual behaviours. In [4, 7] these tools are jointly used to conduct a "controlled experiment" in order to predict effects of tax and benefit reform interventions by using micro-data from national household surveys.

In this context, as a result of the microsimulation of certain fiscal variables and/or a sampling procedure applied to the available alternative options [1], it is quite common that the choice set does not exhibit the required homogeneity across decision makers (households). Even if the latter face the same number of job types (defined on the basis of a discretization of the weekly working hours in intervals, hereafter referred to as classes), microsimulation needs for each decision maker a random selection of a specific amount of working hours within each class, in order to simulate net household incomes, taxes and benefits. This implies that the i^{th} choice option refers to the i^{th} class of weekly working hours, but each household makes his decision by comparing his punctual amounts of working hours and other characteristics of jobs included in his own choice set. In this study, gross and net wage rates, given the amount of working hours, are computed via EUROMOD, a static microsimulation model [10] for tax and benefits, while the remaining variables are based on the Italian Survey on Household Income and Wealth (SHIW)[1]. The resulting partially microsimulated database contains information on households (e.g. singles or couples), while the required sampling procedure for microsimulation produces eight distinct choice sets $\{\mathscr{C}_h\}_{h=1}^{8}$, each one defined by 10+1 jobs with a specific amount of working hours[2]. Formally, household j, with $j = 1,\ldots,J$, is assigned the h^{th} choice set when $\mathscr{C}_j = \mathscr{C}_h$. In what follows, we distinguish the variables available in such database in two groups: variables directly introduced in the analysis as explanatory variables, and variables used to create groups of individuals as homogeneous as possible by means of a preliminary cluster analysis. We focus only on

[1] Also tax and benefits are, therefore, simulated according to the current fiscal system. See [7] for further details.

[2] Each choice set is composed by jobs with a different and increasing amount of working hours. For instance, the first choice set, $\mathscr{C}_1$, proposes jobs with 0, 1, 9, 17, 25, 33, 41, 49, 57, 65, 73 working hours, while the last one, $\mathscr{C}_8$, proposes with 0, 8, 16, 24, 32, 40, 48, 56, 64, 72, 80 working hours.

labour choices made by single and non-single females, labelled female-single and female-couple.

Due to the particular structure of the available data, this article discusses the validity of the independence of irrelevant alternatives (IIA) assumption[3] associated with widely used RUMs, such as logit, conditional logit and multinomial logit models, and tries to overcome it by incorporating the decision maker heterogeneity. The main contribution is a statistical model, specifically a Bayesian mixed multinomial logit model (MMLM) [5], able to address both the violation of the IIA assumption and the just described choice set variability. In recent labour supply studies (see [6, 7] and references therein) the bias induced by the discretization of weekly working hours, and the random selection of the choice set are unaddressed problems yet[4].

2 Methods, data and results

RUMs assume a utility maximization process in order to select one of the available alternative options. For each agent j, with $j = 1,\ldots,n$, with choice set $\mathscr{C}_j = \mathscr{C}_h$, we define a random variable describing his utility U_{ij} for each alternative c_i^h in $\mathscr{C}_h = \{c_1^h, c_2^h, \ldots, c_I^h\}$. We assume, for every $j, i = 1,\ldots,I$ and $h = 1,\ldots,H$, the conditional distribution $U_{ij}|\mathscr{C}_h \sim f_{ih}(\cdot|V_{ij})$, where V_{ij} is the ground truth utility or the score assigned to each c_i^h in $\mathscr{C}_h$ [2]. In particular, $U_{ij}|\mathscr{C}_h : c_i^h \to \mathbb{R}$ and we assume $\mathbb{E}[U_{ij}] = V_{ij}$.

In our case, agents are provided with choice sets with the same cardinality, I, but made up of different alternatives across decision makers. The j^{th} agent decision process defines a permutation τ^j of $\{c_1^h, c_2^h, \ldots, c_I^h\}$ such that a linear order can be defined $[c_{\tau^j(1)} \succ c_{\tau^j(2)} \succ \ldots \succ c_{\tau^j(I)}]$. The latter manifests individual preferences to which correspond an equivalent order of the random utilities $\boldsymbol{U}_j = \{U_{1j}, U_{2j}, \ldots, U_{Ij}\}$ such that

$$\mathsf{Pr}(c_{\tau^j(1)} \succ \ldots \succ c_{\tau^j(I)} | \boldsymbol{V}_j = \{V_{1j}, \ldots, V_{Ij}\}) = \mathsf{Pr}(U_{\tau^j(1)} > \cdots > U_{\tau^j(I)}). \qquad (1)$$

Under RUMs, conditionally on h, every U_{ij} is given by the sum of V_{ij} and a stochastic (unobserved) component, ε_{ij}, i.e. $U_{ij} = V_{ij} + \varepsilon_{ij} \; \forall \; i = 1,\ldots,I;\; j = 1,\ldots,n$. Therefore, the j^{th} agent selects the alternative c_i^h in the choice set $\mathscr{C}_j$, if and only if $U_{ij} > U_{kj} \, \forall \, k = 1,\ldots,I; k \neq i$ where $\varepsilon_{ij} = U_{ij} - V_{ij}$ is a random variable (r.v.) whose mean is 0. In turn, $V_{ij} = \mathbf{x}'_{ij}\boldsymbol{\beta}$ where $\mathbf{x}_{ij}$ is a $r \times 1$ vector of observed explanatory variables (for individual j and choice i), and $\boldsymbol{\beta}$ denotes a $r \times 1$ vector of fixed effects.

[3] The IIA assumption has been first used in the Luce's Axiom of Choice [11] and postulates that, when estimating the probability to select a job across a particular slate of alternatives in $\mathscr{C}$, the likelihood of choosing job a over job b will not change based on whether a third job $c \notin \mathscr{C}$ is present.

[4] Only few contributions on voters, as for instance [8], address these issues with $|\mathscr{C}_j| \neq |\mathscr{C}_i|$ for some $j \neq i$, i.e. when the cardinality of choice sets is different across decision makers.

The stochastic component ε_{ij}, instead, represents subjective noises and accommodates different sources of uncertainty like unobservable characteristics, unobservable variations in individual utilities, measurement errors and functional misspecification [12].

Assuming i.i.d. standard Gumbel or Extreme Value Type I errors, we obtain the well known multinomial logit model (MLM) [14]. To avoid the IIA irrealistic assumption and to model household heterogeneity we introduce in the expected utility V_{ij} a random component $\mathbf{z}'_{ij}\gamma_{ij}$, where z_{ij} is a $s \times 1$ design vector (assumed to be known) and γ_{ij} is a vector of s individual-specific and/or choice-specific random effects. In particular, here we exploit the individual-specific information stored in the variables not represented in $\mathbf{x}'_{ij}$ by performing a suitable hierarchical cluster analysis to assign each household j to a cluster k_j. Then, a random component $\alpha_j k_j$ is included in V_{ij}, with α_j denoting the random effect associated to cluster id k_j. Similarly, we introduce a second individual-specific random effect, δ_j, for female-couple, to make the choice made by individual j dependent on the choice made by her partner in the couple, labelled p_j. Notice that both individuals in the couple are assigned the same choice set. Finally, we take into account the above described heterogeneity of choice sets by including a random effect, η_j, of the choice set $\mathscr{C}_j$, to which decision maker j is assigned. Hence, in the more general case, the probability π_{ij} to select alternative i by agent j, for $\mathbf{z}_{ij} = \{k_j, p_j, \mathscr{C}_j\}$ and $\gamma_{ij} = \{\alpha_j, \delta_j, \eta_j\}$, can be rewritten as

$$\pi_{ij} = \mathsf{Pr}(Y_j = i|\mathscr{C}_j = \mathscr{C}_h) = \frac{\exp\{\mathbf{x}'_{ij}\boldsymbol{\beta} + \alpha_j k_j + \delta_j p_j + \eta_j \mathscr{C}_j\}}{\sum_{i=1}^{I} \exp\{\mathbf{x}'_{ij}\boldsymbol{\beta} + \alpha_j k_j + \delta_j p_j + \eta_j \mathscr{C}_j\}} \tag{2}$$

where Y_j is a random variable that takes values between 1 and I, the cardinality of the choice set $\mathscr{C}_h$, $h = 1,\ldots,8$. The probability in eq. (2) can be embedded in the following hierarchy:

$$Y_j \sim \mathsf{Multinom}(1, \boldsymbol{\pi}_j)\ \forall j = 1,\ldots,n \tag{3}$$

$$\mathsf{Logit}(\pi_{ij}) = \mathbf{x}'_{ij}\boldsymbol{\beta} + \mathbf{z}'_{ij}\gamma_{ij} \tag{4}$$

$$\boldsymbol{\beta} \sim \mathsf{N}(\mu_{\boldsymbol{\beta}}, V_{\boldsymbol{\beta}}), \quad \gamma_{ij} \sim \mathsf{N}(\mathbf{0}, V_\gamma), \quad V_\gamma \sim \mathsf{IW}(\Psi, \nu), \tag{5}$$

where $\boldsymbol{\pi}_j = \{\pi_{1j},\ldots,\pi_{Ij}\}$ is a vector including the "success" probabilities for each alternative in the choice set $\mathscr{C}_j$. We assign an Inverse Wishart (IW) prior distribution to the random effect (co)variance matrix V_γ while fixed effects are assigned a normal distribution. Such a hierarchical model is now applied to study whether or not the probability of choosing job i, given its features and household characteristics, is the same in the two groups of female-single and female-couple. Estimates are based on simulated (tax, benefit, gross income) and real data at a micro level, respectively from EUROMOD and SHIW[5].

[5] Here variables microsimulated by EUROMOD are based on real data provided by the Bank of Italy from the SHIW-1998 and on the 1998 Italian fiscal policy. The microsimulation model enables to calculate, in a comparable way, the effects of taxes and benefits on household incomes and work incentives.

Available data consist of 291 observed female-single and 2955 female-couple. Agents are aged between 20 and 55, neither retired nor students. They can choose among 10 different types of jobs (i.e. $i = 1, \dots, 10$) and the non labour-market participation (indexed as job 0)[6]. Type of jobs are defined on the basis of a discretization of the weekly working hours 0, 1–8, 9–16, 17–24, 25–32, 33–40, 41–48, 49–56, 57–64, 65–72, 73–80. Eight distinct choice sets $\{\mathscr{C}_h\}_{h=1}^{8}$, given the sampled weakly working hours, group singles and couples, and a new variable stores the choice set id h when $\mathscr{C}_j = \mathscr{C}_h$[7]. A hierarchical cluster analysis for each sub-population defines the cluster id for female-single and female-couple[8]. This implies that we ignore uncertainty about clusters resulting from this analysis, but we are currently working to implement more sophisticated grouping techniques, as fuzzy clustering. Variables used as predictors are the ones typically used in the literature: weekly hours of work, gross wages, age, son, choice set, taxes and benefits. Only the last two variables and gross wages were simulated with EUROMOD[9].

A Markov Chain Monte Carlo method with a block Gibbs sampling algorithm is implemented to estimate model coefficients using the `R` package `MCMCglmm` [9]. Algorithms are run for 30000 iterations, with a burn-in phase of 6000 and a thinning interval equal to 10. Hyperprior parameters were set to be: $\mu_\beta = 0$, $V_\beta = \mathbf{I}_4 \cdot 10^{10}$, with $\mathbf{I}_4$ denoting a 4×4 identity matrix. The residual covariance matrix was $\frac{1}{I \cdot 10^2} \cdot (\mathbf{I}_{I-1} + \mathbf{U})$, where $\mathbf{I}_{I-1}$ is a $(I-1) \times (I-1)$ identity matrix and $\mathbf{U}$ is a $(I-1) \times (I-1)$ unit matrix [9], given I as the number of possible choices. For the inverse-Wishart prior, Ψ was set to be equal to $\mathbf{I}_{I-1}$. Standard diagnostic tools confirmed the convergence of runs. Models did not include a global intercept, hence the first 10 estimated coefficients represented actual job type specific intercepts compared to the non-working alternative. Point estimates, under the proposed Bayesian MMLM compared to a MLM, are set out in Table 1.

The main improvements in the results under the MMLM can be appreciated both in the sign of the 10 choice coefficients, counterintuitive under the MLM, and in the large number of HPD intervals bounded away from zero.

Comparison between Experience-based Food Insecurity scales

Confronto tra scale di insicurezza alimentare basate sull'esperienza

Federica Onori, Sara Viviani and Pierpaolo Brutti

Abstract In order to face food insecurity as a global phenomenon, it is essential to rely on measurement tools that guarantee comparability across countries. Although the official indicator adopted by the United Nations in the context of the Sustainable Development Goals (SDGs) and based on the Food Insecurity Experience Scale (FIES) already embeds cross-country comparability, other experience-based scales currently employ national thresholds. In this paper we address the issue of comparability by presenting two different studies. The first one between FIES and three national scales (ELCSA, EMSA and EBIA) included in national surveys in Guatemala, Ecuador, Mexico and Brazil. The second one between the adult and children versions of these national scales. Different methods from the equating practice of educational testing are explored: parametric, nonparametric, classical and based on the Item Response Theory (IRT).

Abstract *Al fine di affrontare il problema dell'insicurezza alimentare come un fenomeno globale, è essenziale poter contare su strumenti di misurazione che garantiscano comparabilità tra Paesi. Nonostante l'indicatore ufficialmente adottato dalle Nazioni Unite nel contesto dei Sustainable Development Goals e basato sulla scala FIES, formalmente assicuri questa possibilità, altre scale di insicurezza alimentare utilizzano soglie nazionali. Questo lavoro propone due studi di comparabilità. Il primo riguarda la scala FIES e le scale nazionali ELCSA, EMSA ed EBIA, mentre il secondo confronta le scale nazionali riferite a famiglie con e senza minori. Vengono implementati diversi metodi di confronto utilizzati nell'educational testing: parametrici, nonparametrici, classici e basati sull'Item Response Theory (IRT).*

Key words: Food insecurity, Test equating, Item Response Theory, SDGs

1 Introduction

Food insecurity is formally defined as *the state of being without reliable access to a sufficient quantity of affordable and nutritious food* and food security is one of the target of the Sustainable Development Goals (SDGs) of the 2030 Agenda adopted by the United Nations. A number of indicators have been proposed to measure food insecurity and among all, *experience-based food insecurity scales* have proved to be valid and reliable tools to this aim [1]. These scales address the *access dimension* of food insecurity from the point of view of individual behaviours by directly asking people about the four aspects of psychological concern, food quality, food quantity and hunger. The first experience-based food insecurity scale was formulated in the United States where since 1995, the Household Food Security Survey Module (HFSSM) has been applied annually to monitor the phenomenon. Countries in Latin America, inspired by the HFSSM, developed their own national scales and, in this study we consider the *Brazilian Scale of Food Insecurity* (EBIA), the *Latin American and Caribbean Food Security Scale* (ELCSA) and the *Mexican Food Security Scale* (EMSA) [8], all included in national surveys for periodical monitoring. In order to provide a *global* measurement tool for food insecurity, in 2013 FAO launched the Voices of the Hungry project and introduced the Food Insecurity Experience Scale (FIES) [3]. Conceived as a global adaptation of the previous experience-based scales, the FIES was designed to produce formally comparable prevalences of food insecurity across countries and an index based on FIES was adopted as one of the official indicators for tracking progresses toward target 2.1 of the SDGs. Despite a common evolution, each national scale use specific thresholds to measure prevalences of food insecurity for *nominally* the same level of severity, and the problem of comparability arises. This paper aims at addressing this issue by proposing two comparability studies employing both classical and IRT-based methods from the educational testing field. A first study is proposed that compares FIES and the national scales ELCSA, EMSA and EBIA, while the second study computes, for each national scale, the corresponding raw scores between the adult and the children-referenced versions of the scale. In section 2 we present our data and the methods applied. In section 3 we focus on the main results and conclusions.

2 Materials and Methods

Equating is a statistical method that is used to adjust for differences in difficulty between tests' forms built to be similar in content and difficulty, so that scores can be used interchangeably [5]. The common evolution of EBIA, EMSA, ELCSA and FIES makes their Survey Modules similar to each other, allowing for statistical equating procedure. Nonetheless, the way they ”build” measures of food insecurity from observations differ under three main aspects: methodology, reference period and reporting unit. In fact, survey Modules used for ELCSA, EMSA and EBIA measure food insecurity at the *household* level and with a reference period of 3 months, while in this paper we consider for FIES a recalling period of 12 months referring to the *adult individual* (people age 15 or more). As far as for the methodology, national statistical offices using either ELCSA, EMSA or EBIA adopt a **deterministic** approach: a *raw score* is computed for each household by counting the number of items affirmed by that household. Prevalences of food insecurity at different levels of severity are then calculated as percentages of households scoring within a certain range expressed in terms of raw scores (Table 1). Conversely, FIES methodology is **probabilistic** in nature relying on the Item Response Theory (IRT) and, more specifically, on the Rasch model as the main tool for data validation and scale building [4]. Following this methodology a common metric called Global Standard is used as the reference metric to adjust model parameters estimates at each application and each respondent is assigned a distribution of his/her food insecurity along the latent trait used to compute percentages of the population whose severity is beyond global thresholds. Two indicators are then computed: the Prevalence of Food Insecurity at moderate or severe levels ($FI_{Mod+Sev}$, threshold -0.25 on the Global Standard) and the Prevalence of Food Insecurity at severe level (FI_{Sev}, threshold 1.81 on the Global Standard) [3]. Finally, FIES consists of one single scale based on 8 items referred to the adults, while EBIA, EMSA and ELCSA consist of two distinct scales, one for households without children and one for households with children, each one with specific thresholds for the different levels of food insecurity (Table 1).

Scale	Food insecurity Level	Households without children	Households with children
ELCSA	mild	1 to 3	1 to 5
	moderate	4 to 6	6 to 10
	severe	7 to 8	11 to 15
EMSA	mild	1 to 2	1 to 3
	moderate	3 to 4	4 to 7
	severe	5 to 6	8 to 12
EBIA	mild	1 to 3	1 to 5
	moderate	4 to 6	6 to 10
	severe	7 to 8	11 to 15

Table 1 National classification of food insecurity using ELCSA, EMSA and EBIA.

2.1 First Study: Equating FIES and National Scales

The aim of this comparability study is to find raw scores on the national scales EBIA, EMSA and ELCSA that are *equivalent* to the continuous FIES global thresholds used to compute the two indicators $FI_{Mod+Sev}$ and FI_{Sev} (i.e. -0.25 and 1.81). Data come from the administration of EBIA in Brazil in 2013, EMSA in Mexico in 2014 and ELCSA in Ecuador and Guatemala in 2016 and 2014 respectively and, in order to perform equating with FIES, only adult questions of the national scales have been considered. Equating between FIES and national scales was carried out by means of three equating methods for investigation purposes:

1. **IRT True Score** (IRT-TS) equating
2. **Linking** via a linear transformation applied to ability parameters
3. **Minimization** of the difference between prevalences of food insecurity

The *IRT-True Score equating* (IRT-TS) method is an IRT-based technique that consists of three steps [2]: at first, an IRT-model is fitted to the data (Estimation), then the parameters' estimates are put on a common metric through a linear transformation based on a set A of common items (Linking) and finally, equivalent expected Raw Scores are computed through the Test Characteristic Curves (TCC) of the two tests (Equating). In this study, two IRT models have been fitted to the data, namely the Rasch model and the nonparametric Mokken Scale [7] with a Kernel smoothing estimation of the Item Characteristic Curves (ICCs) [6]. When the nonparametric IRT model is considered, a Kernel smoothing estimation of the ICCs is computed and the points on the latent trait for which the corresponding estimated ICCs equals 0.5 are taken as the item severities used to estimate the linear transformation. The Standard Error of Equating (SEE) [5] for the IRT-TS method was estimated using 1000 bootstrap replications and, due to the computational costs of the procedure, is only provided together with the fitting of the Rasch model.

The second method (Linking) consists in considering the linear transformation obtained at the second step of the IRT-TS method and applying it to the estimated ability parameters of the Rasch model. Once ability parameters are adjusted to the Global standard metric, raw scores corresponding to the ability parameters that are the closest to the two global thresholds are considered as the *equivalent* raw score.

Finally, the third method (Minimizing) consists in computing prevalences of food insecurity at the household level applying the FIES methodology to the data used for the national scales and comparing the prevalences so obtained with the percentages of population scoring from a certain raw score on. The two raw scores that realize the minimum distance with the two global thresholds are considered the *corresponding* raw scores in accordance to this method.

2.2 Second Study: Comparing Adult- and Children-referenced item scales

This second analysis aims at comparing the Adult and the Children scales within each national scale. To this aim, we consider the scores obtained by the households with children on the two Module Surveys following the approach also known as the Single Group (SG) data collection design [5]. Equating of the Adult and Children scales in the four countries was carried out through implementation of five equating methods for investigation purpose: IRT True Score equating with the Rasch model, Mean, Linear, Equipercentile and Kernel Equipercentile equating methods [5].

3 Results

Outcomes from the first comparability study are summarized in Table 2, reporting the raw scores equivalent to the global thresholds used for $FI_{Mod+Sev}$ and FI_{Sev}. Results show that the global threshold used for $FI_{Mod+Sev}$ sometimes reflects a *less severe* condition of food insecurity compared to the one measured by national scales for the moderate category of food insecurity, all equated raw scores being either equal to or around one point less than the thresholds currently used by ELCSA, EMSA and EBIA (compare Table 1). On the contrary, the global threshold used for FI_{Sev} generally reflects a *more severe* condition of the food insecurity than the one captured by the national scales for the severe level of food insecurity, equated raw scores being either equal to or one point higher than the national thresholds currently in use.

FIES	Food Insecurity Scales	Internal Monitoring	IRT-TS Rasch (SEE)	IRT-TS NP	Linking	Min. Diff.
$FI_{Mod+Sev}$	ELCSA (Guatemala)	4	3.3 (0.19)	3.4	3	4
	ELCSA (Ecuador)	4	4.2 (0.14)	4.1	4	4
	EMSA (Mexico)	3	2.0 (0.23)	2.0	2	2
	EBIA (Brazil)	4	4.0 (0.09)	4.0	4	5
FI_{Sev}	ELCSA (Guatemala)	7	7.8 (0.18)	8.0	8	8
	ELCSA (Ecuador)	7	7.1 (0.18)	7.7	7	8
	EMSA (Mexico)	5	6.0 (0.26)	6.0	6	6
	EBIA (Brazil)	6	7.9 (0.07)	8.0	8	8

Table 2 Raw Scores on the national scales equivalent to the thresholds for $FI_{Mod+Sev}$ and FI_{Sev}.

Regarding the second comparability study, the equated raw scores on the Children scale shown in Table 3 seem to suggest that sometimes the current thresholds reflect a different severity of the condition measured by the two scales referred to households with and without children, respectively. This is mainly evident for the most severe category of food insecurity, for which the corresponding raw scores on the Children scale for ELCSA in Guatemala and EMSA in Mexico are generally around one point *higher* than the thresholds currently in use and between one and two points *lower* for EBIA (column ”Severe”). On the other hand, we see that the corresponding raw scores for the moderate food insecurity substantially align with the thresholds currently in use for this category (column ”Moderate”). Moreover, minor differences emerge between the behaviour of ELCSA in Guatemala and Ecuador (analysis not shown), possibly due to the specific features of the phenomenon in the two countries, confirming the importance of an equating analysis even between applications of the same scale. Finally, among all methods implemented, the Equipercentile equating method is the one whose results generally resemble the current thresholds the most.

We believe that these comparability studies can contribute in creating a more homogeneous and consistent picture of the phenomenon of food insecurity by allowing the utilization of results from application of different scales. As a consequence, this would enable a more reliable monitoring of the progress toward the goal of a global food security, as expressed in target 2.1 of the Sustainable Development Goals.

Scale	Equating	Moderate		Severe	
	Method	Raw score	(SEE)	Raw score	(SEE)
ELCSA Guatemala	IRT-TS	6.2	(0.09)	12.1	(0.1)
	Mean	6.6	(0.07)	12.2	(0.07)
	Linear	6.5	(0.07)	11.7	(0.11)
	Equip	6.3	(0.09)	11.3	(0.15)
	Kernel Equip	6.1	(0.02)	12.0	(0.04)
EMSA Mexico	IRT-TS	4.8	(0.12)	8.7	(0.13)
	Mean	5.5	(0.05)	9.5	(0.05)
	Linear	5.1	(0.07)	8.6	(0.10)
	Equip	4.8	(0.13)	8.1	(0.14)
	Kernel Equip	4.5	(0.03)	8.8	(0.04)
EBIA Brazil	IRT-TS	4.8	(0.12)	8.7	(0.13)
	Mean	5.5	(0.05)	9.5	(0.05)
	Linear	5.1	(0.07)	8.6	(0.10)
	Equip	4.8	(0.13)	8.1	(0.14)
	Kernel Equip	4.5	(0.03)	8.8	(0.04)

Table 3 Raw scores on the Children scale respectively corresponding to 4 and 7 on the Adult scale (Guatemala), 3 and 5 on the Adult scale (Mexico) and 4 and 7 on the Adult scale (Brazil).

Sovereign co-risk measures in the Euro Area
Dipendenza del rischio sovrano tra paesi dell'area Euro

Giuseppe Arbia, Riccardo Bramante, Silvia Facchinetti, Diego Zappa

Abstract We propose a method to extract significant risk interactions between Countries adopting the Graphical Lasso algorithm, used in graph theory to sort out the spurious effect of common components. In this context, the major issue is the definition of the penalization parameter. We propose a search algorithm aimed at the best separation of the variables (expressed in terms of conditional dependence) given an a priori desired partition. The case study focuses on Sovereign Bond Yields over the period 2009–2017. The proposed algorithm is used in systemic risk estimation of the Euro area sovereigns.

Abstract *L'algoritmo Glasso è noto nella letteratura associata alla teoria dei grafi per filtrare correlazioni spurie, se presenti. Il principale problema di questo metodo è la calibrazione del parametro di penalizzazione. In questo lavoro viene proposto un algoritmo volto a trovare la miglior separazione delle variabili in esame, in termini di indipendenza condizionale, assegnata una partizione ottimale definita a priori. L'applicazione esamina la relazione tra rendimenti dei bond sovrani nell'area Euro nel periodo 2009–2017 al fine di verificare l'assunto della separazione o della interdipendenza tra paesi Core e Periferici.*

1 Introduction

We propose an original approach based on Graphical Lasso (GLasso; see Friedman et al. 2008) to investigate government bond yield data interactions from a systemic risk perspective.

The recent debt crisis in the Euro Area has turned researchers' attention to sovereign default risk measurement of. Specifically, the degree of co–movements of Sovereign bond spreads among countries can help us to understand how correlations of default probabilities – as measures of perceived country risk – evolve over time and are diffused in space. For both descriptive purposes and quality picture representation, Figure 1 depicts the corresponding bond trajectories from January 2009 to October 2017, focusing only on the 4 major developed countries in the EU (Italy, Spain, Germany and France).

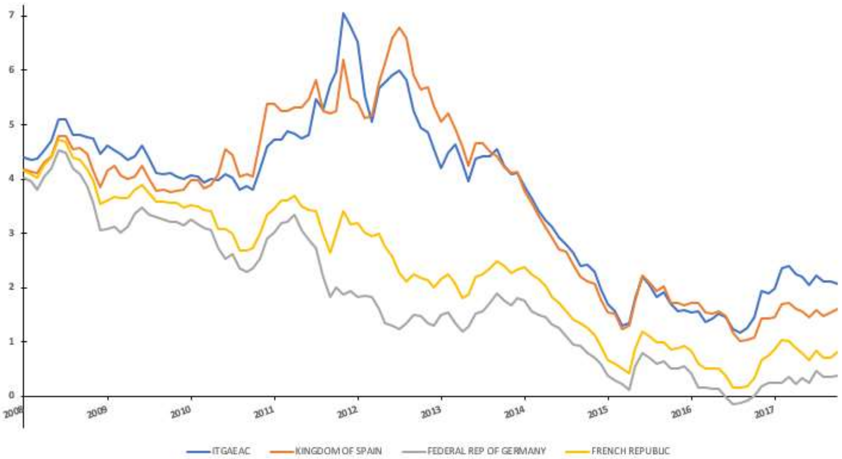

Fig. 1. Ten–year Sovereign Bond Yields

The pattern of the series in the graph unambiguously shows the effect of the crisis on Italy and Spain. Bond yields have dramatically risen from 2011 to 2013, a period affected by wide changes in global risk aversion. In particular, from 2010 yields began moving upwards, continuing to widen sharply in 2011. The sharp decline started in the second half of 2012 due to the European Central Bank policies, with a subsequent stabilization around a roughly flat trend.

In this paper, we propose the use of GLasso to focus the study only on relevant sovereign risk co–movements within the Euro Area assuming the conditional independence between Core and Peripheral Countries (ECB, 2016)[1], following the approach described in Arbia et al. (2018).

[1] For an application of GLasso in the financial field see, for example, Goto and Xu, 2015.

More specifically, the aim of this paper is twofold. First of all, our contribution focuses on the choice of the penalty parameter within the GLasso framework. As this choice is in most cases subjective and expertise-driven, we propose to modify the calibration search algorithm in Friedman et. al (2008) by searching for the minimum of the absolute difference between the Government Bond yield returns expected precision matrix and its estimate after penalization. Secondly, we analyse cross-country contagion effects by investigating – in a rolling framework – the characteristics of the degree of connectivity of the examined countries, in the graph obtained after penalization.

The rest of the paper is organized as follows. Section 2 reports some details about the GLasso algorithm and the procedure developed to calibrate the penalization parameter. In light of the Sovereign debt crisis, the application proposed in Section 3 refers to Euro Zone systemic risk analysis. Conclusions follow.

2 Methodology

Let $X=\{X_1, X_2,..., X_p\}$ be a p–multivariate random variable. Let Σ and $\Theta=\Sigma^{-1}$ be its covariance and precision matrix, respectively. It may be shown that Θ is proportional to the partial correlation matrix and so Θ can be effectively used to characterize the interrelationship of the variable of interest through the associated graph (Edwards, 2000).

The key role played by Θ justifies the many approaches proposed to estimate it efficiently and robustly with respect to abnormal deviations (see e.g. Ledoit & Wolf, 2012). A recent approach is represented by the GLasso algorithm which uses a regularization framework to estimate the covariance matrix under the assumption that its inverse is sparse. The aim of GLasso is to estimate Σ or Θ by removing the elements that likely denote spurious correlations. The way to achieve this is by introducing a penalization into the maximum likelihood estimation of the precision matrix using an L_1 penalty function over nonnegative definite matrices Θ:

$$\arg\max_{\Theta\succ 0}\{\log\det\Theta - \mathrm{tr}(S\Theta) - \lambda||\Theta||_1\} \qquad (1)$$

where $||\Theta||_1$ is the L_1 norm of Θ, S is the empirical covariance matrix and λ a scalar parameter that controls the size of the penalty. The smaller the value of λ is, the higher will be the degree of dependence between the variables and the density of the graph.

According to the work of Banerjee et al. (2008), it is possible to define the dual of sparse maximum likelihood problem in (1) as

$$\arg\max_{W}\{\log\det W : ||W - S||_\infty \le \lambda\} \qquad (2)$$

where $W=S+U$ and U is a symmetric matrix that allow to represent $||\Theta||_1$ as

$$||\Theta||_1 = \max_{||U||_\infty \le 1} \mathrm{tr}[\Theta U]$$

The dual problem (2) estimates the covariance matrix while the primal problem (1) its inverse. Moreover, log function is a monotone increasing function, thus we can also use the equivalent problem removing the log.

For further details on GLasso algorithm see Friedman et al. (2008), Banerjee et al. (2008) and Witten et al. (2011), among other.

The penalized maximum likelihood estimation for Σ can be computed $\forall\lambda \geq 0$.

Let Θ_H and $\widehat{\Theta}_\lambda$ represent the expected/desired precision matrix and the estimate of Θ after penalization, respectively. We define a flexible search algorithm to solve:

$$\min_{\lambda} \left\| \Theta_H - \widehat{\Theta}_\lambda \right\|_1 \tag{3}$$

It allows us to define a conditional dependence structure without the constraint to get a solution that exactly matches that structure. Differently from standard GLasso constraints procedures, the solution to Equation (3) allows some elements of Θ to be different from zero.

3 Empirical evidence from Euro Area Sovereign bond markets

Graphical Lasso algorithm has been applied to 10-year Government bond yields monthly data covering 17 countries in the Eurozone. This includes five Peripheral Countries, five Core Countries and seven "Other" remaining countries, which subsequently (except for Finland) adopted the Euro[1]. Data spans the period from January 2009 to October 2017; covariance and precision matrices, along with the corresponding λ parameters, are estimated over three rolling windows of size 150, 200 and 300 days.

To reflect the evolution of systemic risk and assess the degree of connection among the Core, Peripheral and "Other" countries we dynamically apply the GLasso algorithm to estimate at time *t* the precision block matrix Θ_t as follows:

$$\Theta_t = \begin{bmatrix} {}_{PP}\Theta_t & {}_{PC}\Theta_t & {}_{PO}\Theta_t \\ {}_{CP}\Theta_t & {}_{CC}\Theta_t & {}_{CO}\Theta_t \\ {}_{OP}\Theta_t & {}_{OC}\Theta_t & {}_{OO}\Theta_t \end{bmatrix}$$

where *t* is the time index and subscripts *P*, *C* and *O* indicate Peripheral, Core and remaining (Other) countries, respectively.

Our aim is to apply Equation (3) to extract graphs with a good balance between sparsity and density, avoiding the selection of large λ, which may artificially inflate sparsity in the precision matrix. Specifically, the goal is a zero *PC* block in Θ_t e.g., the Peripheral and Core Countries are conditionally independent and no co–risk between the two groups is considered. The dynamics of λ_t according to the results

[1] Luxembourg is excluded from the analysis since no data are available.

obtained by the application of Equation (3) is reported in Figure 2, by comparing the MLE and L_1 estimates.

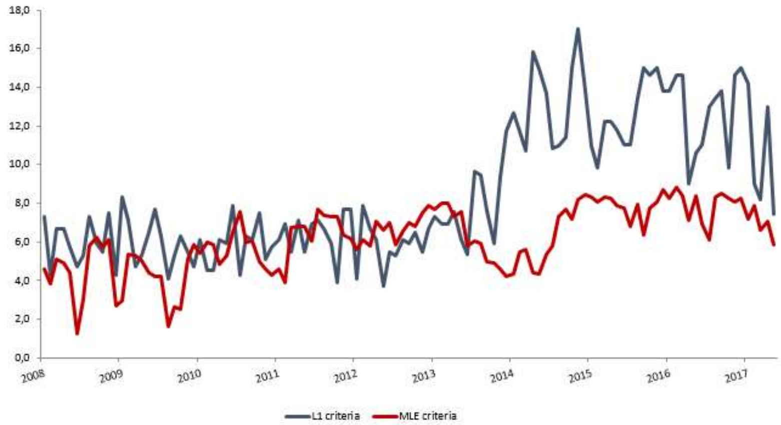

Fig. 2. λ_t comparison: *MLE* versus L_1 criterion

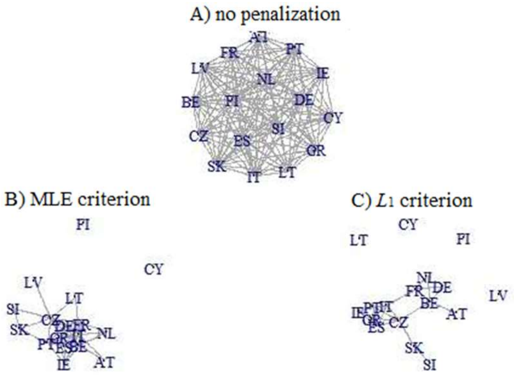
This series give evidence of a sharp increase in λ_t values – when the L_1 criterion is considered – during the mounting sovereign debt crisis. Moreover, while 2014 seems to represent a lower boundary of the crisis, the aftermath of a continued erratic pattern indicates that the sovereign debt crisis seems far from a final resolution.

As an example, Figure 3 shows the graphs obtained by using the best solution to Equation (3): that is, the application of MLE (Figure 3B) and L_1 criterion (Figure 3C), referring to the last rolling time window (October 2017).



A) no penalization

B) MLE criterion

C) L_1 criterion

Fig. 3. Network with A) no penalization, optimal B) MLE and C) L1 values

The graphs map out the active connections obtained in the two frameworks, giving evidence of the capabilities of the L_1 criterion to filter out the spurious effects of common components. In particular, the reinforced interconnectedness within the *PP* countries after the crisis are shown and the evidence of only an active contagion transmission channel between *PP* and *CC* groups referred to the country pair Italy-France is given. MLE solution, on the other hand, lacks of a clear pattern.

4 Conclusions

This paper exploited the Graphical Lasso algorithm to extract significant correlations in Government bond yields returns series. A calibration criterion to identify the best regularization parameter along time and cross–sectionally has been proposed.

Empirical evidences from the Euro area show that the proposed method allows to extract the relevant systemic risk contributions and identify the most interconnected nodes (countries), thus lowering the network dimension and isolating spurious relationships. We also show that the penalization parameter can be used as an indicator of the intensity of the crisis and that a better description of the relationships between Peripheral and Core Countries is obtained using the L_1 criterion instead of the *MLE* one.

Simultaneous unsupervised and supervised classification modeling for clustering, model selection and dimensionality reduction

Modellizzazione simultanea di metodi di classificazione non-supervisionata e supervisionata per classificare, validare il modello e ridurre la dimensione dei dati

Mario Fordellone and Maurizio Vichi

Abstract In the unsupervised classification field, the choice of the number of clusters and the lack of assessment and interpretability of the final partition by means of inferential tools denotes an important limitation that could negatively influence the reliability of the final results. In this work, we propose to combine unsupervised classification with supervised methods in order to enhance the assessment and interpretation of the obtained partition, to identify the correct number of clusters and to select the variables that better contribute to define the groups structure in the data. An application on real data is presented in order to better clarify the utility of the proposed approach.

Abstract Nella classificazione non supervisionata, la scelta *a priori* del numero ottimale di gruppi da considerare e la mancanza di interpretazioni inferenziali, rappresenta un grosso limite per questi modelli. In questo lavoro, proponiamo la combinazione di modelli di classificazione non-supervisionata e supervisionata per identificare il numero ottimale di gruppi da considerare, selezionando le variabili che incidono in modo significativo sulla partizione trovata. E' prevista un'applicazione su dati reali.

1 Introduction

In the unsupervised classification techniques, clusters of homogeneous objects are detected by means of a set of features measured (observed) on a set of objects without knowing the membership of objects to clusters. In these applications the aim is to discover the heterogeneity structure of the data. Often, techniques based on separability and homogeneity criteria of the groups are used, giving *a priori* the number of groups [9].

Conversely, supervised classification is based on the idea to forecast the membership of new objects (output) based on a set of features (inputs) measured on a training set of objects for which the membership to clusters is known. Therefore, in these applications the aim is to generalize a function or mapping from inputs to outputs which can then be used speculatively to generate an output for previously unseen inputs [4, 6].

In this work, we propose a clustering algorithm based on the use of supervised classification modeling. In particular, the approach consists in the combination of K-Means (KM) and Logistic Regression (LR) modeling in order to find the correct number of clusters, select the most important variables and have an assessment on the partition identified through KM. An application on real data is finally proposed.

2 K-Means and Logistic Regression modeling into a clustering algorithm

In unsupervised classification modeling we are not interested in prediction, because we do not have an associated response variable y [5] like in a supervised classification model. The proposal of this paper consists in the combination of the unsupervised (i.e., K-Means (KM)) and supervised classification (i.e., Logistic Regression (LR)) approaches, where the latter, aiming to evaluate and to improve the former with adding data structure information. For simplify, we will call this approach K-Means - Logistic Regression (KM-LR). In particular, KM-LR is composed by the following principal steps:
Given the $n \times J$ data matrix $\mathbf{X}$, for $K = 2, \ldots, Kmax$, where $Kmax$ is the maximum number of clusters the researcher thinks the data might have, the algorithm works as follows:

1. let g_K be the unknown categorical membership variable which is estimated by using KM on the n-dimensional multivariate variables in $\mathbf{X}$ thus minimizing the objective function $\left\|\mathbf{X} - \mathbf{U}\bar{\mathbf{X}}\right\|^2$ [7];
2. g_K is used as response variable of the LR model with explanatory variables $\mathbf{x}$; LR is applied on g_K for estimating the probabilities for its $K-1$ response categories $\pi_k(\mathbf{x})$, and to estimate the probabilities for its *baseline* category $\pi_0(\mathbf{x})$, here fixed $k = 1$ [1];

3. if in second step some LR coefficient are not statistically significant, then we exclude the corresponding variables and we repeat from the step 1, otherwise $K = K + 1$.

Stopping rule: the algorithm continues until when the *Kmax* is reached. At the end, the optimal K is identified, together with a reduced set of statistically significant variables and a set of inferential tools to assess the quality of the partition.

In this way, through the analysis of the LR results (e.g., explained variance, parameters significance, residual variance, etc.) we have an evaluation of the partition obtained by KM. In fact, a good performance of the LR model on the response variable derived by the KM outcome, means that the variables included in the model well-explain the groups structure in the data. Moreover, through the LR coefficients analysis we can see which variables contribute most to identify the groups structure and to what extent they do it (then, analyzing statistical significance, estimates value, and sign of the coefficients).

In the next section, an application on real data is presented.

3 Application on real data

In this section a real data application of K-Means - Logistic Regression (KM-LR) is presented. The data set named *Wine Recognition Data*, is available at the UCI repository website (http://archive.ics.uci.edu/ml/). It is the result of the chemical analysis of wines grown in an Italian region, derived from three different cultivars. The 13 constituents were measured on 178 types of wine from the three cultivars: 59, 71 and 48 instances are in class one, two and three, respectively.

In the analysis we have tried to select the optimal number of clusters without considering the *a priori* information that $K = 3$, and using the KM-LR algorithm, i.e. through the maximization of *chi-squared* test computed on the partitions obtained by K-Means (KM) and Logistic Regression (LR). For comparison purpose, other two approaches have been used. The procedure has been random repeated 50 times from 2 to 10 clusters. In Table 1 have been reported the results obtained by *chi-squared* (first column), *Gap-method* proposed by Tibshirani [10] (second column), and Calinski and Harabasz [3] criterion (third column).

Thence, the best performance has been obtained by KM-LR approach, where the optimal number of clusters has been captured 36 times on 50 (72%). Whereas, KM-*Gap-method* has been obtained worst performance, since the optimal number of clusters has been captured 5 times only (10%). Then, the KM-LR approach seems to reduce the effect of the local minima problem of the KM algorithm [2], which is more relevant in the case no modification of the KM partition is proposed as in the KM-*Gap-method*, and KM-*Calinski-Harabasz*.

In Table 2 the estimation results of LR applied on the groups labels identified through KM model as response variable and including only variables with significant coefficient as predictors are shown.

Table 1 Optimal K selection from 2 to 10 clusters on the 50 random starts

	Chi-squared		Gap-method		Calinski-Harabasz	
K	Count	Percent	Count	Percent	Count	Percent

178 observations, 164 error degrees of freedom
Dispersion: 0.138, AICc=160.34, BIC=185.95
R-Squared Adj.=0.8135
F-statistic: 93.70, p-value=5.19E-55

From Table 2 we can note that the model shows a good performance, with about 80% of the total variance explained. In the model the variables *Ash*, *Alcalinty of Ash*, *Total phenols*, *Nonflavanoid phenols*, *Proanthocyanins*, *OD280-OD315 of diluted wines*, have been excluded because are not statistically significant at the 1% level.

Tables 3 show (i) the confusion matrix between real data partition and KM partition (i.e., KM applied on the complete data) and (ii) the confusion matrix between real data partition and KM-LR partition.

The misclassification Rate and the Adjusted Rand Index [8] applied on the left table (i.e., real partition versus KM partition) are equal to 0.3708 and 0.2977, respectively; whereas, the same indices applied on the right table (i.e., real partition versus KM-LR) are equal to 0.1818 and 0.5465, respectively.

Table 3 Confusion matrix between: (*i*) real data partition and *K*-Means partition; (*ii*) real data partition and *K*-Means - Logistic Regression partition

	K-Means					*K*-Means - LR			
Real	C_1	C_2	C_3	Total	Real	C_1	C_2	C_3	Total
C_1	32	5	22	59	C_1	51	3	5	59
C_2	9	61	1	71	C_2	3	66	2	71
C_3	2	27	19	48	C_3	0	12	36	48
Total	43	93	42	178	Total	54	81	43	178

Moreover, applying LR on the real data partition we obtain the following confusion matrix between the real partition and that one fitted by LR (Table 4).

Table 4 Confusion matrix between real data partition and Logistic Regression partition

	Logistic Regression			
Real	C_1	C_2	C_3	Total
C_1	15	44	0	59
C_2	6	62	3	71
C_3	2	38	8	48
Total	23	144	11	178

Also in this case the performance of KM-LR is better. In fact, the misclassification Rate and the Adjusted Rand Index applied on Table 4 are equal to 0.5225 and 0.0247, respectively. In Table 5 the performances obtained both LR applied on real partition and KM-LR are shown.

Table 5 Comparison between LR and KM-LR

	Logistic Regression	*K*-Means - LR
F-Statistic	14.5000	93.7000
p-value	0.0002	5.19E-55
R-Squared Adj.	0.0710	0.8135
AICc	403.3673	160.3400
BIC	409.6623	185.9500

We can note that the diagnostics indices obtained by KM-LR are very better with respect to those obtained by the LR application on the real data partition. Furthermore, note that in the application of LR on the real data partition, only the variable *Color intensity* has obtained a statistically significant coefficient and then, only this variable has been included in the model.
In Figure 1 the distributions of the three KM-LR clusters on the reduced set of variables are shown.

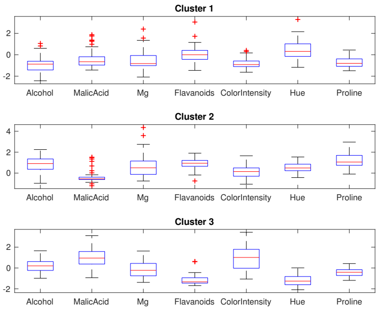

Fig. 1 Boxplots of the three KM-LR clusters distributions represented on the variables included in the model

4 Concluding remarks

In the unsupervised classification approaches, the choice of the number of clusters and the lack of assessment of the final partition are crucial issues that could negatively affect the reliability of the results. In this work we propose an algorithm that combines K-Means (KM) and the Logistic Regression (LR) modeling in order to have an evaluation of the partition identified through KM, assess the correct number of clusters (clustering) and verify the selection of the most important variables (model selection), removing in the model the non-significant variables (dimensionality reduction). In this way, we have a parsimonious set of variables that defines the best partition of data. Thus, the methodology seems promising, however, in a following work, we wish to better discover and assess, by an extensive simulation study, the performances of the proposed methodology.

CONSUMERS' PREFERENCES FOR COFFEE CONSUMPTION: A CHOICE EXPERIMENT INCLUDING ORGANOLEPTIC CHARACTERISTICS AND CHEMICAL ANALYSES

Preferenze del consumatore e consumo di caffè: un esperimento di scelta comprendente caratteristiche organolettiche e analisi chimiche

Rossella Berni, Nedka D. Nikiforova and Patrizia Pinelli

Abstract In this work we propose an innovative approach for the analysis of consumers' preferences for coffee consumption by integrating a choice experiment with a consumer sensory test and chemical analyses (caffeine and antioxidants by HPLC). The same choice experiment has been administered in two consecutive time occasions, e.g. before and after the sensory test (including a descriptive illustration by an expert), in order to analyze the role of tasting in guiding the consumers' preferences. All these elements, e.g. the attributes involved in the choice experiment, the scores obtained for each coffee through the sensory tests and the HPLC analyses, are analyzed through Random Utility Models.
Abstract *Nel presente lavoro si propone un approccio innovativo per l'analisi delle preferenze del consumatore relativo al consumo del caffè. Tale approccio permette di integrare un esperimento di scelta con i risultati derivanti dal test d'assaggio e analisi chimiche (caffeina e composti antiossidanti valutati tramite il metodo HPLC). Lo stesso esperimento di scelta viene somministrato sia prima che dopo il test d'assaggio con l'obiettivo di capire se l'assaggio, unito alla descrizione operata da un esperto, può costituire una "guida" nella definizione delle preferenze del consumatore. Gli attributi dell'esperimento di scelta, i punteggi ottenuti dal test d'assaggio e i risultati HPLC sono stati analizzati con Modelli di Utilità Casuale.*

1 Introduction

In this work, consumers' preferences for the coffee consumption are analyzed with an innovative approach, which integrates a choice experiment with consumer sensory tests and chemical analyses of two different types of coffee ground for moka (e.g. 100% Arabica, and a blending of Arabica and Robusta). More specifically, at the beginning a choice experiment based on optimal design theory is planned. In addition, a coffee tasting is planned in order to better analyze the consumers' preferences. To this end, a scoring card is developed, where tasters have to give a score for each organoleptic descriptor of coffee; this scoring card is administered jointly with the choice experiment. Moreover data relating to the coffee, e.g. quali-quantitative composition (caffeine, antioxidants), were acquired by using a High Performance Liquid Chromatography (HPLC) method and specific calibration curves, and then involved in the modeling step. More precisely, the same choice experiment is administered in two consecutive time occasions (Lombardi et al., 2017), e.g. before and after the sensory test, in order to analyze the role of tasting in the determination of consumers' preferences. All these elements, e.g. the attributes involved in the choice experiment, the scores obtained for each coffee from the sensory test and the HPLC analyses, are jointly analyzed in the modeling step to better evaluate the consumers behavior relating to the coffee consumption and to verify if the tasting session produced a modification in consumer's attitude.

2 Choice experiment and Random Utility Models

In the following Subsection we briefly describe the choice experiment and the collection of the data. Following, the theory of Random Utility Models (RUM) is briefly explained.

2.1 Choice experiment and data collection

At the beginning, a choice experiment based on optimal design theory is planned for building the choice-sets with the following aims: i) an efficient estimation of the attributes for the choice experiment, and ii) the detection of the effect of the sensory assessment's scores obtained through the sensory test. To this end, a compound design criterion (Atkinson et al., 2007) is applied in order to address the issues described above.

In order to collect the data, a background questionnaire about the respondent (age, gender, education) was administered at the beginning. Furthermore the choice experiment was supplied before and after the coffee tasting. For the tasting, a scorecard was developed, in which the consumer/taster is asked to assign a vote (ranging from 1 to 7, evaluated as discrete votes) to each organoleptic characteristic (smell, taste and tactile sensations). Moreover, the two types of coffee ground for moka (100% Arabica, and a blending of Arabica and Robusta varieties) were previously analyzed for their content in polyphenolic antioxidants (chlorogenic acid and other caffeoyl-quinic derivatives) and caffeine by a HPLC/DAD method.

2.2 Choice Modeling

Once data were collected, the preferences expressed by the consumers are analyzed through Random Utility Models. Therefore, as an initial step, the class of Random Utility Models (RUM) is defined. In general, every alternative is indicated by j, so that the choice-set is formed by J alternatives $(1,...,j,...,J)$, while i denotes the respondent $(i=1,...,I)$. The respondent is asked to give his/her preference within each choice-set, formed by two or more alternatives. In the Random Utility class of models, the individual i who chooses the alternative j has a random utility U_{ij} that may be generally expressed as in formula (1). Furthermore, it is assumed that the respondent i maximises his/her utility by choosing the alternative j, belonging to the choice-set C_i so that U_{ij} is the highest of all the utilities U_{ik}, $k=1,...,J$.

Thus, the following expression is characterized by a stochastic utility index U_{ij}, which may be expressed, for each unit i, as a linear function of the attributes for the alternative j, as:

$$\begin{aligned} U_{ij} &= V_{ij} + \varepsilon_{ij} \\ V_{ij} &= x'_{ij}\beta \end{aligned} \tag{1}$$

where V_{ij} is the deterministic part of the utility and is defined here in relation to a vector x_{ij}, containing the characteristics of respondent i and alternative j, β is the vector of unknown coefficients and ε_{ij}, $j=1,...,J$ is the random component. The random component is generally supposed to be independent and also Gumbel or type I extreme value distributed.

It must be noted that each alternative will be characterized by a vector of characteristics (attributes), while the response (dependent) variable is the binary variable related to the expressed preference for each choice-set.

In this study, we start by applying the Multinomial (conditional) Logit model, after we apply the Heteroscedastic Extreme Value-HEV model, described in the following Subsection.

2.2.1 The Heteroscedastic extreme value model

The Heteroscedastic Extreme Value (HEV) model (Bhat, 1995; Hensher, 1999) also belongs to the RUM class. The main feature of this model concerns the modified assumptions on the random component, which is supposedly distributed as a type I extreme value distribution, independently but not identically distributed. It must be noted that this different hypothesis on the random component makes it possible to treat the relaxation on the Independence of the Irrelevant Alternatives (IIA) property differently with respect to the Multinomial Logit model. This relaxation is fundamental and strengthens the improvement with respect to the basic logit model. Furthermore, in the HEV model, different scale parameters between alternatives are estimated. Moreover, the presence of large variances for the error terms influences the effects of changing the systematic utility for the generic alternative j. The main evident advantage is that the scale parameters may be defined as the weights in order to measure the uncertainty relating to the alternatives and the attributes involved. Therefore, the probability that a respondent i chooses the alternative j from a choice-set C_i is:

$$P_{ij} = \int_{\varepsilon} \prod_{k \in C_i; k \neq j} \Lambda \left(\frac{x'_{ij}\beta - x'_{ik}\beta + \varepsilon_{ij}}{\theta_k} \right) \frac{1}{\theta_j} \lambda \left(\frac{\varepsilon_{ij}}{\theta_j} \right) d\varepsilon_{ij} \tag{2}$$

with the error term distributed as follows:

$$f(\varepsilon_{ij};\theta_j) = \lambda \left(\frac{\varepsilon_{ij}}{\theta_j} \right) = \exp \left(-\frac{\varepsilon_{ij}}{\theta_j} \right) \exp \left\{ - \left[\exp \left(-\frac{\varepsilon_{ij}}{\theta_j} \right) \right] \right\} \tag{3}$$

In formula (2), θ_j is the scale parameter for the j alternative and $\lambda(.)$ is the probability density function of the Gumbel distribution, as detailed in formula (3), while $\Lambda(.)$ in formula (2) is the corresponding cumulative distribution function evaluated by considering two distinct choices for the i respondent. In fact, the term $x'_{ij}\beta$ denotes the deterministic part of utility of formula (1) related to alternative j and alternative k, respectively. Note that the integral function is defined on the domain [-∞,+∞] of the random component ε, related to the unit i and the alternative j. In this case, preferences of respondent i are evaluated by considering a scaling term (scale parameter) θ_j for the alternative j in the choice-set C_i i.e., the heteroscedasticity of the error term. In the case-study, two alternatives are included in each choice-set and therefore only one scale-parameter is estimated.

3 Results and Discussion

In what follows, we describe the results we have obtained for the HEV model by considering i) Choice1, that is the choice experiment administered before the tasting (Table 1), and ii) Choice2, that is the same choice experiment administered after the tasting (Table 2). More precisely, the following attributes of the choice experiment has been analyzed through the HEV model: price for a quantity of 250 grams at 3 levels: €4.50 considered as a reference level, €6.00 (labeled as ”Price 2”) and €7.50 (labeled as ”Price 3”); coffee type with two levels: ”-1” for blending Arabica and Robusta, and ”+1” for 100% Arabica; packaging with two levels: ”-1” for soft bag with modified atmosphere, and ”+1” for jar with modified atmosphere; Label

Indication with two levels: ”-1” for the presence of an indication of origin, and ”+1” for a certification about the product sustainability; soft and velvety taste with two levels: ”-1” for fairly present and ”1” for highly present (labeled as Soft Velvety Taste), and typical of a 100% Arabica coffee; intense and aromatic taste with two levels: ”-1” for fairly present and ”1” for highly present (labeled as Intense Aromatic Taste) typical of a blending Arabica and Robusta. It must be noted that in both estimated models we also included the constant (”Constant”) term settled with all the attributes at lower level.

When observing the results for Choice1 (1) and Choice2 (Table 2), we can note that the tasting session, together with the information provided on each type of coffee, have a relevant role in unequivocally guiding the consumers’ preferences. More precisely, in Choice1 the negative signs of the estimated coefficients related to the type of coffee and caffeine indicate a preference toward the blending 100% Arabica. This result is also confirmed when considering the estimated coefficients related to the attributes of soft velvety and intense aromatic taste. In fact, the consumers' preferences go towards a highly present level of soft and velvety taste that is typical for the blend 100% Arabica, and towards a fairly present level of the intense aromatic taste. However, when considering the interaction between caffeine and soft velvety taste, when the level of caffeine increases the presence of soft and velvety taste also increases; therefore we note that this result is not in line with the preference expressed towards the blend 100% Arabica. In fact, the blend 100% Arabica is characterized by a lower level of caffeine with respect to the blend Arabica and Robusta, and therefore the level of caffeine should decrease when the soft and velvety taste increases. Therefore, the result related to the interaction term is probably due to the fact that during the session ”Choice1” the respondents do not have enough knowledge about the two types of coffee, and consequently their preferences are not perfectly defined.

Instead, when considering the session ”Choice2” (results shown in Table 2), we can see a notable change in consumers' preferences with respect to Choice1, e.g., apart from the constant term that is negligible, a clear preference towards the blend Arabica and Robusta is outlined. Moreover, the positive signs of the estimated coefficients related to the type of coffee and caffeine indicates a preference towards the blend Arabica and Robusta. In line with this result, the respondents choose a highly present intense and aromatic taste (typical for the blend Arabica and Robusta) and fairly present soft and velvety taste. The estimated coefficient of the tasting scores (labeled ”Taste Score” in Table 2) obtained through the sensory tests, is positive and slightly significant, by indicating a preference towards the blend Arabica and Robusta. Furthermore, the interaction term between ”Taste Score” and ”Soft Velvety Taste” confirms that, after the intermediate session with the sensory test and information step, the consumers are more capable of differentiating between the two types of coffee. In fact, this interaction indicates that when the ”Taste Score” goes towards the blend 100% Arabica, then the ”Soft Velvety Taste” increases. This result confirms the role of guiding performed by the intermediate session, which helps the respondents for giving a coherent evaluation during the 2^{nd} choice session.

A change in the consumer preferences also concerns the packaging: in Choice1 the estimated coefficients related to the packaging goes towards the soft bag with modified atmosphere, even though this coefficient is not significant. In Choice2 instead the packaging coefficients becomes almost statistically significant with a clear preference towards the jar in a modified atmosphere. When considering the label indication, there is no change in the consumers' preferences between Choice1 and Choice2: in both occasions the respondents choose the indication of geographical origin with respect to the certification of product sustainability. The interaction between the taste score and the label indication, even though not significant, indicates that more the consumers' preferences go towards the blend 100%Arabica, more the importance of the certification of product sustainability decreases. This result could be in accordance with a more perceived quality of 100% Arabica coffees by the consumers, hence, less concerned in this case to sustainability issues.

In Choice1 (Table 1) we can observe that both price coefficients (”Price 2” and ”Price 3”) are negative; this means that the willingness-to-pay decreases when price increases, as expected. Nevertheless, after the tasting session (Choice2) a light increment of a willingness-to-pay is highlighted (the intermediate level of price shows a positive coefficient), even though in Choice2 both price coefficients are always not significant.

Moreover, a highly significant scale coefficient relating to the measurement of the heteroscedasticity effect is obtained for both Choice1 and Choice2 HEV models, e.g. the alternatives are not so irrelevant for the respondents, when doing their choices. In this direction, and with respect to the conditional logit model, the HEV model and the Mixed MNL logit model could be considered as competitive models for identifying and measuring the presence of an over-dispersion when modelling the respondent preferences. Nevertheless, the results for the Mixed MNL logit model are not presented in this paper because they require further investigations.

Statistics for Earthquakes

How robust is the skill score of probabilistic earthquake forecasts?

Sulla robustezza della stima delle performance predittive di modelli sismologici probabilistici

Alessia Caponera and Maximilian J. Werner

Abstract Earthquake scientists continue to improve models of the spatio–temporal evolution of seismicity, including complex aftershock sequences. The Collaboratory for the Study of Earthquake Predictability (CSEP) prospectively evaluates the predictive skill of probabilistic forecasts by such models. Here, we assess the robustness of one popular skill score, the information gain per earthquake, with respect to temporal fluctuations of the seismicity rate. We conduct a numerical experiment with a widely-used temporal stochastic seismicity model, a special case of Hawkes process. Our simulations reveal that the information gain fluctuates substantially with time, because a central limit theorem does not hold in a realistic parameter regime. Our results may eventually contribute to more robust inferences.

Abstract *Gli scienziati della terra propongono modelli probabilistici sempre più sofisticati per descrivere l'evoluzione spazio–tempo dei terremoti. Il CSEP (Collaboratory for the Study of Earthquake Predictability) stima prospettivamente le performance predittive di tali modelli. Qui, viene valutata l'incertezza relativa a uno stimatore utilizzato da CSEP, l'information gain per earthquake. Viene condotto un esperimento numerico con un noto modello temporale di sismicità, caso particolare di processo di Hawkes. Le simulazioni effettuate rivelano che, per valori realistici dei parametri, l'information gain mantiene una variabilità elevata nel tempo. I risultati possono contribuire a rendere le conclusioni inferenziali più robuste.*

1 Introduction

Over the last decade, stochastic and physics-based models of seismicity have matured to sophisticated system-specific forecast models that can reliably forecast the evolution of seismicity, including complex aftershock sequences. The international Collaboratory for the Study of Earthquake Predictability (CSEP) provides independent and prospective evaluations of model forecasts, and thereby aims to support robust inferences about the performances of models and guide model development [8]. One challenge is the lack of data: large earthquakes are rare, especially at the regional scales. In addition, seismicity fluctuates over orders of magnitude because earthquakes cluster in space on faults and in time during aftershock sequences.

Because short-term earthquake forecasts are now starting to inform decision-making of societal relevance, there is an urgent need to understand quantitatively the robustness of performance metrics. Here, we focus on a popular measure of the relative predictive skill of two models: the information gain per earthquake.

Despite the information gain's growing importance, its robustness has not been studied in detail. Using simulations from a popular model of clustered seismicity, we show that the information gain suffers from substantial fluctuations, because a central limit theorem does not hold under realistic parameters. Our ultimate goal is to make CSEP model inferences more robust by providing guidelines for the uncertainty in the information gain.

2 The Information Gain per Earthquake

The information gain per earthquake is defined as the log likelihood ratio between two models, say A and B, divided by the total number of earthquakes N, observed in a given time window, i.e.

$$\mathscr{I}_N(A,B) = \frac{\log L_A/L_B}{N} = \frac{\log L_A - \log L_B}{N}. \tag{1}$$

Popular statistical models for earthquake occurrences are based on marked point processes [1, Chap. 6], with magnitudes and locations as marks. We will refer here only to the time–magnitude analysis, discarding the spatial component.

Consider a marked point process on $\mathbb{R}^+ \times \mathbb{R}^+$, adapted to the filtration $\{\mathscr{F}_t\}_{t\geq 0}$, with conditional intensity function $\lambda(t,m|\mathscr{F}_{t-})$, given the history up to but not including time t. Suppose, in addition, that the process is such that the likelihood, given a realization $\{(t_i,m_i)\}_{i=1}^n$ over the interval $[0,T]$, for some positive finite T, is well defined (for further details, see [1, Chap. 7]). Then, the likelihood L of such a realization is expressible in the form

$$L = \left[\prod_{i=1}^n \lambda(t_i,m_i|\mathscr{F}_{t_i-})\right] \exp\left(-\int_0^T \int_{\mathbb{R}^+} \lambda(t,m|\mathscr{F}_{t-}) \mathrm{d}m\mathrm{d}t\right). \tag{2}$$

Its log likelihood ratio on $[0,T]$ relative to a compound Poisson process [1, Chap. 6] with constant intensity ν and mark distribution $\pi(m)$, that is independent of time t, is given by

$$\log\frac{L}{L_0} = \sum_{i=1}^{n} \log\frac{\lambda(t_i, m_i|\mathscr{F}_{t_i-})}{\nu\pi(m_i)} - \int_0^T \int_{\mathbb{R}^+} \lambda(t,m|\mathscr{F}_{t-})\mathrm{d}m\mathrm{d}t + \nu T. \qquad (3)$$

The basic idea behind the information gain is that a forecast with a higher joint log likelihood is "better". However, before observing an earthquake sequence, $\mathscr{I}_N(A,B)$ is a random variable and has its own uncertainty. Additionally, it depends on the duration of the time interval in which we observe the events. We use simulations from a popular model of seismicity to estimate the uncertainty of this statistic and to explore its robustness to the addition of new sequences.

3 The Epidemic Type Aftershock Sequence (ETAS) Model

The Epidemic Type Aftershok Sequence (ETAS) model was introduced by Ogata [6]. Belonging to the class of marked Hawkes processes [4, 1], the model approximates seismicity by an epidemic process: any earthquake increases the rate of future events for some period of time (Hawkes' self-exciting property), and large quakes induce more aftershocks (higher infection rate).

Formally, the ETAS model corresponds to a marked point process [1, Chap. 6] on $\mathbb{R}^+ \times \mathbb{R}^+$, adapted to the filtration $\{\mathscr{F}_t\}_{t\geq 0}$, with conditional intensity function

$$\lambda(t,m|\mathscr{F}_{t-}) = \left[\mu + \sum_{i:t_i<t} k(m_i)g(t-t_i)\right] p(m), \qquad (4)$$

where $\mu > 0$ represents the background seismicity rate; the term $k(m_i)g(t-t_i)$ is the contribution to seismicity rate by the i-th event (t_i, m_i), specifically

$$k(m) = Ae^{\alpha(m-m_0)}, \qquad m \geq m_0, \qquad (5)$$

is the mean number of direct offspring from an event sized m, m_0 being the magnitude threshold, and

$$g(t) = \frac{c^{p-1}(p-1)}{(t+c)^p}, \qquad t \geq 0, \qquad (6)$$

is the modified Omori law [7] for the occurrence times of direct offspring. Magnitudes are distributed independently according to the Gutenberg–Richter law [3]

$$p(m) = \beta\, e^{-\beta(m-m_0)}, \qquad m \geq m_0, \qquad (7)$$

which is the probability density function of a translated exponential distribution with rate parameter $\beta = b\log 10,\ b > 0$. Magnitudes are independent of past seismicity. $A,\ \alpha,\ c,\ p$ are constant positive parameters. For the sake of simplicity, we fix $m_0 = 0$.

The evolution of the information gain is tied to the evolution of the underlying process, as we will show in Section 4 (see also [1, 2]). Thus, we are interested in studying the behaviour of the process itself over time.

Stability properties of the ETAS model are simpler to derive in its branching process representation; we can interpret the mark m_i as the "type" of an individual in a multi-type Galton–Watson process with a modified time dimension. In this context, stability is closely related to the concepts of criticality and a branching ratio. The branching ratio is defined as the number of descendants for one immigrant over the size of their entire family (all descendants plus the original immigrant); that is

$$\rho = \frac{A\beta}{\beta - \alpha}. \tag{8}$$

Sufficient conditions for the existence of a stationary version [1, 2] are

$$p > 1, \qquad \beta > \alpha, \qquad \rho < 1, \tag{9}$$

which implies a *subcritical* process. When $\rho > 1$, the process is *supercritical*: there is a finite probability of an infinite number of events in a unit time interval.

Now, let $N(T)$ denote the number of events in the interval $(0,T]$[1]. If in addition $\beta > 2\alpha$, it can be shown that, for every sequence $\{T_n\}_{n\in\mathbb{N}}$ such that $T_n \to \infty$, a central limit theorem holds [5], namely

$$\sqrt{T_n}\left(\frac{N(T_n)}{T_n} - \frac{\mu}{1-\rho}\right) \xrightarrow{d} \mathrm{N}\left(0, \frac{\mu(1+\sigma^2)}{(1-\rho)^3}\right), \qquad T_n \to \infty, \tag{10}$$

where

$$\sigma^2 = \frac{A^2\beta}{\beta - 2\alpha} - \rho^2.$$

The previous condition $\beta > 2\alpha$ is necessary and sufficient for the existence of σ^2, and hence the asymptotic variance in (10). These results suggest that

$$\mathbb{E}\left[\frac{N(T)}{T}\right] \approx \frac{\mu}{1-\rho}, \qquad \mathbb{V}\left[\frac{N(T)}{T}\right] \approx \frac{1}{T} \times \mathrm{const} \tag{11}$$

for sufficiently large T. However, the condition $\beta > 2\alpha$ does not hold for quakes.

4 Simulation Study

For each model in Table 1, we simulate ten thousand catalogs within the time window $[0, T_{\max}]$, with $T_{\max} = 10\,000$ days, and compute the information gain per earthquake over a finite grid of time $T_1 < T_2 < \cdots < T_k = T_{\max}$, based on the log likelihood

[1] $N(0) = 0$ almost surely.

ratio in (3). The compound Poisson process used in (3) provides a benchmark. We set $\nu = 5$ and $\pi(\cdot) = p(\cdot)$ as the mark distribution.

Experiment		μ	β	α	n	p	c
1	no clustering	1	2.3	0	0	–	–
2	short memory cl.	1	2.3	0	.5	5	.1
3	long memory cl.	1	2.3	$\beta/3$	.5	1.2	.1
4	no CLT	1	2.3	2.2	.5	1.2	.1

Table 1 Simulation scheme.

Remarkable results are displayed in Fig. 4. Experiment 3 shows well behaved trajectories of the number of events per unit time $N(T)/T$. The sample variance is bounded from above by $1/T$ times the asymptotic variance $\mu(1+\sigma^2)/(1-\rho)^3$ from (10). As a result, the information gain stabilizes around a single value. On the other hand, in experiment 4, for which the central limit theorem does not hold, trajectories and sample variance have a completely different behaviour. The information gain that does not converge to a stable value but continues to fluctuate. This is a result of large seismicity variations caused by the high aftershock rates of great earthquakes.

5 Discussion and Conclusions

The lack of an obvious convergence of the information gain per earthquake to a stable value is a warning flag: a gain measured at a moment in time, even if supported by a large data set, may change substantially in the future. The fluctuations result from the empirically-supported near-equality between the Gutenberg–Richter exponent β and the productivity exponent α. Under these conditions, a central limit theorem, which otherwise ensures convergence, does not hold.

A next step is to investigate the importance of a physically required maximum magnitude that truncates the Gutenberg–Richter law. This will theoretically restore the central limit theorem. However, observed magnitudes near the upper limit are extremely rare, and therefore the finite variance may not reign in the fluctuations for decades. Our ultimate goal is to provide CSEP with guidelines for inferring relative model performance on the basis of the information gain.

Functional linear models for the analysis of similarity of waveforms

Modelli lineari funzionali per l'analisi della similaritá di forme d'onda

Francesca Di Salvo, Renata Rotondi and Giovanni Lanzano

Abstract In seismology methods based on waveform similarity analysis are adopted to identify sequences of events characterized by similar fault mechanism and propagation pattern. Seismic waves can be considered as spatially interdependent three dimensional curves depending on time and the waveform similarity analysis can be configured as a functional clustering approach, on the basis of which the membership is assessed by the shape of the temporal patterns. For providing qualitative extraction of the most important information from the recorded signals we propose an integration of the metadata, related to the waves, as explicative variables of a functional linear models. The temporal patterns of this effects, as well as the residual component, are investigated in order to detect a cluster structure. The implemented clustering techniques are based on functional data depth.

Abstract *In sismologia i metodi basati sull'analisi della similaritá tra onde sismiche vengono impiegati per l'identificazione di eventi caratterizzati dallo stesso meccanismo di frattura o di propagazione. Le onde sismiche possono essere considerate come curve tridimensionali, funzioni del tempo e correlate nello spazio, e l'analisi della similaritá delle forme d'onda si puó configurare come un'analisi di clustering funzionale, secondo cui l'appartenenza di un'onda ad un cluster si stabilisce in relazione al pattern temporale. Al fine di estrarre una corretta informazione dai sismogrammi, viene proposto un approccio che integra nell'analisi anche i metadati, riferiti alle onde; questi vengono considerati come esplicative di un modello lineare funzionale. Il pattern temporale degli effetti e della parte residuale, viene analizzato per l'individuazione di strutture di cluster. Le tecniche di clustering implementate sono basate su misure di 'data depth' funzionale.*

1 Introduction

The problem of investigating the seismotectonic structures of an area involves several methods based on waveform similarity analysis. In particular, seismic networks often record signals characterized by similar shapes and methods studying their similarity are adopted to identify sequences of foreshock, main shock and aftershock; in this field the goal is the definition of group of events characterized by similar fault mechanism and propagation pattern, under the hypothesis that a group of dependent events (multiplets) represents a chain led by seismogenetics background of a common earthquake.
The detection of earthquake families or multiplets is finalized to the identification of sources related to the same fault [6] or to obtain instrumental catalogues of independent earthquakes cleaned of dependent ones [3].

Statistical approaches are powerfull tools for detecting dependent events in a seismic data set; waveform similarity analysis is considered to join seismic episodes into a single multiplet [3]; clustering has been demonstrated as a useful method for identifying members of the same group that possess similar waveform. Different techniques for assessing the cluster membership of a earthquake are also reported in literature [8], [1].

Seismic waveform contains information of multiple attributes, that make up the set of integrating metadata concerning the source, the localization of the recording, the time of the event, the dynamics of the registration. A common opinion is that this class of data are also noisy and most techniques, including clustering, can be optimized by using appropriate data preprocessing. Signal filtering as singular value decomposition, as well as short-time Fourier transforms (STFT) are recognized as proper techniques for extracting the key features [9], [5]. In section 2, this complex functional structure is faced by models with explicit functional effect components; this step allow to integrate information from the metadata and to implement cluster analysis on the residual part of the model. Approaches relied on depth measures are considered in order to construct robust tools for the clustering of the curves. In the application, the approach is applied to a set of recordings of the seismic sequence Amatrice - Norcia - Visso, from August 2016 to January 2017, provided by the Engineering Strong Motion database (ESM).

2 The methodology

Seismic waves, that are three dimensional spatially interdependent curves, can be considered as realizations of a multivariate functional random field:

$$f^p(t) = Y^p(t) + \varepsilon^p(t)$$

The couple $(t, f^p(t))$ denotes the time and the oserved value of the function $Y^p(t)$at time t and $t \in [0,T]$. Standardizing the time interval in $[0,1]$:

$Y^p = \{Y^p : [0,1] \to R\}, p = 1,2,3$ is the set of real-valued functions on the closed interval $[0,1]$:

Each $Y^p(t)$ has a set of attributes, among which here we consider the event (metadata concerning the origin identification) and the distance from epicentre of the site where the signal is recorded; we indicate with I the number of events and with J the number of discretized distances. The curves are then indicized by a pair of indexes (i,j) in order to indicate the recordings $f^p_{ij}(t)$ of the i^{th} event at a distance d_j:

$$Y^p_{11}(t), \dots Y^p_{ij}(t) \dots Y^p_{IJ}(t) \quad | \quad Y^p_{ij} \in Y^p,\ t \in [0,1]$$

.

The presence of these effects on their dynamics is modeled in a functional two-way crossed design [10] [11]:

$$Y^p_{ij}(t) = \mu^p(t) + X_i(t) + Z_j(t) \tag{1}$$

Each curve is decomposed into an event-effect $X_i(t)$ and epicentral distance effect $Z_j(t)$, both affecting its shape. Using the Karhunen-Loéve expansion for the effects $X_i(t),\ Z_j(t)$ the model (1) becomes:

$$Y^p_{ij}(t) = \mu^p(t) + \sum_{k=1}^{\infty} \phi^X_k(t)\xi^X_{ik} + \sum_{l=1}^{\infty} \phi^Z_l(t)\xi^Z_{jl} \tag{2}$$

The proposed approach is described for $p = 1$ but its generalization for $p > 1$ can follow from the framework of functional principal components for multidimensional curves. The functional processes $X_i(t), Z_j(t)$ characterize the observed variability and their covariance operator can be estimated using method of moments estimators from the observed curves, [10]. Principal component decomposition of covariance operators results in structured principal components aims to derive the effects of the two attributes on the temporal pattern of the waves: other structures and correlation on the data are detected on the basis of the shape of the temporal patterns using a functional data depht measure. Based on the concept of data depth, this robust nonparametric tool is applied for clustering purposes in the functional data setting, providing an order within a sample of curves. Data depth notion measures the centrality of an observation within a sample and allows the definition of a natural ordering from center outwards; several depth notions generalize unidimensional concept, here we focus on Modified Band Depth [7]. Given the set of n continuous functions $f(t)$ in $[0,1]$ (the double indicization i,j is not necessary here) and λ, a Lebesgue measure in $[0,1]$, for any f of the sample the *Modified Band Depth* is the portion of time that $f(t)$ is inside the regions, made up of $2,3,\dots,k,\dots,K$ of the n curves:

$$MBD_n(f) = \sum_{k=2}^{K} n_{(k)}^{-1} \sum_{1<\ldots r_1,r_2\ldots<n} \frac{\lambda(A(f;f_{r1},f_{r2}))}{\lambda(T)} \tag{3}$$

where $A(f;f_{r1},f_{r2})$ the region delimited by f_{r1} and f_{r2}, is as follows:

$$A(f;f_{r1},f_{r2}) = \{f(t) : min_{r=r_1,r_2} f_r(t) \leq f(t) \leq max_{r=r_1,r_2} f_r(t)\} \tag{4}$$

Two previous paper [2], [4] describe the algorithm based on the notion of Modified Band Depth and adopted here for clustering the curves.

3 The application

A set of recordings of the seismic sequence Amatrice - Norcia - Visso, from August 2016 to January 2017 is considered; data are preprocessed through alignment techniques [12] dealing with different lengths of the sequences, temporal aspects, and signal filtering. The resulting sequences are aligned signals of the same length, sampled at 10 Hz; the curves are represented in figure 1 (a) .After having estimated the model (2), the estimated effects $\hat{X}_i(t)$ and $\hat{Z}_i(t)$, are represented in figure 1, respectively in (b) and in (c). The figure 2 (left) shows the functional residuals from the functional model (2), that are the input of the Modified Band depth algorithm. The algorithm finds an intrinsic order within the set of the curves, and the similarity between consecutive curves can be analyzed. In the figure 2 (right) the kernel of 50% inner curves is represented (on the top) from the 50% of the the most external curves (bottom). It is evident that the two groups differ not for shape but for the amplitude variability. As intermediate result we report in figure 3 a structure of three groups, the (25%) of the inner curves (a), the (25%) of intermediate curves (b) and the (50%) of the external curves (c): the separation is obtained on the basis of MBD and the clusters are well separated. The deepest curves of the three clusters are compared in (d).

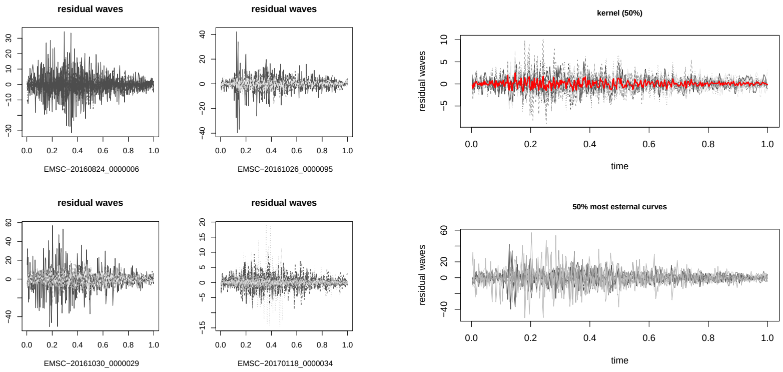

Fig. 2 left: Residuals for the main 4 events; right: the kernel (top) and the external curves (down) of the whole set of residuals from the functional linear model.

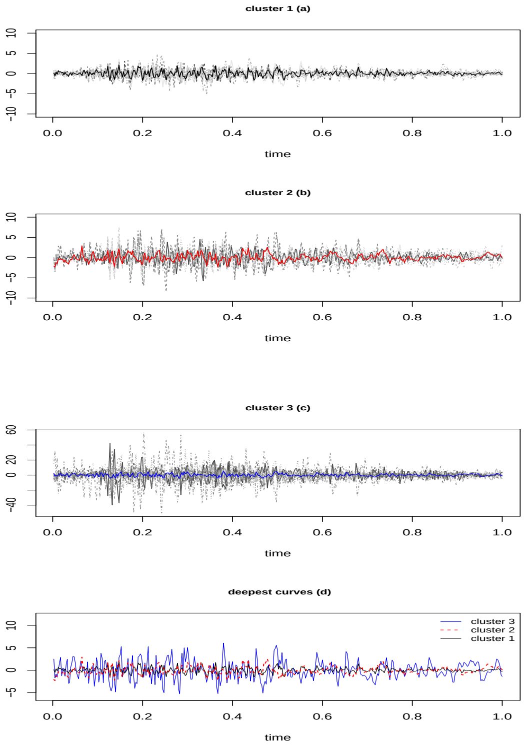

Fig. 3 Three final clusters (a) , (b), (c) obtained from ordered residuals waves. The deepest curves of the three clusters (d).

4 Results and discussion

The proposed approach is an adaptive data-driven method based on the integration of information from metadata in the analysis of the temporal pattern of the waves. Seismic waveform and attributes are used as inputs in a clustering process. Since the seismic waveform contains also some unnecessary information such as noise, they are preprocessed through alignment technique. The functional linear model derives the variability due to the events and the epicentral distance: this results improves the final identification of the clusters of curves with similar amplitude and high correlations. The interest is motivated by further analysis finalized to the study of other seismic features or geological features of the sites. The methodology can be easily extended from two-way to a m-way model [11] and to the case of three-dimensional waves, as the functional principal component analysis is well known technique for $p-$dimensional curves, $p > 1$.

Detection of damage in civil engineering structure by PCA on environmental vibration data
Valutazione del danno in opere infrastrutturali mediante PCA su dati di vibrazione ambientale

G. Agrò, V. Carlisi, R. Mantione

Abstract The dynamic behavior of civil engineering structures is usually studied by means of ambient vibration observations and their performance is analyzed by Peak Picking and/or Operational Modal Analysis methods. This paper reports the first results of a statistical multivariate approach, specifically Principal Component Analysis, to detect a suspected structural damage on a Sicilian highway bridge.
Furthermore, the damage simulated in a simple structural model made it possible to understand the characteristics of the method consisting in comparing the observed data on an undamaged structure with those coming from a damaged one.

Riassunto *Il comportamento dinamico nelle costruzioni civili viene usualmente studiato attraverso prove di caratterizzazione dinamica utilizzando il metodo del Peak Picking e/o quello dell'Analisi Modale Operazionale sul dominio delle frequenze. Il presente lavoro riporta i primi risultati di un approccio statistico multivariato, in particolare l'Analisi in Componenti Principali, al fine di determinare un possibile danneggiamento strutturale di un ponte autostradale siciliano.*
Infine la simulazione del danno in un modello strutturale semplice ha permesso l'individuazione delle variazioni di parametri significativi del metodo utilizzato confrontando i risultati del modello danneggiato con l'omologo integro.

1. Introduction

One of the most used approaches for damage detection in engineering structures is environmental vibration test that allows the gathering of natural frequencies and obtaining the so-called mode shapes and structural dampings. The test is performed using a predetermined number of uniaxial piezometric accelerometers connected to a control unit for the acquisition of environmental acceleration times. By means of Fast Fourier Transform (FFT), the time series are transferred to the frequency domain and the Peak Picking and the Frequency Domain Decomposition (FDD) techniques were used to extract the dynamic parameters from the spectral densities matrices.

The Peak Picking (PP) method leads to reliable results provided that the basic assumptions of low damping and well-separeted modes are satisfied. In fact this method allows to identify the operational deflection shape that, in the case of closely modes, represent the overlap of numerous modes. The Frequency Domain Decomposition (FDD) technique, which represents a significant improvement of the PP, through the Singular Value Decomposition (SVD) of the spectral densities matrices, is able to detect closely spaced modes: the singular value will have a maximum in the resonant frequencies [3,4].

A recent approach in the context of damage identification on engineering structures is the analysis of the principal components (PCA) applied to investigate the existence of any change between a suspected damaged structure and an undamaged similar one adopted as a reference model. The results of the n experimental tests, obtained by means of p sensors, constitute the X matrix, of dimension nxp, which is the starting point for the PCA. The aim of PCA is to reduce the space of p correlated variables in such a way do not lose the bulk of information contained in the data. In synthesis from the data collected in X, the correlation matrix R is calculated such as eigenvectors and eigenvalues of R which are used to identify the subspaces among which choosing the reduced dimension k<p corresponding to a fixed amount of the system variance [1]. This procedure is adopted for the matrix X deriving from the healthy structure and for the matrix Y from the damaged structure. The selected subspaces, one for each systems, are compared by means of the maximum angle θ between the subspaces [6].

Section 2 shows the simulation study, while section 3 shows the results of the analysis on a Sicilian motorway bridge; finally, in section 4, some conclusions are drawn.

2. Numerical application

The system, consisting of two equal masses connected in series through linear springs and adopted for the simulation study (Figure 1), is named a two-degree-of-freedom system (2DOF) and is subject to a free harmonic movement with a natural frequency ω.

The system responses are the vectors u_1 and u_2 that representing respectively the displacement of mass m_1 and mass m_2..

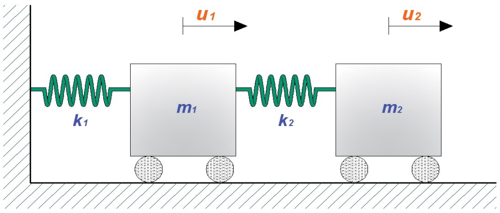

Figure 1: Two degree of freedom mass-spring model undamped and unforced vibration system

The homogeneous linear differential equations of motion, for the 2DOF system, can be written as

$$\mathbf{M}\,\ddot{\mathbf{u}}(t) + \mathbf{K}\,\mathbf{u}(t) = \mathbf{0}$$

or in extended matrix form

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix}\begin{bmatrix} \ddot{u}_1 \\ \ddot{u}_2 \end{bmatrix} + \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{bmatrix}\begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

where **M** is a diagonal mass matrix**,** **K** is a stiffness matrix, while **u** and **ü** are vectors of time varying displacements and accelerations respectively. The trial solution **u**=**U**cos(ωt-φ) with ω *natural frequency*, φ *phase* and **U** *time independent amplitude vector*, lead to solve the classical eigenvalue problem

$$(\mathbf{K} - \lambda\,\mathbf{M})\mathbf{U} = \mathbf{0}$$

where λ_i, i=1,2 are the *eigenvalues*. The *eigenvalues* so obtained depend only from physical parameters of the system. The replacement of $\lambda_i=\omega_i^2$ in the classical eigenvalue problem allows to found the *eigenvectors* U_i corresponding to the natural frequencies, the so-called *mode shapes* [4]. The response of the system is calculated with a sampling frequency of 0.03 sec and the damage is simulated by varying the stiffness of a single spring [5], ($k_1=k_2$=213'330 N/cm, k_2=1, 5, 10, 15, 20, 30 and 40% of k_1), leaving the masses unchanged, $m_1=m_2$=9700 N, and giving an initial displacement. Finally, the simulated response data were perturbed by adding, to each of the time series, a white Gaussian noise with S_d = 15% of the Root Mean Square value of the respective series [2,7]. Natural frequencies were obtained by using the FFT technique that allows to transform the responses from the time domain to the frequency one where we can read the abscissa value of the peaks showed in the graphic of the power spectral density (Figure 2).

Observing Figure 2, where the spectra of the different system conditions are presented (level of damage from 0% to 40%), it is very difficult to detect the presence of damage since the abscissa values of the first peak (frequency) are coincident while for the second one (frequency) the abscissa range variation is very small.

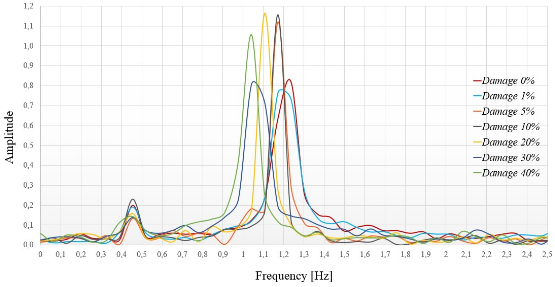

Figure 2: Comparison of frequency

The results of the Principal Component Analysis, applied to the described model, are shown in Figure 3 where the scatterplot of ($u_1(t)$,$u_2(t)$), of the undamaged system is presented and the orthogonal axes (PC1, PC2), a couple for each level of damage, are superimposed.

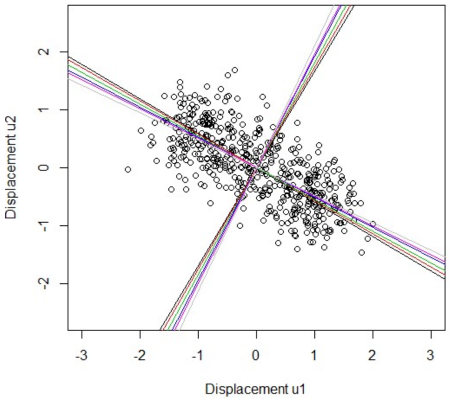

Figure 3: Scatterplot of u_1,u_2 and rotation of the PCA axes for damaged systems

The black axes are related to the undamaged system (dam=0%) and the others are for the systems damaged in increasing way. It can be noted that there is a rotation (in counter-clockwise) of the PC_i axes. The angles θ_i between the black and colored axes could be considered as a measure of the extent of the damage as we will see in the next section.

3. Damage detection: the case of a sicilian highway bridge

The case study concerns a Sicilian highway bridge [8], built in the 70s and 1533 m long; it includes 35 reinforced concrete spans. The bridge consists of isostatic spans, each of which has a deck consisting of four pre-stressing R.C. beams with double T section; each span is 45 m long and 9.8 m wide. Ambient vibration tests were conducted on two adjacent spans 8, considered undamaged, and 9, suspected damaged, using ten uniaxial piezoelectric accelerometers, Figure 4 shows the layout of the sensors. The ambient acceleration time histories were recorded for 2400 sec at interval of 0.01 sec. The present study was conducted using only six vertical sensors, in Figure 4 the red ones, and data were collected in matrices of dimension (240000x6).

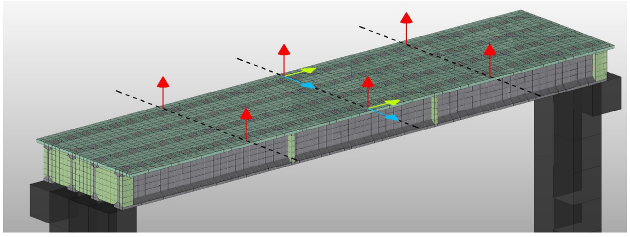

Figure 4: Location of the sensors on the bridge deck

Operational Modal Analysis, according to FDD technique, was used to identify natural frequencies and mode shapes. By comparing the frequency of the spectra of the two spans (Figure 5), the difference in abscissa values of the peaks is very low (less than 10%) and consequently, by means of the PP technique, it is difficult to detect a damage.

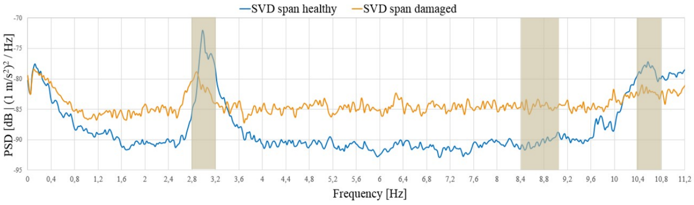

Figure 5: Singular Values of Spectral Densities of Test Setup

The application of the PCA to study the behaviour of healthy span (n.8 matrix X) and damaged span (n.9 matrix Y) led to the identification of optimal four-dimensional subspaces since the percentages of the total variance explained were 75% for healthy span and 80% for damaged span.

In order to measure the difference among the spans, the principal angle between the four-dimensional subspaces was calculated [6]:

$$\cos\theta_k = \max_{d\in D}\ \max_{h\in H} d^T h = \max D^T H \qquad (1)$$

subject to $\|h\| = \|d\| = 1 \quad h^T h = 0\ and\ d^T d = 0$

where $D_{(6x4)}$ and $H_{(6x4)}$ are the matrices of eigenvectors for the damaged and healthy span respectively.

In our case the difference between the two spans exists and it is showed by the angle θ=arcos(-0.7429298)=42°; on this result it is evident that the span 9 has a damage.

Table 3: Cos(θi) calculated by formula (1): maximum value red coloured

H vs D	***PC1***	***PC2***	***PC3***	***PC4***
PC1	**-0.7429298**	0.2386534	0.3945228	-0.3908226
PC2	-0.5139214	0.2406920	-0.2453405	0.3750808
PC3	-0.3328730	-0.1497690	-0.6219700	0.3301877
PC4	-0.1773170	-0.6197478	-0.3634516	-0.6058055

4. Conclusion

The paper presents an investigation of the damage detection capability of the Principal Component Analysis applied to the response structural vibration tests in time domain. The numerical simulation here reported is a starting point of a complete simulation study on different structural models.

On the case study, the analysis of the vibration tests by Peck Peaking technique did not produce easily interpretable evidence while the analysis of the subspaces resulting from the reduction by means of PCA gave evidence of the damage present in the structure.

Statistics for Financial Risks

Conditional Value-at-Risk: a comparison between quantile regression and copula functions

Conditional Value-at-Risk: un confronto tra la regressione quantile e le funzioni copula

Giovanni De Luca and Giorgia Rivieccio

Abstract The popular Value-at-Risk of an institution provides a measure of its own risk. However, in many cases it is of interest to know the measure of the contribution of an institution to the systemic risk, based on the Conditional Value-at-Risk. In this paper we compare the estimation of such measure according to two different methods. The former is based on the quantile regression, the latter on copula functions. In both cases, the heteroskedasticity of the time series is explicity taken into account through a GARCH structure. Moreover, the comparison is also made across different distributional assumptions.

Abstract *Il Value-at-Risk è un'importante misura di rischio di un'istituzione. Tuttavia, in molti casi, è di maggiore interesse la misura del contributo di un'istituzione al rischio sistemico. Tale misura è basata sul Conditional Value-at-Risk. In questo lavoro si confrontano due metodi per la stima del contributo, il primo basato sulla regressione quantile, il secondo sulle funzioni copula. In entrambi casi la struttura eteroschedastica è inclusa attraverso una struttura GARCH. Il confronto è svolto anche considerando diverse ipotesi distributive.*

Key words: systemic risk, quantile regression, copula functions.

1 Introduction

Literature on systemic risk has been recently enriched by the introduction of a new measure, the Conditional Value-at-Risk (*CoVaR*), measuring the effect of an individual financial institution to the systemic risk. *CoVaR* has been proposed in Adrian and Brunnermeier (2011). In its general formulation, it is defined as the Value-at-

Giovanni De Luca

GIorgia Rivieccio
University of Naples Parthenope, via G. Parisi, 13, Napoli, Italy e-mail: rivieccio@uniparthenope.it

Risk (*VaR*) of the financial system given that an institution is under distress. The importance of this measure is given by the possibility of quantifying the contribution of an institution to the financial system distress.

2 Methodology

The Value-at-Risk at level q of the financial system is defined as the q-th quantile of the distribution of the returns Y_f of an index representing the financial system, i.e.

$$Pr\left(Y_f \leq VaR_q^f\right) = q.$$

We denote by $CoVaR_q^{f|Y_i=VaR_q^i}$ the VaR of the index conditional on financial distress of institution i, that is conditional on $Y_i = VaR_q^i$, where Y_i is the return of institution i. As a result, $CoVaR_q^{f|i}$ is implicitly defined by the q-th quantile of the conditional probability distribution $Y_f|Y_i$, that is

$$P\left(Y_f \leq CoVaR_q^{f|i} \left| Y_i = VaR_q^i \right.\right) = q$$

This is the original definition that will be considered in this paper.[1]

The *CoVaR* can be intepreted as the estimate of the effect on the system of a critical situation of institution i. Moreover, it is defined the so-called $\Delta CoVaR_q^{f|i}$, given by

$$\Delta CoVaR_q^{f|i} = CoVaR_q^{f|Y_i=VaR_q^i} - CoVaR_q^{f|Y_i=Median^i}$$

where $CoVaR_q^{f|X_i=Median^i}$ is the q-th quantile of Y_f conditional on a normal situation of institution i, that is the return of institution i is equal to its median. The $\Delta CoVaR_q^{f|i}$ is the increase of $CoVaR_q^{f|i}$ when the institution i goes into distress.

The estimation of the $CoVaR_q^{f|i}$ is usually based on the linear quantile regression technique (Koenker and Bassett, 1978). In this case, the q-th quantile of Y_f, denoted as Y_q^f, is estimated as function of Y_i

$$\hat{Y}_q^f = \hat{\alpha}_q + \hat{\beta}_q Y_i$$

So, the estimate of $CoVaR_q^{f|i}$ is given by

$$\widehat{CoVaR}_q^{f|Y_i=VaR_q^i} = \hat{\alpha}_q + \hat{\beta}_q VaR_q^i$$

while the estimate of $CoVaR_q^{f|Y_i=Median}$ is given by

[1] Girardi and Ergun (2013) have modified the original definition of *CoVaR*, enlarging the conditional event (the institution i is at maximum at VaR_q^i, that is $Y_i \leq VaR_q^i$).

$$\widehat{CoVaR}_q^{f|Y_i=Median^i} = \hat{\alpha}_q + \hat{\beta}_q Median^i.$$

Finally,

$$\Delta\widehat{CoVaR}_q^{f|i} = \hat{\beta}_q(VaR_q^i - Median^i).$$

This procedure does not take into account the heteroskedasticity that typically characterizes financial returns. In this work we modify the quantile regression to take into account this feature of returns. The modified quantile regression approach is based on the following steps:
(a) estimate of a GARCH-type model for returns of both the index of the financial system and institution i and derivation of the standardized residuals η_f and η_i;
(b) estimate of the parameters α and β using a quantile regression such that the q-th quantile of η_f is given by

$$\hat{\eta}_q^f = \hat{\alpha}_q + \hat{\beta}_q \eta^i$$

(c) transformation of the estimated conditional quantiles $\hat{\eta}_q^f$ to obtain $\Delta CoVaR_q^{f|i}$.

An alternative approach is the estimate of $\Delta CoVaR_q^{f|i}$ using the Copula-GARCH approach (Jondeau and Rockinger, 2006). The steps of this procedure are:
(a) estimate of a GARCH-type model for returns of both the index of the financial system and institution i and derivation of the standardized residuals η_f and η_i;
(b) selection of a copula function describing the bivariate relationship between η_f and η_i, $C(F_{\eta_f}, F_{\eta_i})$, where F_{η_f} and F_{η_i} are the distribution functions of the variables η_f and η_i, respectively;
(c) derivation of the conditional copula, $C(F_{\eta_f}|F_{\eta_i})$;
(d) transformation of the estimated quantiles $\hat{\eta}_q^f$ from the conditional copula to obtain $\Delta CoVaR_q^{f|i}$.

Finally, the two procedures are compared through the comparison of the estimates of $\Delta CoVaR_q^{f|i}$.

3 Application to data

We have considered the daily log-returns of eigth assets: A2A, BPER, Enel, FCA, Generali, Intesa San Paolo, STM, Unicredit. Three of them belong to the banking sector (BPER, Intesa San Paolo and Unicredit). The returns have been observed in the period from February 27th, 2013 to January 30th, 2018 (in total we have 1249 observations). The financial system is represented by the FTSEMIB index.

In the quantile regression approach, the estimates have been carried out considering different distributional assumptions in the GARCH specification (in particular we have considered three conditional distribution: Normal, Student's t and Skew Student's t). The same distributional assumptions have been considered in the Copula-GARCH approach, while the copula function is the Student's t copula, characterized by lower and upper tail dependence.

Figure 1 reports the scatterplots of average $\Delta CoVaR_{0.05}^{f|i}$ against the empirical q-th quantile for the eight assets. The top row contains the scatterplots with $\Delta CoVaR_{0.05}^{f|i}$ computed using the quantile regresion approach, in the bottom the scatterplots consider the $\Delta CoVaR_{0.05}^{f|i}$ estimated based on the copula approach. The columns identify the distributional assumptions: Normal (left), Students's t (middle) and Skew Student's t (right). To facilitate the comparison, we have kept the same scale on the y-axis.

The most relevant findings are the following:

1. The quantile regression approach tend to group the assets in two cluster, regardless the distribution of the returns. Interestingly, the two assets with the lowest $\Delta CoVaR_{0.05}^{f|i}$ are two banking institutions (Intesa SanPaolo and Unicredit, that is the biggest Italian banks) shown in the box.
2. According to the copula approach, no clear clustering of the eight assets seems to be plausible. On the other hand, a common feature is evident: Intesa SanPaolo and Unicredit are still the assets with the lowest $\Delta CoVaR_{0.05}^{f|i}$ (still shown inside the box).
3. The values of $\Delta CoVaR_{0.05}^{f|i}$ provided by the copula approach are generally smaller. The details can be found in Table 1 reporting the percentage of cases the $\Delta CoVaR_{0.05}^{f|i}$ obtained by the procedure in row is smaller than the corrensponding measure obtained using the procedure in column. We can conclude that the use of the Student's t copula function which admits tail dependence ensures a more flexible description of the association in the tails of the distributions allowing smaller quantiles.

Table 1 Percentages of success (smaller value) of $\Delta CoVaR_{0.05}^{f|i}$ provided by the copula procedure (marginal distributions are in brackets).

	QR (Gaussian)	QR (Studens *t*)	QR (Skew Student's *t*)
Copula (Gaussian)	75%	75%	75%
Copula (Student's *t*)	100%	100%	100%
Copula (Skew Studens *t*)	100%	100%	100%

Systemic events and diffusion of jumps

Eventi sistemici e diffusione dei jumps

Giovanni Bonaccolto, Nancy Zambon and Massimiliano Caporin

Abstract We propose two indexes informative of the cross-sectional diffusion of jumps from the analysis of a very large dataset of high-frequency returns that is not common in the literature. The two indexes have important implications in terms of asset pricing, as they capture part of the variability in stock returns that is not explained by the factors of the standard capital asset pricing model.
Abstract *Attraverso l'analisi di un ampio dataset di rendimenti ad alta frequenza, non comune nella letteratura, proponiamo due indici che forniscono informazioni sulla diffusione dei jumps tra le varie societá analizzate. Tali indici sono particolarmente informativi in termini di pricing, dato che incorporano una parte della variabilitá dei rendimenti che non é spiegata dai fattori che caratterizzano il tradizionale capital asset pricing model.*

Key words: multiple co-jumps, systemic jumps, systematic jumps, cross-sectional jump diffusion, systemic risk.

1 Data and jump detection

We analyse co-jumps involving a relatively large number of stocks using a huge dataset of high-frequency returns, which is not common in the literature. The

database includes the $N = 3,509$ assets belonging to the basket of the Russell 3000 index for the period January 2, 1998—June 5, 2015.[1] The stock prices are sampled at a frequency of 1 minute from 09:30 a.m. to 04:00 p.m. for each of the 4,344 business days.[2] As a result, we record at the t-th day $M = 390$ 1-minute closing prices for each stock, denoted as $p_{t,i}$, for $t = 1,...,T$ and $i = 1,...,M$. Following a common practice—see [3] and [6], among others—we discard the first 5 minutes of each day to avoid potentially erratic price behaviour resulting from market opening.

[4] note that very high-frequency data are mostly composed of market microstructure noise and suggest to use a 5-minute frequency to mitigate microstructure effects. As a result, our empirical analysis builds on 5-minute returns, that we obtain by aggregating the original 1-minute returns.[3] To cope with market liquidity conditions, we restrict the attention on stocks with a sufficient number of non-null intraday returns to obtain accurate estimates of integrated volatility and jumps. In particular, we implement testing methods, described below, under the condition that, on a given trading day, the percentage of non-zero intraday returns is greater than or equal to 75%. In contrast, we treat the days on which the percentage of non-null returns is lower than 75% as days where no jumps occur. With some abuse of wording, we define assets with more than 25% of intradaily returns equal to zero as illiquid.

We use the *C-Tz* test proposed by [5] to identify the presence of jumps within each trading day in a cross-section of Russell 3000 constituents. Notably, the *C-Tz* test provides greater power than other tests based on multipower variation (see [5]). Following [2], we implement the test after standardising the returns to correct for volatility periodicity. Therefore, we improve the detection of small jumps during low volatility periods and reduce spurious detections of jumps at high volatility times. We detect the presence of jumps at both daily and intradaily levels. Then, we also gain knowledge about the location of jumps during the day. We highlight that only a few works use non-parametric tests to explicitly detect intraday jumps.

2 Common jumps

We analyse the cross-sectional diffusion of jumps by using intradaily returns with a 5-minute frequency. By using the co-exceedance rule of [6], we first implement the *C-Tz* test at the significance level $\alpha = 0.01\%$ to detect intraday jumps. Then, we compute the following variable:

$$C_{t,i} = \sum_{j=1}^{N} \mathbb{I}\{\text{Jump}_{t,i,j} > 0\} \begin{cases} \geq 2 & \text{Co-jump} \\ \leq 1 & \text{Single jump} \end{cases} \tag{1}$$

[1] The dataset is provided by Kibot, and the details are available at http://www.kibot.com. Our dataset includes also dead stocks or stocks that are no longer included in the Russell 3000 index.

[2] The original number of business days in our sample is equal to 4,384. We discard 40 days for which we observe particular tight liquidity conditions.

[3] The results obtained with other frequencies are available upon request.

to verify whether two or more assets record a jump in the same interval, where $\mathbb{I}$ is an indicator function taking the value of 1 when a jump is detected for asset j ($j = 1,\dots,N$, $N = 3509$) at the intraday interval i ($i = 1,\dots,77$ using 5 minutes intervals) on day t ($t = 1,\dots,4344$), and the value of 0 otherwise.

Notably, we checked that the *C-Tz* test is better able to detect common jumps than other common tests in the literature, such as the *s-BNS* test of [1]. It also highlights structural changes from 2001. Interestingly, we observed that around lunchtime co-jumps tend to increase, whereas individual jumps decrease. Several studies report the existence of a U-shaped pattern for the average volume of traded stocks and, in particular, relatively light trading in the middle of the day. The co-jump intraday pattern, with larger detection in the middle of the day, supports such evidence.[4]

Table 1 Asset jumps and market jumps. The table reports the number of days in which we observe at least one RUA jump (N_{RUA}), the amount of days in which we observe at least one intraday jump (N_j) or one co-jump (N_{cj}) in the constituents of the Russell 3000 and the days with both a jump in the index and a jump ($N_{RUA} \cap N_j$) or a co-jump ($N_{RUA} \cap N_{cj}$) in the underlying assets. These statistics are computed for the period January 1998—June 2015. We consider three observation intervals—1, 5 and 11 minutes. The results are obtained by implementing the *C-Tz* test.

Frequency	N_{RUA}	N_j	$N_{RUA} \cap N_j$	N_{cj}	$N_{RUA} \cap N_{cj}$
1 min	1,512.00	4,119.00	1,418.00	3,858.00	1,345.00
5 min	176.00	4,333.00	175.00	4,109.00	172.00
11 min	57.00	4,344.00	57.00	4,269.00	57.00

Jumps of individual stocks may affect the entire market. For instance, market-level news causing co-jumps of individual stocks might also be reflected in jumps of market portfolios. Further, co-jumps of stocks involving the market index can be seen as non-diversifiable events, with important implications for portfolio selection and hedging. Here, we define as systematic the co-jumps that occur simultaneously with a jump in the market index. Likewise, we define as non systematic the co-jump events detected from single-asset co-jumps but not reflected in a jump at the market index level. In short, we label as RUA jumps those that occur on the Russell 3000 index (RUA), our proxy for the market index. Table 1 shows jump days for the market index, jump and co-jump days in the underlying assets and the number of jump and co-jump days that are also RUA jump days. As a robustness check, Table 1 reports the results for three observation intervals, that is, 1, 5 and 11 minutes. Interesting findings emerge from Table 1. First, jump (N_j) and co-jump (N_{cj}) days are positively related to the interval length, whereas the opposite holds for the RUA index (N_{RUA}). Second, the number of days with at least one intraday co-jump is always lower than the corresponding number of days with at least one intraday jump.

[4] Tables and figures displaying such evidences, that we omit here for the sake of space, are available upor request.

Nevertheless, it still takes relevant values: from a minimum of 3,858 days (89% of the sample days) to a maximum of 4,269 days (98% of the sample days). Thus, we observe a co-jump for nearly each day of the sample. We stress that the definition of co-jumps is not particularly restrictive and, thus, we might have co-jumps involving only a small number of assets. Third, columns 4 and 6 of Table 1 present the intersections between jump days in the market index and jump or co-jumps days detected in the underlying assets. $\mathrm{N}_{RUA} \cap \mathrm{N}_j$ and $\mathrm{N}_{RUA} \cap \mathrm{N}_{cj}$ are useful to evaluate the capability of RUA to reflect cross-sectional jump events. Starting from the evidence that the majority of jumps and co-jumps do not occur simultaneously with jumps in the index, it is possible to deduce that the jumps in the index are not really informative of the presence of jumps and co-jumps in the cross-section. Since we are aggregating results for daily frequency, outcomes derived from intraday intervals would show even fewer intersections.

3 Multiple co-jumps, diffusion indexes and pricing

We now define as multivariate jump (or MJ) the subset of co-jumps such that:

$$MJ_{t,i} = \begin{cases} \sum_{j=1}^{N} \mathbb{I}\{\mathrm{Jump}_{t,i,j} > 0\} & \text{if } \sum_{j=1}^{N} \mathbb{I}\{\mathrm{Jump}_{t,i,j} > 0\} \geq K \\ 0 & \text{otherwise,} \end{cases} \tag{2}$$

where $K > 2$.

On the basis of (2), we build two indexes: a daily diffusion index (or DID) and an intraday diffusion index (or DII). The DID, for each day from January 2, 1998 to June 5, 2015, equals the largest number of stocks simultaneously jumping within the day. Note that the index might also take a zero value when no MJ occurs in a given day. The DII, in contrast, has an intradaily frequency of 77 observations per day. Each observation points out the number of stocks involved in a multivariate jump, if present, and 0 otherwise. The aim is to analyse the pricing implications of multivariate jumps by extending the standard capital asset pricing model (CAPM)—see [9], [7] and [8]. For the DID (a daily index), we estimate the CAPM and our two-factor model, respectively defined as follows:

$$R_{t,j} - R_{t,F} = \alpha_j + \beta_j MKT_t + e_{t,j}, \tag{3}$$

$$R_{t,j} - R_{t,F} = \alpha_j + \beta_j MKT_t + \beta_{DID,j} DID_t + e_{t,j}, \tag{4}$$

where $R_{t,j}$ is the daily return of the j-th asset, $R_{t,F}$ is the risk-free return that we record from the Kenneth R. French data library, DID_t is the daily diffusion index computed using the C-Tz test and $e_{t,j}$ is a zero-mean residual; $MKT_t = (R_{t,M} - R_{t,F})$ is the excess return on a capitalisation-weighted stock market portfolio, where $R_{t,M}$ is the daily RUA Index return.

Table 2 shows the statistical significance of estimated β_{DID} (denoted as $\hat{\beta}_{DID}$) along with the variations in the R^2_{adj} values we obtain, including the diffusion index in the CAPM model. The second column of Table 2 reports the percentage of $\hat{\beta}_{DID}$ with absolute t-statistic greater than 1.645 (10% significance level), using different time windows. Considering the full sample, January 2, 1998—June 5, 2015, we observe that 10% of $\hat{\beta}_{DID}$s are statistically significant. This suggests that the diffusion index could be an important risk factor in asset pricing. Table 2 also reports results for different sub-periods, highlighting how the relevance of DID changes over time and, in particular, focusing on economic crises. DID slopes are significantly different from zero in a relevant number of cases for all sub-periods, with values larger than the full-sample regression. Moreover, it appears that DID slopes are more frequently significant during the pre-2008 economic crisis, namely from 2002 until 2006. The analysis of R-squared highlights the ability of DID to capture part of the variation in stock returns not explained by the traditional market factor. Table 2 reports information on the variations in the R^2_{adj} values we obtain, including the diffusion index in the CAPM model. Min and Max correspond, respectively, to the minimum and maximum difference values, while $Q(0.25)$, Median and $Q(0.75)$ show the values for the first, second and third quartiles of the R^2_{adj} variation. Even if the majority of the variations are negative, the third and fourth quartiles suggest that many variations are positive and larger in absolute value with respect to negative variations. Increases are particularly pronounced during the years 2002—2006 and 2012—2015.

We now move our focus to intraday data. Similar to the daily case, we run monthly regressions using 5-minute data to study how DII helps in explaining stock returns. Our two-factor model for intraday data is:

$$R_{t,i,j} - R_{t,i,F} = \alpha_j + \beta_j MKT_{t,i} + \beta_{DII,j} DII_{t,i} + e_{t,i,j}, \tag{5}$$

where $R_{t,i,j}$ is the return on a security j, on day t for the intraday interval i, $R_{t,i,F}$ is the risk-free return that we approximate equal to 0, $DII_{t,i}$ is the C-Tz intraday diffusion index, $MKT_{t,i} = (R_{t,i,M} - R_{t,i,F})$ is the excess return on the Russell 3000 market portfolio and $e_{t,i,j}$ is a zero-mean residual. The use of high-frequency data allows us to obtain long samples of stock returns. Consequently, it is possible to run regressions using data from a reduced number of days and thus track how the significance of β_{DII} changes over time. We estimate the parameters of the model using non-overlapping rolling windows with a size of 22 days, which corresponds to 1,694 5-minute observations, or about one month of data. We observed high fractions of significant betas for almost all intervals from 2004 until 2015. This confirms that multivariate jumps help to explain stock returns by capturing common variations that are missed by the standard market factor and that might have some economic relevance when focusing on high-frequency data. Moreover, we do not observe higher levels of significance during the 2008 pre-crisis months but, instead, high picks clustered in 2007, 2008, 2010 and 2013.[5] Therefore, the DID performs well during calm periods, while the DII is more effective during more turbulent economic phases.

[5] Tables and figures displaying such results, omitted here for the sake of space, are available upon request.

Table 2 $\hat{\beta}_{DID}$ **significance and DID** R^2_{adj} **variation**. Here, we compare the CAPM model defined in (5) with our two-factor model defined in (6). Regressions are subject to the condition that stocks presents at least 251 days (about a year) of non-null returns in the window of interest. Column $\hat{\beta}_{DID}$ reports the percentage of times in which $\hat{\beta}_{DID}$ in (6) is statistically significant at the 0.1 level in the window of interest. From the third to the seventh column we focus on the variation in the coefficient of determination (or CoD) we observe by moving from the CAPM to the two-factor model. Min and Max are respectively the minimum and the maximum difference values whereas $Q(0.25)$, Median and $Q(0.75)$ are the first, second and third quartiles of the same differences.

Window	$\hat{\beta}_{DID}$	$R^2_{adj}(\text{2-factor}) - R^2_{adj}(\text{CAPM})$				
		Min	$Q(0.25)$	Median	$Q(0.75)$	Max
1998-2015	10%	-0.000	-0.000	-0.000	0.000	0.020
2002-2006	35%	-0.001	-0.001	-0.000	0.008	0.072
2007-2011	11%	-0.001	-0.001	-0.000	0.000	0.011
2012-2015	20%	-0.003	-0.001	-0.001	0.000	0.123

Abstract

Girardi and Ergün (2013) (GE) modify Adrian and Brunnermeier's (2016) Conditional Value at Risk (CoVaR) from the maximum loss of the system conditional on the financial institution being in its VaR, to the financial institution being at most at its VaR. Here we extend GE's CoVaR computation using Filtered Historical Simulation and a DCC multivariate GARCH model of Engle (2002). Filtered Historical Simulation allows us to compute one-day ahead forecasts of CoVaR and ΔCoVaR. Additionally, we propose a new Traffic Light System (TLS) for Systemic Risk Detection that provides a comprehensive color-based classification that groups companies according to both the level of stress reaction of the system when the company is in distress and the level of stress of the company. TLS can be used to enhance the performance and robustness of current systemic risk measures.

Keywords: DDC, conditional correlations, CoVaR, FHS, Systemic Risk

1 – Introduction

The recent financial crisis has fueled the search for precise systemic risk measures. Several papers have proposed different systemic risk measures as Billio et al. (2012), Zhou (2010), Huang et al. (2009), Segoviano and Goodhart (2009), Acharya et. al. (2010), Brownless and Engle (2011) and Allen et al. (2010). Girardi and Ergün (2013) (GE) modify Adrian and Brunnermeier's (2011, 2016) Conditional Value at Risk (CoVaR), the VaR of the financial system conditional on an institution being in financial distress. GE propose a change in the definition of CoVaR, from the maximum loss of the system conditional on the financial institution being in its VaR, to the financial institution being at most at its VaR.

CoVaR is an extension of the VaR which only gauges the risk of an institution in isolation. Therefore, computing CoVaR required precise estimation of the relationship between the system and the company. GE report time varying in sample CoVaR estimating a bivariate GARCH model with Engle's (2002) DCC specification for the returns of the institution and the financial system to fit volatility and correlations. Mainik and Shaanning (2012) show that the dependence parameter between institutions and system plays a key role in the accurate systemic risk measurement. In particular, as the institution and the system become more and more correlated, the institution systemic risk increases. This fact makes accurate relationship measures extraordinarily important when analyzing financial distress.

In this paper, we extend GE's CoVaR computation using Filtered Historical Simulation and a DCC (Engle, 2002) multivariate GJR-GARCH model of Glosten, Jagannathan, and Runkle, (1993). Following GE, we start by estimating CoVaR for 58 out of 78 companies used in GE and Acharya et. al. (2010) with an extended sample from January 2000 until January 2018. A novel contribution of this paper is about the distributional assumption on the error. Multivariate normal and skewed-t distributions have already been used in GE. Risk measurement might suffer from the shortcomings involved in assuming a parametric error distribution. Filtered Historical Simulation (FHS) has emerged as one of the best tools for calculating risk measures as VaR and consequently a robust alternative as a procedure to forecast CoVaR. FHS, introduced by Barone-Adesi et al. (1998) and Barone-Adesi et al. (1999) uses a combination of volatility models and past returns to build the probability distribution of the future returns. The daily row returns are first scaled by the volatility that prevail that day and then are multiplied by the current forecast of volatility. The first step, the scaling, is necessary in order to make the past returns stationary and to provide suitable innovations for a simulation process. The second step, the re-scaling, endows the historical returns to reflect the current volatility conditions prevailing in the markets.

Combining the MGARCH specifications and FHS we produce 1-day ahead CoVaR forecast using a multi-step modelling approach: (1) a multivariate GJR-GARCH DCC (Engle, 2002) model is used to fit volatility and correlations; (2) FHS is used to simulate paths of 1-day ahead forecast returns. With FHS the distributional assumptions of the errors are relaxed, although the market condition are taking into account by using the conditional volatility and correlations estimated in step one; (3) from the joint empirical distribution of the simulated returns for the system and company, the empirical CoVaR and $\Delta CoVaR$ are computed. $\Delta CoVaR$ was proposed by Adrian and Brunnermeier (2011, 2016) and is computed as the difference between the CoVaR of the systems and the unconditional financial system VaR. $\Delta CoVaR$ captures the marginal contribution of a particular institution to the overall systemic risk. However, $\Delta CoVaR$ is not sufficient as a precise measurement of company systemic risk.

For instance, what happen to the system in a company's high stress state, when the realized loss exceeded the VaR forecast, might be of particular relevance for an accurate ranking of systemic companies. To see our argument more explicitly, let's assume that two institutions, *j* and *i,* individually contribute to a system's large loss (realized loss exceeds $CoVaR$), they even might have reported the same $\Delta CoVaR$. Nonetheless, when analyzing the company′s losses of *j* and *i*, it might happen that the *i-th company*'s loss is relatively shorter than *j*'s loss (*j'*s companies exceedance is larger than *i*'s company). Under these circumstances, *i* and *j*'s contribution to the systemic risk should not be reported as similar. Institution *i* seems to be riskier than company *j.* Short exceedances in the *i-th company* hurt the system as much as large exceedances in company *j* do.

Our Traffic Light System (TLS) for Systemic Risk Detection proposed in this paper deals with the above issue. *TLS* makes use of loss functions frequently used in backtesting to provide a more accurate systemic risk ranking for financial companies. TLS classifies financial institutions by a color code that will group companies into four categories according to the joint behavior of the company and system exceedances magnitudes.

The remainder of the paper is organized as follows. In Section 2, we describe CoVaR and ΔCoVaR and the way to compute it. Section 3 presents the new TLS. Section 4 describes the results, including a preliminary statistical analysis, and Section 5 presents the conclusions.

2 – Measuring Systemic Risk with ΔCoVaR under Multivariate GARCH

The Conditional Value-at-Risk (CoVaR) is an extension of the Value-at-Risk (VaR) which only gauges the risk of an institution in isolation. The classical formulation of Value-at-Risk implicitly defines it as the *q*-quantile of the return

$$\Pr\left(R_t^j \leq VaR_{q,t}^j\right) = q \tag{1}$$

where $VaR_{q,t}^j$ is the *q%* Value-at-Risk for company j, whose asset returns are R^j. The CoVaR extends the classical VaR definition by adding a conditional event, and points at the estimation of the conditional quantile of the financial system rather than on a single company. In this paper, we use the definition of CoVaR proposed by Girardi and Ergün (2013). They condition the evaluation of the system Value-at-Risk on the event that institution *j* is *at most at* its VaR. Such a choice differs from the most know definition of CoVaR due to Adrian and Brunnermeier (2011). In fact, the latter condition on institution *j* being *exactly* at its VaR. Therefore, Girardi and Ergün (2013) defines $CoVaR_{q,t}^{s|j}$ as the VaR of the system conditional on institution *j* been *at most at* its VaR. This is implicitly defined by the *q%* - quantile of the conditional probability distribution:

$$\Pr\left(R_t^s \leq CoVaR_{q,t}^{s|j} \mid R_t^j \leq VaR_{q,t}^j\right) = q \tag{2}$$

where $CoVaR_{q,t}^{s|j}$ is expressed in terms of R^s, the asset returns of the system and $VaR_{q,t}^j$ is the Value-at-Risk of company *j*. Note that we use the same reference level, *q*, for both the system and the company; this is not a required and we can easily allow for different levels in the VaR of the company and the CoVaR of the system. The CoVaR is a system-based risk measure conditional to the possible presence of a distress in one of the companies included in the financial system.

Adrian and Brunnermeier (2015), followed by Girardi and Ergün (2013), propose not to monitor directly the CoVaR but a different quantity, namely, the marginal contribution to systemic risk of a single institution. They suggest focusing on ΔCoVaR, which is the difference between the Conditional VaR of the system when the institution is in *distress* and the Conditional VaR of the system when the institution is in a *normal state*. In the CoVaR formulation of Girardi and Ergün (2013) this rationalizes as

$$\Delta CoVaR_{q,t}^{s|j} = 100 \times (CoVaR_{q,t}^{s|j} - CoVaR_{q,t}^{s|b^j}) / CoVaR_{q,t}^{s|b^j} \qquad (3)$$

where $CoVaR_{q,t}^{s|b^j}$ is the VaR of the financial system conditional on the *benchmark* state of institution j, b^j, defined as a one-standard deviation about the mean event: $\mu_t^j - \sigma_t^j \le R_t^j \le \mu_t^j + \sigma_t^j$ where μ_t^j and σ_t^j are the conditional mean and standard deviation of institution j, respectively, evaluated with a proper model. For additional details, we refer the reader to Girardi and Ergün (2013).

3.- Traffic Light System for Systemic Risk Detection

This paper presents an approach for reliably assessing financial companies' relative contribution to the systemic market stress as implied by distress states of the companies. Our methodological contribution, summarized into a Traffic Light System (TLS) for Systemic Risk Detection, provides a comprehensive color-based classification that groups companies according to both the level of stress reaction of the system when the company is in distress and the level of stress of the company. In particular, TLS produces a quantitative assessment of relative contribution to systemic stress based on the magnitude of exceedances while both the company and the system are in distress. TLS uses appropriate loss functions to quantify the level company and system's stress.

4 – Data description and main results

4.1. Data description

We work with daily data for 58 US financial institutions on the same four industry groups considered by Girardi and Ergün (2013). Table 1 lists these financial institutions and their type based on two-digit SIC classification code: Depositories Institutions, Securities Dealers and Commodity Brokers, Insurance, and Others. We use the Dow Jones US Financial Index (DJUSFN) as a proxy for the financial system, as Girardi and Ergün (2013). In our case, the full sample goes from January 3rd, 2000 to January 15th, 2018 (4706 observations). A rolling window of 1000 observations is used in the estimation of the model, and 3705 one-day-ahead forecasts are produced since November 3rd, 2003 up to the end of the sample. We compute daily returns as the first difference of log prices, i.e. $[\ln(P_{t+1})-\ln(P_t)]$. We recovered all data from Thomson Reuters Datastream.

4.3. TLS at work

We use TLS to classify the 58 companies used in Girardi and Ergün (2013). Figure 1 shows the companies labelled according TLS. Horizontal axis represents $\left(MD_{t+1}^{i}-\overline{z}_{t+1}^{c}\right)$, i.e. the magnitude of the company's stress state (high stress state when positive, low stress state when negative). Vertical axis represents $(MD_{t+1}^{s|i}-\overline{z}_{t+1}^{s|c})$, i.e. the magnitude of the system's stress state (high stress state when positive, low stress state when negative). The size of the circles is based on the company capitalization in the analyzed period.

5.- Conclusions

The main conclusions are as follows:

1. We provide a new color-based systemic indicator, TLS for systemic risk detection using loss functions frequently used in backtesting to provide a more accurate systemic risk ranking for financial companies.

2.- TLS provides a company ranking system identifying various levels of systemic risk providing a color-based code defined in the line of The Basel Committee's Traffic Light to classify financial institutions. The new TLS is an intuitive, clear and powerful tool for monetary authorities being a complementary to other well-known systemic risk measures.

Bayesian Quantile Regression Treed

Mauro Bernardi and Paola Stolfi

Abstract Decision trees and their population counterparts are becoming promising alternatives to classical linear regression techniques because of their superior ability to adapt to situations where the dependence structure between the response and the covariates is highly nonlinear. Despite their popularity, those methods have been developed for classification and regression, while often the conditional mean would not be enough when data strongly deviates from the Gaussian assumption. The approach proposed in this paper instead considers an ensemble of nonparametric regression trees to model the conditional quantile at level $\tau \in (0,1)$ of the response variable. Specifically, a flexible generalised additive model (GAM) is fitted to each partition of the data that corresponds to a given leaf of the tree, allowing an easy interpretation of the model parameters. Indeed, while the trees structure easily adapts to regions of the data having different shapes and variability, the nonlinear part handles parsimoniously the local nonlinear structural relationship of the quantile with the covariates. Unlike the most popular Bayesian approach (BART) that assumes a sum of regression trees, quantile estimates are obtained by averaging the ensemble trees, thereby reducing their variance. We develop a Bayesian procedure for fitting such models that effectively explores the space of B–Spline functions of different orders that features the functional nonlinear relationship with the covariates. The approach is particularly valuable when skewness, fat–tails, outliers, truncated and censored data, and heteroskedasticity, can shadow the nature of the dependence between the variable of interest and the covariates. We apply our model to a sample of US companies belonging to different sectors of the Standard and Poor's Composite Index and we provide an evaluation of the marginal contribution to the overall risk of each individual institution.

Key words: Quantile regression treed, Bayesian inference, Conditional Value–at–Risk.

1 Introduction

In empirical studies, researchers are often interested in analysing the behaviour of a response variable given the information on a set of covariates. The typical answer is to specify a linear regression model where unknown parameters are estimated by OLS, thereby leading to the approximation of the mean function. Although the mean describes the average response path as a function of the covariates, it provides little o no information about the behaviour of the conditional distribution on the tails. As far as the entire distribution is concerned, quantile regression methods adequately characterise the behaviour of the response variable at different confidence levels providing a complete picture of the relationship with the covariates. Moreover, the quantile analysis is particularly suitable when the conditional distribution strongly deviates from

the Gaussian assumption because it displays heterogeneity, asymmetry or fat–tails, see, e.g., [9]. Linear quantile regression models have been extensively applied in different areas, such as, finance, engineering, econometrics and environmetrics, as a direct approach to quantify the level of risk of a given event, social sciences and quantitative marketing to find appropriate and effective solutions to specific segments of customers, and many other related fields see, [10]. However, despite their relevance and widespread application in empirical studies, linear quantile regression models provide only a rough "first order" approximation of the relationship between the τ–level quantile of the response variable and the covariates. Indeed, as first recognised by [9], quantiles are linear functions only within a Gaussian world, thereby stimulating many recent attempts to overcome this limitation. [6], for example, consider the copula–based approach to formalise nonlinear and parametric conditional quantile relationships. Although quite flexible in fitting marginal data, the copula approach forgets to consider nonlinear interactions among the covariates. Classification and regression trees (CART, [4]) and their population counterparts ([3]) extensively use recursive partitioning algorithms to perform nonparametric regression and variable selection. The attractive feature of decision trees methods rely in their ability to partition the covariates space into disjoint hyperrectangles, thereby improving the local fit. Therefore, CART adapt to situations where the dependence structure between the response and the covariates is highly nonlinear. Despite their extensive use in a wide variety of fields, those methods have been mainly developed for classification and mean regression. In this paper, we adopt the Bayesian point of view and we extend the Bayesian regression trees approach of [7] to deal with conditional quantiles estimation. Quantile estimation have been previously extended within the related context of random forest by [11]. However, unlike random forests, the Bayesian approach to decision trees learning, being likelihood–based, provides a complete inferential tool for model assessment and selection.

2 Quantile regression treed

The linear quantile regression framework for independent and identically distributed data models the conditional τ–level quantile of the response variable Y, with $\tau \in (0,1)$, as a linear function of the vector of dimension $(q \times 1)$ of exogenous covariates $\mathbf{X}$, i.e., $\mathscr{Q}_\tau(Y \mid \mathbf{X} = \mathbf{x}) = \mathbf{x}'\boldsymbol{\beta}$, thereby avoiding any explicit assumptions about the conditional distribution of $Y \mid \mathbf{X} = \mathbf{x}$. This is equivalent to assume an additive stochastic error term ε for the conditional regression function $\mu(\mathbf{x}) = \mathbf{x}'\boldsymbol{\beta}$ to be independent and identically distributed with zero τ–th quantile, i.e, $\mathscr{Q}_\tau(\varepsilon \mid \mathbf{x}) = 0$, and constant variance. Following [12] and [2], the previous condition is implicitly satisfied by assuming that the conditional distribution of the response variable Y follows an Asymmetric Laplace (AL) distribution located at the true regression function $\mu(\mathbf{x})$, with constant scale $\sigma > 0$ and shape parameter τ, i.e., $\varepsilon \sim \mathsf{AL}(\tau, \mu(\mathbf{x}), \sigma)$, with probability density function

$$\mathsf{AL}(Y \mid \mathbf{X} = \mathbf{x}, \sigma, \tau) = \frac{\tau(1-\tau)}{\sigma} \exp\left\{-\frac{1}{\sigma}\rho_\tau(Y - \mu_\tau(\mathbf{x}))\right\} \mathbb{1}_{(-\infty,\infty)}(Y), \tag{1}$$

where $\mu_\tau(\mathbf{x})$ is the quantile regression function and $\rho_\tau(u) = u\left(\tau - \mathbb{1}_{(-\infty,0)}(u)\right)$ denotes the quantile check function at level τ. The quantile regression model postulated in equation (1) assumes the AL distribution as a misspecified working likelihood that correctly identify the conditional quantile function.

Unlike the Bayesian Additive Regression Tree (BART) approach of [8] which considers a sum–of–trees regression where each tree explains only a small portion of the total variance of the dependent variable Y, we model the conditional quantile of the response variable as a function of the covariates as the average of an ensemble of $m \in \mathbb{N}_+$ regression treeds

$$\begin{aligned} \mathscr{Q}(Y \mid \mathbf{X} = \mathbf{x}) &= \mu_\tau(\mathbf{x}) & (2)\\ &\approx \frac{1}{m}\sum_{l=1}^{m} \mathscr{T}_l^{\mathscr{M}_l}(\mathbf{x}), & (3) \end{aligned}$$

where $\mathscr{T}_j^{\mathscr{M}_j}$ denotes the j–th treed of the ensemble, for $j = 1, 2, \dots, m$. In equation (3) each regression trees is composed by a tree structure, denoted by $\mathscr{T}$, and the parameters of the terminal nodes (also called leaves), denoted by $\mathscr{M}$. Therefore, the j–th tree for $j = 1,2,\ldots,m$, denoted by $\mathscr{T}_j^{\mathscr{M}}$, represents a specific combination of tree structure $\mathscr{T}_j$ and tree parameters $\mathscr{M}_j$, i.e., the regression parameters associated to its terminal nodes.

3 Conditional Value–at–Risk estimation

In this section we apply the methodology introduced in the previously section to analyse the tail co–movements between a financial institution j and the whole financial system k. To this aim we consider the Conditional Value–at–Risk (CoVaR) recently introduced by [1], which is defined as the overall VaR of an institution, conditional on another institution being in distress. To be more specific, let (Y_j,Y_k) be the bivariate random variable describing the return of institutions j and k, for $k \neq j$ and assume (Y_j,Y_k) depend on a vector of exogenous covariates $\mathbf{X} = (X_1,X_2,\ldots,X_q)$, then the Conditional Value–at–Risk $\left(\mathrm{CoVaR}_{k|j}^{\mathbf{x},\tau}\right)$ is the Value–at–Risk of institution k conditional on $Y_j = \mathrm{VaR}_j^{\mathbf{x},\tau}$ at the level $\tau \in (0,1)$, i.e., $\mathrm{CoVaR}_{k|j}^{\mathbf{x},\tau}$ satisfies the following equation

$$\mathbb{P}\left(Y_k \leq \mathrm{CoVaR}_{k|j}^{\mathbf{x},\tau} \mid \mathbf{X} = \mathbf{x}, Y_j = \mathrm{VaR}_j^{\mathbf{x},\tau}\right) = \tau, \tag{1}$$

where $\mathrm{VaR}_j^{\mathbf{x},\tau}$ denotes the Value–at–Risk, $\mathrm{VaR}_j^{\mathbf{x},\tau}$ of institution j, i.e., the τ–th level conditional quantile of the random variable $Y_j \mid \mathbf{X} = \mathbf{x}$, defined as

$$\mathbb{P}\left(Y_j \leq \mathrm{VaR}_j^{\mathbf{x},\tau} \mid \mathbf{X} = \mathbf{x}\right) = \tau. \tag{2}$$

Note that both the VaR and the CoVaR corresponds to the τ–th quantiles of the conditional distribution of $Y_j \mid \{\mathbf{X} = \mathbf{x}\}$ and $Y_k \mid \{\mathbf{X} = \mathbf{x}, Y_j = \mathrm{VaR}_j^{\mathbf{x},\tau}\}$, respectively. Therefore, both the VaR and CoVaR equations can be estimated using the Bayesian quantile regression treed models introduced in the previous section.

The financial data we utilise are taken from the Standard and Poor's Composite Index (k) for the U.S market, where different sectors (j) are included. For both the institutions and for the whole system, we consider microeconomics and macroeconomics variables, in order to take into account for individual information and for global economic conditions respectively. Our empirical analysis is based on publicly traded U.S. companies belonging to different sectors of the Standard and Poor's Composite Index (S&P500) listed in Table 1. The sectors considered are: Financials, Consumer Goods, Energy, Industrials, Technologies and Utilities. Financials consists of banks, diversified financial services and consumer financial services. Daily equity price data are converted to weekly log–returns (in percentage points) for the sample period from January 2, 2004 to December 28, 2012, covering the recent global financial crisis. To control for the general economic conditions we use observations of the following macroeconomic regressors as suggested by [1] and [5]: the VIX index (VIX), measuring the model-free implied stock market volatility as evaluated by the Chicago Board Options Exchange (CBOE), a short term liquidity spread (LIQSPR), computed as the difference between the 3-month collateral repo rate and the 3-months Treasury Bill rate, the weekly change in the three-month Treasury Bill rate (3MTB) the change in the slope of the yield curve (TERMSPR), measured by the difference of the 10-years Treasury rate and the 3-month Treasury Bill rate, the change in the credit spread (CREDSPR) between 10-years BAA rated bonds and the 10-years Treasury rate and the weekly return of the Dow Jones US Real Estate Index (DJUSRE). To capture the individual firms' characteristics, we include observations from the following microeconomic regressors: leverage (LEV), calculated as the value of total assets divided by total equity (both measured in book values), the market to book value (MK2BK), defined as the ratio of the market value to the book value of total equity, the size (SIZE), defined by the logarithmic transformation of the market value of total assets, and the maturity mismatch (MM), calculated as short term debt net of cash divided by the total liabilities. To have a complete picture of the contributes from individual and systemic risk we plot the estimated VaR and CoVaR for some of the assets listed in Table 1 in Figure 1. Looking at individual risk assessment, it is clear that the VaR profiles are relatively similar across institutions, displaying strong negative downside effects upon the occurrence of the recent financial crises of 2008 and 2010 and the sovereign debt crisis of 2012. However, the analysis of the time

Model Selection in Weighted Stochastic Block models

Selezione del modello per i modelli a blocchi stocastici

Roberto Casarin, Michele Costola, Erdem Yenerdag

Abstract We propose the weighted stochastic block model (WSBM) as generative model for the financial networks and exploit the topological features of its blocks. This model considers both the edge existence and the edge weight of the network and is independent from the methodology implemented on the estimation of the network. In this paper, we discuss three specifications of the model with by analysing the European financial network.

Abstract In questo lavoro, viene proposto il modello a blocchi stocastici pesato (WSBM) come modello generativo per i network finanziari dove vengono esplorate le caratteristiche topologiche dei blocchi. Questo modello considera sia il peso che l'esistenza del legame ed é indipendente dalla metodologia di stima del network. In questo articolo, discutiamo tre specifiche del modello analizzando il network finanziario Europeo.

Key words: financial networks, stochastic block model

1 Introduction

The study of the financial network topologies and connectedness provides useful tools in monitoring financial stability.

Nodes exhibit often the propensity to be clustered into groups which are internally densely connected but show fewer connections outside. This feature is known as community structure or network modularity [Newman, 2010]. The aim of this paper is to investigate the network topology with focus on the detection of blocks in a broader sense where nodes represents financial assets. The communities are obtained through the Weighted Stochastic Block Model (WSBM) introduced recently by [Aicher et al., 2014] which allows through the blocks to have a compact characterization of the network's structure. This network generative model considers both the edge existence and the edge weight of the network and represents a generalization of the SBM [Holland et al., 1983] which is independent from the methodology implemented on the estimation of the network. By analysing the European financial institutions, we compare three specifications of the model such as the Stochastic Block Model (SBM), the balanced Weighted Stochastic Block Model (WSBM) and the pure WSBM (pWSBM).

2 Weighted Stochastic Block Models

The likelihood function of the basic Stochastic Block Model (SBM) is:

$$\mathscr{L}(A|z,\theta) = \prod_{ij} \theta_{z_i z_j}^{A_{ij}} (1-\theta_{z_i z_j})^{1-A_{ij}} \tag{1}$$

where A is an adjacency matrix of the network, which contains binary values representing edge existence, $A_{ij} \in \{0,1\}$, z is a vector that contains the group label of each node $z_i \in \{1,\dots,K\}$, where K is the number of latent groups. For example, if A is an $n \times n$ adjacency matrix then z is a $(1 \times n)$ vector such as $z = (z_1, z_2, \dots, z_i, \dots, z_n)$. Therefore, vector z represents the partition of the nodes into K blocks and each pair of groups kk' represents a bundle of edge between the groups. The parameter θ in Equation 1 represents a $(K \times K)$ matrix and its elements represent the edge existence parameters, $\theta_{z_i z_j}$, of each edge bundle. The existence probability of an edge A_{ij} is given by the parameter $\theta_{z_i z_j}$ that depends only the membership of nodes i and j. In Equation 1 A_{ij} is conditionally independent given z and θ. Number of latent groups, K, is a free parameter that must be chosen before the model and it controls model's complexity. The model can be also expressed as an exponential family:

$$\mathscr{L}(A|z,\theta) \propto \exp\left(\sum_{ij} T(A_{ij}) \cdot \eta(\theta_{z_i z_j})\right) \tag{2}$$

where $T(x) = (x,1)$ is the vector-valued function of sufficient statistics of the Bernoulli random variable and $\eta(x) = (\log(x/(1-x)), \log(1-x))$ is the vector-valued function of natural parameters.

This is a basic and classical SBM for unweighted networks since, as they are defined, the functions (T,η) produces binary edge values. With a different and ap-

propriate functions of (T,η), a specific form of Weighted Stochastic Block Model (WSBM) can be established by weights that are drawn from an exponential family distribution over the domain of T. In this case, each $\theta_{z_i z_j}$ denotes the parameters governing the weight distribution of the edge bundle $(z_i z_j)$.
However, the models SBM and WSBM that presented above, produce complete graphs. In order to model sparse networks by SBM and WSBM, [Aicher et al., 2014] assumes $A_{ij} = 0$ as a directed edge from node i to j is existed with zero weight. In this case, to denote absence of an edge from node i to j is $A_{ij} = \text{NaN}$. By this, sparse networks can be modelled with two types of information, edge existence and edge weight values, in together by a simple tuning parameter with the following way:

$$\log \mathscr{L}(A|z,\theta) = \alpha \left(\sum_{ij \in E} T_e(A_{ij}) \cdot \eta_e(\theta^{(e)}_{z_i z_j}) \right) + (1-\alpha) \left(\sum_{ij \in W} T_w(A_{ij}) \cdot \eta_e(\theta^{(w)}_{z_i z_j}) \right) \quad (3)$$

where the pair (T_e, η_e) denotes the family of edge existence distribution and the pair (T_w, η_w) denotes the family of edge-weight distribution, $\alpha \in [0,1]$ is a simple tuning parameter that combines their contributions in the likelihood function. E is the set of observed interactions (including non-edges) and W is the set of weighted edges with $W \subset E$.
It is possible to see in Equation 3 that if $\alpha = 1$ then the model reduces to SBM, to Equation 1, and if $\alpha = 0$ the model ignores edge existence information then we call such models as pure WSBM (pWSBM). When $0 < \alpha < 1$, the likelihood function combines both information set, i.e. it is called balanced WSBM if $\alpha = 0.5$.[1]

3 An application to the European financial market

We provide an application of the model and analyse the European financial institutions using the closing price series from Worldscope lists downloaded in Datastream at a daily frequency from 29th May 1997 to 27th May 1998. The network is estimated through Granger causality tests [Billio et al., 2012]. In SBM ($\alpha = 1$), Figure 1, the most systematically important community is Block 3 where the members have the highest out degree. However, there are not particular edge weight characteristics in SBM ($\alpha = 1$) communities. In balanced WSBM ($\alpha = 0.5$) the most important community is Block 2.

Tourism & Cultural Participation

The determinants of tourism destination competitiveness in 2006–2016: a partial least square path modelling approach

I determinanti della competitività di destinazioni turistiche tra 2006 e 2016: un approccio partial least squares a equazioni strutturali

Alessandro Magrini, Laura Grassini

Abstract The present research addresses the analysis of tourism destination competitiveness (TDC) at national level in the period 2006–2016. A partial least square path model (PLS-PM) is developed where TDC and its determinants vary through time according to a second-degree polynomial trend, while their relationships remain constant, thus allowing to draw conclusions on their long-term association. Results show that the most important TDC determinants are cultural heritage, communication technology and tourism infrastructure.
Abstract *Questa ricerca ha l'obiettivo di analizzare la competitività di destinazioni turistiche a livello nazionale nel periodo 2006–2016. È stato sviluppato un modello PLS a equazioni strutturali dove la competitività e i suoi determinanti variano nel tempo secondo un trend quadratico mentre le loro relazioni rimangono costanti, così da poter trarre conclusioni sulla loro associazione a lungo termine. I risultati mostrano che i principali determinanti della competitività sono le risorse culturali, le tecnologie di comunicazione e le infrastrutture turistiche.*

ment [6], the ongoing study of tourism destination competitiveness (TDC) has acquired increasing importance for tourism researchers and policy makers [12]. Over the last decade, several conceptual models for TDC have been proposed [4, 8, 6], and structural equation models (SEMs, see for example [9]) have proved to be a powerful methodology for TDC analysis [11, 10, 2, 7, 1, 16]. The main advantage of SEMs relies in the opportunity to estimate the weights of each indicator and each determinant of competitiveness from data, overcoming the great limitation of constant weights underlying the Tourism and Travel Competitiveness Index [17]. In recent years, particular attention was paid to partial least squares path models (PLS-PMs, see for example [14]), a non parametric formulation of SEMs with weaker sample size requirements, making no assumptions on the distribution of data, and allowing formative constructs. According to several authors, PLS-PMs have introduced a substantial improvement in the methodology for tourism research compared to parametric SEMs, also called covariance-based (CB) SEMs (see the review in [5]). In particular, formative constructs appears more adequate than reflective ones to represent TDC determinants (see the discussion in [11]). However, existing applications focus on one year at a time, failing to capture the substantive (time-invariant) pattern relating TDC and its determinants.

The present research addresses the analysis of TDC at national level in the period 2006–2016. A PLS-PM is developed where TDC and its determinants vary through time according to a second-degree polynomial trend, while their relationships remain constant, thus allowing to draw conclusions on their long-term association.

This paper is structured as follows. In Section 2, a description of the data and the methodology of the research is provided. In Section 3, results are presented. Section 4 includes the discussion of the contribution.

2 Materials and methods

In this research, TDC is understood in the widely accepted definition suggested by [13, page 2]: "*a destination's ability to increase tourism expenditure, to increasingly attract visitors while providing them with satisfying, memorable experiences, and to do so in a profitable way, while enhancing the well-being of destination residents and preserving the natural capital of the destination for future generations*".

The following TDC determinants are considered: core resources and attractiveness (CRA), communication technology (ICT), tourism infrastructure (TOU), demand conditions (DEM).

Data on 20 indicators covering TDC and its determinants (see Table 1 for a description) were gathered from several sources, mostly the World Bank, the World Tourism and Travel Council and the World Economic Forum. The data referred to 264 countries in the period 2006–2016. Destinations were selected in a two-stage procedure. Firstly, the ones with a surface area less than 2000 squared kilometers and less than one million population were merged with a contiguous one, if possible, or excluded. Secondly, the remaining destinations were selected to obtain a dataset with no more than 15% of missing values, as suggested by [15]. The selection procedure led to a total of 130 tourism destinations with a total percentage of missing values of 14%.

A deterministic trend across destinations was taken into account to impute missing values. Due to the limited length of the time series, a total of 15 geographic zones were defined based on physical proximity and economic similarities between the destinations, and each missing datum was replaced with its conditional mean predicted by a linear regression model with destination-specific intercept and geographic zone-specific (instead of destination-specific) second-degree polynomial trend.

The PLS-PM consisted of three parts: a *formative part*, representing the relationships between each TDC determinant and the respective indicators, with the latter determining the former; a *reflective part*, representing the relationships between TDC and the outcomes of tourism activity, with the former determining the latter; and a *structural part* representing the relationship between TDC and its determinants, with the latter determining the former. Destination-specific intercepts and geographic zone-specific second-degree polynomial trends were assumed for each construct.

Let j, k and t indicate the destination, the geographic zone and the year, respectively. The formulation of the PLS-PM was the following:

$$\begin{aligned}
\mathrm{E}[\mathrm{CRA}^{(j,k,t)}] &= \delta^{(j)}_{\mathrm{CRA}} + \gamma^{(k)}_{\mathrm{CRA}} t + \nu^{(k)}_{\mathrm{CRA}} t^2 + \sum_s \lambda_{\mathrm{CRA},s} \cdot X^{(j,k,t)}_{\mathrm{CRA},s} \\
\mathrm{E}[\mathrm{ICT}^{(j,k,t)}] &= \delta^{(j)}_{\mathrm{ICT}} + \gamma^{(k)}_{\mathrm{ICT}} t + \nu^{(k)}_{\mathrm{ICT}} t^2 + \sum_s \lambda_{\mathrm{ICT},s} \cdot X^{(j,k,t)}_{\mathrm{ICT},s} \\
\mathrm{E}[\mathrm{TOU}^{(j,k,t)}] &= \delta^{(j)}_{\mathrm{TOU}} + \gamma^{(k)}_{\mathrm{TOU}} t + \nu^{(k)}_{\mathrm{TOU}} t^2 + \sum_s \lambda_{\mathrm{TOU},s} \cdot X^{(j,k,t)}_{\mathrm{TOU},s} \\
\mathrm{E}[\mathrm{DEM}^{(j,k,t)}] &= \delta^{(j)}_{\mathrm{DEM}} + \gamma^{(k)}_{\mathrm{DEM}} t + \nu^{(k)}_{\mathrm{DEM}} t^2 + \sum_s \lambda_{\mathrm{DEM},s} \cdot X^{(j,k,t)}_{\mathrm{DEM},s} \\
\mathrm{E}[\mathrm{TDC}^{(j,k,t)}] &= \delta^{(j)}_{\mathrm{TDC}} + \gamma^{(k)}_{\mathrm{TDC}} t + \nu^{(k)}_{\mathrm{TDC}} t^2 + \beta_{\mathrm{CRA}} \cdot \mathrm{CRA}^{(j,k,t)} + \\
&\quad + \beta_{\mathrm{ICT}} \cdot \mathrm{ICT}^{(j,k,t)} + \beta_{\mathrm{TOU}} \cdot \mathrm{TOU}^{(j,k,t)} + \beta_{\mathrm{DEM}} \cdot \mathrm{DEM}^{(j,k,t)} \\
\mathrm{E}[X^{(j,k,t)}_{\mathrm{TDC},s}] &= \alpha_{\mathrm{TDC},s} + \lambda_{\mathrm{TDC},s} \cdot \mathrm{TDC}^{(j,k,t)}
\end{aligned} \tag{1}$$

where parameters denoted with letter α, δ, γ, ν, λ and β represent the destination-free intercepts, the destination-specific intercepts, the zone-specific linear trend components, the zone-specific quadratic trend components, the factor loadings and the path coefficients, respectively. The regression with the greatest number of predictors in the PLS-PM has 9 observations per parameter, which allow to detect correlations with absolute value 0.6 with a power of 0.5 [3].

3 Results

Results of PLS-PM estimation are shown in Table 1. The model explains 64% of data variability.

An overall evaluation of the performance of the considered destinations in the period 2006–2016 can be provided by the mean across years of estimated TDC ranks (Table 2). Iceland, with an average rank equal to 1, results the most competitive destination throughout the whole decade. Overall, North and South-West European destinations are the best performing ones (they all appear within the first 25 positions), together with Qatar (17th), Cyprus (19th), United Arab Emirates (23th) and Lebanon (24th).

Table 1 Results of PLS-PM estimation.

Formative part

Indicator	Construct	Std. loading	Variance
Protected areas (% surface area)	CRA	0.1297	1.7%
Number of natural world heritage sites to population	CRA	0.2535	6.4%
Number of cultural world heritage sites to population	CRA	0.8947	80.0%
Number of art museums ($>$ 8000 m^2) to population	CRA	0.5580	31.1%
Number of mobile cellular subscriptions to population	ICT	0.6016	36.2%
Number of individuals using the Internet to population	ICT	0.9837	96.8%
Number of fixed broadband subscriptions to population	ICT	0.9580	91.8%
Number of aircraft departures to population	TOU	0.5089	25.9%
Number of airports to surface area	TOU	0.5814	33.8%
Scheduled available seat kilometers per week	TOU	0.2186	4.8%
Number of hotel rooms to population	TOU	0.2041	4.2%
Number of automated teller machines to adult population	TOU	0.6961	48.5%
Presence of seven major car rental companies	TOU	0.8748	76.5%
Power purchasing parity	DEM	0.5958	35.5%
Consumer price annual inflation	DEM	0.8852	78.4%

Sweden	7.45	Spain	14.73	Germany	20.64
Austria	8.00	Lithuania	15.18	Italy	22.09
Ireland	9.45	France	15.73	United Arab Emirates	22.27
Switzerland	10.45	Portugal	16.73	Lebanon	25.00

4 Discussion

The present research addresses the analysis of tourism destination competitiveness (TDC) at national level in the period 2006–2016. through a partial least square path modelling approach. Differently from existing applications which focus on one year at a time, our contribution is based on time series data and is able to capture the substantive (time-invariant) pattern relating TDC and its determinants.

The main limitation of the present research is represented by the difficulty to find long and almost complete time series. This issue forced us to select 130 on an original number of 260 tourism destinations, and to impute a number of missing values corresponding to almost 15% of total data. The limited length of our time series also precluded a reliable estimation of destination-specific trends, thus we assumed trends to be equal within 15 geographic zones. Being aware that the choice of the geographic zones may significantly affect the results, particular attention was paid to define them so that each included countries with as homogeneous economic characteristics as possible. We hope that future data collection may lead to long enough time series to specify country-specific trends.

The selection of the indicators is a further critical step of our research. In the present contribution, we focused on a limited set of TDC determinants. Future work could consider a broader set of TDC determinants, like public expenditure for the tourism sector, regulation and social aspects.

Participation in tourism of Italian residents in the years of the economic recession

Viaggi e vacanze degli Italiani negli anni della recessione economica

Chiara Bocci, Laura Grassini, Emilia Rocco

Abstract In this study an hurdle model is used to analyze the tourism behavior of Italian residents during the 2004-2013 period. Using the microdata from the quarterly survey on “Trips and holidays in Italy and abroad” carried out by the Italian National Institute of Statistics we investigate the factors that have influenced the tourism participation and the length of stay of residents in Italy in the years of the economic recession. The empirical results show that socio-economic characteristics of the individuals and of their families have an important effect on their tourism participation; that these factors, together with some trips-related characteristics, affect the total number of overnight stays; and that the economic recession impacted negatively on both aspects of tourism behaviour.

Abstract *In questo studio analizziamo il comportamento turistico dei residenti in Italia durante il periodo 2004-2013 mediante un modello hurdle. Utilizzando i microdati dell’indagine trimestrale “Viaggi e vacanze in Italia e all’estero” svolta dall’Istituto Nazionale di Statistica, esaminiamo i fattori che hanno influenzato la partecipazione turistica e la durata delle vacanze degli Italiani negli anni dell’ultima recessione economica. I risultati empirici mostrano che la scelta di fare o non fare un viaggio/vacanza è influenzata da caratteristiche socio-economiche degli individui e delle loro famiglie e che gli stessi fattori, insieme ad altri inerenti i viaggi stessi, influenzano anche il numero totale di giorni di vacanza. I risultati inoltre, mostrano l’impatto negativo della recessione economica su entrambe le fasi decisionali che caratterizzano le scelte turistiche degli italiani.*

1 Introduction

The steady period of economic crisis has seriously affected Italian households that, from 2008 to 2013, have experienced six consecutive years of decrease in purchasing power (available income in real terms), with a -10.4% overall change between 2007 and 2013 [7]. During this recession period, Italian households have shown a reduction in tourism expenditure and a change in travel behavior, as well. In particular, household expenditure surveys show that the expenditure share devoted to hotels and accommodation facilities passed from 2.8% in 2010 to 2.3% in 2013. Household surveys on travel behavior rend us a even worse picture: the annual decrease in the number of trips of residents was nearly -12% in 2010, -19% in 2013. Only in 2015, for the first time after seven years, there has been an increase (+13.5%).

Since tourism is an important driver of economic development, the analysis of the tourism demand of Italian residents is of extreme importance: 1) from an historical perspective, we can be interested in knowing whether, how and why, they have changed their vacation behavior during the years of the economic crisis; 2) for forecasting purposes, the knowledge of the major determinants of household tourism behavior is of extreme usefulness for policy makers. This contribution is concerned with the tourism behavior of Italian residents in the period covering the last economic recession: it investigates whether and how the tourism participation and the total number of overnight stays of Italians have changed in this period. Data on households' and individuals' travel behavior are derived from the survey on *Trips and holidays in Italy and abroad*, currently carried out by the Italian National Institute of Statistics. In the following: Section 2 provides a brief description of the data and the methodology whereas Section 3 discusses the main findings of the analysis.

2 Data and method

From 1997 to 2013 the household survey on *Trips and holidays in Italy and abroad* was carried out quarterly on a national annual sample of about 14,000 households (about 3,500 per quarter for a total annual of about 32,000 individuals). Since 2014 it has become a focus included in the Survey on *Household expenses*, which is carried out monthly on a national theoretical sample of 28,000 families. Given this change, which has been accompanied by several others in the overall survey design, and considering the adoption of the euro currency occurred in 2002, we have limited our analysis to the years from 2004 to 2013. Each year data are observed for the following periods: January-March, April-June, July-September and October-December. In each quarter and for each individual information on vacation and business trips concluded during the quarter and with at least one overnight stay and some socio-demographic characteristic, are recorded. As we are interested in the analysis of the factors that may influence individual tourism choices, we considered only persons at least 15 years old and only the vacation trips. For each trip, the destination, the length of stay, the motivation (leisure and recreation, visiting friends and relatives, and so on), the type of accommodation and the transportation mode are recorded. Available survey micro-data does not include information about the tourism expenditure and the socioeconomic status of the individuals, with the exception of the individual's occupation. Given the data characteristics and the fact that the reduction in the length of stay is one of the main characteristic of current tourism [1], this study examines whether and how the economic recession has affected the total number of overnight stays in a quarter by modelling it through an hurdle model. The hurdle model [5] is a modified count model in which the two processes generating the zeros and the positives are not constrained to be the same. A binomial probability governs the binary outcome of whether a count variate has a zero or a positive realization. If the realization is positive, the hurdle is crossed, and the conditional distribution of the positives is governed by a truncated-at-zero count data model.

The assumptions of the hurdle model are consistent with the phenomenon under study, in which firstly a person decides whether to have a vacation trip and then, conditionally to a positive decision, he decides the number of overnight stays. Therefore the binary process concerning the decision to have at least a vacation in a given quarter has been modelled through a logit regression model in which covariates at both individual level (age, gender, education, occupation, indicator of at least a business trip in the quarter, residential NUTS1 zone) and family level (size, number of children, number of income recipients included retired members) are included. Then the quarterly number of overnight stays, for those who had at least a vacation, has been modelled through a Truncated Negative Binomial regression model which includes, in addition to the variables involved in the first-stage model, trips-related covariates (number of trips for visiting friends and relatives, number of pleasure trips for specific destination: sea, mountain, historical cities, tours and others; number of free accommodation trips; dummy-indicator of at least a trip abroad, total number of vacation trips). Categorical variables for years and quarters are included in both models, as well. Since we consider the number of income recipients as a proxy for household income and we are interest in evaluating its effect on the decision on tourism participation throughout the years, we include a specific interaction term in the first model. Finally, in the second model we allow for different covariates effects on the number of overnight stays for those who only take long vacancies (more than 3 nights at a time) than the others. For this reason, all covariates in the second model are interacted with the dummy indicator *at least one short vacation*. Formally, let y be the number of overnight stays, and $\mathbf{X}$ and $\mathbf{Z}$ the covariates matrices included in the first and the second model respectively, then, the model is:

- I stage: a logit model for the tourism participation

$$P(y_i = 0|\mathbf{X}_i) = exp(\mathbf{X}_i'\beta_1)/(1+exp(\mathbf{X}_i'\beta_1))$$

- II stage: zero-truncated Negative Binomial model for the number of overnight stays given that it is greater than zero

$$P(y_i = j|y_i > 0, \mathbf{Z}_i) = \frac{P(y_i = j \& y_i > 0|\mathbf{Z}_i)}{P(y_i > 0|\mathbf{Z}_i)} = \frac{P(y_i = j|\mathbf{Z}_i)}{[1-P(y_i > 0|\mathbf{Z}_i)]} = \frac{f_{NB}(j)}{[1-f_{NB}(0)]}$$

3 Results and discussion

Looking at previous empirical studies on tourism demand of individuals/households, which mostly investigate tourism expenditures, tourist's choice is conceived as a multi-stage decision process and three categories of travel determinants are generally identified: economic, socio-demographic and trip-related characteristics: they are influential in predicting both the visitors' intention to visit and their willingness to spend money on vacations [8]. According to [1], the same categories of variables affect also the tourist's choice about the vacation length.

Regarding socio-demographic variables our estimates confirm that gender and age may be considered as a proxy of travel preferences and determine travel motivations [8, 3]. Older age groups tend to be less likely to participate in tourism, but show a higher propensity to spent more time in vacation after the decision is make. Moreover, family size is negatively associated with both stages of the tourist's decision process, which can be due to family budget constraints; nonetheless, people with small children (at most 10 years old) seam to be more likely to participate to tourism and to take longer vacations.

Moving on to consider the effect of economic variables, income is one of the most influential and it positively affects all the stages of a tourist's decision process. Tourism individual behavior is also influenced by the business cycle: in an expansion period, people are more inclined to travel on more expensive trips (with greater length of stay) whilst during an economic slowdown more modest domestic trips are preferred [4, 6]. The empirical results, shown in Table 1, agree with these findings. The number of income recipients in a family, which indirectly reflects the household economic condition, have a positive association with the decision to travel and this effect, as shown in Figure 1(a), is more pronounced in the period of economic crisis. Since this variable is also directly related to the occupational status of each family member, it impacts negatively on the quarterly number of overnight stays due to the possible time constraints deriving from the work activity. This agree with the estimated dual effect of the individual occupational status: a stable occupation provide a secure income, increasing the probability of tourism participation, but it reduce the amount of days spent on vacations for those who only take long trips. Moreover, according with [2, 6], unemployed people are less inclined to travel.

Our findings confirm common knowledge that some types of trips strongly determine their length: having more beach holidays or at least one abroad vacation increase the number of total overnight stays for both long and short trips, whereas other motivations have a positive impact only on the total days of short trips. Analogously, most of the overnight stays in long vacations is taken in the Summer trimester, (Figure 1(c)) when the propensity to participate to tourism is higher (Figure 1(b)). This confirms that seasonality is a universal factor in tourism.

Figures 1(b) and 1(c) show that the economic crisis had a negative impact on both tourism participation and on the length of stay, particularly for those tourists that take only long vacations.

The hanging rootogram in Figure 1(d), which compare predicted and observed values, indicates an overall good fitting of the estimated hurdle model.

Cultural Participation in the digital Age in Europe: a multilevel cross-national analysis

La partecipazione culturale nell'era digitale in Europa: un'analisi multilivello transnazionale

Laura Bocci and Isabella Mingo

Abstract Considering a broad spectrum of cultural activities, this study aims to deepening European countries differences in Cultural Participation taking into account micro, meso and macro determinants. For this aim, we used the large dataset provided by the Special Eurobarometer survey n.399 collected in the European countries. The main goals are the following: 1) to outline a multidimensional view of Cultural Participation; 2) to analyse, through a multilevel approach, the determinants of Cultural Participation of European citizens, considering the relationships with both socio-demographic characteristics of people and other relevant contextual features.

Abstract *Considerando un ampio spettro di attività culturali, questo studio mira ad approfondire le differenze della partecipazione culturale nei Paesi europei tenendo conto delle determinanti che possono intervenire, a livello micro, meso e macro. A tal fine, viene utilizzato il dataset dell'Eurobarometro Speciale n.399, rilevato nei paesi europei. Gli obiettivi principali sono i seguenti: 1) delineare una visione multidimensionale della partecipazione culturale nell'era digitale; 2) analizzarne, attraverso un approccio multilivello, le determinanti, considerando sia le relazioni con le caratteristiche socio-demografiche degli individui sia quelle con altre rilevanti caratteristiche di contesto.*

Key words: Cultural Participation, Digital Age, Multilevel analysis.

1 On Cultural Participation

Cultural participation is not only a right enshrined in the United Nations Declaration of Human Rights, but it is also considered a key element for the quality of individual and collective life, as widely recognized by both literature and international Agencies that have contributed to define its concept and setting up of some indicators for its empirical analysis [11,3,1]. At European level, the relevance of this issue is highlighted by the Agenda for Culture adopted in 2007 by the Council of the European Union and the European Council, as well as a number of policy actions set out in the Work Plan for Culture for 2015-2018, adopted by EU Culture Ministers in December 2014.

The concept of Cultural Participation can be made operative on the basis of the main international and European projects: Unesco's Framework for Cultural Statistics in 1986 [10], LEG (Leadership Group on Cultural Statistics) in 2000 [3] and ESSNet-Culture (European Statistical System Network on Culture) in 2011 by Eurostat [1]. These projects, albeit with some differences, agree to adopt a pragmatic definition based on the identification of so-called cultural domains and to include cultural practices that fall into those domains without any distinction in terms of quality and including different types of participation.

Furthermore, these projects emphasize the changes in cultural practices deriving from the rise of ICT (Information and Communication Technology) and especially from the new possibilities offered by the Internet that make cultural participation more complex. Media users have more and more control over the selections of cultural contents offered via different channels, including mobile media. This is the *convergence culture* in which patterns of media use are merging, moving from medium specific content toward content flowing across multiple media channels [6].

In this study, we consider a broad spectrum of cultural activities. The main goal is to deepening European countries differences in Cultural Participation taking into account micro, meso and macro determinants. To this end, the specific objectives are the following:

1) to outline a multidimensional view of cultural participation, considering a broad spectrum of cultural activities;
2) to analyse the determinants of cultural participation of European citizens deepening the direction of the relationships with socio-demographic and other relevant contextual characteristics by using a multilevel approach.

2 Data and Indicators

We analysed the large dataset provided by the Special Eurobarometer survey n.399 collected in the European countries in 2013. This survey detects the attitudes of the European public towards a range of cultural activities, looking at their participation as both consumers and performers of culture. The sample considered in this contribute has a total size of 26,053 individuals aged 15 years and over in 25 european countries[1].

The choice of indicators was driven by the conviction that nowadays Cultural Participation is carried out through traditional activities as well as using the Internet.[2] In the Eurobarometer survey the following 9 variables are dealing with traditional cultural activities: 1- seen a ballet, a dance performance or an opera; 2- been to the cinema; 3- been to the theatre; 4- been to a concert; 5- visited a public library; 6- visited a historical monument or site (palaces, castles, churches, gardens, etc.); 7- visited a museum or gallery; 8- watched or listened to a cultural program on TV or on the radio. Responses modes are: 1- not in the last 12 months; 2- 1-5 times in the last 12 months; 3- more than 5 times in the last 12 months.

Moreover, other variables, which can supplement the previous ones, allow us to take into account some cultural activities performed by the Internet: 1- visiting museum or library websites or other specialized websites ; 2- downloading movies, radio programs (podcasts) or TV programs; 3- watching streamed or on demand movies or TV programs; 4- reading newspaper articles online; 5- downloading music; 6- listening to radio or music; 7- reading or looking at cultural blogs; 8- searching for information on cultural products or events. Responses modes are: 1- not mentioned; 2 - mentioned.

To explain the individual differences of Cultural Participation, other variables were introduced in the analysis. They concern socio-demographic and cultural characteristics of people and some aspects of the community where they live: gender, age, education, occupation, family social class, type of community. Furthermore, since it is reasonable suppose that some features of the country affect significantly Cultural Participation, the following macro level variables were also considered: economic aspects (Gross Disposable Income of Households), political choices (Government Expenditure in Cultural Services), consistency of cultural offer (Employments in Cultural Sector) and level of urbanization (Distribution of Population in the cities)[3].

4 Methods and Results

The previous selected variables were the input for a strategy of analysis that consists in the following two steps: 1) calculate a synthetic index of Cultural Participation at European level; 2) identify the determinants of participation at both individual and country level.

[1] Only countries with a sample size > 1000 were considered. They are: France, Belgium, Netherlands, German, Italy, Denmark, Ireland, Great Britain, Greece, Spain, Portugal, Finland, Sweden, Austria, Czech Republic, Estonia, Hungary, Latvia, Lithuania, Poland, Slovakia, Slovenia, Bulgaria, Romania, Croatia.

[2] The set of variables concern only with one form of cultural participation such as attending and receiving. Others two forms (amateur practice and social participation) are not considered in this contribute.

[3] In addition to these variables (source: Eurostat), other ones were also considered in some preliminary analyses, but they resulted not significant: Government expenditure as % GDP in Education, Cultural enterprises % of total of services, Tertiary education (levels 5-8) of the aged population 25-64 (%), Participation rate in education and training (%), Households Broadband coverage (%).

4.1 A Synthetic Index of Cultural Participation at European level

Considering that the variables dealing with cultural activities, including those carried out via the Internet, are all categorical (both nominal and ordinal), Nonlinear Principal Component Analysis (NPCA) was applied to calculate a synthetic index of Cultural Participation.

As it is known, in NPCA, optimal quantification replaces the category labels with category quantifications in such a way that as much as possible of the variance in the quantified variables is accounted for. Specifically, the method maximizes the first p eigenvalues of the correlation matrix of the quantified variables, where p indicates the number of components that are chosen in the analysis. The aim of optimal quantification is to maximize the Variance Accounted For (VAF) in the quantified variables [4,8].

The first dimension (alpha=0.87, VAF=32.12%) has positive correlations (between 0.5 and 0.7) with all variables. The choice of ordinal analysis levels for the variables has been evaluated by examining their transformation plots: for ordinal variables, they indicate that the categories are in the right order and the difference between categories 1 and 2 is slightly larger than that between 2 and 3. For nominal variables, straight lines indicate that they are linearly related to the other variables. The stability of results have been confirmed according 95% bootstrap confidence regions for eigenvalues, component loadings, person scores and category quantifications [7] estimated using balanced bootstrap with 1000 bootstrap samples.

The first component can be interpreted as a Cultural Participation Synthetic index (CPS). The index (ranging from -1.2 to 3.6; mean=0; median=-0.19; standard deviation=1; asymmetry=0.72; Kurtosis=-0.23) assumes different mean values by gender, age, education and country. It is highest among women, decreases as the age increases, it steps up with higher levels of education and is quite different among European countries: its minimum pertains to Portugal (-0.59), the maximum to Sweden (0.9) with different distributions inside each country.

What are the determinants of those different levels of Cultural Participation in the European countries?

4.2 The determinants of Cultural Participation in the European countries: a multilevel approach

The structure of the data to be analysed is clearly hierarchical, since individuals are nested within countries. Given the intrinsically hierarchical nature of the data set and hypothesizing that the variability of the CPS index can depend on both the people characteristics and the different contexts in which they live, a multilevel approach was used [9].

In our case, data consist of the values of CPS index (dependent variable) and several explanatory variables, both social–demographic individual features and countries variables, referred to i-th respondent in j-th country ($i = 1, \dots, N_j$, $j = 1, \dots ,25$ and $\sum_j N_j = 26{,}053$). Therefore, there are two levels of analysis: level two, the highest, is that of countries, and level one, the lowest and nested within the higher level, is that of the individuals.

Since it is reasonable assume that countries can have a systematic effect on the Cultural Participation of individuals, CPS index values within the same countries are dependent or correlated. In this context a multilevel analysis with no explanatory variables at all, the so called *intercept-only model*, was firstly applied

$$Y_{ij} = \square_{00} + u_{0j} + e_{ij}, \qquad i = 1, \dots, N_j \text{ and } j = 1, \dots, 25 \qquad (1)$$

where e_{ij} represents some individual-dependent residual while u_{0j} is a random country-dependent deviation. Model (1) provides a partitioning of the variance between the first (e_{ij}) and second (u_{0j}) level (residual effect and random effect covariance, respectively) and allows us to evaluate the Intraclass Correlation Coefficient (ICC) for the country effect. ICC can be considered both a measure of the between countries variability and the degree of the non-independence of individuals nested into countries. In our case intercepts vary significantly across countries (Wald Z=3.44, p-value=0.001) and ICC=0.136 (Table 1) shows that about 13.6% of the CPS index variability is due to the variability between countries.

Since these previous results justify a multilevel approach [10,5], we performed an analysis in two steps: first, q level-one (individual) X_q explanatory variables were introduced in the multilevel model and then p level-two (country) Z_p explanatory variables were also put in defining the following final model (3)

$$Y_{ij} = \square_{00} + \gamma_{q0}X_{qij} + u_{0j} + e_{ij}, \qquad i = 1, \dots, N_j \text{ and } j = 1, \dots, 25 \qquad (2)$$

$$Y_{ij} = \square_{00} + \gamma_{q0}X_{qij} + \gamma_{0p}Z_{pj} + u_{0j} + e_{ij}, \qquad i = 1, \dots, N_j \text{ and } j = 1, \dots, 25 \qquad (3)$$

In model (2), taking into account only the individual covariates, ICC= 0.113 was still high, even if less than one obtained from model (1), so there still was a fair amount of variation (11.3%) across countries that can be explained by level-two covariates. Actually, in model (3) ICC drastically decreases to 0.031, a value lower than a cut-off (0.05) fixed by most of the researchers [10,5] (Table 1).

The results from model (3), which is the best of the three models according to AICC and BIC (Table 2), show that all predictors are significant. Compared to the reference value, CPS index increases in youngest aged 15-20 people, who are still studying, is self-employed, is living in cities and belongs to high social class (Table 3). Nonetheless, the results show that differences at individual level are not sufficient to explain all the determinants of Cultural Participation. It is necessary to take into account some characteristics of the countries: all the predictors - economic, cultural, and political - considered in model (3) have a positive influence on CPS index, especially the Employment in cultural sector (that is a proxy of cultural offer) and Gross disposable Income of household (Table 3).

Tourist flows and museum admissions in Italy: an integrated analysis

Flussi turistici e visitatori dei musei in Italia: un analisi integrata

Lorenzo Cavallo, Francesca Petrei, Maria Teresa Santoro

Abstract The main aims of this paper are to analyse cultural tourism in Italy and its relationship with the territory and to provide a tool for policy makers to identify the local dynamics and choose the best development policies. The cultural tourism is studied trough the relation between tourism and cultural statistics.
The analysis uses a spatial approach to identify well-defined geographical areas having significant different - touristic and cultural - characteristics. In order to identify the areas with the greatest cultural-tourism vocation, it is proposed a classification of the municipalities, focusing on some case studies.
Abstract *Il principale obiettivo di questo lavoro è analizzare il turismo culturale e la sua relazione con il territorio, in modo da fornire uno strumento ai policy makers per conoscere le dinamiche del proprio territorio e di intervenire con le adeguate politiche di sviluppo. Attraverso l'analisi spaziale sono individuate le aree geografiche con differenti caratteristiche dal punto di vista turistico e culturale ed è proposta una categorizzazione del territorio italiano in base a una più o meno accentuata vocazione turistica o culturale.*

Key words: cultural tourism, heritage tourism, tourism flows, museums, visitors

1 Introduction

The most visible contribution of culture to local development lies in its ability to attract tourists and the consequent positive effects on spending, incomes and employment (Streeten P., 2006. Leslie D., Sigala M., 2005).

This viewpoint has inspired many studies since the early 1980s that have attempted to demonstrate the impact of culture on local development (OECD, 2005).

[1] Lorenzo Cavallo, Istat; email: cavallo@istat.it; Francesca; Petrei, Istat; email: petrei@istat.it; Maria Teresa Santoro, Istat; masantor@istat.it.

Cultural tourism is one of the largest and fastest growing global tourism markets (OECD, 2009), but what exactly is cultural tourism and how can we measure it? One important obstacle to supplying answers to these questions is both the lack of a standard definition and of data on cultural tourism (Noonan D.S., Rizzo I., 2017). The identification of cultural tourism as a growth market has based more on assertion than hard information and more on isolated observations than systematic analysis. It has therefore been difficult to demonstrate just what cultural tourism is, how important is, how fast it is growing, or to identify the reasons why it has grown (Patuelli R., Mussoni M., Candela G., 2013) (Borowiecki K.J, Castiglione C., 2012) (Cuccia T., Cellini R., 2007 - 2013).

Keeping all that in mind, the main aims of this paper are to analyse cultural tourism in Italy and its relationship with the territory and to provide a tool to policy makers to know the territorial dynamics and identify the right development policies.

2 Sources and methodology

Giving a quantitative measurement of cultural tourism is even more difficult and, considering the difficulty in defining cultural tourism in a one simple way that covers the whole concept, the most practical approach, therefore, seems to be to choose the definition that is most suited to the task at hand (ATLAS, 2005).

In this paper we decided to start with two assumptions: to use only *official statistics* as source, in order to consider data with high and uniform standards of quality; to have the territory as fundamental element for the analysis, because culture, tourism and local development are strongly interconnected with the territory.

2.1 Data

Regarding culture, data on museums and their admissions can be considered, in Italy, as a proxy of the cultural heritage of the territory and are available at a very high territorial detail (at municipality level)[2]. Regarding tourism, we chose official statistics on the capacity of accommodation establishments[3] and the occupancy of accommodation establishments[4], which are available at municipal level.

2.2 Spatial models and zoning operation

[2] http://www.istat.it/it/archivio/6656

[3] http://www.istat.it/it/archivio/14517

[4] http://www.istat.it/it/archivio/15073

Since the early 1950s tourism has been considered as a purely geographical phenomenon and it is proposed an interpretive scheme of the phenomenon, elaborating a spatial model configuration of tourism (Toschi, 1948). Since the late 1960s, the models of interpretation of the spatial structure of tourism have begun to appear in the geographic field and various models are studied (Pearce, 1989), (Zabbini, 2007).

For this analysis, we used a method that well suits the applications supported by GIS systems, that is to divide the territory into homogeneous areas according to some criteria: the zoning operation.

In our analysis, we proceeded in zoning to identify homogenous areas for cultural and/or touristic characteristics trying to give an immediate and clear picture of the Italian territory. Therefore, through a geographical approach, mapping the variables on tourism (arrivals and bed-places) and culture (museums/cultural exhibits and admissions) at Italian municipality level, the analysis allowed us to identify well-defined geographical areas, having significant different tourism and cultural characteristics.

3 The integrated data analysis: classification of the Italian municipalities

For our integrated analysis, we used the final data of the year 2015 on number of establishments, number of arrivals at tourist accommodation establishments (A.E.), number of museums and similar institutions and number of admissions at these institutions. According to the combination of the chosen variables, we classified each municipality in the following categories (table 1):

1. Municipality without A.E. and without museums;
2. Municipality with no. of museums > 0 but without A.E.;
3. Municipality with no. of A.E. > 0 but without museums;
4. Municipality with no. of A.E. and no. of museums > 0.

We attributed the municipalities of this last category to two sub-categories:

4.a Municipality with balanced presence of admissions and arrivals;

4.b Municipality with unbalanced presence of admissions and arrivals.

For this sub-classification, we created an indicator for Italian municipalities[5] based on two variables: arrivals in accommodation establishments and admissions in museums and cultural exhibits.

In summary, for balanced municipalities the two considered flows - admissions and arrivals - are proportionate, highlighting a strong connection between tourism

[5] The first step was to consider the arrivals and admissions for 1,000 inhabitants and standardize the variables. Then we generated a synthetic indicator, ranging from 0 to 1, that, when it presented values around 0.5 (between 0.47 and 0.53, with a range of 5%) the municipality is assigned to the category "4.a", else to the "4.b." (denoting a municipality with an "imbalance" towards one of the two variables).

and culture[6]; for unbalanced municipalities there is a more or less relevant imbalance towards one type of flow.

Table 1: Distribution of the Italian municipalities by the five categories

Category	*N. of Municipalities*	*% on Total*
1	1,005	12.5
2	94	1.2
3	4,608	57.2
4	2,339	29.1
4.a	*652*	*8.1*
4.b	*1,687*	*21.0*
Total	**8,046**	**100**

The municipalities in category 1 are mainly located in the industrial area of the northwest and in the Apennine area of the south; the municipalities in category 2 in the internal areas of the south (including Sardegna) and in the centre-north (see Figure 1). In Toscana, Umbria and Valle d'Aosta, these two categories are completely absent. Municipalities in category 3 are mainly located in the regions of Northern and Southern Italy and, despite being the larger category, there are very few in central Italy.

The balanced municipalities in category 4.a are mainly concentrated in Toscana and Umbria (see Figure 1); then they are along the Adriatic coast of Marche and Emilia-Romagna and in the internal part of Pianura Padana between Bologna and Piacenza. In addition, there are some balanced municipalities in the two provinces of Bolzano and Trento and in southern Italy, along the coast of Puglia and the south coast of Sicilia. Among the balanced municipalities, there are many "provincial capitals", including Milan, which is one of the municipalities with the largest number of arrivals in Italy. In addition, there are some municipalities usually known for non-cultural tourism, such as Rimini (beach tourism) or Merano (winter and thermal tourism), that seem to have clearly realized good local policies to profitably valorize their cultural resources.

The unbalanced municipalities in category 4.b are uniformly spread all over the national territory, with concentrations in the Alpine area and in the internal area of Marche, Lazio, Puglia, Sicilia and Sardegna.

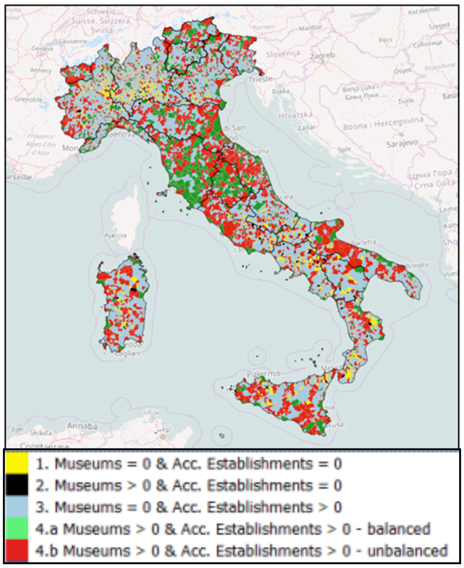
This analysis shows that in Italy, accommodation establishments are widespread on the territory and it is clear that when a municipality has at least one museum, in most cases, there is at least one accommodation establishment. Therefore, the presence of a cultural resource, such as a museum is, really attracts tourists and services for them, encouraging the development of economic activities on the territory.

Moreover, the territorial differences are quite clear: 1) the regional administrative boundaries (Regions have legislative power over tourism matters); 2) the historical disparities among North, Centre and South of Italy and among non-urban areas, metropolitan areas and coastal areas.

[6] The museum offer in these municipalities is an important and "functional" resource for the territory because it actually attracts tourists: these latter not only visit museums but they also spend - nights there. Probably the main motivation of tourists going to these destinations is the culture.

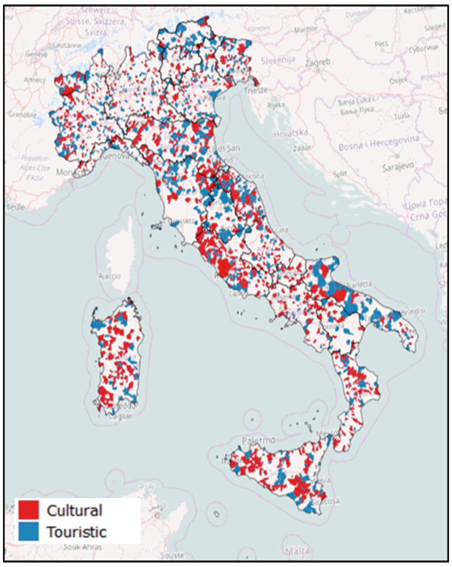
Among the unbalanced municipalities, we define as "municipalities with cultural prevalence (CP)" those having a greater imbalance towards admissions (n. 1,004 municipalities) and as "municipalities with touristic prevalence (TP)" those having imbalance to arrivals (n. 673 municipalities). The unbalanced municipalities are uniformly spread over the territory and more detailed analysis, realized thanks to the knowledge of the territory, reveals important signals (see Figure 2).

Figure 1: Categories of municipalities - Year 2015



🟨 1. Museums = 0 & Acc. Establishments = 0
⬛ 2. Museums > 0 & Acc. Establishments = 0
🟦 3. Museums = 0 & Acc. Establishments > 0
🟩 4.a Museums > 0 & Acc. Establishments > 0 - balanced
🟥 4.b Museums > 0 & Acc. Establishments > 0 - unbalanced

Figure 2: Unbalanced municipality: classification by prevalence (cultural or touristic) - Year 2015



Among the CP municipalities, there are municipalities well known for their specific and attractive cultural resources: Pompei (with its archaeological park), Taormina (with the Greek theater) or Ferrara and Siena, "art cities" with many museums. In these destinations, the phenomenon of "cultural same-day visits" and quick trips are evident. Furthermore, there are also many important provincial capitals, well known as tourist destinations: Roma, Napoli, Pisa, Firenze and Agrigento. These destinations record large numbers of arrivals (they are among the most relevant municipalities from a tourist point of view) but also even a greater presence of same-day visitors for cultural purposes which do not spend nights in accommodation establishments.

Among the TP municipalities, there are all those destinations that have other resources attracting tourists, as well as cultural ones, like as the main destinations for winter activities, thermal, lakeside or beach tourism. In these municipalities there are cultural resources but they are not the main reason for choosing these destinations. In this category, there are also many important municipalities for number of arrivals, as Venice, a destination mainly visited for cultural reasons.

Table 2: Summary of key themes

	Summary of key themes
1	museums and accommodation establishments are widely spread over the Italian territory, although they reveal considerable density in some specific areas
2	arrivals and admissions are highly concentrated in few regions that collect more than half of both flows
3	part of the structural resources of the country, both touristic and cultural, are underused
4	the balanced municipalities are a minority, but they could be an example to follow
5	the unbalanced CP municipalities use well their cultural resources but they have to change to a more structured tourism that leads to greater revenue and local development
6	the unbalanced TP municipalities have big results in tourism sector but could increase more by the development of their cultural resources

4 Final remarks and future outlooks

The main aim of this analysis is to create a tool for policy makers and territorial stakeholders in order to provide them quality statistical information and objective suggestions to make decisions. This is at the initial stage with the intention to develop it using other data to better qualify all the aspects of the territory (e.g. urbanization, coastal/non-coastal, inner areas, parks, etc.). In our opinion, it is essential to start from the territory, in order to define the right local development policies; moreover, a coordinated and efficient governance system is essential in order to plan the actions and follow their developments.

Posterior Predictive Assessment for Item Response Theory Models: A Proposal Based on the Hellinger Distance

Valutazione Predittiva A Posteriori per i Modelli di Item Response Theory: Una Proposta Basata sulla Distanza di Hellinger

Mariagiulia Matteucci and Stefania Mignani

Abstract Bayesian posterior predictive assessment has received considerable attention for investigating specific aspects of fit of item response theory models. In fact, this approach is easy to apply within Markov chain Monte Carlo estimation, it is flexible and free from distributional assumptions. In its classical implementation, the method is based on graphical analysis and the estimation of posterior predictive *p*-values to investigate the degree to which observed data are expected under the model, given a discrepancy measure. In this work, we propose to quantify the distance between the realized and the predictive distributions of the discrepancy measure based on the Hellinger distance. The results show that this measure is able to provide clear recommendations about the investigated aspects of model fit.

Abstract *Lo studio di aspetti specifici dell'adattamento dei modelli di item response theory è stato affrontato di recente con successo in ambito bayesiano usando strumenti della valutazione predittiva a posteriori. Questo approccio infatti è di facile applicazione quando si utilizza il metodo Markov chain Monte Carlo, è flessibile e non dipende da assunzioni distributive. Nella sua implementazione classica, il metodo si basa sull'analisi grafica e sulla stima dei p-value predittivi a posteriori basati su una particolare misura di discrepanza. In questo lavoro, si propone di quantificare la distanza tra la distribuzione realizzata e quella predittiva della misura di discrepanza utilizzando la distanza di Hellinger. I risultati mostrano che questa misura di distanza è in grado di fornire indicazioni chiare circa i particolari aspetti dell'adattamento considerati.*

Key words: posterior predictive model checks, item response theory models, Hellinger distance.

1 Introduction

In educational and psychological measurement, item response theory (IRT) models (see, e.g., van der Linden and Hambleton, 1997) are commonly used to estimate the characteristics of both the categorical items and the test takers. Several IRT unidimensional and multidimensional models have been proposed to account for different data structures. While unidimensional models assume the presence of a single latent variable underlying the response process, the multidimensional ones allow for multiple abilities. In this setting, the issue of model goodness-of-fit is crucial to investigate both absolute and relative fit.

Due to the increasing model complexity, a considerable amount of literature has been recently focused on Bayesian estimation of IRT models via Markov chain Monte Carlo (MCMC) methods due to its flexibility. Starting from a MCMC output, one possibility for examining model fit is using Bayesian posterior predictive model checks (PPMC; Rubin, 1984). Considerable advantages of the method are that it does not rely on distributional assumptions, and it is relatively easy to implement, given that the entire posterior distribution of all parameters of interest is obtained through MCMC algorithms.

The first proposals on the use of PPMC for IRT models deal with differential item functioning, person fit, fit of unidimensional models and item fit (see, e.g., Sinharay, 2006). Later, there was an increasing interest in checking specifically for the behavior of unidimensional models fitted to potential multidimensional data (see, among others, Sinharay, Johnson, and Stern, 2006; Levy, Mislevy, and Sinharay, 2009; Levy and Svetina, 2011). In these studies, PPMC has been implemented with graphical analyses and the estimation of the posterior predictive *p*-values (PPP-values) to investigate the degree to which observed data are expected under the model, given a discrepancy measure. Moreover, Wu, Yuen, and Leung (2014) proposed the use of relative entropy (RE) within PPMC to quantify the information the realized distribution loses when it is approximated by the predictive distribution.

The aim of this study is to propose the Hellinger distance, based on the Hellinger integral (Hellinger, 1909), to measure the distance between the realized and the predictive distributions. Unlike the relative entropy, the Hellinger distance is symmetric, it does obey the triangle inequality and it goes from zero to one. The use of the Hellinger distance is investigated for detecting the misfit of an IRT unidimensional model when response data are multidimensional with both simulated and real data.

2 Posterior Predictive Assessment of IRT Models

PPMC techniques are based on the comparison of observed data with replicated data generated or predicted by the model by using a number of diagnostic measures that are sensitive to model misfit (Sinharay, Johnson, and Stern, 2006). Substantial differences between the posterior distribution based on observed data and the posterior predictive distribution indicate poor model fit.

Given the data **y**, let p(**y**|**ω**) and p(**ω**) be the likelihood for a model depending on the set of parameters **ω** and the prior distribution for the parameters, respectively. In the IRT context, **ω** consists of the item parameters, person parameters, and trait correlations. To examine the differences between the observed and the replicated data, the latter are drawn from the posterior predictive distribution (PPD) of replicated data $\mathbf{y}^{rep}$

$$p(\boldsymbol{y}^{rep}|\boldsymbol{y}) = \int_{\boldsymbol{\omega}} p(\boldsymbol{y}^{rep}|\boldsymbol{\omega})p(\boldsymbol{\omega}|y)\partial\boldsymbol{\omega}. \qquad (1)$$

From a practical point of view, one should define a suitable discrepancy measure D(·) and compare the posterior distribution of D(**y**,**ω**), based on observed data, to the posterior predictive distribution of D($\mathbf{y}^{rep}$,**ω**). Discrepancy measures should be chosen to capture relevant features of the data and differences among data and the model. As a first step in PPMC, a graphical analysis is conducted to investigate the differences among realized and replicated discrepancy measures. Then, the PPP-value is defined as

$$\text{PPP-value} = p\big(D(\boldsymbol{y}^{rep}, \boldsymbol{\omega}) \geq D(\boldsymbol{y}, \boldsymbol{\omega}|\boldsymbol{y})\big). \qquad (2)$$

The PPP-value is estimated by computing the proportion of MCMC replications which satisfy Equation (2). The PPP-values provide a measure of the degree to which observed data would be expected under the model: values close to 0 or 1 mean that the realized values fall far in the tails of the distribution of the discrepancy measure based on PPD, indicating misfit; conversely, values of approximately 0.5 mean that the realized values fall in the middle of the distribution, indicating good fit. As underlined by Levy, Mislevy, and Sinharay (2009), PPMC has several advantages over traditional techniques. The method is easy to apply and flexible because the reference distribution is built empirically and it does not require regularity conditions or asymptotic results. Moreover, PPMC relies on Bayesian estimation, which is based on the full posterior distribution: compared with maximum likelihood techniques, which are based on a point estimate, the method is able to directly incorporate uncertainty into the estimation. However, using PPMC is not equivalent to conducting a classical hypothesis test, and the method should be treated as a diagnostic tool (Gelman, Meng, and Stern, 1996; Sinharay, Johnson, and Stern, 2006).

The choice of a suitable discrepancy measure is crucial in PPMC. Effective diagnostic measures in checking for unidimensionality or multidimensionality are based on the association or on covariance/correlation among item pairs. In the first group, the Mantel-Haenszel (MH) statistic is based on the odds ratio conditionally to the rest score *s*, i.e., the raw test score obtained by excluding the two items. For each couple of items *j* and *j*’, with *j*, *j*’=1,…,*k*, the MH statistic is defined as

$$\mathrm{MH}_{jj'} = \frac{\sum_s n_{11s} n_{00s}/n_s}{\sum_s n_{10s} n_{01s}/n_s}, \tag{3}$$

where $n_{tt's}$ is the number of subjects with rest score *s* who score *t* on item *j* and *t*′ on item *j*′, with *t*, *t*′=0,1, and n_s is the number of subjects with rest score *s*. In the second group, the model-based covariance (MBC) is defined as follows

$$\mathrm{MBC}_{jj'} = \frac{\sum_{i=1}^{n}(Y_{ij}-E(Y_{ij}))(Y_{ij'}-E(Y_{ij'}))}{n}, \tag{4}$$

where Y_{ij} is the response variable for individual *i* to item *j*, with *i*=1,…,*n* and *j*=1,…,*k*, and E(Y_{ij}) is its expected value depending on the specific IRT model and the estimated parameters.

2.1 The Hellinger Distance for PPMC

While the PPP-value counts the number of replications for which the predictive discrepancy exceeds the realized one, the researcher may be interested in measuring the size of the difference itself. For this reason, Wu, Yuen, and Leung (2014) proposed the use of the relative entropy (RE), also known as Kullback-Leibler divergence or information, to evaluate the magnitude of the differences between the realized and the predictive measures with limited information statistics based on low-order margins. However, the RE is asymmetric and it is not upper bounded so it is difficult to establish proper threshold levels for assessing absolute model fit or making comparisons.

To overcome these limitations, we propose the use of the Hellinger distance which is symmetric, it does obey the triangle inequality and its range is 0-1. Since the Hellinger distance is used to quantify the distance between two probability measures, it can be used to measure the distance between the realized and the predictive distribution within PPMC as follows

$$\mathrm{H}(P,Q) = \sqrt{1 - \int \sqrt{p(D(\boldsymbol{y},\boldsymbol{\omega}))p(D(\boldsymbol{y}^{rep},\boldsymbol{\omega}))}d\boldsymbol{y}d\boldsymbol{\omega}}. \tag{5}$$

The direct calculation of (5) is computationally demanding and it is usually done via MCMC. Specifically, it is calculated by using the normal kernel density estimates to represent the probability density functions of the realized and the predictive discrepancy measures, given the MCMC replications. In order to check for model unidimensionality, we propose the use of the Hellinger distance with the MBC discrepancy measure, which is based on both data and model parameters, to take into account a fit measure for each item pair. A MATLAB code was written by the Authors to implement the proposal.

3 Main Results

A simulation study is conducted to investigate the performance of the PPP-values and the Hellinger distance at detecting the misfit of a unidimensional IRT model when the data structure is multidimensional. Two different multidimensional IRT models are considered, namely the multi-unidimensional and additive models (see Sheng and Wikle, 2009). Within a confirmatory approach, the multi-unidimensional model relates each item response to a single latent variable, by allowing for trait correlations. In the additive model, a further overall latent trait is assumed underlying all item responses. All traits may be correlated as well. The corresponding IRT unidimensional model is built under the assumption of unidimensionality.

In the study, response data for tests with 10 items and 1,000 respondents are simulated. The trait correlations are manipulated. A number of 5,000 MCMC iterations are conducted, where 1,000 are used for PPMC. Finally, 100 replications are done for each simulation condition. The MH statistic and the MBC are used as discrepancy measures, with 45 item pairs to be considered. Given the mean of the PPP-values for each item pair over the replications, the proportion of extreme PPP-values (below 0.05 or above 0.95) is estimated pooling the results on all item pairs. Given the mean of the Hellinger distance for the MBC (MBC-H) for each item pair, some summary descriptive measures are computed by pooling the results on all item pairs.

Data are generated from the multidimensional models with a bidimensional structure and then analysed with the unidimensional approach. Due to space limit, the results are not reported in the paper but only briefly discussed in the following. The results on the PPP-values show that, for both discrepancy measures, the proportion of extreme values is above 0.75 for most conditions suggesting bad fit. In particular, the MH statistic outperforms the MBC. In the cases of strong and very strong trait correlations, data are conceived as unidimensional and, consequently, the proportion of extreme PPP-values decreases. The average MBC-H is estimated above 0.8 for most cases showing bad fit. The results are coherent and easily interpretable, in fact, the more the MBC-H is close to one, the bad the fit is. For strongly correlated traits, the MBC-H is estimated on average around 0.65. This means that the data are conceived as unidimensional but the distance measure is still able to catch the discrepancy between the generating model and the one used to analyse response data.

Data coming from a survey conducted by the University of Bologna (Bernini, Matteucci, and Mignani, 2015) to investigate the residents' perceptions toward tourism in terms of perceived benefits and costs are used. A total of 5 items on benefits and 5 items on costs are administered, suggesting a bidimensional latent structure. The unidimensional, multi-unidimensional and additive models are fitted. The results on the PPP-values show that the unidimensional approach is associated to a proportion of about 80% of extreme values. On the contrary, about 30% and 16% of extreme

PPP-values are reported for the multi-unidimensional and the additive model, respectively. Clearly, the additive model shows the best fit. These results are confirmed by the analysis with the MBC-H. On average, the estimated distances are about 0.8, 0.5, and 0.4 for the unidimensional, multi-unidimensional and additive model, respectively.

The approach based on the Hellinger distance seems to be promising to evaluate model fit within posterior predictive assessment. In particular, all measures could be used to investigate misfit due to specific items. A more comprehensive simulation study is needed to check the performance of the method for different simulation conditions.

Well-being & Quality of Life

Is Structural Equation Modelling Able to Predict Well-being?

È possibile stimare il livello di benessere per mezzo di modelli ad equazioni strutturali?

Daniele Toninelli and Michela Cameletti[1]

Abstract The well-being (WB) measurement is an important and challenging task. Quality of life is a multifaceted topic, thus its measure cannot rely anymore on one or few indicators only. Data from large-scale survey projects, such as the European Social Survey (ESS), are a solid basis for testing new methods aimed at measuring the phenomenon. We apply Structural Equation Modelling (SEM) to ESS wave 8 data. Our research aims at evaluating if SEM is a reliable method for estimating the WB and the relative importance of its dimensions in some European countries.

Abstract *Misurare il benessere è una sfida metodologica di rilievo. La qualità della vita è un concetto multidimensionale, la cui misura non può basarsi solo su uno o pochi indicatori. La disponibilità di dati da progetti di indagine su larga scala (come l'European Social Survey - ESS), è una solida base per sperimentare nuovi metodi di stima. In questo lavoro si applica la metodologia SEM (Structural Equation Modelling) per stimare il livello di benessere soggettivo rilevato nei Paesi Europei coinvolti nella wave 8 della ESS e l'importanza delle sue componenti.*

Key words: European Social Survey, quality of life, structural equation models, subjective well-being.

1 Introduction: Well-being & Structural Equation Modelling

Measuring the well-being (WB) became one of the key priorities, for national statistical institutes; nevertheless, this task is challenging, due to both the multi-

[1] Daniele Toninelli, University of Bergamo; email: daniele.toninelli@unibg.it
Michela Cameletti, University of Bergamo; email: michela.cameletti@unibg.it

dimensional and the latent nature of the phenomenon. GDP or other macro-economic indicators are not enough anymore (Stiglitz, Sen & Fitoussi, 2010): they are not able to detect all factors that actually affect the citizens' quality of life. Nevertheless, obtaining a reliable measure of the WB is extremely important, mostly in the framework of official statistics. On the one hand, a low level of WB can highlight critical areas politicians should turn investments towards and, on the other hand, observed changes in the WB could be used to evaluate the impact of implemented policies. This is why several national statistical institutes started developing projects aimed at measuring the WB[1].

In this work, we study the subjective WB (see Diener, 2013) with the main objective of testing the capability of SEM in measuring such a concept in different European countries. The estimates rely on several indicators (obtained from groups of items of the ESS questionnaire) that are supposed to cover the main WB dimensions. SEM allows us to evaluate how each dimension is affecting the latent concept of subjective WB. Moreover, we evaluate if SEM is, generally, able to estimate the WB level of the studied countries, making a direct comparison with measures of WB given by two specific items of the ESS questionnaire (our benchmark). Examples of previous SEM applications to WB include Oliver et al. (2009), Lin & Yeh (2014), Turashvili & Turashvili (2015) and Warner & Rasco (2016). These papers are focused on very specific WB aspects and are based on relatively small samples (mostly made by students) and/or on cross-sectional studies. Our approach, instead, is broader and based on a steady large-scale survey that allows us to develop a cross-country study at the European level. Moreover, we focus on a wide set of items that potentially covers all the main WB dimensions.

2 Data & Method

Our work starts from data collected in 2016 among 18 European countries[2] within the framework of the ESS wave 8. The dataset includes 34,836 records, but we estimate the final model on 26,455 units (8,381 units were excluded due to the listwise deletion method used by the Lavaan R package; missing values are mainly observed for sensitive items such as the ones asking about the household income). In particular, we focus on the measurement of subjective WB, because "measures of subjective well-being provide key information about people's quality of life" (Stiglitz, Sen & Fitoussi, 2010, p. 58). We do not focus, as suggested by Diener (1984) on the three main components of subjective WB (life satisfaction, positive experiences and negative experiences). We rather analyse, independently from their positive/negative nature, a set of indicators that could measure and cover as much as possible all WB dimensions. Table 1 shows how we grouped the items of the wave 8

[1] Such as: the "Better live initiative" (OECD: http://www.oecd.org/statistics/measuring-well-being-and-progress.htm), the BES project (Istat: http://www.misuredelbenessere.it/index.php?id=51), or other studies (UK Office for Nat. Stat.: https://www.ons.gov.uk/peoplepopulationandcommunity/wellbeing).

[2] Austria, Belgium, Switzerland, Czech Rep., Germany, Estonia, Finland, France, United Kingdom, Ireland, Iceland, Israel, Netherlands, Norway, Poland, Russia, Sweden, Slovenia.

ESS questionnaire in order to take into account these dimensions (listed in the first column; the full list of indicators is shown within Figure 1). The second column of Table 1 shows the correspondence to the WB dimensions suggested by Stiglitz, Sen & Fitoussi (2010), referenced as "SSF" (the new dimension we introduced are in bold). The third column shows the number of items taken into account for each dimension. Some couples of dimensions (e.g. *Country attachment and trust* and *Public involvement*) were merged into a common latent dimension (e.g. *atchtrst*) of the SEM model. Religion was excluded because the available variables, even if combined together to obtain two separate items, were too correlated to be included in the SEM model as measurements of a latent religion dimension (and this caused estimation problems). We also avoided to specify a SEM model with WB being directly measure by one religion variable (computed as an average of all the religion variables) without specifying a latent religion construct.

Table 1: *WB dimensions covered by the selected ESS questionnaire items (batt.=battery of items)*

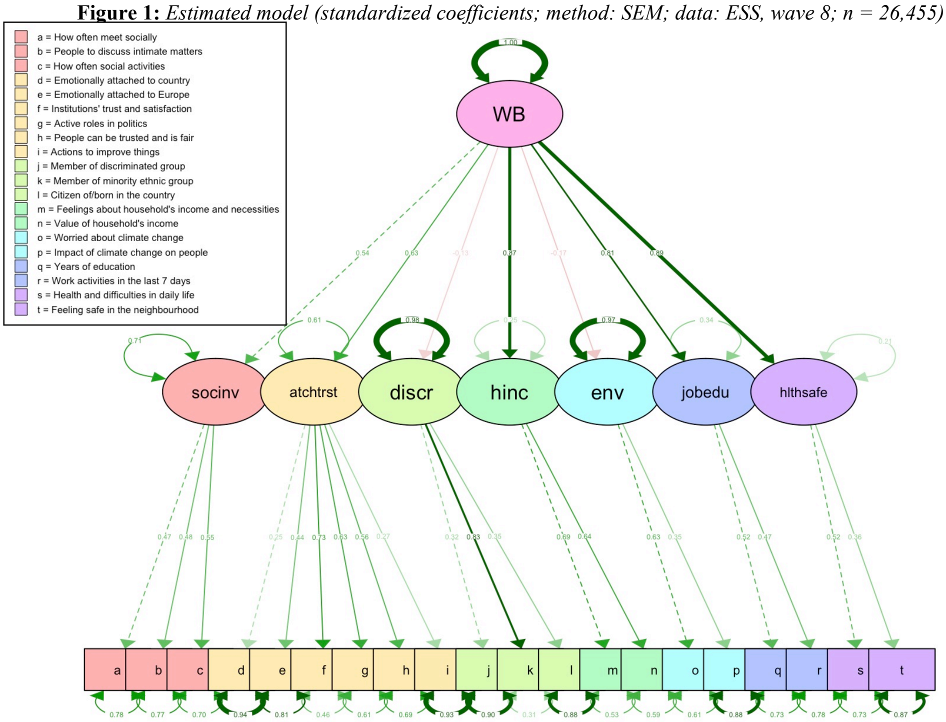
WB dimension *(model name)*	***SSF***	***No. items***
Social involvement (*socinv*)	Social connection	3
Feeling safe (*hlthsafe*)	Insecurity	2
Health conditions (*hlthsafe*)	Health	2
Country attachment & trust (*atchtrst*)	---	4+2 batt.
Public involvement (*atchtrst*)	Political voice	2+1 batt.
Religion	---	4
Discrimination/citizenship (*discr*)	---	4
Environment (*env*)	Environment	2
Income perception (*hinc*)	Material living standards	3
Work status (*jobedu*)	Personal activities / work	1+1 batt.
Education (*jobedu*)	Education	1

We aim at estimating a model based on SEM (see Hox & Bechger, 1999, and Kline, 2011), able to predict the WB level for the studied European countries. For this study, we used the `R lavaan` package (Rosseel, 2012; http://lavaan.ugent.be/). Our objective is twofold. First, we want to understand if and how the WB dimensions differently affect the phenomenon in European countries, studying the standardized coefficients. Second, we evaluate if SEM is a reliable method for estimating the country subjective WB, comparing observed data and SEM estimates. For this second objective, we study three different benchmark, considered by Dolan & Metcalfe (2012) as part of "experience measures" and of "evaluation measures", respectively. These items are: 1) "**Happy**" ("*Taking all things together, how happy would you say you are?*"; 0 to 10 answering scale, with extremes corresponding to "extremely unhappy" and "extremely happy"); 2) "**Satisf**" (*"All things considered, how satisfied are you with your life as a whole nowadays?"*; same scale, with extremes labelled as "extremely dissatisfied" and "extremely satisfied"); 3) "**H-SAvg**": average of the two previous items. For this last variable a high variability was observed, ranging from 5.95 of Russia to 8.16 of Switzerland, with a global (not weighted) average equal to 7.52 (st.dev.=0.565).

3 Results

Applying the SEM on the whole group of countries, we obtained the model shown in Figure 1, where the WB is defined by 7 latent dimensions each composed by a set of at least two indicators or batteries of variables.

Figure 1: *Estimated model (standardized coefficients; method: SEM; data: ESS, wave 8; n = 26,455)*



a = How often meet socially
b = People to discuss intimate matters
c = How often social activities
d = Emotionally attached to country
e = Emotionally attached to Europe
f = Institutions' trust and satisfaction
g = Active roles in politics
h = People can be trusted and is fair
i = Actions to improve things
j = Member of discriminated group
k = Member of minority ethnic group
l = Citizen of/born in the country
m = Feelings about household's income and necessities
n = Value of household's income
o = Worried about climate change
p = Impact of climate change on people
q = Years of education
r = Work activities in the last 7 days
s = Health and difficulties in daily life
t = Feeling safe in the neighbourhood

The model converges after 139 iterations. It does not generally provide an adequate fit ($\chi^2(163) = 16{,}429$, $p<.001$); nevertheless, this is likely to happen with a very large sample (Kline, 2011, p. 209). The model does not perform well also according to the Comparative Fit Index (CFI=.764), indicating a not satisfying improvement in fit over a baseline independence model (the usual threshold is >0.90). RMSEA (=.061) shows a good fit (it should be smaller than .10), instead.

Despite the difficulties of the model in reproducing the empirical covariance matrix, all path coefficients are statistically significant ($p<.001$). According to the completely standardized solution and considering *socinv* as the reference dimension, the dimensions that mostly affect the subjective WB are (standardized loadings within parentheses): *discr* (-0.130), *env* (-0.170); *atchtrst* (0.626); *jobedu* (0.813); *hinc* (0.869); *hlthsafe* (0.888). Thus, both being worried about the climate change and being discriminated negatively affect the perceived WB, whereas an active work status, the household income, the current health conditions and the perceived safety positively affect the WB. To a lower extent, we also note a positive linkage with how much the respondent has an active role in politics or trusts in/is satisfied about public institutions (such as government, police).

Note that the model presented in this paper is not the optimal one: for example, excluding the latent dimensions *env*, *jobedu* and *hlthsafe*, both the CFI (=.830) and the AIC index (=1,582,693 vs 2,158,450 of the full model) show a better fit than using the full model. Nevertheless, we decided to keep the full version, in order to be able to explore the complete list of generally recognized WB dimensions.

In order to check if the SEM works in detecting the subjective WB level, starting from its dimensions, we compare the perceived WB level (measured through the *H-SAvg* variable, third column of Table 2) and the estimates obtained using the SEM (fourth column of Table 2) for all European countries.

Table 2: *Countries rankings: by observed WB (H-SAvg) and by model estimates (WB-SEM)*

Rank H-SAvg	***Country***	***WB H-SAvg***	***Rank Happy***	***Rank Satisf***	***WB SEM***	***Rank WB-SEM***
1	Russian F.	5,949	1	1	-0,194	**1**
2	Czech Rep.	6,803	2	3	-0,100	**2**
3	France	6,887	3	2	-0,094	**4**
4	Estonia	7,172	4	4	-0,080	**5**
5	Slovenia	7,299	5	5	-0,071	**6**
6	Poland	7,401	7	6	-0,065	**7**
7	Ireland	7,404	6	7	-0,049	**8**
8	UK	7,555	8	8	-0,010	**10**
9	Belgium	7,614	10	9	-0,005	**11**
10	Germany	7,644	11	10	0,035	**13**
11	Austria	7,743	9	12	-0,018	**9**
12	Iceland	7,827	13	11	-0,096	**3**
13	Netherlands	7,876	14	13	0,048	**14**
14	Sweden	7,902	12	14	0,110	**17**
15	Norway	8,043	15	15	0,115	**18**
16	Israel	8,107	16	17	0,107	**16**
17	Finland	8,128	18	16	0,034	**12**
18	Switzerland	8,165	17	18	0,061	**15**

The Spearman’s rank correlation coefficient shows that all associations between our model estimates and the WB variables are significant (α=0.01) and high: ρ=.804 for *Happy*; ρ=0.851 for *Satisf*; ρ=0.835 for *H-SAvg*. The Kendall’s tau coefficient confirms these results (with associations equal or higher than 0.686 and significant, for α=0.01). The Pearson correlation coefficients between the WB model estimates by country and the three observed variables are all also quite high and significant (p<0.001): 0.841 for *Happy*; 0.859 for both *Satisf* and *H-SAvg*.

4 Conclusions

SEM is able, taking into account several latent dimensions, to estimate the relative WB level of different European countries and to help in detecting, at an aggregate level, the dimensions actually more important. Nevertheless, the estimated model shows fitting issues. Since we estimate a general model for all the European countries, this could be caused by the diversity of studied contexts: determinants of the subjective WB can be different across countries. However, estimating country-specific models should probably fix this issue. This strategy should also depict more closely the relative importance of different dimensions in affecting subjective WB. Moreover, we did not use any weights in estimating our model, thus estimates could be mainly driven by the most populated countries. This preliminary work was developed in order to understand if SEM is able to estimate WB, on the basis of items measuring different WB dimensions. This is just a first step. For further research, we suggest to use data coming from social networks and/or obtained using web-scraping in order to create indexes useful to update the information made available by large-scale survey projects, such as the ESS.

The well-being in the Italian urban areas: a local geographic variation analysis

Il benessere nelle aree urbane italiane: un'analisi della variabilità locale

Eugenia Nissi and Annalina Sarra

Abstract Following the place-based well-being literature, this paper is aimed at assessing inequality between Italian province capital cities in terms of their performance in promoting human and ecosystem well-being. The case study rely on the theoretical framework adopted by ISTAT within the Ur-Bes project. The available indicators are used to derive a multidimensional urban well-being index. To this end we adopt a two-steps procedure. Firstly, by using the geographically weighted PCA we assess the spatial variability for each Ur-Bes pillar data and obtain for each dimension a composite index. In the second stage, the ranking of the Italian province capital cities according to their efficiency in promoting equitable and sustainable well-being is facilitated by DEA.

Abstract *In questo lavoro ci si propone di valutare il benessere equo-sostenibile delle province italiane. Il caso studio fa riferimento al modello concettuale di benessere adottato dall'ISTAT nell'ambito del progetto Ur-Bes. Gli indicatori disponibili sono utilizzati per ricavare un indice multidimensionale del benessere urbano. A tal fine, viene impiegata una procedura a due fasi. Inizialmente, attraverso la ACP ponderata geograficamente, si valuta la variabilità spaziale per ciascun dominio dell' Ur-Bes e si ottiene per ogni dimensione un indice composito. Nella seconda fase, l'impiego della tecnica DEA consente di ottenere un indice globale di misura del benessere equo-sostenibile e di confrontare l'efficienza delle province italiane nel promuoverlo.*

1 Introduction

The last two decades have witnessed a growing interest on the measurement of well-being and quality of life, as documented in many theoretical and empirical studies. Some of these researches focus on the well-being assessment at local level (see, among others, Bai et al., 2012). Basically, the root of understanding local well-being (in regions and cities) lies in the intersection of well-being and public policy. In this respect, more fine-grained measures of well-being will help policy-makers to enhance the design and targeting of policies and improve their capacity to respond to the paramount and varied needs of residents. Well-being is a multidimensional phenomenon, whose definition and theorization requires the specification of a conceptual framework for its assessment at national as well as at local level. The conceptual framework providing grounds for the discussion in this paper has been that adopted by ISTAT within the “Equitable and Sustainable Well-Being" project, whose Italian acronym, used hereafter, is BES (see ISTAT- Cnel, 2012), which, in turn, is based on the conceptual model published by OECD (Hall et al. 2010). This theoretical framework reflects the conceptual complexity of well-being and highlights its dependency upon attributes specific to each person and on attributes shared with other people or revealing the relations between them or how a society is peaceful, resilient, cohesive.

Our case study considers the Italian Province capital cities as units of analysis and employs the urban Bes (Ur-BES) report data, which refers to 64 particular indicators, belonging to 11 dimensions, identified within the equitable and sustainable well-being initiative (BES). The paper sheds light on the construction of a multidimensional urban well-being index for the Italian Province capital cities and, following the place-based well-being literature, on assessing inequality between Italian province capital cities in terms of their performance in promoting human and ecosystem well-being. In our analysis, a special focus is placed on the importance of surveying the spatial dimension of the local well-being indicators and their related variables. Most of the existing literature on the construction of composite indicators neglects to consider the spatial heterogeneity of the units in the computation of their relative composite indicators scores. As matter of fact, it may happen that the value of a composite indicator may be more dependent on a certain sub-indicator in a given location, and another sub-indicator in different location. To ascertain this kind of spatial dependence can reveal useful for policy decision makers in tackling problems in an efficient way, and distinguishing their causes at local level. With regards to this research issue, we propose a two-step approach. Firstly, for each of the well-being dimensions we employ the Geographically Weighted (GW) Principal Component Analysis (PCA). The GW PCA, introduced by Harris et al. 2011, can be deemed a local version of the traditional PCA in that it takes spatial variations across a study region into account and produce maps of spatial variations of each local principal component and local variance at each place. This variant of global PCA is chosen due its merits in assessing the spatial variability of each Ur-BES pillar data dimensionality and checking how the elementary indicators influence the corresponding spatially-varying component. In the second stage of our empirical procedure, the synthesis of Ur-Bes elementary indicators obtained through the GW PCA, is included in a unitary Data Envelopment Analysis (DEA) model to derive a spatial composite index. The employment of DEA facilitates the ranking of the Italian province capital cities according to their efficiency in promoting equitable and sustainable well-being. The rest of paper proceeds as follows. In Section 2 we give some details of the theoretical background of the GW PCA technique, then we present the basic of DEA model, as well as the specific model selected for our case study. The results are discussed in Section 3.

2 Methodological approach

In our two step-procedure we start by reducing the dimensionality of Ur-Bes elementary indicators by using GW PCA. Next, the reduced set of variables is employed in a unitary input DEA model to assess the relative efficiency of the Italian Province capital cities in producing equitable and sustainable wellbeing. The following sub-sections describe both GW PCA and DEA techniques.

2.1 Geographically Weighted PCA

GW PCA is a local spatial form of the PCA able to provide locally derived sets of principal components for each location (Harris et al. 2011). GW PCA adapt PCA for spatial effects with respect to spatial heterogeneity. We assume that the vector of observed well-being variables at location i have a multivariate normal distribution, with mean vector $\boldsymbol{\mu}$ and variance-covariance matrix $\boldsymbol{\Sigma}$ ($x_i \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$). The mean vector $\boldsymbol{\mu}$ and variance-covariance matrix $\boldsymbol{\Sigma}$ are now function of location i, with coordinates (u,v). This implies that each element of the mean vector and the variance matrix is, in turn, function of position and are expressed as $\boldsymbol{\mu}(u,v)$ and $\boldsymbol{\Sigma}(u,v)$, respectively. The geographically weighted principal components are obtained through the decomposition of the geographically weighted variance-covariance matrix:

$$\boldsymbol{\Sigma}(u,v) = \mathbf{X}^T \mathbf{W}(u,v) \tag{1}$$

where $\mathbf{W}(u,v)$ is a diagonal matrix of weights. As for any geographically weighted methods, diverse kernel functions (gaussian, exponential, bi-square) can be employed to generate the diagonal matrix of weights, under the control of a parameter known as bandwidth. Geographically weighted principal components are obtained using the decomposition of the variance-covariance matrix. More specifically, the local principal component at location (u_i, v_i) can be written as:

$$\mathbf{L}(u_i, v_i)\mathbf{V}(u_i, v_i)\mathbf{L}(u_i, v_i)^T = \mathbf{\Sigma}(u_i, v_i) \tag{2}$$

where $\mathbf{L}(u_i, v_i)$ is the matrix of the geographically weighted eigenvectors and $\mathbf{V}(u_i, v_i)$ is the diagonal matrix of the geographically weighted eigenvalues. For p variables, the GW PCA provides p components, p eigenvalues, p set of component loadings and p set of component scores for each data location in the study area. Full technical details underlying GW PCA are described in Harris et al (2011).

2.2 Unitary input DEA model

Data Envelopment Analysis (DEA) is a widely used non-parametric method of measuring the efficiency of organisational units, termed Decision Making Units (DMUs), within production contexts, characterised by multiple outputs and inputs (Charnes et al., 1978). Over the past three decades, the scope of DEA has broadened considerably. In particular, DEA has been employed as a valid instrument to construct social and economic well-being indicators (see, among others, Despotis 2005). The adaption of DEA to the measuring of environmental and social aspects has required the changing of the objective function in the standard model in order to recognize the change in focus. To deal with the case of the production of human well-being and ecosystem, it is possible conceptualise a production process where each city is a “firm" which uses government resources to produce well-being outputs, such as better education, improvement of health status, greater access to labour markets, reduction of environmental pollution and so on. Accordingly, each city is assumed to have one “government" and hence one unit of input, and it produces the aforementioned outputs. Because we do not have the classic production context, but we can only rely on secondary variables, obtained as rates or combinations of primary variables, a DEA model with a single constant input can be suitably adopted. For the purpose of our work, we make use of the approach proposed by Lovell and Pastor (1999), in which the CCR and BCC models are equivalent. By adopting the output orientation, the linearized unitary input DEA-model is expressed by the following linear programming:

$$\max \quad h_0 \tag{3}$$

$$s.t \quad \sum_{k=1}^{n} \lambda_k y_{jk} \geq h_0 \, y_{j0} \quad \forall j \tag{4}$$

$$\sum_{k=1}^{n} \lambda_k \leq 1 \tag{5}$$

$$\lambda_k \geq 0 \quad \forall k \tag{6}$$

In equations (3-6) h_0 denotes the inverse of efficiency of the DMU under analysis (DMU_0), y_{jk} is the j_{th} output ($j = 1 \dots s$) of the DMU_k ($k = 1 \dots n$) and λ_k is the individual contribution of each DMU in the formation of DMU_0's target. Nissi and Sarra (2018) propose an integrated DEA-entropy approach to strength the discrimination power of that model.

3 Results and Conclusions

Our analysis is restricted to 103 province capital cities and takes into account eight out of eleven domains of the original Ur-Bes dataset: "*Health*", "*Education and Training*", "*Work and Life Balance*", "*Economic well-being*", "*Social Relationships*", "*Security*", "*Landscape and Cultural Heritage*", "*Environment*". Following the methodology described in the previous section, we first compute a spatial composite index for each pillar of Ur-Bes through the GW PCA. The GW PCA analyses have been carried out in R using the GWmodel package (Gollini et al.2013). We used a bi-square kernel function with adaptive bandwidths, whose sizes are selected automatically and objectively via cross-validation and not based on a priori decision. The output of the GW PCA allows to highlight the local change in the structure of multivariate data and how the original well-being indicators influence the local principal components retrieved for each of the Ur-Bes pillars. The GW PCA makes possible to display the localized proportions of the total variance (PTVs) and ascertain if the spatial patterns in the PTVs vary significantly across the study region. In general, for the majority of the urban well-being domains, the maps of PTVs, not displayed here, reveal that the highest PTVs are often located in the province capital cities of the South of Italy. Some exceptions are recorded for the "Security" pillar, for which the PTVs data are lower in the province capital cities of Central Italy. In the areas where highest PTVs are detected the local correlation (or local collinearity) among well-being data is assumed high, suggesting that not all Ur-Bes indicators need to be considered. By retaining only the first component, that accounts for a substantial proportion of the variability in the original data, it is possible, for a given local well-being domain, to extricate how each of the elementary indicators influences the selected pillar. For instance, in the domain "Health", the local principal components reveal multifaceted geographical variations in the variables with the largest loadings. From GW PCA results, we see that first component is mainly represented, in the province capital cities of Piemonte and Trentino

Alto Adige, by the age-standardised cancer mortality rate (19-64 years old); by life expectancy at birth (male) in most cities of central Italian regions and in Sardinia, and by life expectancy at birth (female) and mortality rate for road accidents (15-34 years old) for the Southern province capital cities. The spatial variation of the first local component of the “Education and Training" domain, reveals that it mainly considers the participation to primary school and this elementary indicator dominates in the most urban areas, with some exceptions for a number of province capital cities of Calabria and Sicily, where the leading variable is represented by the early leavers from education and training. This analysis is replicated for each dimension of Ur-Bes. Once weights are obtained for each variable in each location, the spatial composite indicator for the urban well-being dimensions, has been computed as the weighted sum (linear combination) of the variables, location by location. For the arising composite indices a data transformation has been undertaken to respect their positive o negative linkages with equitable and sustainable well-being and assure strictly positive data. In the second stage of the analysis, the overall well-being index is obtained via a unitary input DEA model, with entities defined only by outputs. We found that efficiencies are between 78.8% and 100%, while the mean efficiency is 97.2%. A large number of efficient cities are located in the North and Central part of Italy. Thirty-four cities achieve a well-being efficiency score which is below the average. In the last positions of the ranking we find Napoli, Salerno, Foggia, Bari, Benevento, Isernia, Caserta, Ascoli Piceno, Chieti, Macerata and Agrigento.

Comparing Composite Indicators to measure Quality of Life: the Italian “Sole 24 Ore” case

Un confronto tra indicatori compositi per misurare la qualità della vita: il caso italiano de “Il Sole 24 Ore”

Gianna Agrò, Mariantonietta Ruggieri and Erasmo Vassallo

Abstract The measure of Quality of Life is still a topic widely discussed in the literature. In Italy, the newspaper "Il Sole 24 Ore" publishes a famous ranking that highlights a strong disparity between Northern and Southern Italy areas. In this paper, some methods are compared in order to show how different types of normalization and aggregation can influence the results.

Riassunto *La misura della qualità della vita continua ad essere un argomento ampiamente discusso in letteratura. In Italia, il quotidiano "Il Sole 24 Ore" pubblica una nota graduatoria che evidenzia una forte disparità tra le aree del Nord e del Sud Italia. In questo lavoro, si confrontano alcune procedure per mostrare come diversi tipi di normalizzazione e di aggregazione possano influenzano i risultati.*

Key words: Quality of Life, Composite Indicators, BoD approach, standardization

1 Introduction

The newspaper "Il Sole 24 Ore" has been publishing for 25 years a ranking of Quality of Life (QoL) for Italian provinces according to the NUTS3 classification. This survey produces every year a great media resonance, recalling a long-debated issue about the so-called "Questione Meridionale"; economic and social territorial disparities are highlighted by a strong polarization among the provinces of North Italy, with higher levels of QoL than the provinces of the South (Felice, 2013;

[1] Gianna Agrò, DSEAS, University of Palermo; email: gianna.agro@unipa.it

Mariantonietta Ruggieri, DSEAS, University of Palermo; email: mariantonietta.ruggieri@unipa.it

Erasmo Vassallo, DSEAS, University of Palermo; email: erasmo.vassallo@unipa.it

IlSole24Ore, 2017). Actually, this result is strongly influenced by the choice of the basic dimensions, the kind of data and indicators, the standardization and aggregation techniques to obtain a Composite Indicator (CI). There is no doubt that the economic and the social context presents a greater level of discomfort in the South of Italy (ISTAT, 2017a), but this can not immediately be related to lower levels of QoL. It is very difficult to provide a univocal definition of QoL, as this concept invests personal and/or community aspects, depending on subjective and/or objective well-being and happiness (Cummins, 1998; Nussbaum and Sen 2003). Certainly, the concept of QoL is much more than "standard of living" one, that is basically connected to income levels (ISTAT, 2017b). The absence of a clear and univocal definition makes the concept more difficult to translate into data, indicators and measures that are free of criticism. Nevertheless, the aim of this paper is not to discuss about the different definitions of QoL used in the theoretical and applied literature, but to focus on the statistical techniques used to standardize and synthesize data, influencing the final ranking of the Italian provinces. Although we highlight many perplexities on the redundancy of some data and their ability to correctly represent some dimensions, here we accept the choice of "Il Sole 24 Ore" about pillars and indicators used in its QoL dossier, well-known by journalists and politicians. In particular, we compare four procedures, described in the Section 2, including the BoD-DEA method, which provides endogenous weights emphasizing the strength of each province (Giambona and Vassallo, 2014). The results and comments are reported in Section 3, while in Section 4 we draw some conclusions.

2 "Il Sole 24 Ore" quality of life and BOD approach

The 2017 "Il Sole 24 Ore" dossier uses 42 indicators divided into 6 dimensions (income and consumption, labor and innovation, environment and services, demography and society, justice and safety, culture and leisure), each consisting in 7 indicators to measure QoL among the 110 Italian provinces, according to the NUTS3 classification of the territory. In this paper, we do not discuss the choice of indicators and dimensions of the analysis that, moreover, is not constant over time, but the procedure used to aggregate the data. In particular, the dossier proposes to standardize each of the 42 indicators for the *i*-th province with $std.value_i=(indicator\ value_i\ /\ max(indicator\ values))\cdot 1000$ if the indicator polarity is positive (higher values correspond to a better condition) and $std.value_i=(min(indicator\ values)/indicator\ value_i\ )\cdot 1000$ if the polarity is negative (lower values correspond to a better condition). In this way, the best province (benchmark) always assumes a maximum score of 1000 and the other provinces assume decreasing values up to a minimum; then a simple arithmetic mean among indicators/dimensions provides an overall score for each province. This method has the advantage of being very simple and intuitive, but it ignores some statistical features of data, for example the different variability exhibited by the different indicators. Besides, the simple arithmetic mean is a fully compensatory aggregation procedure; this implies that the indicators and dimensions have the same importance and they can also be considered perfectly complementary. A better way to standardize the indicators is to use the min-max procedure, i.e. *std.value*$_i$ *= (indicator value*$_i$ *- min(indicator values))/(max(indicator values)-min(indicator values))* if the polarity is positive and *std.value*$_i$ *= (max(indicator values) - indicator value*$_i$*)/(max(indicator values)-min(indicator values))* if the indicator polarity is negative; in this way, the standardized values always range between 0 and 1 for all indicators (OECD, 2008). Obviously, the compensatory nature of the mean is not resolved.

Among other proposals in literature (Munda and Nardo, 2009), the AMPI index is widely used by some ISTAT reports; it presents a simple solution to the full compensation of the arithmetic mean through the use of a penalty based on a function of variability (Mazziotta and Pareto, 2017). So, the indicators are standardized via min-max rescaled between 70 and 130 and the corresponding mean is reduced if the province has different values (higher variability) among the dimensions, i.e. $AMPI_i = M_i - S_i \cdot cv_i$, where M_i, S_i and cv_i are the mean, the standard deviation and the coefficient of variation, respectively, of the indicators for the i-th province.

Recent developments aim at removing any kind of subjectivity in the choice of right weights for aggregating indicators and/or dimensions. In this framework, the Benefit of Doubt (BoD) based methods have received many consents. These methods exploit the Data Envelopment Analysis (DEA), a frontier technique that has been usually used for measuring the efficiency in production. Several variants of BoD models have been proposed in literature (Rogge and Van Nijverseel, 2018). In this work, we use an appropriate geometric mean of the indicators, in which the weights are endogenously defined, depending on the characteristics of the data according to the principle of BoD. A Composite Indicator $CI_i = \prod_{j=1}^{n} I_{ij}^{w_j}$ is defined, where I_{ij} is the *j*-th indicator of QoL ($j = 1,...,n$) for the *i*-th province ($i = 1,...,m$) with weight w_j determined endogenously by an algorithm based on a multiplicative optimization model, that solves the following problem: $SI_i = \max_{w} \prod_{j=1}^{n} I_{ij}^{w_j}$ with constraints $\prod_{j=1}^{n} I_{ij}^{w_j} \le e$ and $w_j \ge 0$, where e is the Napier's constant (Zhou et al., 2007; Giambona and Vassallo, 2016). In this way, the CI is obtained by multiplying the basic indicators of QoL with weights calculated in the best possible conditions, i.e. increasing as much as possible the composite score for a given province. In short, a low value of the CI for the *i*-th province is due to low values of the indicators that compose it and not to specific weights, calculated to obtain the best, i.e. the maximum possible, result for the *i*-th unit compared to the benchmark province. At the end, we obtain scores between 1 and 2.71 (the Napier's constant), attributable to the most intuitive interval between 0 and 1 by applying the antilogarithm. However, the optimization problem could determine zero weight to some indicators and attribute too much weight to other indicators, and this is not desirable if all the dimensions are relevant. So, we add specific constraints on the weights; in particular, we add proportion constraints to the model: $\left(\prod_{j=1}^{n} I_{ij}^{\,w_j}\right)^{L} \leq I_{ij}^{\,w_j} \leq \left(\prod_{j=1}^{n} I_{ij}^{\,w_j}\right)^{U}$, where *U* and *L* ranging between 0 and 1 to represent the lower and the upper bound (in percentage terms) for the contribution of the *j*-th indicator. In fact, without constraints on the weights, the model could ignore the contribution of the under-performing indicators or dimensions to maximize the best solution, and this is not admissible. In our case *L*=10% (*U* is defined accordingly); we note that bounds slightly lower or slightly higher lead to similar results, so an intermediate value has been chosen among the possible alternatives, taking into account that *L* (to guarantee sufficient flexibility to the method) must be relatively low.

3 Results and comments

This Section presents the results obtained by means of the methods described in Section 3, that is: 1) the original "IlSole24Ore" with min or max standardization on 1000 and use of arithmetic mean (CI.SOLE); 2) the "range" with min-max standardization rescaled between 1 and 10 and arithmetic average (CI.RANGE); 3) the "ampi" with min-max standardization between 70 and 130 and use of a penalized arithmetic mean (CI.AMPI); 4) the "BoD" with min-max standardization, rescaled for calculation purposes between 2-10, and geometric mean with weights endogenously defined (CI.BOD).
In Table 1 the correlation matrix among the considered CIs is reported, showing a very high correlation between the series.

Table 1: Correlation matrix among CIs

	CI.SOLE	CI.RANGE	CI.AMPI	CI.BOD
CI.SOLE	1.00	0.94	0.93	0.82
CI.RANGE	0.94	1.00	0.99	0.93
CI.AMPI	0.93	0.99	1.00	0.94
CI.BOD	0.82	0.93	0.94	1.00

Figure 1 reports the kernel density estimates of the four CIs, where the BoD kernel density estimates uses the Silverman reflection method to avoid bias and inconsistency near the boundaries (Silverman, 1986; Scott, 1992). We note some “twin peaks” distributions, substantially in correspondence with the provinces of the southern and northern Italy. A similar polarization can be seen in BoD, although this distribution suggests a more detailed interpretative framework. In fact, the scores of the different methods are consistent each other, but the rankings are sometimes quite different. In particular, the BoD ranking shows a less intense polarization and the distance North-South appears less severe. In this regard, it is interesting to note the strong change of position of some provinces compared to the original classification of the "IlSole24Ore"; for example, some northern provinces lose many positions:

Monza e Brianza loses 55 positions (from 29 to 84), Verbano-Cusio-Ossola loses 49 positions (from 7 to 56), Sondrio loses 41 positions (from 3 to 44), and so on. On the contrary, other provinces acquire positions, such as Brescia (from 46 to 14), Padova (from 42 to 12), Venezia (from 43 to 15), etc.

4 Conclusions

In this paper four different procedures, able to supply a unique composite indicator measuring the QoL, are applied to data reported on the well-known "IlSole24Ore" QoL dossier. We do not discuss the choice of indicators and dimensions, even if there are many critical aspects, but we focus on the possible consequences in applying different aggregative procedures. The original “IlSole24Ore” procedure uses a simple standardization and a fully compensatory arithmetic mean, similarly the "range" procedure that, instead, uses a better min-max standardization. The "ampi" technique uses again an arithmetic mean, but penalizes the provinces with greater variability among indicators/dimensions. Finally, the BoD method applies different weights to dimensions and provinces according to the specific characteristics of the data; besides, it uses a geometric mean to avoid the problem of a full compensation among indicators or dimensions. The BoD method is more specific and advanced from a technical point of view and addresses some critical aspects compared to simpler methods; nevertheless, it is not possible to assert that an endogenous choice of the weights is better compared to an exogenous one or to a choice of identical weights for units and dimensions. Certainly, the techniques of standardization and aggregation strongly influence the rankings, and this generates many doubts about the utility of these classifications. Finally, this work highlights that all the rankings maintain a strong North-South distinction, but this depends on strongly heterogeneous indicators between northern and southern provinces: with less heterogeneous variables, the ranking differences would be even more evident.

Quality of working life in Italy: findings from Inapp survey

La qualità del lavoro in Italia: i risultati di un'indagine Inapp

Paolo Emilio Cardone[1]

Abstract Job quality is important to all citizens and is also central to policy concerns as Europe tries to boost economic growth and address the demographic challenge and the threats to the welfare systems. Making work sustainable and keeping people in work for longer are two key aspirations of many European countries. Maintaining and developing job quality is crucial for attaining these goals.

The paper aims at analyzing the behavior of the workers as regard the job quality in Italy in terms of working conditions, working time, work-life balance, health and well-being at work, pay and income.

More in detail, the paper provides a statistical picture of job quality in Italy, investigating its variability and relevant inequalities. The analysis is carried out using the quantitative research "*Indagine campionaria sulla Qualità del Lavoro*" (QdL), provided by Inapp ("*Istituto Nazionale per l'Analisi delle Politiche Pubbliche*" – Public Policy Innovation). It provides a rich portrait of workplace trends in Italy over the last fifteen years. Using logistic regression model, it is possible to estimate the job satisfaction level among workers more accurately. Overall the data confirm the existence of strong inequalities among workers and the findings also underline the importance of company and workplace practices in safeguarding health and safety (including against psychosocial risks), improving work–life balance, supporting career development, promoting skills use and development, managing workload and designing meaningful jobs. This requires policy attention, to increase the focus on job quality as part of active labour market policies.

Abstract *Il presente contributo fornisce un quadro statistico della qualità del lavoro in Italia, indagando la sua variabilità e le disuguaglianze rilevanti, analizzando il comportamento dei lavoratori in termini di condizioni di lavoro, orario di lavoro, equilibrio tra vita lavorativa, salute e benessere al lavoro, retribuzione e reddito. L'analisi è stata effettuata utilizzando "l'indagine*

[1] Paolo Emilio Cardone, INAPP-Statistical Office; email: p.cardone@inapp.org

campionaria sulla qualità del lavoro" (QdL), una ricerca quantitativa condotta dall'Inapp (Istituto nazionale per l'Analisi delle politiche pubbliche). Utilizzando un modello di regressione logistica, è stato possibile stimare più accuratamente il livello di soddisfazione del lavoro tra gli occupati. Nel complesso i dati confermano l'esistenza di forti disuguaglianze tra i lavoratori e sottolineano anche l'importanza delle prassi aziendali.

Key words: Ageing workforce; Job quality; Pay and income; Work-life balance; Working conditions; Logistic regression model.

1 Introduction

Job satisfaction for all is a goal for European education, training and employment policies. In particular, the Treaty on the Functioning of the European Union (TFEU) underlines as significant objectives the "promotion of employment, improved living and working conditions…proper social protection, dialogue between management and labour, the development of human resources with a view to lasting employment and the combating of exclusion" (Article 151 TFEU).

In the main slogan of the Europe 2020 strategy – 'smart, sustainable and inclusive growth' – the ideas of working conditions and job quality are implicit rather than explicit; however, 'improving the quality of work and working conditions' is a pivotal objective of the European Commission's 2010 'Agenda for new skills and jobs' initiative[2].

Improving working conditions and job quality continues to be a significant goal in European policies, underpinning Europe's capacity to compete. It is a cross-cutting issue that both influences and is influenced by many other European policies. For example, the Commission's recent industrial renaissance and enterprise policies have implications for working conditions and job quality (European Commission 2017). And conversely, the improvement of working conditions is important for the implementation of other European policies (i.e. innovation and gender equality).

Current European policy concerns include work–life balance (in particular for working parents), fighting undeclared and fraudulent work, extending working life, addressing the challenge of segmented labour markets and ensuring a proper balance between flexibility and security, investing in human capital, preparing individuals for potential risks over their life course, and addressing the significant inequalities that people face in the labour market (Judge and Watanabe 1993).

[2] "*High quality of work goes hand in hand with high employment participation. This is because the working environment plays a crucial role in enhancing the potential of the workforce and is a leading competitiveness factor. In order to innovate and to deliver promptly and efficiently, EU companies depend for their survival and expansion on a committed workforce, thriving in a high-quality working environment, with safe and healthy working conditions*".

The current policy debates on new forms of employment and undeclared and fraudulent work highlight the importance of monitoring working conditions and of providing data and analysis that can both enhance understanding of the common challenges faced by Europe and the Member States and support policymaking in these areas.

Numerous changes (demographic, structural and technological) are affecting the composition of the workforce, employment levels, job content and how workers experience their working lives. These developments challenge the role that work plays in our societies, with working life actors responding in different ways, and have a knock-on effect on working conditions and job quality (Eurofound 2017).

Furthermore, demographic ageing is an irreversible process. The direct effect of population ageing is the increasing share of elderly people, who are in retirement age, compared to the decreasing share of young people (Eurofound 2015).

The ageing of the European working population calls for policy attention to two issues: ensuring that demanding working conditions can be undertaken by an older workforce and ensuring that working conditions are sustainable over the life course to allow people to remain in work longer.

2 Data and methods

In order to achieve this goal, the analysis is carried out using microdata from the quantitative research "*Indagine campionaria sulla Qualità del Lavoro*" (QdL)[3], provided by Inapp[4].

The survey aims to measure working conditions in Italy, analyse the differences among workers, identify groups at risk, highlight issues of concern and areas of progress and, ultimately, contribute to developing policy aimed at improving job quality. In 2015, QdL interviewed over 15.000 workers, both employees and self-employed people, in Italy (with appropriate weights provided by Istat they are 22 million, exactly the workers' amount in Italy). Workers were asked a range of questions concerning employment status, work organisation, learning and training, working time duration and organisation, physical and psychosocial risk factors, health and safety, work–life balance, worker participation, earnings and financial security, as well as work and health (Clark 1998).

Going beyond the objective measures of job quality, the report also looks at workers' own assessment of their working lives. It finds associations between the different dimensions of job quality and factors such as engagement, financial

[3] For more details: http://inapp.org/it/dati/qualitadellavoro

[4] National Institute for Public Policy Analysis, former ISFOL - National Research Institute for Vocational Education and Training Employment, that changed its company name in INAPP (*Istituto Nazionale per l'Analisi delle Politiche Pubbliche – Public Policy Innovation*) on December 1st 2016 (www.inapp.org)

security, the development of skills and competences, health and well-being, the reconciliation of work and private life, and the sustainability of work.

The first part describes the main characteristics of the workforce in Italy. Apart from traditional aspects, such as employment levels broken down by occupation, sector or employment status, it also looks at indicators such as sex, age, educational attainment, country of origin, seniority, health status and household circumstances.

Subsequently it focuses on developments in job quality in Italy. The current analysis is based on the following seven indices: physical environment; work intensity; working time quality; social environment; skills and discretion; prospects; and earnings. The indices cover extrinsic and intrinsic job features captured from an objective perspective. They are based on positive and negative self-reported features of the job, which measure the concrete experiences of work and have been proven to have a causal effect (either positive or negative) on the health and well-being of workers. The analysis of each index's components is supplemented by other features of the job or the working environment, such as dealing with customers or place of work. Other organisational resources provided through employee representation at the workplace are also considered.

Special attention is paid to the perspective of the individual job-holder: how their skills match their job, what their level of engagement is with their job, whether it provides them with financial security, what their work–life balance and time preferences are like, and how they juggle their different roles as worker, family member and citizen. Finally, issues around health and well-being, as well as workers' views on the sustainability of work, are explored.

QdL paints a wide-ranging picture of Italy at work, across occupations, sectors and age groups. Its findings highlight actions for policy actors to help them address the challenges facing Italy today and provide detailed information on a broad range of issues, including exposure to physical and psychosocial risks, work organisation, work–life balance, and health and well-being.

The topics covered include employment status, working time duration and organisation, work organisation, learning and training, physical and psychosocial risk factors, health and safety, work-life balance, worker participation, earnings and financial security, as well as work and health, with a special attention to gender mainstreaming.

Since its launch in 2002 the "*Indagine campionaria sulla Qualità del Lavoro*" has provided an overview of working conditions in Italy in order to:

- assess and quantify working conditions of both employees and the self employed;
- analyse relationships between different aspects of working conditions;
- identify groups at risk and issues of concern as well as of progress;
- monitor trends by providing homogeneous indicators on these issues;
- contribute to national policy development in particular on quality of work and employment issues.

Using multivariate analysis (logistic regression models with Stata software) it is possible to estimate the job satisfaction level more accurately (Liu 2016). The model has been developed for employed adults only and includes, first of all, adults' socio-demographic characteristics (age, gender and citizenship), secondly, job and size enterprise.

In order to achieve this goal, we have used "Satisfaction" as the dependent variable (weighted model). Satisfaction = 1 if the worker is satisfied.

Concretely, in our study the following variables are considered (tab. 1):

- ***Gender***. Categorical. Dummy variable: Female, Male (reference cat.).
- ***Age group***. Categorical. Six intervals. From 18 to 24 (reference cat.); 25 to 34; 35 to 44; 45 to 54; 55 to 64; 65+.
- ***JobISCO***. Categorical. Nine levels. Elementary occupations (reference cat.); Managers; Professionals; Technicians and associate professionals; Clerical support workers; Services and sales workers; Craft and related trades workers; Plant and machine operators and assemblers; Military forces.
- ***Education level***. Categorical. Three levels. Secondary school (reference cat.); High school; University.
- ***Training***. Four levels: No training (reference cat.), Yes, paid by me; Yes, paid by other; Yes, paid by me and others.

3 Conclusions

Overall, the survey finds, structural inequalities and differences in terms of gender, employment status and occupation are still significant. In the last 10 years, there has been limited progress in some aspect of job quality.

Going beyond the objective measures of job quality, the report also looks at workers' own assessment of their working lives. It finds associations between the different dimensions of job quality and factors such as engagement, financial security, the development of skills and competences, health and well-being, the reconciliation of work and private life, and the sustainability of work.

Looking at the findings through the lens of the job quality profiles, jobs in the 'poor quality' profile would benefit most from actions to support the various dimensions of job quality and labour market policies focused on moving workers into better-quality roles (Cedefop 2015).

More generally, job quality can be supported by a wide-ranging set of policies and actions aimed at addressing the issues raised in the survey's analysis of job quality indices and profiles and that support workers throughout their working lives. In addition to policy initiatives at EU level, by national authorities and social partners, progress can also be achieved through workplace practices and policies at company level.

The improvement of working conditions takes place in a context of subsidiarity. Governments and social partners, companies and workers all have a role to play. Yet experience has shown that the EU is also a key player and has contributed to improving working conditions through its various measures with regard to the improvement of health and safety at work and gender equality, and its wider coordination of employment policies

Finally, vocational training plays an important role because the nature of jobs is changing, necessitating changes in the skills that are required of workers and adapting lifelong learning systems to the needs of an ageing workforce. The recent crisis has also highlighted the importance of education and training at all stages of life, in particular for older adults to avoid unemployment, vindicating the messages that "it is never too late to learn" and learning must be for all. This requires older people to maintain and update the skills they have, particularly in relation to new technologies. Continuous learning and development of an ageing workforce are important for employers' survival in competitive markets, as well as for maintaining older people's employability.

Well-being indices: what about Italian scenario?

Indici di benessere: lo scenario italiano

Silvia Facchinetti and Elena Siletti

Abstract This paper proposes a review of the Italian well-being scenario, introducing its peculiarities and defects. The aim is to provide a detailed image, also to policy-makers, describing the accuracy, timeliness and territorial coverage. All these characteristics are a challenge for a good planning, for a correct international comparison or to integrate well-being indices with new data, represented, as example, by big data.

Abstract *Questo lavoro propone una rassegna delle misure del benessere in Italia, presentandone peculiarità e difetti. L'obiettivo è fornire un'immagine dettagliata, anche ai policy-makers, descrivendone l'accuratezza, la tempestività e la copertura territoriale. Tutte queste caratteristiche rappresentano una sfida per una buona pianificazione, per un corretto confronto internazionale o per l'integrazione con nuove fonti di dati, rappresentate, ad esempio, dai big data.*

Key words: well-being indices, social indicators, quality of life, official statistics

1 Background

The importance of well-being has been widely acknowledged and its measurement is a matter that scholars have been tackling for a long time. Traditionally the most commonly employed indicator was the Gross Domestic Product (GDP) thanks to its ability to connect goods and services with different nature, to its linear methodology, to its objectivity and clearness, and the usefulness in international comparisons.

Silvia Facchinetti
Department of Statistical science, Università Cattolica del Sacro Cuore, largo Gemelli 1 Milano, e-mail: silvia.facchinetti@unicatt.it

Elena Siletti
Department of Economics, Management and Quantitative Methods, Università degli Studi di Milano, via Conservatorio 7 Milano, e-mail: elena.siletti@unimi.it

Many issues have been raised about the adequacy of GDP as an indicator of well-being, concluding that the use of GDP as a proxy of well-being can lead to misleading conclusions [3]. On the one hand negative events such as natural disasters, earthquake or foods, or big car accidents, reduce wealth of society but can increase GDP; on the other hand it doesn't take into account distribution of income, so that a great disparity and poverty of capabilities wouldn't be noticed. To overcome the GDP issues, alternative approaches have been developed across the years and they are still nowadays a core topic. A recent theoretical framework about well-being is the capability approach proposed by [7]. Following this approach, in 2007, the European Commission, European Parliament, Club of Rome, Organization for Economic Co-operation and Development (OECD) and WWF, hosted the conference titled "Beyond GDP". In August 2009, the European Commission released its road map, the Communication "GDP and beyond: Measuring progress in a changing world", when the so-called Stiglitz Commission [8] suggested to build a complementary statistical system, focused on social well-being and suitable for measuring sustainability. Shortly, going beyond GDP implies to develop indicators that are as clear and appealing as GDP, but more inclusive of environmental and social aspects of progress [6]. The proposed measure accounts a wide set of indicators representing both objective and subjective assessment, and including also people's perception of quality of life. The commission suggests to take into consideration the following aggregated dimensions: Material living standards, Health, Education, Personal activities including work, Political voice and governance, Social connections, Environment and insecurity. Following this advise, have been developed a huge number of indicators [3], with different structures, considering a great variety of dimensions and for many purposes. International examples of those indices are: the Human Development Index, the Better Life Index, the Happy Planet Index, the Canadian Index of Well-being and the Gross National Happiness Index.

In the field of subjective well-being, new measure have been recently proposed using big data: [9] developed a system to predict the life satisfaction of Facebook users based on lexical and topical features, many studies used Twitter data for the same purpose ([4]). In Italy, [2] proposed the iHappy index, an indicator of happiness that, using information from million of tweets, measures the average level of idiosyncratic happiness in the 110 Italian provinces. [5] developed the Social Well-being Index (SWBI), a multidimensional well-being composite indicator relying always on Twitter data and derived from a new human supervised technique of sentiment analysis (see [1] for details). All these proposals try to overcome the lack in official statistics, they use this new kind of information represented by big data whether by integrating them with statistics or by themselves, in any case for this kind of proposals the methodological challenges are still many and open.

In this paper we review the traditional indices used to measure well-being in Italy, their purposes, limitations, and their progressive evolution. This simple description is the starting point to understand well-being measurement in our Country, how it is addressed, and what is the quality of this kind of data. In future steps of our research we will propose new approaches to maximize advantages and to cut down limitations of the treated indices.

2 The Italian case

The interest in Italy towards well-being is constantly increasing, also due to the fact that there are still a number of open questions related to its measurement. First of all, we need accurate indices to face the European and international comparison in the best possible way. But above all it is increasingly necessary to inform policy-makers about the perceived effect of local policies. Then availability of sub-national data would be extremely useful, and due to the active well-being process that rapidly changes over time, high frequencies information would be even more welcome. For all these reasons the knowledge, and the characteristics of information sources about well-being in Italy is a straightforward and actual interest.

In the following subsections we describe: the Better Life Index (BLI), used for comparison in international context, the Fair Sustainable Well-Being Index (BES), elaborated by the Italian Institute of Statistics (ISTAT) as the Italian answer to the Stiglitz Commission proposal, and the “Il sole 24 ore” Quality of Life (QoL) index, that has a long history in the Italian society.

2.1 The Better Life Index - BLI

The BLI initiative, launched in 2011, is built around eleven topics that reflect what the OECD has identified as essential to well-being in terms of material living conditions (Housing, Income and wealth, Jobs and earnings) and quality of life (Social connections/community, Education and skills, Environmental quality, Civic engagement and governance, Health status, Life satisfaction, Personal security or safety, Work and life). Each dimension is built on one to four specific indicators that are averaged with equal weights, and have been chosen on the basis of a number of statistical criteria such as relevance and data quality and in consultation with OECD member countries. As the BLI gathers many indicators, expressed on different units, in order to compare and aggregate the values a normalisation, according to a standard formula, is performed. Moreover, thanks to its web platform, to visualise and compare the performances of the members, it is also possible to mix the set of dimensions, giving different weights, in order to elaborate an index coherently with one’s preferences (see [6]).

Data mostly come from official sources such as the OECD or National Accounts, United Nations Statistics, National Statistics Offices. Instead, some indicators are based on data from the Gallup World Poll: a division of the Gallup Organization that regularly conducts public opinion polls in more than 140 countries around the world. Unfortunately, about time frequency, almost always information is delayed. With reference to the Italian 2017 index only the 21% refers to 2016, sometimes the measure is the 3-year average 2014-2016, and for all the other indicators there is a greater lag, that, for example, for ”time devoted to leisure and personal care” arrives to 18 years. To aggravate the situation of this index, essentially born for comparisons between countries, the fact that these delays change with the country considered.

At the moment, most of the indicators in the BLI are not available at a more disaggregated level for a great number of countries, but there is a regional edition (https://www.oecdregionalwellbeing.org). However, in this case, the situation worsens even more, it should be noted that in the June 2016 release, currently on line as the latest available, the most updated data for Italy dates back to 2014. Perhaps because of these source disparities between countries, in all the OECD publications, they talk about "first year available" and "last year available", without specifying, if not in the most specific material, the true reference for each country.

2.2 The Fair Sustainable Well-Being Index - BES

The BES (Benessere Equo Sostenibile) is setting up from a dashboard of twelve dimensions: Economic well-being; Education and training; Environment; Health; Landscape and culture heritage; Politics and institutions; Research and innovation; Security; Service quality; Social relationship; Subjective well-being; Work and life balance. Although it is clear conceptually and statistically similar to the Better Life Index, in the first two years the BES does differ it avoided any form of aggregation: in the periodical report, for each dimension, the entire set of proxies, with 130 indicators, is presented and discussed. For this reason, from 2013 to 2014, the only available aggregation form was provided by IRES Piemonte (the Regional Institute for Economic and Social Research of Piemonte). Since 2015, ISTAT provided by its self a general and domain specific composite indicators for Italian regions, nevertheless, for the composite indicator of the single dimensions often not all the indicators are accounted. Concerning time frequency, also in this case quite always the information is delayed. Only for instance, for Health in 2015 no one indicators refers to 2015, the 36% refers to 2014, and the 64% is more delayed. In addition to the regional edition, there are, for some years and some Italian provinces or chief towns, some pilot versions of the BES in which the indices considered are not the same and the subjective component is not provided for.

2.3 The "Il Sole 24 Ore" Quality of Life Index - QoL

Since 1990, the Italian business newspaper "Il Sole 24 Ore" publishes a well-being index of the Quality of Life (QoL) for all the Italian provinces.This composite indicator is strictly objective and it is defined along six categories, namely: Income, savings and consumption; Environment, services and welfare; Business, work and innovation; Justice, security and crime; Demographics, family and integration; Culture, leisure and participation. Since 2016, the considered indicators for every topic pass from six to seven, achieving a total number of 42 indicators. Note that, as the QoL index cover only material quality of life, it becomes for media a benchmark indicator for Italian well-being. Despite efforts to improve the quality, the index, in addition to having a low frequency with only an annual data, often shows delayed information. This is a serious flaw when decision makers want to base their choices on such information. Moreover, the indicators associated to the different dimensions change over the time, and in some cases the same indicator correspond to different dimension year by year. For example, the ”broadband coverage”, traditionally in Environment, services and welfare topic, from 2013 to 2014 pass to Culture, leisure and participation. Furthermore, also when the indicator is the same, sometimes is detected with different measures. For instance, the information about ”shows” in Culture, leisure and participation some years has been detected as number of shows, number of cinemas, or number of cinema seats per inhabitants. For this reasons with time series we are obliged to use the score and not the real value of the variables.

3 Negative and positive aspects of Italian well-being indices

This review shows that well-being information actually provided for Italy has been improved according to the suggestions of scientific international community. In Table 1 a synthesis of their principal traits. Especially, BES takes into account both subjective and objective dimensions, and with its great number of indicators, it performs a good multifaced source of information. Nevertheless, despite all efforts made to improve the measures of well-being, all the indices still presents several gaps. First of all, concerning time frequency, in addition to be designed as low frequency data the info is often delayed. Moreover, some indicators associated to the different dimensions change over time or the same indices correspond to different dimension year by year, or they are detected with different measures. Finally many indicators are not available at a more disaggregated level: they do not allow comparisons of disparities within a country or between social groups.

4 Conclusion

All the indices flaws, summarised above, are serious issues when decision makers want to base their choices on them, or when you need to make national or international ranking. To overcome this matter and to improve the quality of well-being data, the efforts could be address to a better data planning or to the integration of official statistics with more frequent and light surveys with new kind of information like social networks or big data. Before doing this, we can’t forget to solve the linked methodological issues, and official statistics must however be more accurate, more frequent and considered local level too, without forgetting the subjective dimension.

Table 1 Synthesis of the principal traits for the three considered indices

Index	*Starting year*	*Frequency*	*Dimensions*	*Indicators' number*		*Subjective*	*Level*
BLI	2013	Annual	Housing	3	24	Subjective dimension "life satisfaction" with only 1 indicator	National Regional level with delays and disparities
			Income and wealth	2			
			Jobs and earnings	4			
			Social connections/community	1			
			Education and skills	3			
			Environmental quality	2			
			Civic engagement and governance	2			
			Health status	2			
			Life satisfaction	1			
			Personal security/safety	2			
			Work and life	2			
BES	2013	Annual The 19% of the indicators are surveyed with more delay	Work and life balance	14	130	The subjective dimension, with its 4 indicators is available at regional and not for provincial level	Regional There is a local pilot experience only for few self-selected provinces from 2013 to 2015
			Economic well-being	10			
			Education and training	11			
			Environment	15			
			Health	14			
			Landscape and cultural heritage	12			
			Politics and institutions	12			
			Service quality	11			
			Research and innovation	7			
			Security	11			
			Social relationships	9			
			Subjective well-being	4			
QoL	1990	Annual	Income, savings and consumption	7	42	Unconsidered	For the 110 Italian provinces
			Environment, services and welfare	7			
			Business, work and innovation	7			
			Justice, security and crime	7			
			Demographics, family and integration	7			
			Culture, leisure and participation	7

How can we compare rankings that are expected to be similar? An example based on composite well being indicators.

Confronti tra graduatorie simili. Un esempio basato su indicatori compositi di benessere.

Silvia Terzi e Luca Moroni[1]

Abstract We compare 5 different well-being rankings derived from the following composite indicators: Human Development Index, Inequality Adjusted Human Development Index, Legatum Prosperity Index, Good Nation Index, Development Sustainable Goals Index.

Abstract *Confrontiamo tra loro 5 diverse graduatorie di benessere basate sui seguenti indicatori composti: Human Development Index, Inequality Adjusted Human Development Index, Legatum Prosperity Index, Good Nation Index, Development Sustainable Goals Index.*

Key words: well being, concordance, local concordance

1 Well being indicators and derived rankings

The most widely-used and well-known composite indicator of well being is the Human Development Index (HDI). It is a summary measure of average achievement in key dimensions of human development: *a long and healthy life,*

[1] Silvia Terzi Department of Economics RomaTre University; silvia.terzi@uniroma3.it
Luca Moroni, Department of Economics RomaTre University; luca.moroni@uniroma3.it

being knowledgeable and have a decent standard of living [3]. The HDI is the geometric mean of normalized indices (life expectancy, education, Gross National Income) for each of the three dimensions. However this index does not account for disparities (inequalities) within each dimension across the population; thus United Nations Development Programme also computes an Inequality adjusted HDI (IHDI). The IHDI combines a country's average achievements in health, education and income with how those achievements are distributed among country's population by "discounting" each dimension's average value according to its level of inequality.[2]

Other well being indicators available for a large number of countries worldwide are: the Legatum Prosperity Index, the Good Country Index, the Sustainable Development Goals Indicator. The Legatum Prosperity Index (LPI) [8], based on 104 indicators , is an aggregation of nine sub-indexes: (1) economic quality, (2) business environment, (3) governance, (4) education, (5) health, (6) safety & security, (7) personal freedom, (8) social capital, (9) natural environment.

The Good Country Index (GCI) [1] is based on 35 indicators related to the following 7 dimensions: (i) Science, Technology & Knowledge; (ii) Culture; (iii) International Peace and Security; (iv) World Order; (v) Planet and Climate; (vi) Prosperity and Equality; and (vii) Health and Wellbeing.

The Sustainable Development Index (SDGI) is based on several normalized indicators for each of the 17 Sustainable Development Goals (see [6] for the list of indicators and goals).

A careful insight into these different indicators goes beyond the standards allowed for our communication. Otoiou et al [5] explore whether the variables used in computing three of the most widely known indicators of well-being and social progress, the HDI, LPI, and Happy Planet Index, can be used to develop a relevant cluster structure, which can then be used to assess the validity and reliability of the country rankings obtained by these indicators. Among other comments and conclusions, they argue that the optimal cluster structure is very close to HDI country rankings. Making moves from the assumption that all the quoted indicators are well being indicators, and that what receives attention from media and policy makers are the country rankings of these different composite indicators, our interest focuses on the ranking comparison. How can we measure the similarities or the distances or the agreement between the different rankings? Is one of these rankings to be preferred with respect to the others? Are our comparisons in line with Otoiou et al.?

[2] A different kind of adjustment has been suggested by Terzi [7]: to correct HDI by means of a Multidimensional Poverty Indicator. This gives rise to the *corrected HDI*. However, MPI is available only for a subset of the countries for which HDI is computed so we decided not to consider MPI; not as a well-being indicator nor as a correction factor.

2 Ranking comparisons

First of all let us examine the correlations among the rankings of the 5 chosen indexes (Good Country [1], Human Development [3], Inequality Adjusted HDI [3], Legatum Prosperity [8], Sustainable Development Goals [6]) for n = 120 countries, for the most recent available years (2017 for GCI and SDGI; 2016 for the others).

	GCI	HDI	IHDI	LPI	SDGI
GCI	1.000	0.843	0.852	0.851	0.836
HDI	0.843	1.000	0.983	0.896	0.939
IHDI	0.852	0.983	1.000	0.888	0.958
LPI	0.851	0.896	0.888	1.000	0.872
SDGI	0.836	0.939	0.958	0.872	1.000

Table 1: correlations among rankings

Also, we have the concordance:

Kendall's $W = 0.913$.

From the correlations and from Kendall's coefficient, the 5 rankings appear to be very close (in particular HDI, IHDI, SDGI).

However what could interest mostly the policy makers are the differences in rankings of the best and of the worst performing countries. For this reason we resort to Top-Down concordance coefficient [4].[3] The Top-Down concordance coefficient is derived by computing Kendall's W not on ranks R$_i$ but instead on Savage scores

$$S_{R_i} = \sum_{j=R_i}^{n} \frac{1}{j}$$

In particular we have a top-down *low* concordance coefficient based on W (W_{TDL}) by substituting each rank R_i with the respective Savage score S_{R_i} when our interest is for the concordance among the lowest ranks, i.e. the top of the distribution; and a top-down *high* concordance coefficient when our interest is for the highest ranks, i.e. to bottom of the distribution. In this case we substitute each rank R_i with the Savage score:

$$S_{n-R_i+1} = \sum_{j=n-R_i+1}^{n} \frac{1}{j}$$

thus obtaining the Top-Down (high) concordance coefficient W_{TDH}. By the way, this is the same as calculating W_{TDL} on the descendent rankings of the objects.

For our rankings we have:

[3] If interested in the agreement among two rankings this could be achieved by means of weighted rank correlation, derived from Spearman's ρ (see for example Dancelli et al [2]).

Top-Down Kendall high $W_{TDH} = 0.892$,
Top-Down Kendall low $W_{TDL} = 0.839$.

Thus the 5 rankings are closer in the tail of the distributions than for the best performing countries.

To have an even closer insight of the concordance in the top or bottom or in the central rankings, we consider a local headcount function. We partition the set of the first $n = 120$ natural numbers (the ranks of the 120 observed countries) in contiguous subsets of fixed size s (for example 10% of the observations; 12 in our case) of consecutive naturals, and count for each subset how many units (countries), for at least one of the $d = 5$ rankings, rank in that subset. A local headcount of $s = 12$, the minimum of its range, means that in the interval spanned by the subset there are exactly s units, whose ranks are thus very close on all indicators. Conversely, a local headcount of $min(n, s.d) = 60$, the maximum of its range, means that in the span of the subset no unit ranks more than once.

The interpretation we suggest for the local headcounts is that they are inverse indicators of local concordance, because the headcounts are smaller when the ranks are closer and bigger when the ranks are spaced; so we derive a local concordance function as the maximum, $min(n, s.d) = 60$, minus the value of the local headcount. Moreover, we calculate the local headcount and the local concordance for each subset of s consecutive naturals in $(1, \ldots, n)$, and associate the value to the central rank of the subset, so that we can plot a smooth curve (Figure 1); the local concordance of the partition subsets are enhanced in red.

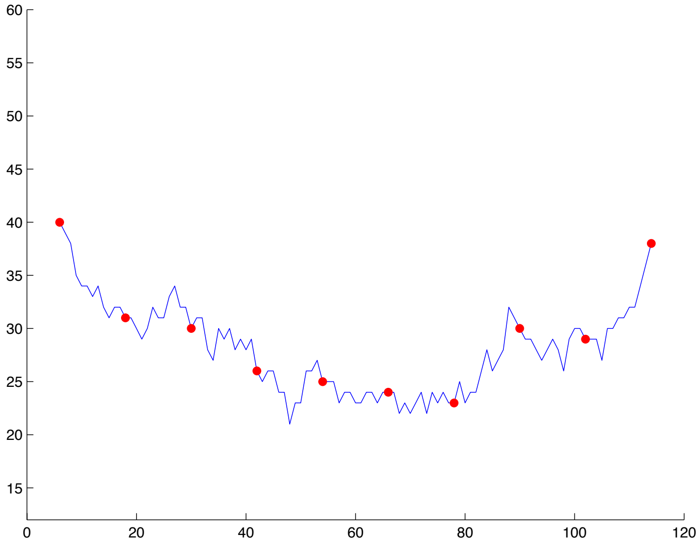

Figure 1: local concordance function

Alternatively we could be interested in finding out which well being indicator best represents all the others.

Let us define a centrality measure $C_{1(J)}$ for each ranking J that counts to how many units it assigns the median rank among the 5. Let us also define a de-centrality measure $C_{2(J)}$ as the sum of the differences between the unit's rank (in the J-th ranking) and the median rank. These values are summarized in Table 2.

Rankings	C_1	C_2
GCI	13	1365
HDI	36	449
IHDI	40	411
LPI	24	1079
SDGI	29	721

Table 2: centrality and de-centrality

Thus the ranking that best represents all the five well-being rankings is IHDI.

The same conclusion appears from Figure 2, in which on the *x*-axis we represent the countries ordered by means of their median rank and on the *y*-axis the ranks and their median.

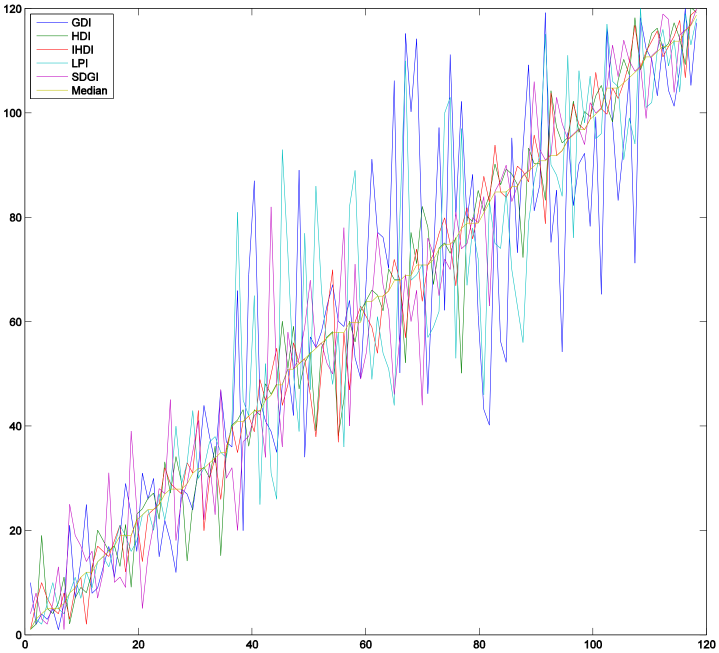

Figure 2: rankings and median by country vs ranking of medians

3 Concluding remarks

Although for the chosen well-being indicators Kendall's coefficient is high (W = 0,913), there are differences among the five rankings. In particular, there are differences among the units ranked in the center of their ranking (as can be seen by means of our local concordance function) and asymmetries in concordance among highest and lowest ranks (as can be seen by computing top-down concordance coefficients). From Figure 2 we can draw similar considerations: the greatest variability among ranks is in the centre of the plot; moreover, it can be seen that the farthest-away-from-the-others ranking is the GCI based ranking, whereas the most intermediate is based on IHDI, and this conclusion is reinforced by our centrality and de-centrality measures in Table 2. Overall, our findings seem consistent with Otoiu's findings [5].

A distribution curves comparison approach to analyze the university moving students performance

L'analisi delle preformance degli studenti universitari in mobilità, secondo un approccio basato sul confronto tra curve di distribuzione

Giovanni Boscaino, Giada Adelfio, Gianluca Sottile

Abstract Nowadays in Italy we observe a one-directional migration flow of university students, typically from the South to the North. It represents the new millennium migration flow: people migrate looking for better job opportunities already during their educational path, believing that northern universities may provide more opportunities for being more successful. This paper aims to study the performance of those Sicilian students that move to the northern universities, to take the second level degree, in comparison with those remain in Sicily. We want to test the empirical evidence that shows a similar performance between the two groups of students. We use different measures of performance and follow a new methodology based on the comparison among the distribution curves. Results seems to confirm our idea, highlighting some difference.

Abstract *Da qualche anno anche l'Italia sta assistendo a un flusso migratorio di studenti, che da un povero Sud si dirige verso un più ricco Nord. Se un tempo la migrazione avveniva nel momento di cercare lavoro, adesso questa è anticipata da studenti che ritengono di avere meggiore successo se conseguono il titolo al Nord. L'obiettivo di questo studio è verificare l'ipotesi secondo la quale gli studenti che restano per iscriversi alla Laurea Magistrale hanno un percorso simile rispetto a quelli che si iscrivono a un percorso magistrale del Nord. Considerate diverse misure di performance, e svolto i confronti attraverso una nuova procedura di raffronto tra curve di distribuzione, i risultati non mostrano sostanziali differenze.*

Key words: performance, student migration, distribution comparison

1 Introduction

The intra-European students' mobility is one of the targets of the Bologna Process to promote EU integration and foster a higher quality educational system. As known, the individual student mobility is a great opportunity to gain experience, to increase the knowledge of other cultures, to enhance human capital formation, networks, and relational abilities. Literature offers a lot of papers on the international student mobility [7] [4] [11] and its determinants, and they underline the influence of the socio-economic and cultural conditions of both the areas of origin and the destination. Actually, other factors could influence the wish of moving abroad, such as the quality of the receiving universities and the migration costs.

Studies on internal student mobility are rather scant on UK [8] and on Netherlands [13], where domestic student mobility flows are almost entirely unidirectional – from South to North – mirroring the internal economic migration. This is the case of Italy too: in fact, the migration flows from the South to the North of Italy, historically due to the different job opportunities, has changed in students migration flows. Probably, this is due to the expectation of students who think they will be more successful if they graduate in a more economically developed area [3].

Literature offers several studies about student performance, mainly devoted to find its determinants, and often based on different measures [16] [1] [5]. On the other hand, it is not so common to find papers about the performance of the university moving students [12] [3] [6]. Our research focuses on this new point of interest, and in particular on students that enroll in a university second level degree at institutions outside the students region of origin.

Comparison is made using a new method for curve clustering [15], since we compare the distribution curves (marginal and conditional to some given socio-demographic characteristics) of students, both in terms of performance and time to the degree.

2 The new method for clustering of curves

The clustering of distribution curves here performed is based on a new method to find similarities of curves in a quantile regression coefficient modeling framework, also multivariate, in which the effect of covariates on a response variable is represented by curves in the space of percentiles [9] [10]. In particular, let y be the response of a dependence model problem, in [15] the authors first estimate the regression coefficient functions $\beta_1(p \mid \boldsymbol{\theta}),\ldots,\beta_q(p \mid \boldsymbol{\theta})$, namely effects curves, and then assess if these q curves, that describe the effects of each covariate on the response, can be clustered based on similarities of effects, as a variable selection procedure.

The proposed clustering approach is based on a new measure of dissimilarity that uses both the shape of a curve and its distance with respect to other curves:

- the *shape* of a curve is evaluated using its second derivative. Moreover, two different curves are similar in shape if, at any given point, the signs of the second derivatives are concordant;
- the *distance* between two curves is evaluated as their with respect to other curves. Two curves are said close if their distance at any given point is lower than a fixed value.

Let i and i' be two different curves, $\boldsymbol{p} \in (0,1)$ the vector of percentiles. Then

$$d^{ii'}_{\text{shape}}(\boldsymbol{p}) = I(\text{sign}(\beta''_i(\boldsymbol{p} \mid \boldsymbol{\theta})) \times \text{sign}(\beta''_{i'}(\boldsymbol{p} \mid \boldsymbol{\theta})) = \mathbf{1})$$
$$d^{ii'}_{\text{distance}}(\boldsymbol{p}) = I(|\beta_i(\boldsymbol{p} \mid \boldsymbol{\theta}) - \beta_{i'}(\boldsymbol{p} \mid \boldsymbol{\theta})| \leq f(\alpha, \text{dist}(\boldsymbol{p}))),$$

where $f(\cdot,\cdot)$ is a cut-off function, that depends on a probability value α, and on dist($\boldsymbol{p}$), the vector of the distances between two curves across all percentiles. Finally, the proposed dissimilarity measure between two curves is defined as

$$d(i,i') = 1 - \int_0^1 \left[d^{ii'}_{\text{shape}}(p) \cdot d^{ii'}_{\text{distance}}(p)\right] \mathrm{d}p. \tag{1}$$

In [15], the new measure is used, to account for their concordance at each point, and any hierarchical clustering method can be applied. The method has been developed in the R package `clustEff` [14]. The proposed approach is very flexible and can be generalized to different contexts.

3 Data, Methodology and results

Thanks to a partnership with the Italian Ministry of Education and Research (MIUR) and four Italian Universities (University of Cagliari, University of Palermo, University of Siena, University of Torino), we refer to the whole dataset of the students enrolled in 2008 at any Degree Course offered by any Italian University, and followed for 8 years. In such a way, it is possible to follow the whole career of the students and their eventual mobility along the Italian area.

The dataset is very large, more than 100,000 records, where the record is the student. Many variables are available: gender, age, nationality, residence, diploma mark, high school diploma type, university and degree course attended at each year of observation, residence, average mark and total credits gained at each year.

In particular, the statistical unit is the student that graduates at the first level degree and that enrol in a second level degree course. The comparison regards three groups of students: i) the group of the Southern graduates that enrol in one of the universities in the South of Italy; ii) the group of the Southern graduates that enrol in the Northern university; iii) the group of resident in the North of Italy and still studying in the North.

Our specific question is “is there any difference in performance between moving and unmoving students?”. We refer to the Southern students as a first step analysis of the consistent migration flow from the South to the North of Italy (fig. 2). The chords represent the migration flows, linking the leaving and destination regions. As thicker is the chord, as more significant is the migration flow. The Fig. 1 highlights that main attractive universities are in the Centre-North of Italy, in particular in Lombardia, Piemonte, Emilia Romagna and Lazio.

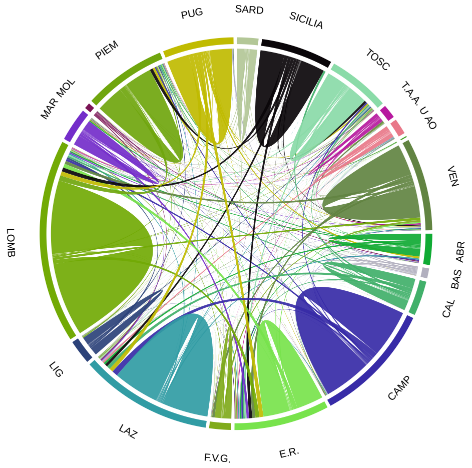

Fig. 1 Chord Diagram: migration student flows within Italy

The performance, in this paper, is measured accounting for two different perspectives: i) marks, ii) gained educational credits. In order to account both for the information of marks and credits, we use a new indicator that combines marks and credits in a unique measure, keeping unchanged the mark-scale [2]. In such a way, there is no need to analyze the two distributions of marks and credits because the new measure weights each mark by the correspondent exam credit.

We report the analysis of the distribution of the transformed mark conditioned to the High School Diploma Type (binary variable “Lyceum”, “No-Lyceum”), and our procedure identifies four clusters, together with interesting results, suggesting the necessity of further analysis (fig. 2). Indeed, Northern No-Lyceum students still studying in the North perform worse

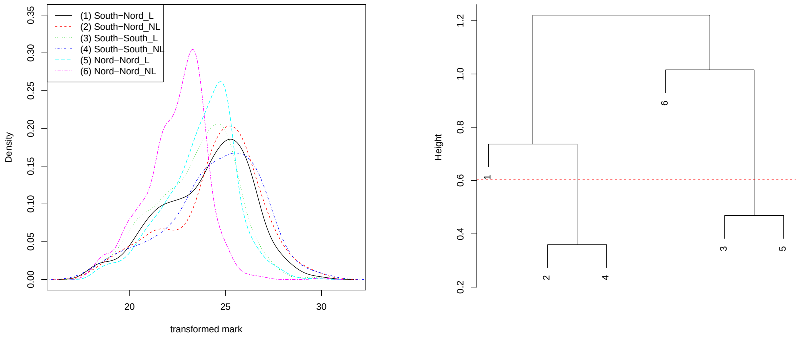

Fig. 2 Output of the proposed algorithm: the distribution curves (on the left) and the corresponding dendrogram (on the right)

than others and stay separate from the other students. Southern and Northern Lyceum student performance is similar (density curves are in the same cluster) when they do not migrate, and stay studying in their macro-area of residence (i.e. South or North, respectively). The third cluster is the one of the Lyceum Southern students migrating in the North, that perform on average a slightly better than the students of the two previous clusters. Finally, No-Lyceum Southern student performance does not change both if they migrate to the North or they continue their studies in the Southern Universities, and they seem to perform better, on average, than the students of the three previous cluster.

We perform the analysis of the distribution of the transformed mark conditioned to the gender too but, although the clustering approach identifies three clusters, results do not show difference in performance.

These results, just provisional and partial, suggest the use of the proposed approach such as an exploratory method for studying this kind of dependence, based on the comparison of distribution functions. Indeed, further analysis (not here reported for the sake of brevity) considering a quantile regression model approach for the student performance, confirms our exploratory analysis results and highlights some differences with respect to other variables, like topic area of the degree course and going into detail of the geographical areas for students of the three groups.

A Partial Ordering Application in Aggregating Dimensions of Subjective Well-being

Una applicazione dell'ordinamento parziale nella sintesi di dimensioni del benessere soggettivo

Paola Conigliaro

Abstract Starting from the interest for the relationships between labour status and subjective well-being, we focused analysis upon European Union Statistics on Income and Living Conditions 2013 ad-hoc module on subjective well-being. Following the OECD Guidelines on Measuring Subjective Well-being (2013), we assumed the multidimensionality of well-being as a premise. In order to preserve the multidimensionality of the concept of SWB, we applied an aggregating method based on partial ordering. This note compare results of Partial Ordering methodology with results of other aggregating methods.

Abstract *Muovendo dall'interesse per il rapporto tra stato lavorativo e benessere soggettivo, questo studio si concentra sul modulo ad-hoc sul benessere soggettivo dell'Indagine europea sul reddito e sulle condizioni di vita (Eu-SILC) 2013. In accordo con le Linee guida OCSE sulla misurazione del benessere soggettivo (2013), assumiamo in premessa la multidimensionalità del benessere soggettivo. Per preservare tale multidimensionalità, è stato adottato un metodo di aggregazione delle dimensioni del benessere basato sull'ordinamento parziale. Questo contributo confronta i risultati della metodologia di Ordinamento Parziale con i risultati di altri metodi di aggregazione.*

Key words: Subjective Well-being indicators, Decent work, Partial Ordering Methodology.

1 Introduction – Field of Study

The principles of Decent work presently inspire the struggle against poverty, and the promotion of an equitable, inclusive and sustainable development (ILO, 2017). They lie on three main levels: universal rights, job quality, and subjective well-being in relation to work. Macro and micro social conditions influence the relationships between work and subjective well-being.

The present work originates from a study on the relationships between labour status and subjective well-being. It analyses data from the European Union Statistics on Income and Living Conditions 2013, with respect to the Italian dataset. Eurostat (2013) adopted, in fact, in that edition of Eu-SILC an ad-hoc module on subjective well-being. The module is inspired by the Guidelines on Measuring Subjective Well-being (OECD, 2013). The Guidelines, summarising main literature in term of subjective well-being indicators, identified three main dimensions of subjective well-being: cognitive, affective and eudaimonic.

1.1 The three main dimensions of Subjective Well-being

The cognitive dimension is revealed with questions about the satisfaction for life as a whole, based on assessment scales, usually of seven or eleven values. The basis of Life Satisfaction assessment is the comparison between an individual's past conditions, their ambitions and their performance in contrast to other people. (Michalos, 1985). Satisfaction of life as a whole is commonly considered the synthesis of the entire domain of satisfaction.

Emotional status refers to affects, which can be positive (trust, joy, happiness) or negative (worry, fear). In the well-being evaluation, most of the tools adopted to measure the emotional status come from mental health measurements scales. The five questions of SF-36 questionnaire (those concerning mental health status) or the WHO-5 are the most widespread. Usually questions on emotional status refers to the last 4 weeks. Studies demonstrated that, in the short term, positive and negative affects lay on a logical continuum, while in the long term, they may result as independent dimensions (Diener, 1984). To measure emotional status, Eu-SILC module applied the five Items on Mental Health of the SF-36 Questionnaire.

The third relevant dimension of well-being is Eudaimonia. The word refers to the concept used by Aristotle. Even if translated as happiness, it does not belong to the hedonic related terms. It denotes a sense of purpose, corresponding to a good. psychological functionality that goes beyond conscious evaluation or emotional feeling; it mostly regards self-realization, termed flourishing (Diener et al, 2009, Huppert and So, 2013). The relationships between working conditions and subjective well-being appear conceptually connected with this last dimension. The Eu-SILC module adopted as proxy of eudaimonic well-being a sole question on Meaning of life.

OECD in above mentioned Guidelines recognizes the relevance of the three dimensions, which refers to non-elementary concepts. It also suggests to choose indicators able to represent the multidimensionality of the concepts. The patterns of analysis have to respect this multidimensionality, and the choice of data processing methods has to conserve the informative potential (Maggino, 2015)

2 Data analysis

Eu-SILC is a sample statistical survey, which EU Member States have conducted since 2004, according to EC Regulation n.1177/2003. It allows cross-sectional and longitudinal comparison within and between countries.

The well-being ad-hoc module (2013) consists of 22 subjective items: nine questions on satisfaction (0-11 scale); one question on meaning of life (0-11); five questions on emotional status (a five-step scale); four questions on trust (0-11); two questions on personal relationships (binary variables); one question on physical security perception (a five-step scale).

Eurostat (2015) formulated its analysis comparing national aggregate data. Furthermore, according to specific knowledge needs, Eurostat chose to consider Life Satisfaction as the main dimension of subjective well-being. The results confirmed the common assumptions which recognize a relationship between labour status and subjective well-being.

The present analysis is applied to the Italian micro-data, because the micro-level analysis can offer further research perspectives. As the well-being module did not allow proxy answers, the response rate was below 70% for Italy, with a non-respondent share of 72.7% between people under-26. We chose to select individuals between 26 and 65 years (less than 16 thousands of respondents).

3 Some results

In a previous work (Conigliaro, 2018) we explored the micro-data, analysing the relationships between Self Defined Labour Status (SDLS) and three dimensions of subjective well-being. The three dimensions considered were Life Satisfaction (0-10), Meaning of Life (0-10), and the composite dimension of Emotional Status (ES).

The most delicate choice concerned the processing of the five items revealing ES. The five items involved belong to the mental health trait questions of the SF-36 Questionnaire. To calculate the mental health score, the authors of the questionnaire calculate the sum of the five scores (Ware et al., 1993). In the Eurostat report the so called "Mental well-being" index is instead computed by averaging the five-scale scores, recoding them into a range 0-100 (Eurostat, 2016). There are many other aggregating methods (e.g. Diener et al, SPANE, 2009); scholars consider feasible to aggregate in a sole measure values from different items revealing emotions.

In order to minimize intervention on data, we calculated the average value between items, based on a five-step scale, and carried the results into a five-step scale. The following Table 1 reports the correlation between ES and its components.

Table 1. CORRELATION BETWEEN EMOTIONS' ITEMS AND CALCULATED EMOTIONAL STATUS

Kendall's Tau-b	Nervous	Down in the dumps	Depressed	Peaceful	Happy
Emotional status	.686**	.684**	.726**	.689**	.636**

** Correlation is significant at the 0.01 level (2-tailed). Sig. 0.000. Number of records 15,281

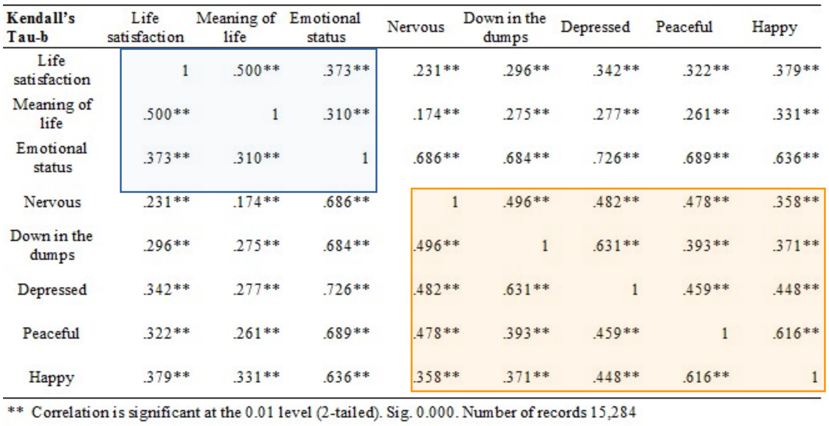
We compared the distribution of respondents according to the three dimensions of subjective well-being between different Labour status. The item that we adopted concerned the self-defined labour status (SDLS). It was expressed in 10 modalities.

We observed that:

- Permanently disabled, inactive, and unemployed have lower levels of Life Satisfaction (LS) and ES
- Meaning of Life (MoL) values are always higher for all respondents
- Each dimension of SWB has a different relationship with SDLS. Labour Status, in fact, seems to influence ES rather than MoL
- The relationship between SDLS and SWB assumes several nuances; these arise from the conjunction of some discriminants, e.g. gender, age, education, which influence that relationship. For example, MoL is lower for women when they are unemployed, but differences form employees are less evident when compared to that registered for men.

We also observed that in the whole sample (regardless SDLS) there is a low correlation between the three dimensions of SWB (Table 2.

Table 2- CORRELATION BETWEEN LIFE SATISFACTION, MEANING OF LIFE, EMOTIONAL STATUS AND FIVE AFFECTS



Kendall's Tau-b	Life satisfaction	Meaning of life	Emotional status	Nervous	Down in the dumps	Depressed	Peaceful	Happy
Life satisfaction	1	.500**	.373**	.231**	.296**	.342**	.322**	.379**
Meaning of life	.500**	1	.310**	.174**	.275**	.277**	.261**	.331**
Emotional status	.373**	.310**	1	.686**	.684**	.726**	.689**	.636**
Nervous	.231**	.174**	.686**	1	.496**	.482**	.478**	.358**
Down in the dumps	.296**	.275**	.684**	.496**	1	.631**	.393**	.371**
Depressed	.342**	.277**	.726**	.482**	.631**	1	.459**	.448**
Peaceful	.322**	.261**	.689**	.478**	.393**	.459**	1	.616**
Happy	.379**	.331**	.636**	.358**	.371**	.448**	.616**	1

** Correlation is significant at the 0.01 level (2-tailed). Sig. 0.000. Number of records 15,284

Observing the distribution of respondents within the three dimensions' space defined by the three variable of SWB (recoded in five-step scale), we registered that just the 26.3% of respondents declare the same level of subjective well-being for all dimensions. We can easily reclassify another 52.5% of respondents in an ordinal way, while for 21.2% of respondent any classification may be arbitrary. These questions could not arise in calculating average values. Applying a logical ordering of cases, we had been able to allocate more or less 75% of respondents, and to compare the distributions according to SDLS. But it was an empirical way to classify respondents. We concluded that, to preserve the multidimensionality of SWB it would be necessary to adopt a more punctual aggregating method based on logical ordering of respondents.

4 Partial ordinal methodology and first results

In a second work (Conigliaro, Alaimo, 2017) we applied a Partial Order methodology to aggregate multiple dimensions of well-being. This methodology allows, in fact, to deal with ordered variables referred to multidimensional information concerning complex phenomena.

A partially ordered set (Poset) is a set X equipped with a partial order relation, that is a binary relation satisfying these properties (Fattore et al 2015):

Reflexivity $p \leq p \ \ \forall \ p \in X$
Antisymmetry $p \leq q$ and $q \leq p$, then $p=q$, p,q □ X
Transitivity $p \leq q$ and $q \leq r$, then $p \leq q$, p,q, r □ X

In this case we recalculated the synthetic index of Emotional Status applying Parsec, which is a package developed in R by A. Arcagni and M. Fattore (2014).

We saw that the correlation between the five items concerning affects, were not so high. This result and other observations on conjoint distribution of levels of emotions, showed that there where a significant number of respondents which are both happy and sad, serene and nervous. Also the correlation between each affect and happiness was not so high, so that it could be not appropriate to adopt the happiness indicator as a proxy of emotional status, as Eurostat did (Eurostat, 2015).

The methodology adopted in those analysis was the simplest form of POSET, that compared the five dimensions of emotional status expressed in five-steps order. Data processing defined a set of 11 co-graduate levels of respondents.

In this way we assumed this as a new variable of 11 dimension that we can analyse at micro level.

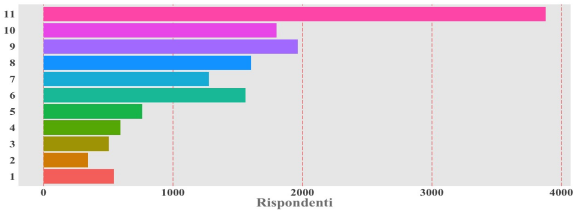


Figure 1: Number of Respondents According to ES. Aggregate Measure

Then we compared the level of ES according to SDLS.

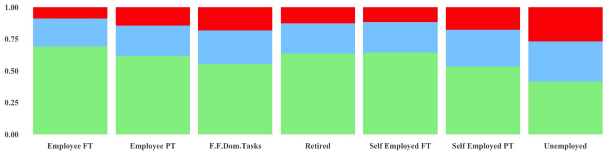

Figure 2: Level of ES According to SDLS (*percentage*)

Eventually, we calculated a well-being level applying the Partial ordering methodology to the three dimensions of subjective well-being.

The procedure adopted leads to interesting results. The Partial ordering methodology, in fact, does not hide differences between respondents that choose different response mixes.

5 Further steps of the study

The POSET methodology allows to bring ahead the analysis, defining a chain of possible answers organized in an ordinal way. It is furthermore possible to calculate the probability of error in attributing each respondent to one or another of the level of this chain.

Nevertheless, before applying higher sophisticated tools, we repute necessary to carry out a more punctual exam of measures resulting in applying this methodology.

So we intend to compare the distribution of level of subjective well-being according to different aggregative methods. We chose: 1) the average value; 2) the counting value; 3) the partial ordered value. Just to simplify the computational procedure, we decide to apply the test to a smaller number of respondents chosen with a quote sampling procedure between unemployed and full time employee.

A note on objective Bayes analysis for graphical vector autoregressive models

Lucia Paci and Guido Consonni

Abstract Vector Autoregressive (VAR) models are widely used to estimate and forecast multivariate time series. However, the large number of parameters of VAR models can lead to unstable inference and inaccurate forecasts, particularly with many variables. For this reason, restrictions supported by the data are usually required. We propose an objective Bayes approach based on graphical VAR models for learning contemporaneous dependencies as well as dynamic interactions among variables. We show that, if the covariance matrix at each time is Markov with respect to the same decomposable graph, then the likelihood of a graphical VAR can be factorized as an ordinary decomposable graphical model. Additionally, using a fractional Bayes factor approach, we are able to obtain the marginal likelihood in closed form and perform Bayes graphical model selection with limited computational burden.

Key words: Bayesian model selection, decomposable graphical model, fractional Bayes factor, multivariate time series

1 Introduction

Vectore Autoregressive (VAR) models represent the workhorse models for estimating and forecasting multiple time series and widely applied in many fields such as macroeconomics, environmental sciences, neuroscience and genomic.VAR models are very flexible and allow to account for both contemporaneous dependencies among variables as well as their evolution over time. However, the large number of parameters of the VAR model usually leads to unstable inference and inaccurate

Lucia Paci

Guido Consonni
Università Cattolica del Sacro Cuore, Milano, e-mail: guido.consonni@unicatt.it

forecasts, particularly when dealing with many variables. This suggests to introduce parsimonious models.

Several solutions have been proposed in the literature. For instance, the Bayesian stochastic search variable selection approach, introduced by [9], has been extensively applied to select restrictions in VAR models. As an alternative, graphical modeling can be employed for the identification of the VAR model [6, 1, 2].

Following the latter track, we propose an objective Bayes approach for learning contemporaneous dependencies and dynamic interactions among variables under a graphical VAR model. We argue that, if the covariance matrix at each time is Markov with respect to the same decomposable graph, then the likelihood of a graphical VAR can be factorized as an ordinary decomposable graphical model. Additionally, using a fractional Bayes factor methodology, we are able to obtain the marginal likelihood in closed form and perform Bayes graphical model selection with limited computational burden.

2 Vector Autoregressive Model

Let $\mathbf{y}_t$ be a $(q \times 1)$ vector of observations collected at time t, $t = 1, \dots, T$. The reduced form of a stable VAR of order k, VAR(k), is given by

$$\mathbf{y}_t = \sum_{i=1}^{k} \mathbf{B}_i \mathbf{y}_{t-i} + \varepsilon_t, \qquad t = 1, \dots, T, \tag{1}$$

where $\mathbf{B}_i$ are $(q \times q)$ matrices of coefficients or lag matrices, determining the dynamics of the system and ε_t is a $(q \times 1)$ dimensional white noise process, that is $\varepsilon_t \mid \Sigma \sim N_q(\mathbf{0}, \Sigma)$, independently over time. Clearly, the observations depend linearly on the previous k observation vectors, where k is assumed to be known. Exogenous variables can be added to the model, leading to straightforward modifications of the results shown here. For simplicity, the intercept is also omitted in the following.

Let $\mathbf{z}_t = (\mathbf{y}'_{t-1}, \dots, \mathbf{y}'_{t-k})'$ denote the $(kq \times 1)$ vector of lagged observations at time t and $\mathbf{B} = \left(\mathbf{B}'_1, \dots, \mathbf{B}'_k\right)'$ be the $(kq \times q)$ obtained by matrix stacking the coefficients. Hence, equation (1) can be written as

$$\mathbf{y}_t = \mathbf{B}'\mathbf{z}_t + \varepsilon_t. \tag{2}$$

For given initial values $\mathbf{Y}_0 = (\mathbf{y}'_0, \mathbf{y}'_{-1}, \dots, \mathbf{y}'_{-k+1})'$, which we assume throughout to be available, the (conditional) likelihood of VAR(k) in (1) is written in the form

$$f\left(\mathbf{y}_1, \dots, \mathbf{y}_T \mid \mathbf{B}, \Sigma\right) = \prod_{t=1}^{T} f\left(\mathbf{y}_t \mid \mathbf{z}_t, \mathbf{B}, \Sigma\right), \tag{3}$$

where the conditional distribution $f\left(\mathbf{y}_t \mid \mathbf{z}_t, \mathbf{B}, \Sigma\right)$ in (3) is the multivariate normal distribution $\mathbf{y}_t \mid \mathbf{z}_t, \mathbf{B}, \Sigma \sim \mathcal{N}_q\left(\mathbf{B}'\mathbf{z}_t, \Sigma\right)$. Let $\mathbf{Y} = (\mathbf{y}_1, \dots, \mathbf{y}_T)'$ be the $(T \times q)$ matrix collecting all observations and $\mathbf{Z}$ be the $(T \times kq)$ matrix containing all the lagged variables, i.e., $\mathbf{Z} = (\mathbf{z}_t, \ldots, \mathbf{z}_T)'$. Equation (1) can be rewritten in matrix form as

$$\mathbf{Y} = \mathbf{ZB} + \mathbf{E}, \tag{4}$$

where $\mathbf{E} = (\varepsilon_1, \ldots, \varepsilon_T)'$ is the $(T \times q)$ matrix of errors following a Matrix Normal distribution with zero mean, row identity matrix $\mathbf{I}_T$ and column (or cross) covariance Σ, that is, $\mathbf{E} \mid \Sigma \sim N_{T,q}(\mathbf{0}, \mathbf{I}_T, \Sigma)$. Therefore, we can write the likelihood of VAR(k) as

$$f(\mathbf{Y} \mid \mathbf{B}, \Sigma) = (2\pi)^{-\frac{Tq}{2}} |\Sigma|^{-\frac{T}{2}} \exp\left\{-\frac{1}{2} \operatorname{tr}\left[\Sigma^{-1}\left(\left(\mathbf{B}-\hat{\mathbf{B}}\right)' \mathbf{Z}'\mathbf{Z}\left(\mathbf{B}-\hat{\mathbf{B}}\right) + \hat{\mathbf{E}}'\hat{\mathbf{E}}\right)\right]\right\} \tag{5}$$

where $\operatorname{tr}(\cdot)$ is the trace operator, $\hat{\mathbf{E}} = \mathbf{Y} - \mathbf{Z}\hat{\mathbf{B}}$ and $\hat{\mathbf{B}} = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{Y}$ is the OLS estimator of the coefficient matrix, requiring $T \geq kq$. In other words, the likelihood of the VAR model can be expressed as the likelihood of a multivariate regression model where the predictors are the lagged variables.

3 Fractional Bayes inference

To complete the Bayesian specification of the VAR(k) model in (1), a prior distribution for model parameters $\mathbf{B}$ and Σ is required. In this work, we employ an objective approach for model selection based on the Fractional Bayes Factor (FBF), see [11]. The idea of the FBF is to train a noninformative prior using a small fractional power b of the likelihood function, converting the noninformative prior into a proper prior that is then used to compute the marginal likelihood using the complementary fraction power $1-b$ of the likelihood.

Starting with a improper prior $p^D(\mathbf{B}, \Sigma) \propto |\Sigma|^{-(a_D+q+1)/2}$ and setting $b = T_0/T$, we can show that the fractional prior for VAR(k) is the Matrix Normal-Inverse Wishart $\mathscr{MNIW}(\underline{\mathbf{B}}, \underline{\mathbf{C}}, \nu, \underline{\mathbf{R}})$, where $\underline{\mathbf{B}} = \hat{\mathbf{B}}$, $\underline{\mathbf{C}} = T/T_0\,(\mathbf{Z}'\mathbf{Z})^{-1}$, $\nu = a_D - kq + T_0$ and $\underline{\mathbf{R}} = T_0/T\;\hat{\mathbf{E}}'\hat{\mathbf{E}}$. Hence, the fractional prior density is given by

$$p^F(\mathbf{B}, \Sigma) = K\left(\underline{\mathbf{C}}, \underline{\mathbf{R}}, \nu\right) |\Sigma|^{-\left(\frac{a_D+T_0+q+1}{2}\right)} \exp\left\{-\frac{T_0}{2T} tr\left[\Sigma^{-1}\left(\left(\mathbf{B}-\hat{\mathbf{B}}\right)'\left(\mathbf{Z}'\mathbf{Z}\right)\left(\mathbf{B}-\hat{\mathbf{B}}\right) + \hat{\mathbf{E}}'\hat{\mathbf{E}}\right)\right]\right\}, \tag{6}$$

where

$$K\left(\underline{\mathbf{C}}, \underline{\mathbf{R}}, \nu\right) = (2\pi)^{-kq^2/2} |\underline{\mathbf{C}}|^{-q/2} |\underline{\mathbf{R}}/2|^{\nu/2} \Gamma_q(\nu/2)^{-1} \tag{7}$$

is the normalizing constant with $\Gamma_q(\nu/2)$ the q-dimensional gamma function evaluated at $\nu/2$. Prior (6) is proper under two conditions: i) $a_D + T_0 - kq + 1 > q$ so that $\nu > q-1$; ii) $T - kq > q - 1$ so that $\hat{\mathbf{E}}'\hat{\mathbf{E}}$ is (almost surely) positive define. The first condition becomes $T_0 > q + kq - 1$ if $a_D = 0$, or $T_0 > kq$ if $a_D = q-1$, i.e., a larger T_0 is needed in the case $a_D = 0$. Since b has to be minimal, [5] recommend to set $a_D = q-1$ and $T_0 = kq+1$ such that $\nu = q$. The second condition simplifies to $T > q+kq-1$ that looks realistic when dealing with long time series.

Combining prior (6) with likelihood (5) we obtain a posterior distribution that is a Matrix Normal-Inverse Wishart with updated parameters, i.e., $\mathscr{M}\mathscr{N}\mathscr{I}\mathscr{W}(\overline{\mathbf{B}}, \overline{\mathbf{C}}, \overline{\nu}, \overline{\mathbf{R}})$, where $\overline{\mathbf{B}} = \hat{\mathbf{B}}$, $\overline{\mathbf{C}} = (\mathbf{Z}'\mathbf{Z})^{-1}$, $\overline{\nu} = a_D - kq + T$ and $\overline{\mathbf{R}} = \hat{\mathbf{E}}'\hat{\mathbf{E}}$.

Because of conjugacy, the fractional marginal likelihood of VAR(k) is available in closed form and can be obtained, up to a multiplicative factor, as the ratio of the prior and posterior normalizing constants, leading to

$$m^F(\mathbf{Y}) = \pi^{-\frac{(T-T_0)q}{2}} \left(\frac{T_0}{T}\right)^{\frac{(a_D+T_0)q}{2}} \left|\hat{\mathbf{E}}'\hat{\mathbf{E}}\right|^{-\frac{T-T_0}{2}} \frac{\Gamma_q\left((a_D-kq+T)/2\right)}{\Gamma_q\left((a_D-kq+T_0)/2\right)}. \tag{8}$$

Let $\mathbf{Y}_J$ be the $T \times |J|$ submatrix which contains selected columns of data matrix $\mathbf{Y}$ belonging to a subset J of cardinality $|J|$ of the full set of q variables. Using the result presented in [5], we can obtain the fractional marginal likelihood $m^F(\mathbf{Y}_J)$ based on the submatrix $\mathbf{Y}_J$ by making the following substitutions in (8):

$$q \to |J|, \qquad a_D \to a_D - |\overline{J}|, \qquad \hat{\mathbf{E}} \to \hat{\mathbf{E}}_J = \mathbf{Y}_J - \mathbf{Z}\hat{\mathbf{B}}_J, \tag{9}$$

where $\overline{J}$ denotes the complementary set of J and $\hat{\mathbf{B}}_J$ is the $kq \times |J|$ submatrix of $\hat{\mathbf{B}}$ whose column contain the OLS estimates of the regression coefficients for the selected responses. To ensure positive definiteness of $\hat{\mathbf{E}}_J'\hat{\mathbf{E}}_J$, the condition $|J| < T - kq + 1$ must be satisfied, when setting $a_D = q-1$ and $T_0 = kq+1$.

4 Graphical VAR

[7] introduced the class of time series chain graphs (TSCG). More specifically, let $Y = \{Y_t(a), t \in \mathbb{Z}, a = 1, \ldots, q\}$ be a q-variate stationary stochastic process and $V = \{1, 2, \ldots, q\}$ be the set of indexes. Let $G = (V_{TS}, E)$, be a graph with $V_{TS} = V \times \mathbb{Z}$ and edge set E, whose edges have at most lag k and which is invariant under translation. If $\mathbf{B}_i(b,a)$ is the (b,a)-element of matrix $\mathbf{B}_i$ in (1) and $\Omega(a,b)$ is the (a,b)-entry of precision matrix $\Omega = \Sigma^{-1}$, then the VAR model with the following constraints on the parameters

$$\begin{array}{lcll} (a,t-i) \;\to\; (b,t) & \in E \;\Leftrightarrow\; \mathbf{B}_i(b,a) \neq 0 & & i = 1, \ldots, k \\ (a,t) \;—\; (b,t) & \in E \;\Leftrightarrow\; \Omega(a,b) \neq 0 & & t = 1, \ldots, T \end{array}$$

represents a VAR(k, G) model. Thus, a nonzero element in $\mathbf{B}$ corresponds to a directed edge in the graph reflecting the recursive structure of the time series while undirected edges specify contemporaneous interactions among variables, that is a covariance selection model. Hence, our goal is making inference on graph G.

4.1 Covariance selection model

Let $G^u = (V, E^u)$ be the undirected graph representing the contemporaneous dependencies at any time t, and assume that Σ is Markov with respect to G^u. For the graph-theory terminology in this section we refer the reader to [10]. Also, we confine our analysis to the class of decomposable graphs for all time points. Recall that G^u is decomposable when all cycles in G^u admit a chord, that is an edge joining two non-consecutive vertices of the cycle. Let $\mathscr{C}$ and $\mathscr{S}$ denote the set of cliques and separators of the graph G^u, respectively. Then, we can show that the likelihood of a graphical VAR(k,G) factorizes as following:

$$f(\mathbf{Y} \mid \mathbf{B}, \Sigma, G^u) = \frac{\prod_{C\in\mathscr{C}} f\left(\mathbf{Y}_C \mid \mathbf{B}_C, \Sigma_{CC}\right)}{\prod_{s\in\mathscr{S}} f\left(\mathbf{Y}_S \mid \mathbf{B}_S, \Sigma_{SS}\right)}, \tag{10}$$

where $\mathbf{B}_C$ and $\mathbf{B}_S$ are the $kq \times |C|$ and $kq \times |S|$ matrices whose columns contain the coefficients of the selected responses $\mathbf{Y}_C$ and $\mathbf{Y}_S$, respectively.

If $\mathbf{B}$ is unconstrained and Σ is in $M^+(G^u)$, the set of all symmetric positive-definite matrices having elements in Σ^{-1} set to zero for all $(a,b) \notin E^u$, then a natural noninformative prior on $(\mathbf{B}, \Sigma \mid G^u)$ is

$$p^D(\mathbf{B}, \Sigma \mid G^u) \propto \frac{\prod_{c\in\mathscr{C}} |\Sigma|^{-|C|}}{\prod_{s\in\mathscr{S}} |\Sigma|^{-|S|}}, \tag{11}$$

which is a limiting form of an Hyper-Inverse Wishart distribution [8]. Training prior (11) with a fraction $b = T_0/T$ of the likelihood, the fractional prior for a VAR(k,G) becomes a Matrix Normal Hyper-inverse Wishart distribution [3], $\mathscr{MNHIW}(\underline{\mathbf{B}}, \underline{\mathbf{C}}, \delta, \underline{\mathbf{R}})$, where $\underline{\mathbf{B}}$,$\underline{\mathbf{C}}$, $\underline{\mathbf{R}}$ are defined as above and $\delta = T_0 - kq$. Therefore, the prior density is

$$p^F(\mathbf{B}, \Sigma \mid G^u) = H(\underline{\mathbf{C}}, \underline{\mathbf{R}}, \delta) \\ \times \frac{\prod_{c\in\mathscr{C}} |\Sigma_{CC}|^{-(|C|+T_0/2)} \exp\left\{-\frac{T_0}{2T} \operatorname{tr}\left[\Sigma_{CC}\left(\left(\mathbf{B}_C - \hat{\mathbf{B}}_C\right)' \mathbf{Z}'\mathbf{Z}\left(\mathbf{B}_C - \hat{\mathbf{B}}_C\right) + \hat{\mathbf{E}}_C'\hat{\mathbf{E}}_C\right)\right]\right\}}{\prod_{s\in\mathscr{S}} |\Sigma_{SS}|^{-(|S|+T_0/2)} \exp\left\{-\frac{T_0}{2T} \operatorname{tr}\left[\Sigma_{SS}\left(\left(\mathbf{B}_S - \hat{\mathbf{B}}_S\right)' \mathbf{Z}'\mathbf{Z}\left(\mathbf{B}_S - \hat{\mathbf{B}}_S\right) + \hat{\mathbf{E}}_S'\hat{\mathbf{E}}_S\right)\right]\right\}}, \tag{12}$$

where the normalizing constant is

$$H(\underline{\mathbf{C}}, \underline{\mathbf{R}}, \delta) = \frac{\prod_{c\in\mathscr{C}} (2\pi)^{-|C|kq/2} |\underline{\mathbf{C}}|^{-|C|/2} |\underline{\mathbf{R}}_{CC}/2|^{(\delta+|C|-1)/2} \Gamma_{|C|}\left((\delta+|C|-1)/2\right)^{-1}}{\prod_{s\in\mathscr{S}} (2\pi)^{-|S|kq/2} |\underline{\mathbf{C}}|^{-|S|/2} |\underline{\mathbf{R}}_{SS}/2|^{(\delta+|S|-1)/2} \Gamma_{|S|}\left((\delta+|S|-1)/2\right)^{-1}}.$$

In other words, a Markovian structure is assumed a priori for the lag coefficients that follows the structure of the likelihood. Thus, using prior (12), the fractional marginal likelihood has a closed form obtained, again, as the ratio of the prior and posterior normalizing constants. Equivalently, we can write

$$m^F(\mathbf{Y} \mid G^u) = \frac{\prod_{c \in \mathscr{C}} m^F(\mathbf{Y}_C)}{\prod_{s \in \mathscr{S}} m^F(\mathbf{Y}_S)}, \tag{13}$$

where, following [4], $m^F(\mathbf{Y}_C)$ and $m^F(\mathbf{Y}_S)$ are computed by means of (9) with $J = c$ and $J = s$, respectively, when setting $a_D = q - 1$. Again, formula (9) provides a valid marginal likelihood if $T > |C| + kq - 1$, for each $c \in \mathscr{C}$.

As a final remark here, we stress that the joint likelihood of a graphical VAR(k,G) factorizes as an ordinary decomposable graph model, even though the decomposable structure is assumed conditionally at each time step. As a result, the closed form of the marginal likelihood allows to perform Bayes graphical model selection of VAR(k,G) models with easy computation.

A simulation study (not presented here for brevity) shows the capability of the approach to recover the underlying graph according to different scenarios (sample size, number of variables, number of lags, lag matrix). Future work will explore the possibility to build a joint prior model that simultaneously accounts for restrictions both on lag coefficients and covariance matrix.

Bayesian Population Size Estimation with A Single Sample

Stima della numerosità di una popolazione utilizzando un solo campione

Pierfrancesco Alaimo Di Loro and Luca Tardella

Abstract The estimation of the size of a finite population is a problem encountered in a variety of applications. One standard statistical approach relies on *mark-recapture* sampling, which may require high costs and annoyance to the population of interest. These considerations have motivated the search for alternative sampling strategies that allow to estimate the size of a population from a single capture. Hettiarachchige [4] proposes a method that is viable when the population is made of only two generations: a group of generators and one of generated units. We investigate Bayesian methods alternative to the frequentist estimators used in [4]. Preliminary results give evidence of competing performance of the Bayesian approach, which in some cases sensibly outperforms the frequentist alternatives.

Abstract La stima della numerosità di una popolazione è un problema comune a vari ambiti di applicazione. Le procedure di stima sono solitamente basate sul noto metodo *cattura-ricattura*, il quale comporta elevati costi e disturbo della popolazione. Tali considerazioni hanno stimolato la ricerca di tecniche che permettano di ottenere un stima utilizzando un unico campione. Hettiarachchige [4] propone un metodo applicabile nel caso in cui la popolazione sia composta di due sole generazioni: un gruppo di unità generatrici ed uno di unità generate. L'obiettivo del nostro lavoro è quello di ottenere un'estensione Bayesiana dell'originale modello frequentista. Risultati preliminari evidenziano accuratezza degli stimatori Bayesiani sensibilmente migliore rispetto alle alternative frequentiste.

Key words: population size, capture-recapture, mark-recapture, single sample, Bayesian inference, moment estimator, MLE.

1 Introduction

The problem of estimating the size or any other demographic parameter of a population of interest for which there is no complete enumeration or reference list is common to a variety of applications: ecology (e.g. natural and wildlife populations), reliability, epidemiology, social sciences. However, most of the literature regarding this matter has been developed in the statistical ecology field, where *capture-recapture* methods have been the ruling paradigm for the whole second half of the 20th century.

The modern foundation of these methods was laid in [2] and [6] and they are all based on the pioneering *mark-recapture* sampling technique which originated the well-known *Lincoln-Petersen* estimator. The most basic version consists of taking a random sample of size n_1 from the population and mark the captured individuals. They are then returned to the population and, at a later occasion, a second sample of size n_2 is taken. The previously applied tags allow to recognize if and how many of the captured individuals were already been sampled at the previous occasion. If m of them already have a tag, then the *Petersen* estimator is: $\hat{N}_P = (n_1 n_2)/m$.

The biggest issue with the application of such methods is that they require the population to be sampled at least twice. The necessity of at least one further capture occasion leads to increasing costs and, furthermore, can cause an ever-increasing annoyance to the population of interest. The latter can alter its natural equilibrium, leading to a change of conditions from one capture to the other. This may introduce bias in the estimates when those changes are not taken into proper account and requires behavioural adjustments on the basic model [3] . Moreover, there are a lot of situations in which the captured individuals cannot be returned to the population, making the procedure impractical. These considerations have motivated the search for procedures that allow to estimate the size of a population in alternative ways.

In the last decades genetic data have become increasingly important in ecology and conservation biology and their use in estimating the population size have been considered [5]. The underlying idea is that the degree of biological relationship between a sample of individuals from the population provides information about the population itself and DNA profiles can be used to detect the degree of relatedness between individuals. [7] exploit this idea in analogy to the traditional capture-recapture method and argued in favor of a *single sample* version of the Petersen estimator. An individual is marked by its presence in the sample, and "recaptured" if the sample contains one or more close relatives. In practice, it allows to generalize from "recapture of self" to "recapture of closely-related kin" ([1]), where the detection of kinship is based on the idea that an individual share more alleles with a parent than with a biologically unrelated individual.

However, as it has already been underlined in [7], this approach is sensibly more complex than the ordinary *capture-recapture* method. The effectiveness of this method depends on hypotheses on the population that are hardly matched in real life and relies on accurate estimates of the kinship coefficients between individuals. The complexity of the method has been reduced by [4], who put himself in a

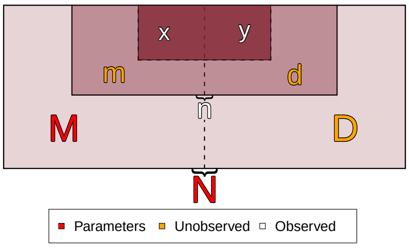

Fig. 1 Schematic visualization of the structure of population and of the quantities involved in the sample. Different colors are used to distinguish between parameters, latent variables and observed quantities.

simpler framework where kinship misclassification plays a slightly less important role. The framework of study will be more extensively investigated in Section 2.

Our contribution to [4]'s work is to introduce a suitable way of implementing Bayesian methods (Section 3) alternative to the frequentist estimators used by the original author. A comparative analysis of these estimators is provided at the end of the section. We finally provide an outline of some promising developments and extensions that may improve on the precision of the proposed estimates in Section 4.

2 General Framework

Let us introduce formally the assumptions of the model. The population structure considered in [4] is composed of only two generations: the individuals from the first generation are denoted as *mothers* and the individual from the second as *daughters*. For the purpose of this paper our main interest will be in estimating the size of the population of the *mothers*.

The two generations are assumed mutually exclusive and collectively exhaustive, and the population to be closed. A sample is taken and perfect identifiability of mother-daughter couples is assumed. The appropriateness of this assumption is discussed in [4].

In practice, we are dealing with a random sample from a population of N individuals, where M are "mothers" and D are "daughters" ($N = M + D$). The captured individuals will be in part mothers and in part daughters. We are able to recognize

	Latent		**Observables**
		$n = m + d$	all units in the sample
m	all mothers in the sample	x	all *identified* mothers in the sample
$(d_i)_{i=1}^{m}$	daughters for each mother in the sample	$(y_i)_{i=1}^{x}$	*id.* daughters for each *id.* mother in the sample
$d = \sum_{i=1}^{m} d_i$	all daughters in the sample	$y = \sum_{i=1}^{x} y_i$	all *identified* daughters in the sample

Table 1 Quantities of interests involved in the single sample

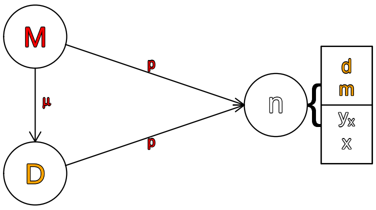

Fig. 2 Graphical visualization of the generating process of the data. Parameters in *red*, latent variables in *orange* and observables in *white*.

as daughters only those daughters whose mothers have been captured and viceversa. The relevant quantities involved in the single sample are visualized in Figure 1 and listed in Table 1 with appropriate notation:

Probabilistic Model. It is assumed that each mother has generated, at a previous time, a certain number of daughters D_i according to a $Pois(\mu)$. The total number of daughters in the population is then $D = \sum_{i=1}^{M} D_i \sim Pois(M\mu)$. The parameter μ is constrained to the set $[1, +\infty)$ by [4] for reasons related to the existence of the moment estimator. Our Bayesian approach, theoretically, does not require such an assumption but we will stick to this constraint to ensure a fair comparison. Furthermore, each individual is supposed to be captured independently with equal probability p.

The total number of mothers in the population M is the parameter of interest, while μ and p are just nuisance parameters. The situation is graphically reported in Figure 2.

An explicit form of the *marginal* likelihood can be obtained using a conditioning argument:

$$P(n,x,(y_i)_{i=1}^{x}|M,\mu,p) = \sum_{m=x}^{M\wedge(n-y)} P(n,x,(y_i)_{i=1}^{x}|m,M,\mu,p)P(m|M,p). \qquad (1)$$

$P(m|M,p)$ is the probability to capture independently m mothers given that there are M mothers in the population and they are captured with probability p[1], which is:

$$P(m|M,p) = Bin(m|M,p) = \binom{M}{m} p^m (1-p)^{M-m}.$$

The joint density of $(n,x,(y_i)_{i=1}^{x})$ conditioned on (m,M,μ,p), and hence the likelihood of the model, can be shown to be equal to:

$$P\left(n,x,(y_i)_{i=1}^{x}|\, m,\, M,\mu,p\right) = \binom{m}{x} \frac{e^{-M\mu p}(\mu p)^y}{\prod_{i=1}^{x} y_i!} \frac{((M-m)\mu p)^{(n-m-y)}}{(n-m-d)!}.$$

[1] This probability obviously does not depend on the mean number of daughters μ per mother.

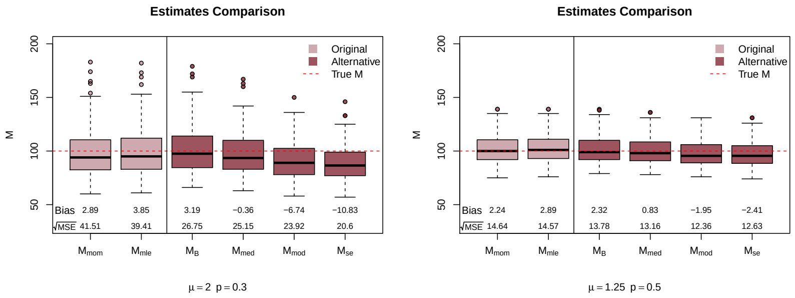

Fig. 3 Box-plots of the resulting estimates obtained for the 100 different simulation set for each estimator. From left to right: *Moment* and *Maximum Likelihood* estimators, posterior *Mean*, *Median*, *Mode* and *PMSE minimizer*

3 The Bayesian Extension

Some undesirable peculiarity of the likelihood such as presence of non-unique solutions and computational problems led [4] to discard the maximum likelihood estimator. The author decided to resort to a moment-based estimator in order to overcome these problems. However, the method of moments is still affected by well-known boundary solution instability.

We propose an estimation procedure based on a Bayesian approach, which should be able to regularize the model likelihood without incurring in the moment estimator deficiencies. Furthermore, Bayesian methods allow to include prior information on the demographic parameters of the population whenever such information is available and can eventually replace in a sensible way the *ad-hoc* constraint on μ.

Independent priors have been assigned to the parameters M, μ and p, so that the posterior distribution can be written as:

$$\pi\left(M,\mu,p|n,x,(y_i)_{i=1}^{x}\right) \propto \mathscr{L}(M,\mu,p;n,x,(y_i)_{i=1}^{x})\pi(M)\pi(\mu)\pi(p)$$

The forms chosen for the priors of each parameter are:

- low-informative $TruncatedGamma(0.05, 0.025)$ and $Beta(0.001, 0.001)$ priors for μ and p;
- inverse prior $\pi(M) \propto \frac{1}{M^a}$ for M, with $a = 0, 1, 2$.

Posterior samples from the joint posterior of the parameters have been obtained via *Metropolis-Within-Gibbs* algorithm, where a Gibbs-style update is performed for M and a bi-variate Normal random walk M-H is performed for (μ, p). The considered Bayesian estimators are: the posterior mean $\hat{M}_B$, the posterior median $\hat{M}_m$ and the approximated PMSE minimizer[2] $\hat{M}_{se}$.

[2] The *Posterior Mean Squared Error* minimizer is the value that minimizes the MSE with respect to the posterior distribution of the quantity of interest: $\text{argmin}_{a\in\mathscr{M}} \sum_{M\in\mathscr{M}}(M-a)^2\pi(M|\cdot)$, where M is the quantity of interest and $\mathscr{M}$ its domain.

Preliminary Results. A simulation study has been carried out in order to verify the effectiveness of the proposed Bayesian estimators. For different configurations of μ and p, with fixed $M = 100$ mothers, the simulation of mother-daughter sampling have been replicated for $S = 100$ times, producing $S = 100$ realizations of all the alternative estimators. The comparative performance is assessed in terms of *Mean Squared Error*. Our preliminary results are exposed in Figure 3 and give evidence of competing performance of the Bayesian approach which, especially in some configurations, sensibly outperforms the frequentist alternatives.

4 Concluding remarks and further Developments

We have proposed a Bayesian framework for the estimation of the population size in presence of a single sample. This technique relies on the pairing of mothers and daughters in the sample through the use of genetic markers on the line of [4]. We have shown that the Bayesian framework allows to reduce the error of the classical estimators up to 50% in specific parameter settings. Indeed, we are currently workin on many other improvements and extensions to the proposed Bayesian methodology:

1. formal derivation of non-informative priors and principled informative priors possibly removing the unnatural *ad-hoc* constraint $\mu > 1$;
2. inclusion of other kind of kinships and/or other covariates in order to reduce the variability of the unidentified part of the sample;
3. relaxation of restrictive model assumptions like the identical capture probability and the perfect identification.

Classification of the Aneurisk65 dataset using PCA for partially observed functional data

Classificazione del dataset Aneurisk65 utilizzando la PCA per dati funzionali parzialmente osservati

Marco Stefanucci, Laura Sangalli and Pierpaolo Brutti

Abstract When functional data are observed over a domain that is subject-specific, most of the techniques for functional data analysis are invalidated. Recently, new methods able to handle this situation were developed and in particular we focus on well-known functional PCA. With the aim of classifying the Aneurisk65 dataset, we apply a few possible methods and we show that carrying out the analysis over the full domain, where at least one of the functional data is observed, may not be the optimal choice. This is also confirmed in a simulation study, where the best interval for classification lies between the common domain and the full domain.

Abstract *Ogniqualvolta dei dati funzionali vengono osservati su un dominio dipendente dal soggetto considerato, non è più possibile utilizzare la gran parte delle tecniche per l'analisi di dati funzionali. Recentemente sono stati sviluppati nuovi metodi in grado di affrontare questa situazione e noi tratteremo la ben nota ACP funzionale. Con lo scopo di classificare il dataset Aneurisk65, abbiamo applicato diversi metodi e mostreremo che eseguire l'analisi sul dominio completo, dove è osservato almeno uno dei dati funzionali, può non essere la scelta ottimale. Ciò è confermato anche da uno studio di simulazione dove il migliore intervallo per la classificazione giace tra il dominio comune e il dominio completo.*

In the last 20 years, functional data analysis emerged as one of the fastest growing fields of modern statistics [1]. Functional data can be viewed as realizations of a functional objects, and in general are collected as discrete and noisy observations. The domain where the data are observed is usually common to all the statistical units, while the observation grid may vary across units. When the domain is unit-dependent, standard procedures are invalidated and a practical solution is to restrict the analysis to the intersection of the domains, where all the curves are observed. However, including intervals where the data are only partially observed may result in a more powerful statistical analysis and in the last decade some authors developed methodology handling this particular situation.

The Aneurisk65 dataset is an important example of partially observed functional data. The data consist in the profiles of radius and curvature of the internal carotid artery of 65 subjects suspected to be affected by cerebral aneurysms [2] and are displayed in figure 1. The domain where all the curves are available is highlighted in light-gray. Outside this domain individual observations are progressively lost when moving towards the full domain. In this application it is relevant to investigate whether the morphology of the internal carotid artery influences aneurysms pathogenesis and this can be done considering that the data can be divided in two groups - displayed in orange and blue in the figure - depending on the presence and location of the cerebral aneurysms.

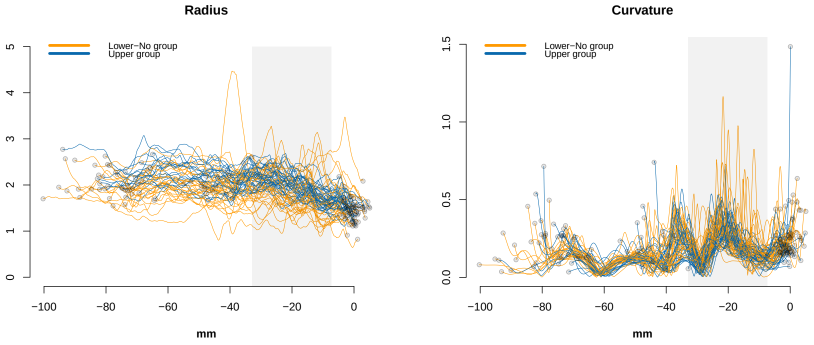

Fig. 1 The Aneurisk dataset.

In [2] a discriminant analysis based on the scores of the principal components of the radius and curvature profiles is presented, restricting the attention to the portion of the domain common across subjects. Our contribution is to improve the discrimination results by considering also portions of the domain where not all data are observed. In doing this, we need a methodology for functional principal components analysis in the case of partially observed data. Here we consider some proposals: the first one [3] is based on a spline reconstruction of the eigenfunctions, the second [4] is a method that estimates the principal component scores using conditional expectations, the third [5] is a generalization of the power method for extracting eigenvectors of a given matrix and the last one [6] is a fully functional approach in which the missing part of each score is predicted via best linear approximation of its conditional expectation.

We then use these methods to perform a discrimination based on the scores of the first K principal components. We show that carry out the analysis on the largest possible domain may not be the best choice for classification purposes. In fact, we suggest to explore different intervals, ranging from the common domain to the full domain. More specifically, we divide the domain where the data are partially observed in L portions, and we consider a collection of progressively larger domains I_l for $l \in \{0,\dots,L\}$, with $I_{l-1} \subset I_l$, where I_0 is the common domain and I_L is the full domain. We select the optimal number of principal components and the optimal domain extension I_l via cross-validation. For all the methods, the best interval for classification is between the common domain and the full domain and such an interval is the same for all the approaches, see figure 2. In this application, the approach [5] achieves the best result, corresponding to a 9 misclassified subjects, thus outperforming the result in [2]. Note that the application of the methodologies for partially observed data on the full domain does not lead to any improvement in the discrimination.

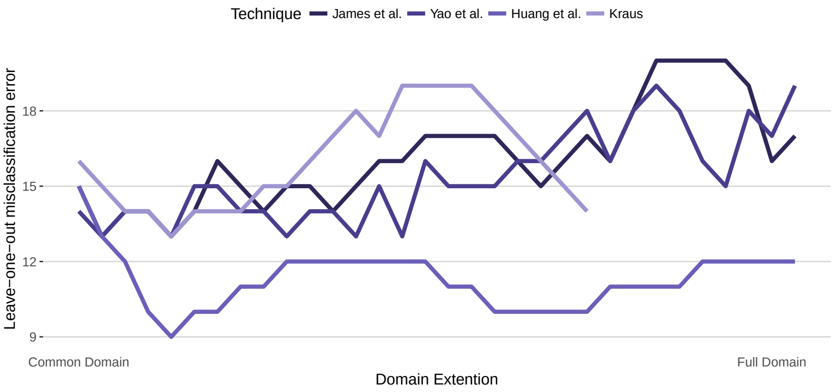

Fig. 2 Performances on the Aneurisk dataset.

In order to understand better the behaviour of the domain extension technique, we carry out simulations. We generate functional data over the interval $I_L = [0,1]$. We then completely retain the data generated over the interval $I_0 = [1/3, 2/3]$, while we censor them over the intervals $I_{\mathtt{left}} = [0,1/3]$ and $I_{\mathtt{right}} = [2/3,1]$, by sampling the starting point of each functional datum uniformly over $I_{\mathtt{left}}$, and its ending point uniformly over $I_{\mathtt{right}}$. The data are generated from a cubic B-splines basis with 16 internal knots, corresponding to a total of 20 bases. We generate two groups of 50 units each with the only difference being the mean function, see figure 3. The 100

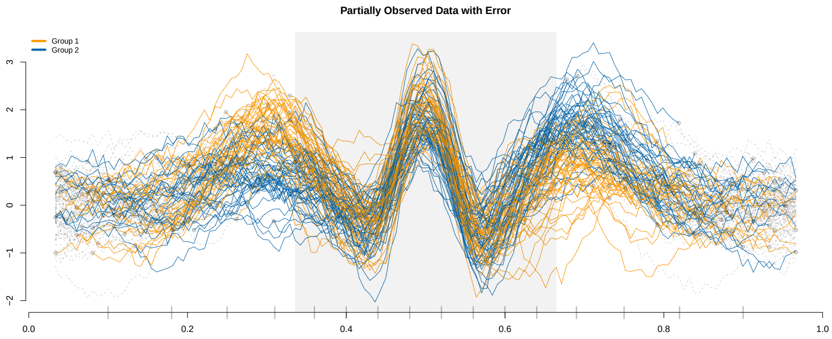

Fig. 3 Simulated data.

generated curves are evaluated on a regular grid of 150 points in $[0,1]$, contaminated with gaussian noise and finally classified over a set of progressively larger domains. This simulation is repeated 50 times.

In order to compare the performances of the four methods, we also apply standard PCA to the fully observed data. The results are presented in figure 4. The figure displays the boxplots of the leave-one-out misclassification error, for various tech-

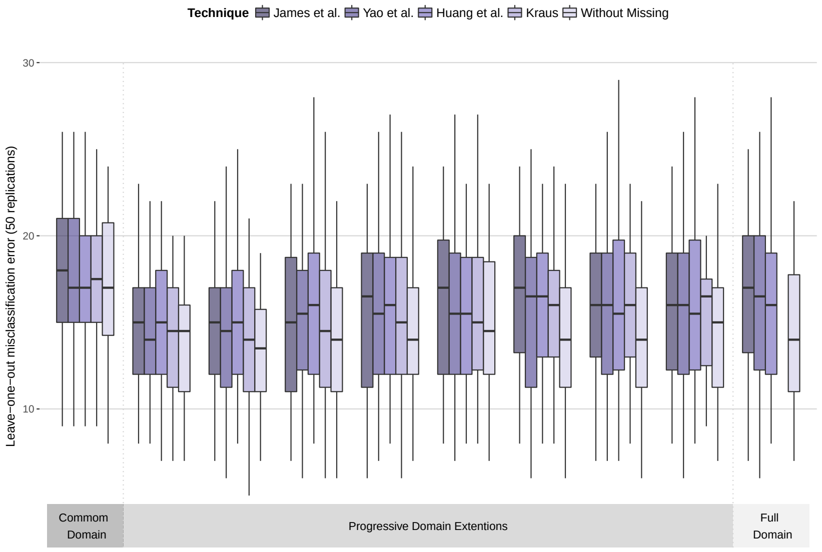

Fig. 4 Simulation results.

niques, for various domain extensions. For all methods, the misclassification error decreases when we start extending the domain with respect to the common domain, but then progressively increases as we approach the full domain. None of the methods outperforms the other. In conclusion, extending the domain with respect to the common domain improves the discrimination between the two groups; on the other hand, larger domain extensions, and in particular the full domain, do not lead to the best discrimination results.

Deep Learning to the Test: an Application to Traffic Data Streams

Metodologie di apprendimento approfondito applicate a dati di traffico stradale

Nina Deliu and Pierpaolo Brutti

Sommario Deep learning is a broad class of machine learning techniques based on learning data representation through multiple levels of abstraction. It has been successfully applied in several areas of research, but very few literature addressed the problem of traffic flow forecasting. Thus, driven by the belief that deep learning algorithms may capture the sharp traffic data non-linearities, we aimed to develop a deep architecture, namely a feed-forward neural network, and evaluate its performances in predicting short-term traffic streams. We illustrate our methodology, consisting in a predictors selection step and a subsequent training step, using traffic speed data of the Grande Raccordo Anulare road of Rome for the month of June 2016.

Sommario *Gli algoritmi di apprendimento approfondito costituiscono una vasta classe di algoritmi machine learning basati sulla rappresentazione dei dati tramite molteplici livelli di astrazione. Essi sono stati applicati con successo in diverse aree di ricerca, tuttavia solo una piccola parte della letteratura deep learning si è interessata al problema della previsione di dati di traffico. Considerando la capacità di questi algoritmi di catturare non linearità presenti all'interno dei dati, ci siamo proposti di sviluppare un'architettura deep learning per prevedere il traffico a breve termine. Illustriamo la nostra metodologia, consistente in una fase di selezione dei predittori e una di apprendimento della rete, considerando una dataset di dati di velocità di veicoli sulla rete autostradale Grande Raccordo Anulare di Roma.*

1 Introduction

Deep learning is a rather wide class of machine learning techniques based on learning data representation through multiple levels of abstraction. These methods have dramatically improved the state of the art in computer vision, natural language processing, speech recognition, object detection and many other domains such as drug discovery and genomics. However, according to the complexity of data, the prediction problem may be more or less difficult to perform. For instance, when aiming to model a time series, one should take into account the sequence dependence among the input values and handle the underlying temporal dynamics. While some areas relying on time series are well exploited and widely modelled with deep neural networks (e.g., speech recognition or financial applications [1]), some others are still poorly addressed, especially in the Italian research literature. One of these, is represented by road traffic modeling, which is a challenging and increasingly relevant field of research, as real-time forecasting may give travelers the ability to choose better routes and authorities the ability to manage the transportation system. Driven by the belief that deep learning algorithms might be able to capture nonlinear spatio-temporal effects in recurrent and non-recurrent traffic patterns, we aimed to develop a deep architecture and to asses if it may outperform standard modelling approaches in predicting short-term traffic streams.

2 Methods and Data

Deep learning algorithms, also known as deep artificial neural networks (ANNs) are statistical models directly inspired by biology, more precisely by the neural network of the human brain [2]. An ANN is organized as a graph, whose nodes or units are structured in multiple layers and interconnected by links to propagate activation from the initial to final units. Each link has a weight that determines the relative strength and sign of the connection, and each unit applies an activation function to the weighted sum of all incoming activations. The quintessential and most common deep learning architecture is the feed-forward neural network (FFNN), and it can be viewed as a directed acyclic graph [3].

The model: feed-forward neural network

Feed-forward neural networks are represented as a composition of many different non-linear functions, with the characteristic of flowing information hierarchically from the initial inputs X to all the neurons of the network through intermediate computations.

Formally, a deep feed-forward architecture can be described as follows. Let's suppose our network is composed by L hidden layers indexed as $l = 1, \dots, L$. Let $Z^{(l)}$ denote the vector of inputs into a generic layer $l+1$, $Z^{(0)}$ the vector of original inputs X and $Z^{(L+1)}$ the output vector of predictions $\hat{Y}(X)$. Using a matrix-vectorial notation, the model is given by

$$\begin{aligned} X &= Z^{(0)} \\ Z^{(1)} &= f^{(1)}\left(W^{(1)}Z^{(0)} + b^{(1)}\right) \\ \dots & \\ Z^{(L)} &= f^{(L)}\left(W^{(L)}Z^{(L-1)} + b^{(L)}\right) \\ \hat{Y}(X) &= Z^{(L+1)} = f^{(L+1)}\left(W^{(L+1)}Z^{(L)} + b^{(L+1)}\right). \end{aligned}$$

where $f^{(1)},\dots,f^{(L+1)}$ are the non-linear activation functions, $W^{(1)},\dots,W^{(L+1)}$ the weight matrices and $b^{(1)},\dots,b^{(L+1)}$ the bias or activation levels.
In summary, a feed-forward algorithm applies $L+1$ non-linear transformations to the input data X. Each transformation takes as input the output of the previous transformation, and gives a new abstract representation of the data.

Dataset

This study is based on a dataset of vehicle traffic streams obtained from QMap S.r.l. company, specialized in Intelligent Transport System and Info-mobility. All data were acquired by Global Positioning System (GPS) probes, which typically contain information on latitude, longitude, altitude, heading, speed and, most importantly, precision. This technology offers a low capital cost, a low installation cost, and a low data collection cost combined with a high location accuracy.
More precisely, data analyzed in this study consist in vehicle traffic speeds concerning the Grande Raccordo Anulare (GRA) road, that is a toll-free, ring-shaped orbital motorway, with 68.2 kilometres of circumference that encircles Rome. It represents one of the highest traffic volume Italian freeways, exceeding 160,000 vehicles per day (58 millions per year) [4]. In our dataset, the GRA road is partitioned in overall 279 locations (500 meters segments). For each location, it was recorded the respective traffic speed for the whole month of June 2016. With a length of 30 days and with observations available every 3-minutes interval, for this month were collected overall 14,400 observations for each GRA location.

3 Deep Learning for Traffic forecasting

Traffic speed data are represented as an ordered sequence of elements indexed by a regular (e.g., every day or ever year) time interval t and by a spatial index s. The goal in vehicle traffic forecasting is to develop a predictor of the quantity of interest. Suppose that for a certain location s we have observations up to time t, which we denote with $x_s^t := (x_{1,s},\dots,x_{t,s})$, and we want to predict the traffic speed for that location at a future time $t+t'$, i.e., $X_{t+t',s}$. Considering S the overall number of locations, the input matrix X^t of all the available observations is given by

$$X^t = \begin{bmatrix} x_{1,1} & \dots & x_{t-k,s} & \dots & x_{1,S} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ x_{t,1} & \dots & x_{t,s} & \dots & x_{t,S} \end{bmatrix}$$

The time point $t = 1$ is referred to the starting point of data collection or the first time for which we have information concerning the variable. However, it may be often reasonable to select an appropriate sub-interval time period and use a subset of observations for prediction, for example taking as initial time point $t-k$ and use $(x_{t-k,s},\dots,x_{t,s})$ to predict $X_{t+t',s}$. In this case, our deep learning predictor of $X_{t+t',s}$ is given by

$$\begin{aligned} X^t_{t+t',s} &= \hat{Y}(x^t_s) = \hat{Y}(x_{t-k,s},\dots,x_{t,s}) = \\ &= f^{(L+1)} \circ \dots \circ f^{(1)} \left(W^{(1)} x^t_s + b^{(1)} \right) = \\ &= f^{(L+1)} \circ \dots \circ f^{(1)} \left(Z^{(1),t}_s \right), \end{aligned}$$

where $f^{(1)},\dots,f^{(L+1)}$ and L represent the hyperparameters of the deep artificial neural network.

Our prior assumption is that to predict traffic at a given location we might need to use only recent measurements. In addition, is computationally prohibitive and somehow unreasonable to use data from every single road segment to forecast the speed of that location. The problem of selecting an optimal initial time point $t-k$ and the relevant locations, thus an optimal input matrix, is equivalent to perform a predictor selection task to find the spatio-temporal relations in the data. A predictor selection problem requires an algorithm to find a sparse model [5].

Predictor Selection

Our predictors selection procedure involves two widely used models in the time series framework, with the first one being an Autoregressive Integrated Moving Average (ARIMA) model [6, 7]. By taking into account the temporal dependencies in the data, it allows us to estimate the optimal number of temporal lags to be used. The estimated number of lags k is then used to identify the spatial relation as well, by developing a sparse Vector Autoregressive Model (sVAR). We thus consider the problem of finding a sparse matrix A in the following model:

$$X^t_{t+t'} = Ax^t + \varepsilon_t, \;\; \varepsilon_t \sim N(0,V),$$

where A is a matrix of size $S \times Sk$, with S the number of locations and k the number of previous measurements or lags.

Our predictors selected as the result of finding the sparse linear model are then used as input values at the first layer to build the deep learning model.

The training process

The training problem of our supervised deep learning model consists in finding the set of learning parameters $(\hat{W},\hat{b})$ that optimally predicts the outcome of interest. To do this, we use a training set $D = \{Y_i, X_i\}_{i=1}^{N}$ of input-output pairs to train the model by solving an optimization problem as the following

$$\arg\,\min_{W,b} \frac{1}{N} \sum_{i=1}^{N} ||Y_i - \hat{Y}^{W,b}(X_i)||_2^2. \tag{1}$$

When we have a non-linear model, the most loss functions cannot be optimized in a closed form [8] and are required iterative numerical optimization procedures, such as gradient descent [9]. Gradient descent algorithm tells us how to learn the the parameters we're interested in, but it supposes the ability to compute the gradient of the loss function, i.e., all the partial derivatives. A good algorithm employed to this purpose is Back-propagation [10]. It demonstrated to behave really better and faster than other earlier methods, becoming the workhorse of learning in neural networks. The feed-forward deep neural network was implemented with the `h2o` package in `R`. It was evaluated on both in-sample and out-of-sample metrics (i.e., mean squared error and R^2) based on a random split of 70%, 10% and 20% for the training, validation and test set, respectively.

4 Results and Conclusions

Before testing our deep learning model, we performed a Grid Search to find the optimal network (number of layers L, number of units N_l for each layer l, the activation functions f, and the regularization lasso λ_1 and ridge λ_2 penalty parameters). Based on $N = 10^4$ Monte Carlo samples, we obtained the following neural network

$$\begin{aligned} f &= \texttt{ReLU} \\ (\lambda_1, \lambda_2) &= (1\mathrm{e}-5, 0) \\ \texttt{structure} &= (100, 50, 100, 50). \end{aligned}$$

In Table 1 we show the training and test error of our deep learning model compared with a general linear model (GLM). Both models are based on the same input sets, in a first step we consider the previous 10 time measurements and in a second step we only take into account the optimal spatio-temporal structure estimated with the ARIMA and sVAR models.

We noticed a non uniform model performance throughout the day, based on recurrent and non recurrent patterns of the proposed time series. However, compared to general linear models, the deep learning models showed much better results in terms of both in sample and out of sample outcomes, particularly with the optimal number of lags and the selected two adjacent locations.

Further significant improvements are likely to be obtained with other classes of deep learning, e.g., recurrent neural networks [11] or long short term memory networks [12], and future analyses should be carried out to evaluate their performances.

Tabella 1 In Sample and Out of Sample metrics according to a general linear model (GLM) and a deep learning model (DLM). 10 and 2 indicates 10 and 2 previous time measurements. All the values are based on a Monte Carlo sample.

	MSE		R^2	
Model	In Sample	Out of Sample	In Sample	Out of Sample
GLM10	36.48	37.95	0.89	0.89
DLM10	28.36	36.53	0.92	0.89
GLM2	37.47	37.57	0.89	0.89

Estimating the number of unseen species under heavy tails

Sulla stima del numero di nuove specie nell'ipotesi di code pesanti

Marco Battiston, Federico Camerlenghi, Emanuele Dolera and Stefano Favaro

Abstract Species sampling is a popular subject in several scientific disciplines. Assuming to be provided with an initial sample of size n, a crucial issue is the estimation of the number of new species that will be observed in an additional sample of size λn, being $\lambda > 0$. The case $\lambda < 1$ has been successfully tackled in [6] and [7], but the most interesting situation $\lambda \geq 1$ has been addressed only recently in [11]. We will show that the solution of [11] is unsatisfying when the species' proportions have regularly varying heavy tails. Under this assumption, we provide another estimator for the number of new species and we empirically show its performance.

Abstract *Il campionamento di specie è di particolare interesse in molti contesti. Avendo a disposizione un campione di ampiezza n, un problema particolarmente rilevante consiste nella stima del numero di nuove specie che verranno osservate nelle prossime* λn *osservazioni, con* $\lambda > 0$. *Per il caso* $\lambda < 1$ *il problema fu risolto in [6, 7], mentre il caso* $\lambda \geq 1$ *è stato affrontato solo di recente in [11]. Mostreremo che la soluzione proposta in [11] non è soddisfacente quando le porzioni delle varie specie hanno code pesanti. Sotto opportune ipotesi sulle code delle porzioni, proporremo uno stimatore per il numero di nuove specie e mostreremo le sue proprietà attraverso alcune simulazioni.*

Key words: Good-Toulmin type estimators, regular variation, species estimation, two parameter Poisson-Dirichlet prior

1 Introduction

Consider a generic population of individuals $(X_i)_{i\geq 1}$ belonging to different species $(X_i^*)_{i\geq 1}$ with unknown proportions $(p_i)_{i\geq 1}$. Given an initial sample of size n, say $(X_1,\dots,X_n)$, from the population of interest, a crucial problem is the estimation of hitherto unseen species that will be observed in an additional sample of size λn, being $\lambda > 0$. More precisely, denoted by $N_{n,i}$ the frequency of the i-th species in the sample, one is typically interested to estimate the quantity

$$U_{\lambda n} := \sum_{i\geq 1} \mathbb{1}_{\{N_{n,i}=0\}} \mathbb{1}_{\{N_{\lambda n,i}>0\}},$$

i.e. the number of new species that will be observed in an additional sample $(X_{n+1},\dots,X_{\lambda n-n})$ of size λn.

The first solution of this problem have been suggested in the seminal contributions of [6] and [7]. To fix the notation, we denote by $M_{n,r}$ the number of species with frequency r in $(X_1,\dots,X_n)$, for any $1\leq r\leq n$, and by $m_{n,r}$ the corresponding value in the observed sample. Besides K_n represents the number of distinct species in $(X_1,\dots,X_n)$, and k_n the observed value. The following estimator for $U_{\lambda n}$

$$\hat{U}_{\lambda n} := -\sum_{j\geq 1} (-\lambda)^j m_{n,j} \tag{1}$$

has been provided in [7]. Such an estimator works very well whenever $\lambda < 1$, but it is useless for $\lambda \geq 1$, due to the exponential growth of the coefficients $(-\lambda)^j$. In order to predict $U_{\lambda n}$ for $\lambda > 1$, [1, 7] suggested to use the so–called Euler's transformation, which converts the series in (1) into another one having the same sum, but featuring a faster convergence of its partial sums. However, no theoretical guarantees for the resulting estimator have been established until the work by [11]. They have been able to define a general estimator $U_{\lambda n}$ for the case $\lambda > 1$, which amounts to be

$$\hat{U}^L_{\lambda n} := -\sum_{j\geq 1} (-\lambda)^j \mathbb{P}[L\geq j] m_{n,j}, \tag{2}$$

where L is a random variable whose tail probability compensates for the growth of $(-\lambda)^j$. If L is the Binomial random variable with parameter $(k,(1+\lambda)^{-1})$ then (2) coincides with the Euler-smoothed estimator of [1], with k being the truncation level of (2).

In order to illustrate the performance of (2), we consider a population of 10^6 species whose proportions p_i's are masses of the Zipf distribution, i.e. $p_i \propto i^{-s}$ for some $s > 0$. The parameter s controls the tail of the distribution, to large values of s corresponds heavy tails distributions. Figure 1 shows the estimator (2) for different choices of s, i.e. from left to right and top to bottom $s = 0.6, 0.8, 1.0, 1.2, 1.4, 1.6$. All experiments are averaged over 100 iterations. The true value is shown in black, and estimated values are colored according to the three choices of the distribution of L considered in Table 1 of [11]: i) a Poisson distribution with parameter $(2\lambda)^{-1}\log_e(n(\lambda+1)^2/(\lambda-1))$; ii) a Binomial distribution with parameter $(2^{-1}\log_2(n\lambda^2/(\lambda-1)),(\lambda+1)^{-1})$; iii) a Binomial distribution with parameter $(2^{-1}\log_3(n\lambda^2/(\lambda-1)),2(\lambda+2)^{-1})$. Shaded bands correspond to one standard deviation. Figure 1 highlights how the tail behavior of the p_i's affects the experimental performance of the estimator $\hat{U}^L_{\lambda n}$: the heavier the tail of $(p_i)_{i\geq 1}$, or rather the lower the species discovery rate, the worse the performance of $\hat{U}^L_{\lambda n}$. The underestimation phenomenon thus suggests that the methods proposed by [1] and then by [11] are not useful for heavy-tailed p_i's. Indeed those methods rely on analytic considerations aimed at improving the rate of convergence of the estimator (1), without acting on the species compositions $(p_i)_{i\geq 1}$. Heavy-tailed species proportions is a common setting in several application areas (see, e.g., [14, 15]), hence the definition of an estimator for $U_{\lambda n}$ under the assumption of heavy-tailed proportions p_i's is a problem of paramount importance.

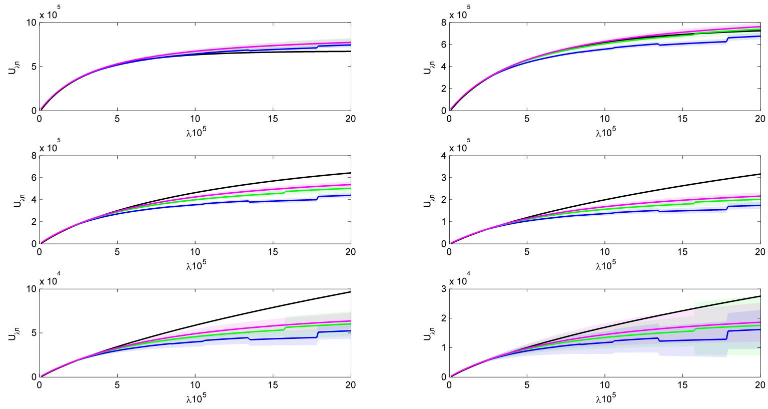

Fig. 1 Estimator of $U_{\lambda n}$ in six Zipf scenarios. The true value is drawn in black, the estimated values are colored in blue (L being the Poisson distribution), green (L being the binomial distribution with success probability $1/(\lambda+1)$) and magenta (L being the binomial distribution with success probability $2/(\lambda+2)$). The shaded bands correspond to one standard deviation.

In the present paper, we introduce the estimator of $U_{\lambda n}$ under heavy–tailed proportions p_i's, showing that it has an opposite behaviour with respect to that highlighted in Figure 1, namely the estimations improve as the parameter s of the Zipf distribution increases. In Section 3 we briefly discuss how to choose the best estimator of $U_{\lambda n}$ among those presented here in relation to the problem at the hand.

Finally we hint possible connections with the Bayesian nonparametric approach, which merit further investigation.

2 Good-Toulmin estimators under regular variation

In the previous section we have seen that the higher the tail of $(p_i)_{i\geq 1}$ (i.e. the higher the parameter s of the Zipf law), the worse the underestimation of $\hat{U}^L_{\lambda n}$. In order to define a suitable estimator for large values of s, we impose a specific assumption on the tails of $(p_i)_{i\geq 1}$, more precisely we resort to the theory of regular variation [8]. In the sequel we will use the notation $f \sim g$ to mean $f/g \to 1$, besides define $\nu(\mathrm{d}x) := \sum_{i\geq 1} \delta_{p_i}(\mathrm{d}x)$ and the measure $\overline{\nu}(x) := \nu[x,1]$. We will say that $(p_i)_{i\geq 1}$ is regularly varying with regular variation index $\alpha \in (0,1)$ if $\overline{\nu}(x) \sim x^{-\alpha}\ell(1/x)$ as $x \downarrow 0$, where $\ell(t)$ is a slowly varying function, that is $\ell(ct)/\ell(t) \to 1$ as $t \to +\infty$ for all $c > 0$. Karlin [8] has proven that in such a context

i) $K_n \overset{\text{a.s.}}{\sim} \mathbb{E}[K_n] \sim \Gamma(1-\alpha)n^{\alpha}\ell(n)$,
ii) $M_{n,r} \overset{\text{a.s.}}{\sim} \mathbb{E}[M_{n,r}] \sim \frac{\alpha\Gamma(r-\alpha)}{r!}n^{\alpha}\ell(n)$

where $\Gamma(\cdot)$ represents the Gamma function. The regular variation index is not known *a priori* and needs to be estimated from the data. This issue can be easily addressed taking the ratio of the number of species with frequency one and the total number of species, namely $\hat{\alpha} := \frac{M_{n,1}}{K_n}$ is a (strongly) consistent estimator of α. For additional details on regular variation refer to [8] and [5].

We now define an estimator for $U_{\lambda n}$, when $\lambda > 1$ and the sequence $(p_i)_{i\geq 1}$ has regularly varying heavy tails. In order to to this, we consider (2) when L is a Binomial random variable with parameters $(2^{-1}\log_2(n\lambda^2/(\lambda-1)), (\lambda+1)^{-1})$, and we tune this estimator under the hypothesis of regular variation, thus obtaining

$$\hat{U}^L_{\lambda n}(\alpha) := k_n \sum_{z=1}^{k_L} \binom{z+\alpha-1}{z} \left(\frac{\lambda}{\lambda+1}\right)^z, \tag{3}$$

where k_L is the truncation level, i.e. $k_L := 2^{-1}\log_2(n\lambda^2/(\lambda-1))$. Note that $k_L \to +\infty$ as $n \to +\infty$.

Finally it is worth noticing that in (3) the regular variation index α is unknown, hence, in order to use the estimator $\hat{U}^L_{\lambda n}(\alpha)$, one should replace α with the corresponding consistent estimator $\hat{\alpha} = \frac{M_{n,1}}{K_n}$.

We now consider the same Zipf's scenarios presented in Section 1 to illustrate the performance of (3). Figure 2 shows $\hat{U}^L_{\lambda n}(\hat{\alpha})$ for different choices for the parameter s of the Zipf distribution, i.e. from left to right and top to bottom $s = 0.6, 0.8, 1.0, 1.2, 1.4, 1.6$. All experiments are averaged over 100 iterations. The true value is shown in black, the estimated value in red, and the shaded band corresponds to one standard deviation. By a comparison between Figure 1 and Figure 2, one immediately realizes that $\hat{U}^L_{\lambda n}(\hat{\alpha})$ has an opposite behaviour with respect to

$\hat{U}^L_{\lambda n}$. That is, the heavier the tail of $(p_i)_{i\geq 1}$, or rather the lower the species discovery rate, the better the performance of $\hat{U}^L_{\lambda n}(\hat{\alpha})$.

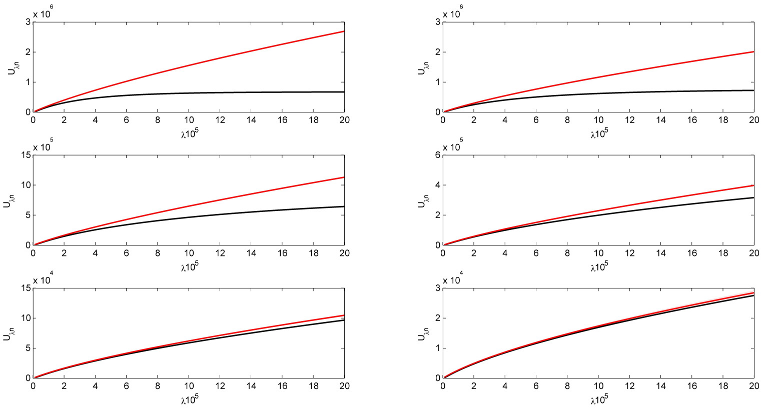

Fig. 2 Estimator of $U_{\lambda n}$ in six Zipf scenarios. The true value is drawn in black, the estimated value in red. The shaded bands correspond to one standard deviation.

3 Discussion

In this paper we focused on the estimation of the number of unseen species that will be observed in a future sample of size λn. The performance of the estimators presented here has been assessed empirically for the ubiquitous Zipf distribution with parameter s. We have shown that the estimator (2) proposed by [11] is useful when $s \leq 1$, but it radically worsens when $s > 1$. For this reason, in Section 2, we have tuned such an estimator under the assumption of regularly varying heavy tails p_i's. In Figure 2, we have empirically shown that $\hat{U}^L_{\lambda n}(\hat{\alpha})$ performs very well when $s > 1$, but not when $s \leq 1$, featuring an opposite behaviour with respect to $\hat{U}^L_{\lambda n}$. In real applications the parameter s is not given and one has to decide whether to employ either $\hat{U}^L_{\lambda n}$ or $\hat{U}^L_{\lambda n}(\hat{\alpha})$. In order to face this issue one can find an estimate of the parameter s by means of linear regression as suggested in [10], thus using $\hat{U}^L_{\lambda n}$ if the resulting estimator of s is less than 1, $\hat{U}^L_{\lambda n}(\hat{\alpha})$ otherwise.

An interesting open problem which merits further investigation is the connection between the estimator of the number of unseen species $\hat{U}^L_{\lambda n}(\alpha)$ presented here and the Bayesian nonparametric estimator derived in [2] and [3]. The Bayesian viewpoint needs the specification of a prior distribution for the species proportions $(p_i)_{i\geq 1}$, namely one needs to choose a prior distribution for the random probability measure $\tilde{p} = \sum_{i\geq 1} p_i \delta_{X_i^*}$. In such a context $(X_1,\dots,X_n)$ is a sample coming from an exchangeable sequence of observations driven by $\tilde{p}$, i.e.

$$\begin{aligned} X_i \,|\, \tilde{p} &\overset{\text{iid}}{\sim} \tilde{p}, \qquad i=1,\dots,n, \\ \tilde{p} &\sim \mathscr{P}, \end{aligned} \tag{4}$$

where $\mathscr{P}$ is the distribution of $\tilde{p}$. A common choice for $\mathscr{P}$ is the law of the two parameter Poisson-Dirichlet process, which was introduced in [12] and further investigated in [13]. The sequence $(p_i)_{i\geq 1}$ is such that $p_1 = v_1$ and $p_i = v_i \prod_{1\leq j\leq i-1}(1-v_j)$, for any $i \geq 2$, where the v_j's are independent random variables, each v_j is distributed according to a Beta distribution with parameter $(1-\alpha, \theta + j\alpha)$, for $\alpha \in (0,1)$ and $\theta > -\alpha$. In [4], the authors have proven that the celebrated Good-Turing estimator of the discovery probability is asymptotically equivalent, for a large sample size, to the Bayesian nonparametric one under the assumption of a two parameter Poisson-Dirichlet prior. Analogously, we would like to asses whether $U_{\lambda n}$ is asymptotically equivalent to the regularly varying nonparametric estimator $\hat{U}^L_{\lambda n}(\alpha)$ for specific choices of $\mathscr{P}$, as the sample size n increases.

How to measure cybersecurity risk

Misurare il cyber rischio

Silvia Facchinetti, Paolo Giudici and Silvia Angela Osmetti

Abstract In the last years there have been a scholars increasing interest in cybersecurity risk measurement. This paper proposes a methodology to measure cyber risk, using ordinal data, to prioritise appropriate interventions. The method relies on the construction of a Criticality index: a new measure of risk based on the cumulative probabilities of the ordinal variable that represents the level of severity for different risk event. Its properties are derived and compared with alternative measures employed in operational risk measurement. we apply our proposal to real data of a telecommunication service company. The proposed measure is found to be quite effective to rank cyber risk types and, therefore, allow selective preventive actions.
Abstract *Negli ultimi anni si è registrato un interesse crescente da parte degli studiosi al problema del cyber rischio e alla sua misurazione. Dato che in tale contesto i dati sono spesso di natura ordinale, nel presente lavoro proponiamo un indice per stimare il cyber rischio utilizzando dati qualitativi riguardanti il livello di severità dei cyber attacchi. Noi analizziamo le caratteristiche dell'indice, e lo confrontiamo con misure alternative utilizzate nella valutazione del rischio operativo. La nostra proposta viene applicata ai dati di una compagnia di telecomunicazioni, riguardanti la severità dei cyber attacchi subiti dai clienti della compagnia. L'indice risulta efficace per classificare le diverse linee di business in base alla loro rischiosità e quindi per consentire tempestive azioni preventive.*

Key words: criticality index, risk measure, ordinal variables, cyber attacks

1 Introduction

In the last years the number of cyber attacks in information technology (IT) systems is surging. Therefore, cybersecurity has become more of a concern for businesses. Among operational risks caused by IT systems, cyber risks are gaining increasing importance, due to technological advancements and to the globalisation of financial activities (see e.g. [2],[3]). Therefore the cybersecurity risk measurement is an increasing interest for scholars (see e.g. [1],[6]).

We propose a methodology to measure cyber risks, starting from ordinal random variables, that represent the levels of severity for different risk events (expressed on ordered categories, such as ”high”, ”medium” or ”low” risk), in different business lines. In particular we propose, for different business lines, a cybersecurity risk index that is based on the relative frequencies of the severity levels. As a result, we obtain an ordinal measure of risk which will be used to compare different events and business lines, producing an ordering among risks useful to prioritise intervention in process controls.

Besides the theoretical proposal, we will present empirical evidences on the performance of our index, using a real data set, that concerns cyber risk measurement in a telecommunication company.

2 Proposal

Let $X \sim \{x_k, p_k; k = 1, 2, \ldots, K\}$ be a categorical random variable with ordered categories x_k and probabilities $p_k = P(x_k)$, that represents a severity variable, with decreasing levels, $k = 1, 2, \ldots, K$.

We define a *Criticality Index* for the categorical random variable X with the following expression:

$$I = \frac{1}{K-1} \sum_{k=1}^{K-1} (K-k) p_k = \frac{\sum_{k=1}^{K} F_k - 1}{K-1}, \tag{1}$$

where $F_k = \sum_{l=1}^{k} p_l$ are the values of the cumulative distribution function of the ordinal variable X, for $k = 1, 2, \ldots, K$.

It is a natural measure of risk for ordinal variables, with values in $[0,1]$. It thus provides a risk measure easy to interpret and suitable for the comparison of the risk level between different risk events and/or business lines.

We propose to estimate cybersecurity risk in each business line/event type combination by the sample version of the *Criticality Index*, obtained by replacing the probabilities p_k with their estimators $\hat{p}_k = r_j/n$ for $k = 1, 2, \ldots, K-1$:

$$\hat{I} = \frac{1}{K-1} \sum_{k=1}^{K-1} (K-k) \frac{r_k}{n} = \frac{\sum_{k=1}^{K} \tilde{F}_k - 1}{K-1}, \tag{2}$$

where

$$\tilde{F}_k = \sum_{l=1}^{k} \frac{r_l}{n} \text{ for } k = 1,2,\dots,K,$$

is the empirical cumulative distribution function, $r_l = \sharp(\tilde{x}_i \equiv x_l)$ is the number of observations in the sample equal to the category x_l, with $r_l \in \mathbf{N}$ and $\sum_{l=1}^{K} r_l = n$ (n is the total number of risk events observed for the j-th business line).

It is possible to demonstrate that the *Criticality Index* estimator is asymptotically normally distributed for $n >= 30$. Moreover, $\hat{I}$ is an unbiased and consistent estimator for I [4].

3 Application

We apply our proposal to real data provided by a telecommunication company that installs telephone exchange systems and offers post-installation technical assistance for upgrading and problem resolution in different event types, that include, in particular, Network communications. The service is offered to a wide range of customers, that are grouped in several business lines.

The main research problem is to estimate for each business line, a measure of cybersecurity risk based on ordinal data, collected by the customer care center, describing the level of severity of cyber attack suffered by customers.

The data are reported in Table 1. Each row shows a business line and each column reports how many times a cyber problem in Network communication has been reported, for levels of severity equal to high (H), medium (M) and low (L).

Table 1 Data for Network communication event type

Business Line	H	M	L
Banking	23	128	4
Computers	3	26	0
Cooperatives	13	93	2
Defence	34	149	7
Health	43	222	8
Hotels	10	108	3
Industry	13	94	7

In Table 2, column 2 and 3, we report the *Criticality Index* estimates and its associated asymptotic confidence interval.

We show that Defence is the business line with the highest level of risk, followed by Health and Banking. Therefore, a mitigation intervention to prevent cyber risk should prioritise the Defence business line, and the customers in that business line.

To evaluate the robustness of our results we compare them with what could be obtained with the approach proposed by [5] in the context of operational risks. We apply their Stochastic Dominance Index (SDI) to our data and their suggested

Table 2 *I* and SDI risk measure estimates and their respective confidence intervals (CI)

Business line	$\hat{I}$	CI	SDI	Bayesian CI
Banking	0.561	0.517-0.606	0.708	0.685-0.728
Computers	0.552	0.473-0.630	0.701	0.654-0.734
Cooperatives	0.551	0.503-0.599	0.701	0.676-0.723
Defence	0.571	0.527-0.616	0.714	0.692-0.735
Health	0.564	0.529-0.599	0.709	0.692-0.726
Hotels	0.529	0.488-0.570	0.686	0.665-0.706
Industry	0.526	0.472-0.580	0.684	0.657-0.711

Bayesian procedure to derive a confidence interval, by means of a Gibbs Sampling algorithm with R=10000 interactions. What obtained is reported in Table 2, column 4 and 5. Note that since $n \simeq 30$ for all the business lines in Table 2, is not strictly necessary to apply a Bayesian approach to derive confidence intervals of our index, we can apply the asymptotic normality. Bayesian confidence intervals may instead be useful for ”rare” problem business lines, for which an asymptotic confidence interval is not possible.

By compare the results of Table 2, we observe, obviously, a different values for the two indices since they are calculated in different way: SDI is based on the observed frequencies, whereas our index is based on the observed relative frequencies of the severity variables conditional on the total n of that business line. Moreover, we observe that the SDI values are always higher than the results obtained with our approach. By comparing the results for different BLs, we show that our index and the SDI produce a consistent ranking, indicating similar priorities of intervention. This confirm that our index could be suitable to measure the level of risk, to compare the level of risk for many BLs or even types and that it can be considered as a synthetic priority of intervention indicator.

Implementation of an innovative technique to improve Sauvignon Blanc wine quality

Applicazione di una tecnica innovativa per migliorare la qualità di vini Sauvignon Blanc

Filippa Bono[1], Pietro Catania[1] and Mariangela Vallone[1]

Abstract The purpose of the study was to compare two different pressing systems of Sauvignon Blanc grapes using an innovative wine press manufactured by Puleo Srl Company (Marsala, Italy). Grape pressing is a very important step in the winemaking process as it may promote the presence and/or absence of enzyme processes on the must, leading to the creation of different products in terms of chemical composition from the same grapes. Chemical composition of must firstly and wine after, obtained from the two pressing mode, was analysed in first instance with PCA method.

Results are encouraging and open up new research prospective with the aim of applying innovative techniques to improve the quality of the final product.

Abstract *Scopo del lavoro è valutare due diversi sistemi di pressatura delle uve Sauvignon Blanc ottenute impiegando una macchina innovativa prodotta dalla ditta Puleo di Marsala. La pressatura dell'uva è un passo molto importante nel processo di vinificazione in quanto può favorire la presenza e/o l'assenza di processi enzimatici sul mosto, portando alla creazione di diversi prodotti in termini di composizione chimica a partire dalle stesse uve. Le componenti chimiche del mosto prima e del vino dopo, ottenuti con due differenti modalità di pressatura, sono stati confrontati con il metodo PCA.*

I risultati sono incoraggianti per nuove prospettive di ricerca con l'obiettivo di applicare sistemi di pressatura innovativi a migliorare la qualità del prodotto finale

1 Introduction

Oxygen plays a crucial role in the winemaking process and it can influence the composition and quality of the must and wine. Oxygen can influence the composition and quality of wine drastically, either positively or negatively. Oxygen exposure occurs naturally during mechanical harvesting, crushing and pressing. In must, during alcoholic fermentation and during ageing of white and red wines oxygen has different effect [1]. The use of sulphur dioxide as an anti-oxidant dates back to the early 18th century and the protection of wine from unwanted oxidative spoilage has been recognized [2]. There is very little scientific research on the effect of oxygen use during fermentation on wine composition or sensory proprieties. Furthermore these effects change with grapes cultivar. Smith et al. [3] studied the oxygen influence in fermentation, colour, tannin and sensory of shiraz wines. Recently, Boselli et. al. [4] observed the effect of Nitrogen gas on three white grapes varieties (Chardonnay, Grechetto and Orvieto) obtaining the strongest protective effect of nitrogen on phenolics in Chardonnay and Grechetto musts. They showed that Nitrogen gas is therefore particularly recommended not only in positive pressure, but also for vacuum-pressing of white grapes containing high levels of catechin or gallic acid due to early harvest or peculiar varietal composition. Interest in wine press innovation suggest the opportunity to carry out real-time experiments to assess the effect that different types of wine presses may have on the must and, consequently, on the quality of the wine. In our study we consider two different wine pressing modes applied on Sauvignon Blanc grapes using a modern press by Puleo s.r.l (Marsala, Italy). Aim of the study is to identify if the two wine pressing modes influence must and wine characteristics.

The statistical method to compare results is the Principal Component Analysis (PCA).

2 Data and Methods

Grapes pressing represents a very important phase in winemaking since it can promote the presence and/or absence of enzymatic processes endogenous to the juice itself, leading to the creation of different products in terms of chemical composition, although starting from the same grapes.

The most important elements influencing the quality of wine in grapes pressing are: press type; oxygen in the tank; level of pressing; juice extraction time. In the analysis, Sauvignon Blanc grape variety is considered. Grapes were manual harvested in the third decade of August 2016, the must composition was observed in three different times during winemaking (29th August, 1th September, 3th September). The analyses on wine were performed at the end of fermentation.

Pneumatic discontinuous press is actually the most used machine in quality wine making.
In our study the "Vortex System" pneumatic press developed by Puleo Srl was used. The “Vortex system” puts the idea of pressing under inert gas with nitrogen recovery towards a new and more advanced perspective. The idea of using inert gas in pressure during working cycle, guarantees a continuous draining action highly greater than any other kind of pressing, with excellent results in product quality/yelds. A further advantage is the immediate extraction of the must from the cylinder to the storage tank thanks to the “Vortex” created inside the press. During grapes processing, the inert gas is continuously filtered to be purified by any pollution due to unwanted parts that can be carried by the gas itself. This wine press has a close tank and two operating modes: the traditional Air Pressing mode (AP) and the Nitrogen Pressing mode (NP).
The AP mode is a traditional pneumatic press with a close tank. Grape must is extracted from the inner draining channels and comes out from nozzles to an external collection tray. In the NP mode, grapes contact with air is minimized, lesser than any pneumatic press with close tank.
Analytical determination on must and wine were performed by Foss Integrator WineScan™, (FOSS Italia S.p.A.). The must and wine determinations were alcohol [%/vol], density [g/l], sugar [g/l], pH, total acidity [g/l], volatile acidity [g/l], malic acid [g/l], citric acid [g/l], tartaric acid [g/l], potassium [g/l], polyphenols [mg/l], ashes[g/l], APA (readily assimilable nitrogen) [g/l], gluconic acid [g/l], methanol [g/l], CO2, absorbance at 280, absorbance at 325, catechins [mg/l]. The observations are in triplicate respectively in 29th August, 1th September, 3th September.
The PCA method is used to compare the must and the wine characteristics obtained in the different press modes.

3 Results

Table 1 shows descriptive statistics in must composition obtained with the two pressing modes, AP and NP. These differences in must composition determine the quality of the final wine. Must obtained in the NP pressing mode had a lower level of alcohol, pH, total acidity, methanol and CO_2 than AP, while the levels of APA, potassium, sugars, malic and citric acids and polyphenols were particularly higher than AP.
In particular, the higher level of acids obtained in NP mode is favourable to the development of ester profile that determines the aromatic component of wines.
The presence of polyphenols is very important as antioxidant and preservatives. The NP pressing mode doubles polyphenols than the AP pressing mode.
PCA analysis was performed to evaluate changes in must’s components obtained with the two pressing modes.

Table 1. Descriptive statistics of must composition in AP and NP modes

	AP				*NP*			
Variable	***Mean***	***Std. Dev.***	***Min***	***Max***	***Mean***	***Std. Dev.***	***Min***	***Max***
Alcohol	10.84	1.51	8.90	12.55	10.35	1.88	7.89	12.12
Density [g/l]	1.01	0.02	0.97	1.04	1.01	0.02	0.98	1.04
Sugar [g/l]	39.58	22.85	15.85	69.00	44.14	29.27	15.98	82.49
pH	3.41	0.05	3.33	3.51	3.38	0.04	3.33	3.44
Volatile Acidity [g/l]	0.21	0.01	0.18	0.22	0.18	0.01	0.16	0.20
Malic acid [g/l]	2.66	0.15	2.50	2.99	3.52	0.13	3.35	3.73
Citric acid [g/l]	0.29	0.04	0.24	0.36	0.31	0.04	0.26	0.37
Tartaric acid [g/l]	2.57	0.15	2.35	2.78	2.47	0.16	2.20	2.66
Potassium [g/l]	988.63	52.54	926.37	1073.00	1153.22	28.74	1107.60	1189.99
Polyphenols [mg/l]	269.92	32.15	221.19	321.16	468.70	56.88	380.00	528.53
Ashes [g/l]	2.38	0.10	2.24	2.56	2.64	0.11	2.50	2.80
APA [g/l]	28.18	17.50	6.52	50.00	80.18	18.10	58.68	103.90
Gluconic acid [g/l]	2.54	0.13	2.34	2.72	2.56	0.16	2.30	2.80
Methanol [g/l]	0.45	0.51	0.10	1.15	0.14	0.02	0.12	0.19
CO_2	1418.73	156.31	1236.00	1638.56	1251.59	261.60	948.00	1615.00

Table 2. shows eigenvalues of PCA performed on must data. Following the eigenvalue>1 criterion, three components are extracted that overall explain 82% of the total variance of must components. The score plot gives us a feeling for the similarities and differences between the pressing mode in component loading.

Table 2. Eingenvalues of the must Principal Component

Component	Eigenvalue	Difference	Proportion	Cumulative
Comp1	5.583	0.322	0.372	0.372
Comp2	5.261	3.824	0.351	0.723
Comp3	1.438	0.649	0.096	0.819

The correlation between elements of must and the first principal component extracted suggests us to name it as *fermentation* component due to its positive correlation with sugars, citric acid, methanol and CO_2 and negative correlation with alcohol and APA. The second component measures *antioxidant and preservative* characteristics given its correlation with malic acid, polyphenols and ashes and negative correlation with volatile acidity. The third component can measure the *must character* just its correlation with tartaric acid and pH. The Graph 2 shows the score plot that highlights a net separation between musts obtained with the two pressing modes, AP and NP, in the combination of the three components extracted.

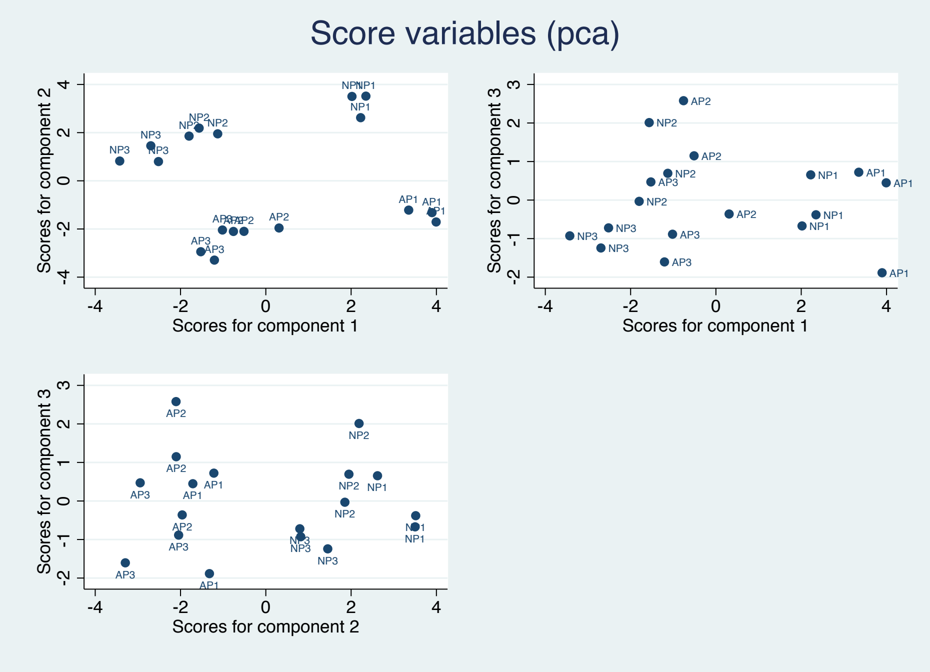

Figure 1: Score plot in must

Starting from up in the right of the graph, AP1 (must in the first time of observation) is opposite to NP3. The NP pressing mode has higher antioxidant and preservative characteristics associated with lower fermentation component than AP pressing mode. Down on the left we note also a net separation between second and third components that measure the character of must and its stability.

The component 3 has a higher correlation both in AP and NP when values are observed in time 2 even if with a net separation between the data of the two pressing modes. Component 2 has the highest correlation at time 1, i.e when grape juice is extracted.

The PCA on wine data shows two principal components that explain on the whole the 92% of the total variability of wine in the elements observed. In particular, the first component is expressive of the innovative press system showing a net separation of the wines obtained in the two pressing modes (Fig. 2). T test shows significant differences between the two pressing modes in all the elements except absorbance at 520 nm, absorbance at 620 nm, catechins, acetaldehyde (data not shown). Density, total extract, pH, total acidity, malic acid, citric acid, ashes, polyphenols, calcium, copper and sulphates in NP are higher than AP. Alcohol, sugars, volatile acidity, potassium, glycerine, absorbance at 420 nm, methanol and CO_2 observed in NP are significantly lower than AP.

Concluding, the application of NP pressing mode produced a wine with higher qualitative characteristics than the wine obtained with the AP pressing mode.

Starting from the results obtained by the PCA method, future studies will focus on the possibility of making an "ideal" wine through the estimation of a quality indicator based on the must characteristics. This indicator could also be useful to support the role of oenologists in the different phases of winemaking.

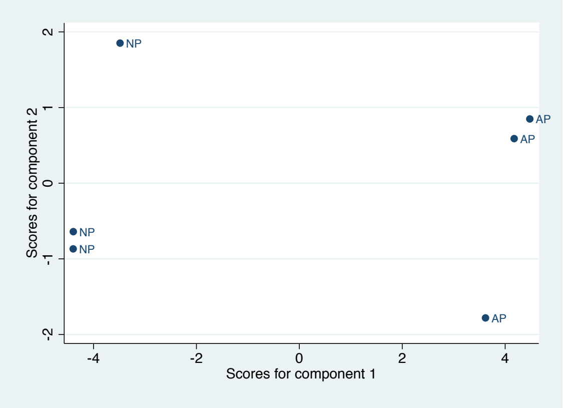

Figure 2: score plot of wine determinations in NP and AP mode

Investigating the effect of drugs consumption on survival outcome of Heart Failure patients using joint models: a case study based on regional administrative data.

Indagine sull'effetto del consumo di farmaci sulla probabilità di sopravvivenza di pazienti con Scompenso Cardiaco mediante l'utilizzo di modelli congiunti: un caso studio basato su dati amministrativi regionali.

Marta Spreafico, Francesca Gasperoni, Francesca Ieva

Abstract In this work, we propose an innovative approach for investigating the effect of drugs consumption on survival outcomes of patients affected by Hearth Failure (HF), a widespread chronic heart disease. In order to achieve this goal, we consider Joint Models approach [7] on administrative dataset of Lombardia Region. In this database several information is collected about patients' pharmacological history, which can be used to recover time-dependent data concerning drug assumptions over time. Through the application of this data, we are able to study the influence of longitudinal processes given by pharmacological treatments consumptions on patients' survival outcomes.

Abstract *In questo lavoro proponiamo un approccio innovativo per indagare l'effetto del consumo di farmaci sulla probabilità di sopravvivenza dei pazienti affetti da Scompenso Cardiaco. A tal fine, consideriamo l'approccio dei modelli congiunti [7] applicandolo al dataset amministrativo di Regione Lombardia. Questo database raccoglie diverse informazioni sulla storia farmacologica dei pazienti, le quali possono essere utilizzate per risalire a variabili tempo-dipendenti rigurdanti il consumo del farmaco nel tempo. Attraverso l'uso di questi dati, siamo in grado di studiare l'influenza del processo longitudinale dato dai trattamenti farmacologici sugli esiti di sopravvivenza dei pazienti.*

Key words: Heart Failure, drug consumption, adherence, administrative data, time-varying covariate, joint models.

1 Introduction

Heart Failure (HF) is a chronic cardiac disease, widespread all over the world especially among people over 65 years. About 80,000 new cases per year are recorded [5]. In pharmacoepidemiology the concept of adherence, which generally refers to whether a patient takes a prescribed medication according to schedule [1], is a key factor in effective disease management of many chronic conditions. Drug Utilization Research (DUR) is the branch of pharmacoepidemiology that deals with the use of drugs and it has the goal of facilitating the rational use of drugs in patients populations. For these purposes administrative data allow to measure the effective drug utilization given the limitation of not being able to assert if the patient is currently consuming the dispensed drug. In fact, in order to evaluate the use of a drug we need a statistical measure of consumption. Among possible measures introduced in [9], one of the most used is the Defined Daily Dose (DDD), which is defined as *"the assumed average maintenance dose per day for a drug used for its main indication in adults"*. DDDs can be recovered using the Anatomical Therapeutic Chemical (ATC) classification system introduced by the World Health Organization (WHO) in 1976. ATC code allows to identify phramacological classes and includes information about drug's DDD and routes of administration. DDD is a unit of measure and it does not necessarily correspond to the Prescribed Daily Dose (PDD) by a doctor. In addition to evaluate the assumed drug quantity, we want also to establish if the drug is taken continuously during all the follow up period. There exist lots of different adherence measures. According to [4], we use Proportion of Days Covered (PDC), that is:

$$\text{PDC} = \frac{\text{number of distinct coverage days}}{\text{number of days in the observation period}} \in [0,1] \tag{1}$$

Finally, using PDC, we are able to determine adherent (PDC $\geq$ 0.80) and non-adherent patients or we can categorize them in four levels of PDC, which are $[0;0.25)$, $[0.25;0.5)$, $[0.5;0.75)$ and $[0.75;1]$.

2 The dataset

In the Lombardia Region dataset patients hospitalized for HF from 2000 to 2012 are considered, as described in [6]. For our work, we use a representative sample composed by 1,333,954 events related to 4,872 patients with their first HF hospitalization between 2006-2012.

Each patient, identified by its unique anonymous ID code, is followed from the

starting date (i.e. discharge from first HF hospitalization) until death or censoring. Administrative censoring date is December 31st, 2012. For each patient, age, gender, a list of comorbidities [2] and procedures he/she underwent are recorded.
Moreover, each record in the dataset is related to an event, which can be a hospitalization or a pharmacological prescription. In the first case, the dates of admission and discharge, together with the lenght of stay in hospital are given. In the second one, ATC codes, dates of prescription and coverage days are provided. We focus our work on five pharmacological classes: ACE-Inhibitors (ACE), Angiotensin Receptor Blockers (ARB), Beta-Blocking agents (BB), Anti-Aldosterone agents (AA) and Diuretics (DIU).
Finally, for each type of drug, we calculate patients' PDC and adherence level, setting an observation period of 365 days (one year), as done in [4].

3 Time-Varying covariates

When dealing with longitudinal and/or survival data, time-dependent covariates are often of interest. Since in classical survival models adherence is usually considered as a binary fixed variable, we are interested in representing pharmacological information as a time-varying covariate, which is a more realistic representation. In particular, we want to consider treatments as time-dependent internal covariates, since they are modified according to the development of the illness.
In order to do that, we compute a time-dependent variable which indicates the total days covered by the type of drug up to time t. We set an observation period of 365 days and we consider only distinct days, which means that, in case of overlapping periods between two prescriptions, we consider the first event entirely and only the days of the second one not covered by the first. Furthermore, we hypothesize that all the prescribed types of drug are assumed by patients during the whole period of hospitalization.
Each patient could potentially have five different curves, one for each pharmacological class (ACE, ARB, BB, AA and DIU) depending on which drugs he/she assumes. An example of these types of curves is given in Fig. 1.
In our analysis all types of drug lead to similar results, so in Section 4 we report only those based on ACE to avoid repetitions.

4 Joint Model of survival and drug assumption for HF patients

In 2010 Rizopoulos proposed a Joint Model (JM) for dealing with internal time-dependent covariates [7] and wrote the associated R package `JM` [8]. We use this approach in order to investigate how patients' time-to-event outcome are influenced by longitudinal data (pharmacological treatment curves).
Let $y_i(t)$ denote the value for the longitudinal outcome at time point t for the i-th

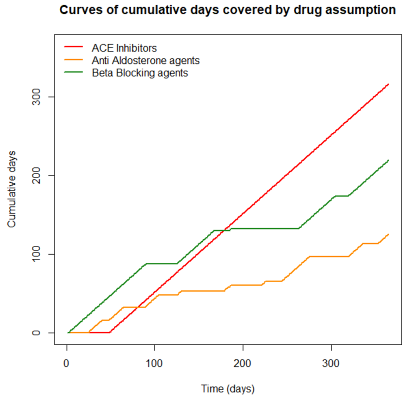

Fig. 1 Examples of time-varying curves of cumulative days covered by drug assumption for a random patient which assumes ACE (red), BB (green) and AA (orange).

subject. $y_i(t)$ is not actually observed at all time points, but only at the very specific occasions t_{ij} so the observed longitudinal data consist of the measurements $y_{ij} = \{y_i(t_{ij}), j = 1,...,n_i\}$. Let $m_i(t)$ denote the true and unobserved value of the longitudinal outcome at time t. Rizopolous supposes that there is a linear relationship between $y_i(t)$ and $m_i(t)$:

$$y_i(t) = m_i(t) + \varepsilon_i(t) = \widetilde{X}_i^T(t)\gamma + Z_i^T(t)b_i + \varepsilon_i(t) \tag{2}$$

where γ is the vector of the unknown fixed effects parameters, b_i is the vector of random effects, $\widetilde{X}_i(t)$ and $Z_i(t)$ denote row vectors of the design matrices for the fixed and random effects and $\varepsilon_i(t)$ is the normally distributed measurement error term with $\varepsilon_i(t) \sim \mathcal{N}(0,\sigma^2)$. Moreover, the random effects b_i are assumed independent of $\varepsilon_i(t)$ and normally distributed with $b_i \sim \mathcal{N}(0,D)$.
To quantify the effect of $m_i(t)$ on the risk for an event, Rizopoulos introduces the following *relative risk model*:

$$\lambda_i(t|\mathcal{M}_i(t), X_i) = \lambda_0(t)\exp\{X_i^T\beta + \alpha m_i(t)\} \tag{3}$$

where $\mathcal{M}_i(t) = \{m_i(u), 0 \le u < t\}$ denotes the history of the true unobserved longitudinal process up to time point t, $\lambda_0(\cdot)$ denotes the baseline risk function (unspecified or approximated using step functions or spline-based approaches), X_i is a vector of baseline covariates, β is the vector of regression coefficients and α is a parameter that quantifies the effect of the undelying longitudinal outcome to the survival risk for an event.
Finally, coeffients β and α have to be estimated through maximization of the log-likelihood, that is a computationally challenging task for which some numerical approximation methods are needed. In order to do that, we take advantage of the algorithms implemented in `JM` package (see [8] for details).

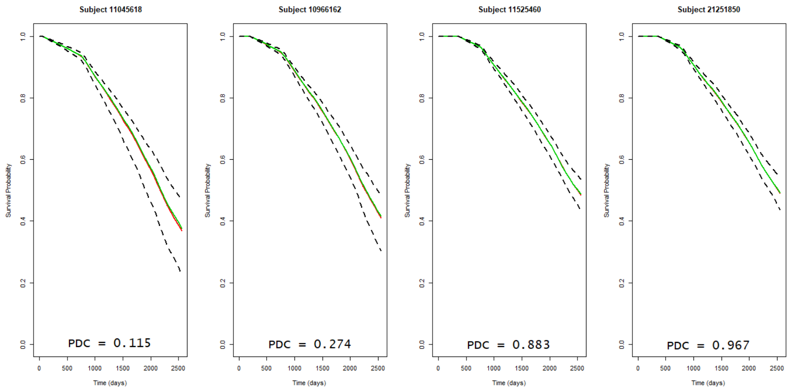

Fig. 2 Survival probability plots for female patients with 80 years old, one hospitalization and two comorbidities. From the left panel patients have a PDC of 0.115, 0.274, 0.833 and 0.967.

In our analysis the longitudinal process $m_i(t)$ is given by the square root of the value of cumulative days covered by drug assumption, whereas the survival process is adjusted according to age, gender, hospitalizations and comorbidities covariates. Moreover, we use a piecewise-constant baseline risk function and the Gauss-Hermite integration rule to approximate integrals in log-likelihood.

It results that all the covariates are significant at 5%, except for gender. In particular, being younger corresponds to a higher survival probability, whereas having a higher number of hospitalizations or of initial comorbidities corresponds to a lower survival risk, as it might be expected. We observe that the higher the value of final PDC, the higher the survival. Furthermore, having a lower PDC leads to larger confidence intervals over time, as shown in Fig. 2, so the uncertainty about the prediction of the survival outcome increases.

5 Conclusion

Modelling the drug assumption process as time-varying covariates in a joint model setting is a promising tool for exploring the effects of pharmacological treatments on survival. For example, it allows us to confirm some pharmacoepidemiological intuition as the fact that medication nonadherence is commonly associated with adverse health conditions [4] in a more suitable way.

Some improvements may be included into the model proposed in (2) in order to provide a more proper modelling of the functional covariate. Moreover, a lot of work is needed in order to include simultaneously all the treatments in a not trivial way. Limitations of administrative data should be overcome through suitable integration of administrative data with clinical registries, as proposed in [3].

Mapping the relation between University access test and student's university performance

Test d'accesso e performance universitaria

Vincenzo Giuseppe Genova, Antonella Plaia

Abstract The access test is the most used tool to evaluate the initial preparation of an italian student before enrolling at the university. Although the necessity to select the most deserving students seem unquestionably reasonable, we have to wonder if it appears to be a good predictor of university performance. In order to answer this question, the university careers of the students enrolled at two Degree Courses at the University of Palermo (academic year 2013/2014) were analysed. The very aim of this paper is to propose a graphical tool, the Student Efficiency Nomogram, that shows the access test scores together with the first-year performance of the student.

Abstract *Lo strumento più utilizzato in Italia per verificare la preparazione iniziale di uno studente universitario è il test d'accesso. Per quanto la necessità di selezionare gli studenti più meritevoli appaia indiscutibilmente ragionevole, bisogna chiedersi se il test d'accesso risulti essere un buon predittore della futura performance universitaria. Per rispondere a tale quesito sono state analizzate le carriere universitarie degli studenti di due corsi di laurea immatricolati presso l'Università degli Studi di Palermo nell'A.A. 2013/2014. In questo lavoro proponiamo uno strumento grafico, il Nomogramma d'efficienza studentesca, per mettere in relazione i punteggi conseguiti al test d'accesso con la performance dello studente alla fine del primo anno di studi universitari.*

Key words: Selective access test, first-year university career, Student Efficiency Nomogram

Antonella Plaia, Vincenzo Giuseppe Genova
Dipartimento di Scienze Economiche, Aziendali e Statistiche, University of Palermo, Viale delle Scienze, Edificio 19, 90128 Palermo, Italy, e-mail: antonella.plaia/vincenzogiuseppe.genova@unipa.it

1 Introduction

The Ministerial Decree n. 270 enters in force on 20^{th} October 2004, establishing that an adequate initial preparation is required among the minimum prerequisites to access a degree course. The most used tool to evaluate the initial preparation of a student is the access test, which is intended to select the most deserving students who will potentially continue their studies with success.[2]

The goal of this study is to understand if there exist a relationship between the access test and the student's performance. For this purpose, the analysis was carried out on the student population of two degree courses, say A and B, enrolled at the University of Palermo in the academic year 2013/2014.

2 Data and variables

The analysed dataset was provided by Sistema Informatico d'Ateneo. The dataset consisted of 504 records in 10 variables, where each record identify a statistical unit, i.e. a student enrolled on one of the two degree courses during the academic year 2013/2014. The dataset was made up of information about the student's university career and information about the score at the access test, where the latter were provided by one of the Companies in charge for the Access tests at the University of Palermo. The variables taken into account were the number of ECTSs earned the student at the end of the first academic year, the average mark at the end of the first year, and the scores for each area of knowledge. The areas of knowledge for Degree course A were Law and Economics; Italian; Logic and Philosophy; History. For degree course B they were Biology; Chemistry; Physics; Mathematics.

The analysis was focused on the first-year university career, as it has been shown that the first year is a good predictor of student performance. According to our goal, we decided to calculate the number of years expected to obtain the degree as the ratio between the number of ECTSs to get the degree (180-300 in Italy) and the number of ECTSs actually earned by the *i-th* student at the end of the first year.[1]. Actually, this is a rough prevision of the time to get the degree, but this is not the aim of this paper.

3 Student Efficiency Nomogram

According to our goal, we decided to propose a graphical method which can simultaneously evaluate different student performance indicators. The graphical method shows simultaneously: the student's average mark; the number of ECTSs earned at the end of the first year; the number of years expected to obtain degree; and the access test score.

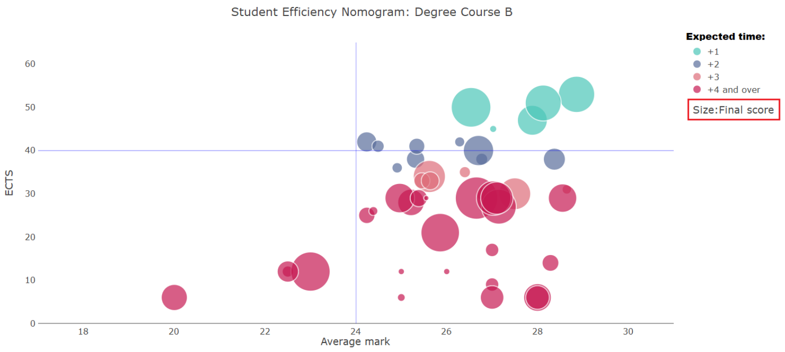

Fig. 1 Student efficiency Nomogram: Degree Course B, final score

As shown in Figure 1, the Student Efficiency Nomogram can be represented in a Cartesian coordinate system. On the horizontal axis it shows the student's average mark and on the vertical axis it shows the number of credits acquired by the student at the end of the first year. The origin of the Cartesian axes is fixed at the point of coordinates (24, 40), this choice was made in accordance with the MIUR directives. Indeed, according to the Ministry point of view, a student earning more than forty ECTSs at the end of the year is considered an efficient student.[3]

Looking at average mark, it has been decided to divide the range of values into two parts. Where, under 24, we identify a student below average and vice versa a student above average. In addition, the pair of points ($ECTS_i$, $Average\ mark_i$) identifies the number of ECTSs and the average mark of the *i-th* student at the end of the first academic year.

According to this graphical method, we have three possible scenarios: *i)* the student is highly efficient ($ECTS > 40, Average\ mark > 24$); *ii)* the student is inefficient ($ECTS < 40$, $Average\ mark < 24$); *iii)* the student is in an in between situation: efficient, but he/she doesn't show high marks or he/she is not efficient but with high mark ($ECTS > 40$, $Average\ mark < 24$ or $ECTS < 40$, $Average\ mark > 24$).

In addition, we were also interested in evaluating the information regarding the number of years expected to obtain degree and the access test score. In order to take into account this information in the graph, we assign to each observation a colour which identifies the time expected for the degree and we scale the point size proportionally to the scores gained at the access test. So, if on the one hand this tool allows to understand if the student is efficient or not, on the other hand it allows to verify if the access test was a good tool to evaluate students at the entrance. Indeed, if it was a good tool, you would expect to identify in the upper right quadrant, students with a high access test score, while in the lower left quadrant, students with a low score.

4 Results

From Figures 1 and 2 e) we can see that only 20% of the statistical units falls into the efficiency region. It is also necessary to point out that the size of the point, which expresses the total score obtained in the access test, seems to be randomly distributed among the regions of the graph. Moreover, with the exception of only 3 statistical units for Degree Course A, none of the observed students, according to the indicator used in this paper, will take is degree in time (3-5 years).

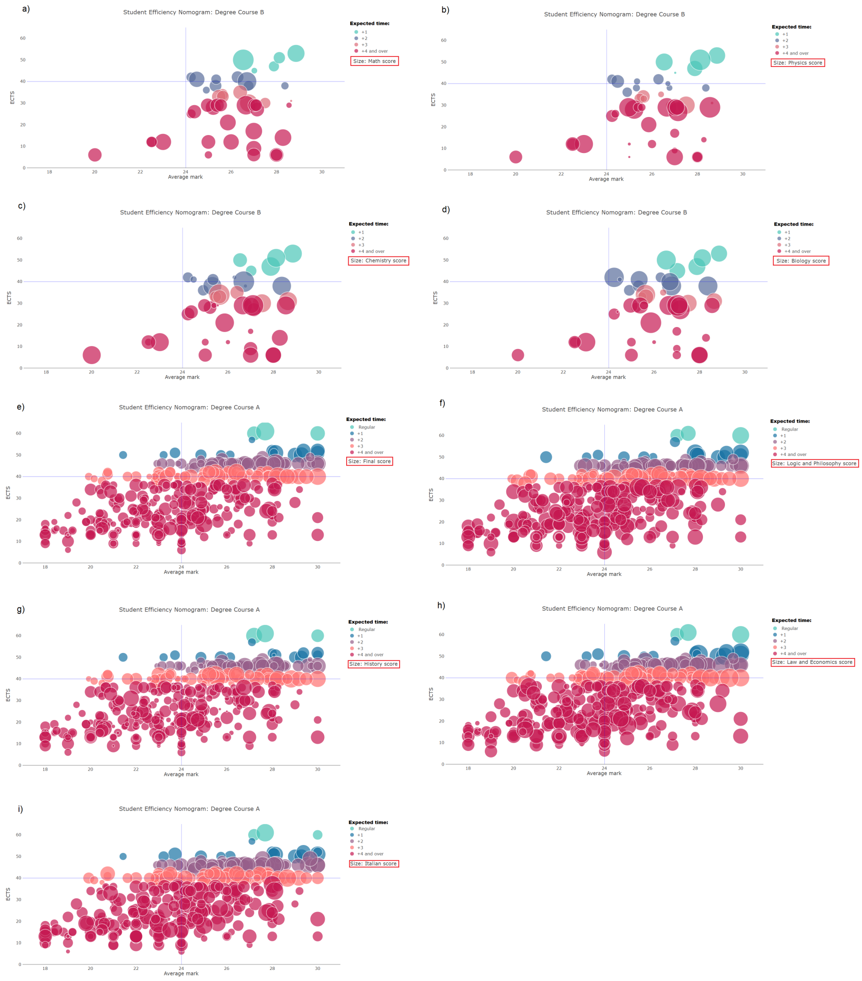

Fig. 2 Student efficiency Nomogram, Degree Courses A and B

We were interested in evaluating each areas of knowledge and in particular, we wanted to understand if at least one of the areas of knowledge of the access test was a good predictor of the student's career.

Figure 2 shows the Student Efficiency Nomograms of both the degree courses related to each areas of knowledge. We can notice that all areas of knowledge do not appear as good predictors of the university career performance. Anyway, Biology and History seem to have a greater discriminant effect, but not enough to call them predictors of student's performance.

To validate our graphical method a zero-one inflated (Course A) and a zero inflated (Course B) model were applied [4, 5], and in particular we have analyzed the relationship between the fraction of ECTSs and the set of explanatory variables for both the Degree Courses.

Table 1 Model coefficients of Degree Course A

μ **(fraction)**	**Estimate**	**S.e**.	***p-value***
Intercept	−2.70	0.39	0.000
Law and Economics score	0.45	0.29	0.12
High school mark	0.02	0.004	0.000
Classical high school	0.24	0.21	0.26
Teacher-training high school	−0.12	0.27	0.64
ITC high school	−0.36	0.29	0.21
Scientific high school	0.18	0.22	0.41
Male	−0.19	0.09	0.03
α **(zero-inflated)**	**Estimate**	**S.e.**	***p-value***
Intercept	5.40	1.66	0.001
History score	−1.99	1.25	0.11
Law and Economics score	−2.34	1.34	0.08
High school mark	−0.04	0.02	0.01
Classical high school	−2.53	0.62	0.000
Teacher-training high school	−0.68	0.67	0.30
ITC high school	−0.88	0.74	0.23
Scientific high school	−2.09	0.63	0.001
τ **(one-inflated)**	**Estimate**	**S.e.**	***p-value***
Intercept	−18.46	8.79	0.03
High school mark	0.15	0.09	0.09
ϕ **(precision)**	**Estimate**	**S.e.**	***p-value***
Intercept	−0.43	0.04	0.000

Looking at Table 1 (Degree Course A), we can notice that the History score, and the Law and Economics score reduce the probability of obtaining zero ECTSs at the end of the first year, but they haven't a significant effect on average (Table 1 - top section). Table 2 (Degree Course B) shows a reduction in probability of obtaining zero ECTSs due to the Physics score Table 2 - mid section), but we can notice only a significant positive effect on average (Table 2 - top section) due to the Biology score. The same analysis was carried out analyzing the relationship between the *Average mark* and the set of explanatory variables, whithout obtaining results significantly different from those in Tables 1 and 2.

Table 2 Model coefficients of Degree Course B

μ **(fraction)**	**Estimate**	**S.e.**	***p-value***
Intercept	-8.72	1.29	0.000
Physics score	1.06	0.66	0.11
Chemistry score	-2	0.89	0.03
Biology score	3.39	1.55	0.03
High school mark	0.05	0.007	0.000
Classical high school	1.13	0.32	0.001
Scientific high school	1.02	0.19	0.000
Male	0.76	0.17	0.000
Public school	1.13	0.62	0.07
α **(zero-inflated)**	**Estimate**	**S.e.**	***p-value***
Intercept	-1.48	5.53	0.78
Classical high school	-4.15	2.03	0.04
Scientific high school	-3.55	1.68	0.04
Physics score	-6.34	3.81	0.10
High school mark	0.06	0.06	0.32
ϕ **(precision)**	**Estimate**	**S.e.**	***p-value***
Intercept	20.37	0.02	0.000
Classical high school	-19.14	0.31	0.000
Scientific high school	-18.28	0.26	0.000

According to these results, we can conclude that our graphical tool is an easy way to analyze the student performance in relationship with access test.

Multivariate analysis of marine litter abundance through Bayesian space-time models

Analisi multivariata dell'abbondanza di rifiuti marini attraverso modelli bayesiani spazio-temporali

C. Calculli, A. Pollice, L. Sion, and P. Maiorano

Abstract This work focuses on the analysis of abundance data for marine litter categories, collected during trawl surveys regularly conducted at local scale, in the Central Mediterranean. Here marine litter data are modeled in order to estimate the effects affecting the dynamics of litter assemblages at different spatio/temporal scales. A correlated response model with latent variables is proposed. This modeling approach is particularly suitable to infer potential environmental covariates while controlling for correlation between litter categories and providing a method for residual ordination. MCMC estimation is implemented within the Bayesian hierachical framework that allows to integrate environmental and anthropogenic processes into a single model.

Abstract *Questo lavoro riguarda l'analisi delle abbondanze di diverse categorie di rifiuti marini, censiti durante campagne di pesca a trascico condotte su scala locale nel Mediterraneo centrale. In questo ambito, i dati sui rifiuti sono modellati al fine di investigare i fattori che influiscono sulle dinamiche di aggregazione dei rifiuti su scala spazio/temporale. Viene presentato un modello con risposte correlate che rappresenta un approccio particolarmente idoneo per investigare l'influenza di covariate ambientali, controllare la correlazione tra categorie di rifiuti e fornire un metodo per l'ordinamento residuale. Stime MCMC sono implementate nel contesto bayesiano gerarchico che permette di integrare processi ambientali e antropogenici in un unico modello.*

1 Introduction

Marine litter has recently become a recognized global and local ecological concern that might jeopardize the status of marine ecosystems. The debris quantity and its distribution on the Mediterranean seafloor are still not well-known although the effects on the sea bed and on the marine living communities are pretty clear [1]. Experimental bottom trawl surveys carried out in the Mediterranean basin in the last years represent a valuable source of information about wastes; litter typologies can be seen as special items caught by the trawl net together with marine species. While single-species distribution models have been commonly used to explain and predict the response of different taxa to environmental variation, the analysis at the community-level is still lacking. Some innovative approaches that explicitly acknowledge the multivariate nature of species assemblages were recently proposed [2, 4]. These approaches model the actual processes that determine the assemblage of community samples, taking into account for the various sources of correlation across species. In this study we analyze multivariate litter abundance data using a correlated response model in the spirit of [2]. This model merges univariate Generalized Linear Models with latent variables to account for the residual correlation across litter categories, *e.g.* due to environmental interactions or unaccounted covariates. Latent variables provide a method for "residual ordination". The whole implementation is performed in a hierarchical Bayesian framework.

2 Materials and Methods

2.1 Study area and data

Litter data are collected during experimental trawl surveys conducted from 2013 to 2017 in the North-Western Ionian Sea as a complementary (voluntary) activity of the international project MEDITS (MEDiterranean International Trawl Surveys). The North-Western Ionian is the deepest sea in the Mediterranean basin characterized by a complex geomorphology and the presence of important fisheries as well as main harbours. An increasing touristic activity is developing along the Ionian coasts, thus the sea bottoms are here exposed to a strong increase in anthropogenic impact.The same 70 depth-stratified hauls are carried out between 10 and 800 m in depth every year, summing to 350 hauls in 5 years. Wastes caught during the trawl surveys are classified in 8 categories: plastic, rubber, metal, glass/ceramic, cloth/natual fibres, processed wood, paper/cardboard, other/unspecified. The number of collected items for each litter category was scaled to the swept surface unit (1 km^2), thus obtaining density indices (N/km^2) for each litter category and survey at every haul location. Litter density is a semi-continuous zero-inflated non-negative variable. Preliminarily, to investigate factors influencing the density of litter categories, we consider only the seafloor depth as environmental covariate.

2.2 Statistical framework

To investigate assemblage of litter in terms of density and composition, a mixture model where latent variables are included alongside the measured covariates is proposed. In particular, densities of litter categories are jointly modeled as semi-continuous zero-inflated multivariate responses assuming the Tweedie distribution model. The mean density μ_{ij} of the j-th litter category at the i-th haul is specified by the following mixture model:

$$g(\mu_{ij}) = \alpha_1(t_i) + \alpha_2(s_i) + \beta_{0j} + \sum_{k=1}^{p} \beta_{jk} X_{ik} + z_i' \theta_j \quad i = 1, \dots, 350; \quad j = 1, \dots, 8 \quad (1)$$

where $g(\cdot)$ is the link function, $\alpha_{1,2}(\cdot)$ are effects adjusting for differences in site and time (year) on the overall litter density, β_{0j} is the litter type-specific intercept and β_{jk} is the type-specific regression coefficient of the k-th covariate (preliminarily, only the seafloor depth). Finally, $z_i = (z_{i1}, \dots, z_{iq})'$ is a q-dimensional vector of latent variables, while $\theta_j = (\theta_{j1}, \dots, \theta_{jq})$ are the corresponding litter type-specific loadings. Latent variables can be considered here as missing informative predictors for the multivariate response inducing residual correlation between litter categories. Independent weakly informative $N \sim (0, 10)$ priors were assumed for all site and time effects, type-specific intercepts, type-specific regression coefficients, latent variables and loadings. Uniform priors $U \sim (0, 30)$ are adopted for all dispersion and variance parameters in the model. Inferences for model in Eq. 1 were implemented by the `boral` package [2] that provides an interface between `R` and `JAGS` [5] for multi-species models with latent variables.

3 Results

The model in Eq.1 was fitted with 1 to 3 latent variables and with fixed or random site and time effects. All model estimates were obtained using 20,000 iterations, discarding the first 5,000. The Geweke diagnostic and the graphical inspection of trace plots provided clear evidence of the convergence of MCMC chains for all model parameters. As reported in Table 1, the best models in terms of lowest BIC consider random site/time effects. Results for the model with two latent variables, that also enable to draw a scatterplot of the ordinations as for distance-based techniques, suggest a positive correlation between plastic and glass litter due to depth (Figures 1A-B). Strong, positive residual correlations are observed: plastic is correlated with all other materials except for metal and other/unspecified wastes. Estimated spatial effects represented in Figure 1C, allow to identify some *hot-spots* assemblages for all litter categories. This work represents a starting point for the analysis of space/time structured multivariate litter data. Further developments include the selection among

Table 1: Values of the BIC for models with 1-3 latent variables (LVs) and fixed/random site and time effects

	site/time effects	
	fixed	random

Power Priors for Bayesian Analysis of Graphical Models of Conditional Independence in Three Way Contingency Tables

Power Prior per l'analisi bayesiana di modelli grafici di indipendenza condizionale in tabelle di contingenza a tre vie

Katerina Mantzouni, Claudia Tarantola and Ioannis Ntzoufras

Abstract In this paper we illustrate a comprehensive Bayesian analysis of graphical models of conditional independence, involving suitable choices of prior parameters, estimation, model determination, as well as the allied computational issues for three way contingency tables. Each conditional independence model corresponds to a particular factorization of the cell probabilities and a conjugate analysis based on Dirichlet prior can be performed. Unit information interpretation priors are used as a yardstick in order to identify and interpret the effect of any other prior distribution used. The posterior distributions of the graphical models parameters, are obtained using simple Markov chain Monte Carlo (MCMC) schemes. A real data application will be analytically presented in the poster.

Abstract *In questo lavoro sviluppiamo un'analisi Bayesiana completa di modelli grafici di indipendenza condizionale, inclusa la scelta di opportuni parametri iniziali, stima, scelta del modello, nonché i problemi computazionali collegati per le tabelle di contingenza a tre vie. Ogni modello di indipendenza condizionale corrisponde a una fattorizzazione particolare delle probabilit di cella e puó essere eseguita un'analisi coniugata utilizzando prior Dirichlet. Prior di tipo Unit information sono usate come termine di paragone per identificare e interpretare l'effetto delle altre prior proposte. Le distribuzioni a posteriori dei parametri dei modelli grafici, sono ottenute utilizzando semplici schemi Markov della catena Monte Carlo (MCMC). Nel poster verrà descritta un'applicazione a dati reali.*

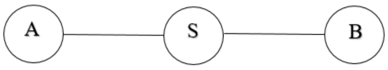
1 Graphical Models of Conditional Independence

The use of graphical models to describe association between categorical variables dates back to the work of Darroch *et al.* (1980), where graphical log-linear models were introduced. Graphical models turns out to be an efficient methodology for categorical data analysis and in this paper we focus of on graphical models of conditional independence. Conditional independence is important when modelling highly complex systems.

A undirected graph $G = (\mathscr{V}, E)$ is characterized by a vertex set $\mathscr{V}$ and an edge set E. For sets A, B and $S \subset \mathscr{V}$, A nd B are conditionally independent given S, whenever A and B are separated by S, all path in the graph connecting A and B pass through S. Discrete random variables X_v, $v \in \mathscr{V}$ defined by undirected graphs and the cliques of the graph correspond to the maximal terms in log-linear model.

Dawid and Lauritzen (1993) described the Bayesian framework for decomposable models. Figure 1 shows such a model which also embodies the assumption that A and B are independent given S.

Fig. 1 A decomposable undirected graphical model



The cliques of this graph are A, S and S, B and there is a single intersection S. The factorization form of the joint distribution given by:

$$P(ABS) = \frac{P(AS)P(SB)}{P(S)} = P(A|S)P(B|S)P(S) \tag{1}$$

In this paper we focus in decomposable models in three way contingency tales, for which the graph is chordal. These are the closed form log-linear models and their parameter can be estimated without the utilization of iterative methods.

2 Conjugate Priors

In the following we work using conjugate priors on the probability parameters and then calculate the corresponding log-linear parameters using Monte Carlo schemes. For the specification of the prior distribution on the probability parameter vector we initially consider a Dirichlet distribution with parameters $\alpha = \big(\alpha(i), i \in \mathscr{I}\ \big) = \big(\alpha_{abc}, a = 1, \ldots, |\mathscr{I}_A|, b = 1, \ldots, |\mathscr{I}_B|, c = 1, \ldots, |\mathscr{I}_C|\ \big)$ for the vector of the joint probabilities of the full table π. Hence, for the full table $\pi \sim \mathscr{D}i(\alpha)$ with prior density given by

$$
\begin{aligned}
f(\pi) &= \frac{\Gamma(\alpha)}{\prod\limits_{i\in\mathscr{I}} \Gamma\Big(\alpha(i)\Big)} \prod_{i\in\mathscr{I}} \pi(i)^{\alpha(i)-1} \\
&= \frac{\Gamma(\alpha)}{\prod\limits_{a=1}^{|\mathscr{I}_A|}\prod\limits_{b=1}^{|\mathscr{I}_B|}\prod\limits_{c=1}^{|\mathscr{I}_C|} \Gamma\Big(\alpha_{abc}\Big)} \prod_{a=1}^{|\mathscr{I}_A|}\prod_{b=1}^{|\mathscr{I}_B|}\prod_{c=1}^{|\mathscr{I}_C|} \pi_{abc}^{\big(\alpha_{abc}-1\big)} = f_{\mathscr{D}i}(\pi;\,\alpha)
\end{aligned}
\tag{2}
$$

where $f_{\mathscr{D}i}\big(\pi;\ \alpha\big)$ is the density function of the Dirichlet distribution evaluated at π with parameters α and $\alpha = \sum_{i\in\mathscr{I}} \alpha(i)$.

When no prior information is available then we usually set all $\alpha(i) = \frac{\alpha}{|\mathscr{I}|}$ resulting to

$$
E\big[\pi(i)\big] = \frac{1}{|\mathscr{I}|} \ \text{ and } \ V\big[\pi(i)\big] = \frac{|\mathscr{I}|-1}{|\mathscr{I}|^2(\alpha+1)}\ .
$$

Small values of α increase the variance of each cell probability parameter. Usual choices for α are the values $|\mathscr{I}|/2$ (Jeffrey's prior), $|\mathscr{I}|$ and 1 (corresponding to $\alpha(i)$ equal to $1/2$, 1 and $1/|\mathscr{I}|$ respectively); for details see Dellaportas and Forster (1999). The choice of this prior parameter value is of prominent importance for the model comparison due to the well known sensitivity of the posterior model odds and the Bartlett-Lindley paradox (Lindley, 1957, Bartlett, 1957). Here this effect is not so adverse, as for example in usual variable selection for generalized linear models, for two reasons. Firstly, even if we consider the limiting case where $\alpha(i) = \frac{\alpha}{|\mathscr{I}|}$ with $\alpha \to 0$, the variance is finite and equal to $(|\mathscr{I}|-1)/|\mathscr{I}|^2$. Secondly, the distributions of all models are constructed from a common distribution of the full model/table making the prior distributions 'compatible' across different models (Dawid and Lauritzen, 2000 and Roverato and Consonni, 2004).

3 Power Priors

In graphical model literature there is a debate about the use of conjugate priors based on Dirichlet distributions; see for example in Steck and Jaakkola (2002), Steck (2008) and Ueno (2008). The parameters of the Dirichlet prior should be carefully specified. In order to do this we adopt ideas based on the power prior approach of Ibrahim and Chen (2000) and Chen *et al.* (2000). We use their approach to advocate sensible values for the Dirichlet prior parameters on the full table and the corresponding induced values for the rest of the graphs.

3.1 Specification of Prior Parameters Using Imaginary Data

Let us consider imaginary set of data represented by the frequency table $n^* = (n^*(i), i \in \mathscr{I})$ of total sample size $N^* = \sum_{i \in \mathscr{I}} n^*(i)$ and a Dirichlet 'pre-prior' with all parameters equal to α_0. Then the unnormalized prior distribution can be obtained by the product of the likelihood of n^* raised to a power w multiplied by the 'pre-prior' distribution. Hence

$$\begin{aligned} f(\pi) &\propto f(n^*|\pi)^w \times f_{\mathscr{D}i}\big(\pi;\ \alpha(i) = \alpha_0, i \in \mathscr{I}\big) \\ &\propto \prod_{i \in \mathscr{I}} \pi(i)^{wn^*(i)+\alpha_0-1} \\ &= f_{\mathscr{D}i}\big(\pi;\ \alpha(i) = wn^*(i) + \alpha_0, i \in \mathscr{I}\big)\ . \end{aligned} \tag{3}$$

Using the above prior set up, we expect a priori to observe a total number of $wN^* + |\mathscr{I}|\alpha_0$ observations. The parameter w is used to specify the steepness of the prior distribution and the weight of belief on each prior observation. For $w = 1$ then each imaginary observation has the same weight as the actual observations. Values of $w < 1$ will give less weight to each imaginary observation while $w > 1$ will increase the weight of believe on the prior/imaginary data. Overall the prior will account for the $(wN^* + |\mathscr{I}|\alpha_0)/(wN^* + N + |\mathscr{I}|\alpha_0)$ of the total information used in the posterior distribution. Hence for $w = 1$, $N^* = N$ and $\alpha_0 \to 0$ then both the prior and data will account for 50% of the information used in the posterior.

For $w = 1/N^*$ then $\alpha(i) = p^*(i) + \alpha_0$ with $p^*(i) = n^*(i)/N^*$, the prior data n^* will account for information of one data point while the total weight of the prior will be equal to $(1 + |\mathscr{I}|\alpha_0)/(1 + N + |\mathscr{I}|\alpha_0)$. If we further set $\alpha_0 = 0$, then the prior distribution (3) will account for information equivalent to a single observation. This prior set-up will be referred in this paper as the unit information prior (UIP). When no information is available, then we may further consider the choice of equal cell frequencies $n^*(i) = n^*$ for the imaginary data in order to support the simplest possible model under consideration. Under this approach $N^* = n^* \times |\mathscr{I}|$ and $w = 1/N^* = \frac{1}{n^* \times |\mathscr{I}|}$ resulting to

$$\pi \sim \mathscr{D}i\Big(\alpha(i) = 1/|\mathscr{I}|, i \in \mathscr{I}\Big)\ .$$

The latter prior is equivalent to the one advocated by Perks (1947). It has the nice property that the prior on the marginal parameters does not depend on the size of the table. This property is retained for any prior distribution of type (3) with $w^* = 1/N^*$, $p^*(i) = 1/|\mathscr{I}|$ and $\alpha_0 \propto 1/|\mathscr{I}|$.

3.2 Comparison of Prior Set-ups

Since Perks' prior (with $\alpha(i) = 1/|\mathscr{I}|$) has a unit information interpretation, it can be used as a yardstick in order to identify and interpret the effect of any other prior distribution used. Prior distributions with $\alpha(i) < 1/|\mathscr{I}|$, or equivalently $\alpha < 1$, result in larger variance than the one imposed by our proposed unit information prior and hence they a posteriori supports more parsimonious models. On the contrary, prior distributions with $\alpha(i) > 1/|\mathscr{I}|$, or $\alpha > 1$, result in lower prior variance and hence they a posteriori support models with more complicated graph structure. So the variance ratio between a Dirichlet prior with $\alpha(i) = \alpha/|\mathscr{I}|$ and Perks prior is equal to

$$VR = \frac{V\big(\pi(i)\big|\ \alpha(i) = \frac{\alpha}{|\mathscr{I}|}\big)}{V\big(\pi(i)\big|\ \alpha(i) = |\mathscr{I}|^{-1}\big)} = \frac{2}{\alpha+1}\ .$$

In this parer we considered the comparison of the information from the following prior choices:

(i) the Jeffrey's prior with $\alpha(i) = 1/2$;
(ii) the Unit Expected Cells prior (UEC) with $\alpha(i) = 1$;
(iii) the Unit Information Prior (UIP) which is derived by a power prior with $\alpha(i) = p^*(i)$, $w = 1/N^*$ and $a_0 = 0$; where $p^*(i)$ is the sample proportion of cell i estimated from a set of imaginary data $n^*(i)$;
  (a) Perks' prior (UIP-Perks') with $\alpha(i) = 1/|\mathscr{I}|$ which is equivalent to UIP coming from a table of imaginary data with all cell frequencies equal to one;
  (b) the Unit Information Empirical Bayes Prior (UI-EBP), which is derived by UIP with $p^*(i)$ set equal to the sample proportions $p(i) = n(i)/N$.

It is observed that Jeffreys' prior variance is lower than the corresponding Perks' prior. The reduction is even greater for the Unit Expected Cell prior reaching. Finally, for the Empirical Bayes prior, based on the UIP approach, the prior variance for each $\pi(i)$ is equal to $V[\pi(i)] = \frac{1}{2}p(i)\big(1-p(i)\big)$. Hence it depends on the observed proportion and can vary from zero (if $p(i) = 0$ or 1) to $1/8$ if $p(i) = 1/2$. For values in the interval $(0.058, 0.942)$ the variance of the UI-EBP is higher than the corresponding UIP variance reaching its maximum when $p(i) = 1/2$ where it is 4.6 times the corresponding UIP prior variance. For $p(i) = 0.058$ or 0.942 the variances of the UIP and UI-EBP are equal while for the remaining values, UIP variance is higher.

3.3 Illustrative examples

We consider a data set presented by Healy (1988) regarding a study on the relationship between patient condition (more or less severe), assumption of antitoxin (yes or not) and survival status (survived or not); see Table 1.

Table 1 Antitoxin data

		Survival (S)	
Condition (C)	Antitoxin (A)	No	Yes
More Severe	Yes	15	6
	No	22	4
Less Severe	Yes	5	15
	No	7	5

We compare posterior model probabilities under the four different prior setups, we compare the results obtained with our yardstick prior, the UIP-Perks' prior ($\alpha(i) = 1/|I|$), with those obtained using Jeffrey's ($\alpha(i) = 1/2$), Unit Expected Cell ($\alpha(i) = 1$), and unit information Empirical Bayes ($\alpha(i) = p(i)$) priors.Under all prior assumptions the maximum a posteriori model (MAP) is SC+A , assuming the conditional independence of Antitoxin from the remaining two variables.

Random Garden: a Supervised Learning Algorithm

Giardino Casuale: un Algoritmo di Apprendimento Supervisionato

Ivan Luciano Danesi, Valeria Danese, Nicolò Russo and Enrico Tonini

Abstract Classification and Regression Trees model and two other tree-based models are considered. These latter tree-based models are the Random Forest and the Random Garden, presented in this work. The feature selection impact on the different algorithms is investigated. The described procedures are applied to 18 Customer Relationship Management data sets constructed in Banking field. The goal is binary classification. Our results show that the best algorithm depends on data set characteristics, as dimensions, proportion of success events and the application of feature selection.

Abstract *Gli alberi di classificazione e di regressione e altri due modelli ad albero sono considerati. Questi ultimi sono la Foresta Casuale e il Giardino Casuale, presentato in questo lavoro. L'impatto della selezione delle variabili è investigato. Le procedure descritte sono applicate a 18 tabelle costruite per la gestione della relazione con i clienti in un contesto bancario. Lo scopo è una classificazione binaria. I nostri risultati mostrano come il migliore algoritmo dipenda dalle caratteristiche dei dati, come dimensioni, proporzione di successi e l'applicazione di procedure di selezione delle variabili.*

1 Introduction

In Big Data era, the Customer Relationship Management (CRM) has been receiving a great deal of attention. CRM can leverage on several data sources. During the years, clients' data have been collected in many forms. Today there is the technology for the storage of all of these data in the same place, as well as the tools for merging and using them.

In this work we apply tree-based classification models to different data sets of an important financial institution. Such data sets are constructed in CRM field. The goal of classification applications is to discriminate between success and failure events. The success events are defined as CRM relevant occurrences (*e.g.* claims or product purchases).

Firstly, the features useful for the modeling step are selected. During feature selection step, we consider either a supervised and an unsupervised approach.

Secondly, three tree-based models are applied. A Classification and Regression Tree (CART) model is used as benchmark for our evaluation. The *random forest* algorithm, the most diffused algorithm for bagging and ensembling trees, is then considered. Finally, the *Random Garden*, a CART bagging designed for high dimensional data, is applied.

The tree-based models are estimated on the different data sets, with and without feature selection.

In Section 2 the feature selection techniques and the algorithms are briefly outlined. The results are presented in Section 3 and discussed in Section 4.

2 Section Heading

2.1 Feature Selection

Usually the higher the number of features that can be collected, the more relevant is discriminating between valuable predictors (to be kept) and not (to be discarded). The consequences of including non-informative features in a model may be different, depending on the selected algorithm. Furthermore, in presence of a high number of features, some relevant ones could not be included in trees splitting process enough times to correctly determine the results, as pointed out in [5].

Feature selection procedures can be mainly divided in two categories: wrapper methods and filter methods ([4]). The former involves the use of predictive algorithms while the latter approach analyzes the features one by one and keeps only the ones satisfying a defined rule.

As wrapper methods, we consider the permutation test and as filter one the analysis of variance and correlations predictors. From now on, we refer them as our features selection (FS) procedures through which we generate the datasets.

2.2 *Considered Tree-Based Algorithm*

2.2.1 Classification and Regression Trees

Classification and Regression Trees (CART) are constructed to generate a response or a class Y using a set of inputs $X_1, \dots, X_p$ by means of binary splits (see [2] for details).

2.2.2 Random Forest

Random forests (RF) [1] improve predictive accuracy by generating a large number of random trees, then classifying a case using each tree in this new *forest*, and deciding a final predicted outcome by combining the results across all the trees.

More specifically, from the available data a number k of bootstrapped training samples is considered. On each of these k samples, a prediction tree is constructed considering, at each split, a random sample of $m < p$ predictors. This selection of predictors is performed in order to avoid that the strongest predictors would determine the top split in almost all the estimated trees. On the contrary, sampling at each split m predictors, the strong predictor is considered $(p-m)/p$ times. The result is a *forest* composed by *decorrelated* trees. This is done since averaging not-correlated quantities leads to a variance reduction, otherwise higher averaging high-correlated quantities. In random forests the trees are usually fully grown.

2.2.3 Random Garden

In this work, we introduce an algorithm for ensembling fully grown CART in order to generate a forest. The trees are different from each other by randomly selecting both the individuals (bagging) and the features, like random forest. More in detail, the algorithms is composed by the following steps.

1. The features are divided into two groups, based on their impact on the response variable. Features impact on the response variable is evaluated by using the p-value of a correlation test between features and the response variable. The choice of correlation test depends on variable type:

   - $F-$test for binary features;
   - χ^2-test for categorical features with more than 2 levels;
   - Wilcoxon test for numerical features.

   Features with p-value less or equal to critical value 0.05 are considered highly relevant, otherwise less relevant. The former and the latter group constitute the sample F_R and F_N of features respectively. Clearly $F_R \cup F_N = F$, where F is the complete set of features.
2. Each tree is constructed by

a. Sampling with a replacement of a number of records equal to the total amount of observations, thus considering on average 63.21 % different observations in each sample (see [2]).
b. Sampling *mtry* number of features, set by default equal to the square root of the dimension of F. This sample is constructed in a stratified way from F_R and F_N sets. From F_R are extracted q_R features, where q_R is the proportion of F_R dimension with respect to F dimension. Conversely, from F_N are extracted q_N=*mtry*-q_R features.
c. Growing a fully grown CART (not pruned).

3. Considering the mean of all CART outputs as predicted response variable.

The result is a forest of trees with a lower number of freedom degrees than Random Forest trees. Since the trees are constructed one by one and well-finished, we name this algorithm as Random Garden (RG).

The procedure described above for RG is different from RF mainly due to the random feature selection, since it is performed in a stratified way. An example of RF definition with stratified random feature selection is given by xRF algorithm introduced in [5]. In this study our aim is to stress the differentiation of the trees. As a matter of fact, we do not extract the features at each split as in xRF, but we sample features once for each tree during RG construction.

3 Application

3.1 The Data

The application is performed on 18 datasets collected in a financial institution [1]. Datasets are related to Bank customers and are constructed by merging different sources of data and this has been the first step of the analysis. The response variable is binary (0 or 1, for failure and success respectively). Data sets characteristics are in Table 1.

By looking at Table 1, we can identify three clusters of datasets with respect to Ncust and Pev characteristics. The clusters index is indicated in Table 1. In particular we observe three clusters.

Cluster 1. Population with higher number of customers and lower proportion of success events.
Cluster 2. Population with lower number of customers and lower proportion of success events.
Cluster 3. Population with lower number of customers and higher proportion of success events.

[1] More details about the datasets are not provided due to Legal and Compliance issues.

Table 1 Index number of data set (DS), number of features (Nfeat), number of customers (Ncust), number of events (Nev), proportion of success events in percentage (Pev) and relative cluster (Cluster) for the 18 data sets.

DS	Nfeat	Ncust	Nev	Pev	Cluster
1	311	576546	1983	0.344	1

17	932	421887	8903	2.110	1
18	578	11801	515	4.364	2

3.2 Results

Datasets are divided in training and test sets. The training set is used for model estimation and is composed by the 30% of the observations, while the testing set is used for model performance evaluation and is composed by the remaining 70% of the observations. We apply Monte Carlo cross-validation. This procedure creates multiple splits of data into train and test sets and each split is randomly performed from the full dataset. The number of random splits is set equal to 50.

For every combination of dataset, Monte Carlo split and algorithm/feature selection configuration, the model is trained and tested for measuring the performance indicators. Overall, 5400 different models are trained. We choose Area Under ROC Curve (AUC) as performance metric due to its relevance in this application ([3]). As a matter of fact, we are interested in *ranking* the customers according to the model output. We report a summary for AUC values in Table 2.

4 Discussion

The approaches show good performances applied to the different datasets in almost all the trials. As expected, results can be very different among the datasets.

Algorithms performances, measured as AUC score, seems to be related to the cluster where each dataset belongs to. By way of example, in Clusters 1 and 2 which

Table 2 AUC values on average for the three dataset clusters for the different algorithm and FS configurations.

FS	Algorithm	Cluster 1	Cluster 2	Cluster 3
no	CART	0.7136	0.7568	0.8702
	RF	0.7977	0.7833	0.8827
	RG	0.8074	0.7995	0.8359
yes	CART	0.7470	0.7359	0.8589
	RF	0.7935	0.7690	0.8767
	RG	0.8026	0.7923	0.8403

are the ones exhibiting the lowest percentages of positive targets, RG algorithm performs better, RF one performs worse although much better than CART. On the other hand, on Cluster 3 datasets which are the ones with a smaller customer size and more balanced in terms of positive targets proportion, RF is the algorithm performing better, followed by CART and RG. Regarding the impact of the FS procedure, the more valuable improvement is observed only for CART.

Declaration of Interest

The views and opinions expressed in this paper are those of the authors only, and do not necessarily represent the views and opinions of UniCredit Business Integrated Solutions S.C.p.A. or any other organization. All the computations have been conducted on anonymized data on UniCredit servers by UniCredit employee. The results have been observed only in aggregated form.

Spatiotemporal Prevision for Emergency Medical System Events in Milan

Andrea Gilardi, Riccardo Borgoni, Andrea Pagliosa, Rodolfo Bonora

Abstract Organizing the emergency medical system in a big city is an extremely difficult task given the huge number of people that everyday pass through the city area. In this paper we employ a spatio-temporal process to model the emergency event occurrences in Milan. The proposed approach has been found effective in predicting events through the city area and computationally efficient despite the big amount of data to be processed.
Abstract *L'organizzazione di un servizio di emergenza sul territorio risulta essere un compito complesso nelle aree metropolitane come Milano dato l'enorme numero di persone che vi transitano quotidianamente. In questo lavoro si adotta un modello spazio temporale per rappresentare la dinamica delle chiamate di emergenza sul territorio del capologuo Lombardo. Il metodo adottato si é dimostrato essere efficace nel prevedere gli eventi sul territorio comunale nel periodo di tempo considerato e computazionalmente efficiente nonostante la consistente mole di dati da elaborare.*

Key words: emergency medical system, spatio-temporal point process

1 Introduction

Given the large number of people that everyday pass through the metropolitan area, the organization of the emergency medical system (EMS) in Milan is an extremely

Andrea Pagliosa, Rodolfo Bonora
AREU (Azienda Regionale Emergenza Urgenza)

difficult task. Numerous studies have proposed different models for the optimal allocation of ambulances in the territory and each of these models is based on ad-hoc predictions for the future locations of emergency events. In this paper we implemented an algorithm that predicts the distribution of the ambulance interventions in Milan for every hour of the day and every place of the urban area.

All ambulance dispatches from 1st of January 2015 till 25th of September 2017 have been considered for a total of, approximately, 500’000 events. The spatial distribution of the events is reported in (Figure 1-(a)). The figure clearly points out an anomalous pick of event intensity in the north-west part of the map caused by the universal exposition hosted by Milan (EXPO) that took place in this area in 2015. All the events occurred in the EXPO area have been removed from the subsequent analysis.

This type of data is challenging for several reasons:

Sparsity: even if the dataset is extremely large, there are only 21 events per hour on average scattered on an area of about 180 km^2;

Computational challenges: the numerical estimation of a spatio-temporal model is particularly difficult considering the long training time of the algorithms;

Seasonality: the total number of events per hour exhibits both daily and weakly seasonality (Figure 1-(b)).

2 Spatio-Temporal Model

Using the approach suggested in [5], we modeled Milano’s ambulance demand on a continuous spatial domain $S \in \mathbb{R}^2$ and a discretized temporal domain of one-hour intervals $T = \{1, 2, \ldots, \}$. We assumed that ambulance demand follows a Non-homogeneous Poisson Process [1] with intensity function $\lambda_t(\mathbf{s})$ for each time period t. Furthermore, we decomposed this intensity function as

$$\lambda_t(\mathbf{s}) = \delta_t f_t(\mathbf{s}), \quad \mathbf{s} \in S \subseteq \mathbb{R}^2,\ t \in \mathbb{N} \tag{1}$$

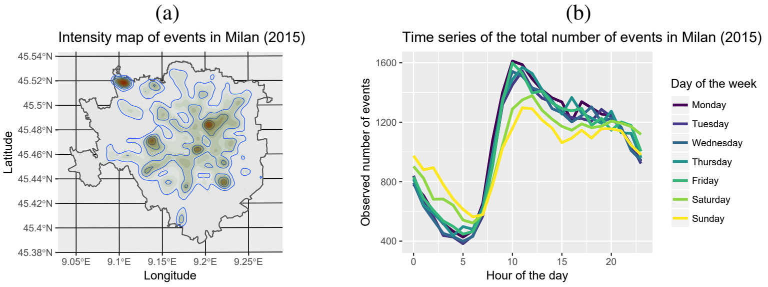

Fig. 1 Spatial distribution of the events in Milan during 2015 (a). Temporal distribution of the number of interventions per hour of the day (b).

where δ_t models the expected number of events during the period t in the region S and $f_t(\mathbf{s})$ represents the continuous spatial density of the ambulance demand at time t. A dynamic latent factor structure has been assumed for the temporal component and it has been estimated iteratively (Section 2.1). The spatial component has been estimated non-parametrically via a weighted kernel (Section 2.2).

2.1 The temporal component

Following the approach suggested in [3, 2], we assumed a dynamic latent factor model for the temporal component δ_t and estimated it using smoothing splines [4]. More specifically we supposed that it is possible to predict the mean value δ_t using a set of deterministic covariates, namely the hour of the day, the day of the week and the week of the year, that were included in the model by applying constraints on the factor loadings as explained below.

To avoid negative values we modelled the intra-day pattern on the log scale and we assumed that it can be approximated using a linear combination of a small number K of factors[1] i.e.

$$\log \delta_{ij} = L_{i1} f_{1j} + \ldots + L_{iK} f_{Kj}, \quad i = 1, \ldots, 365, \quad j = 1, \ldots, 24. \tag{2}$$

The model can be expressed in matrix form as $\log \Delta = LF'$. The matrix L is further partitioned as

$$\log \Delta = LF' = (H_1 B_1 + H_2 B_2) F' \tag{3}$$

where H_1 and H_2 are the incidence matrix that identifies the day of the week and the incidence matrix that identifies the week of the year respectively, whereas B_1 and B_2 are matrices of unknown coefficients with suitable dimensions.

Since both F and L are unknown matrices, we implemented the following algorithm [2] to estimate them:

1. using singular value decomposition we decomposed the matrix of the observed counts logarithms as UDV' and we obtained an initial estimate $L = UD$ and $F' = V'$;
2. considering F as known, we updated the estimate of L using a *gam* model with a Poisson response variable and the day of the week and the week of the year as covariates;
3. considering L as known, we updated the estimate of F using again a *gam* model with a Poisson response and the hour of the day as covariate;
4. we iterated 2 and 3 until convergence.

[1] The value of K was chosen by training the model on the data collected in 2015 data validating it using 2016 data.

2.2 The spatial component

The continuous spatial density function $f(\cdot)$ has been estimated at a future time period u using the spatio-temporal weighted kernel density estimator [5]

$$f_u(\mathbf{s}) = \frac{\sum_{t \in \mathscr{T}_{obs}} \omega(\mathbf{s}_{i,t}, u) K_{\mathbf{H}}(\mathbf{s} - \mathbf{s}_{t,i})}{\sum_{t \in \mathscr{T}_{obs}} \omega(\mathbf{s}_{i,t}, u)}, \qquad \mathbf{s} \in S \tag{4}$$

where $\mathscr{T}_{obs}$ represents a set of past periods, $\omega(\cdot)$ a weight function and $K_{\mathbf{H}}(\cdot)$ a multivariate gaussian Kernel with bandwidth matrix $\mathbf{H}$.

Figure 1-(b) shows that the observed number of events exhibits both daily and weakly seasonality. The aim of the weight function is to take advantage of these patterns and select those observations that are mostly influential in predicting the density function at a generic future time point u. Analysing the data it emerged that the strength of these patterns was different in different areas of Milan. For this reason we divided the municipality in $C = 9$ neighbourhoods and the weight function was estimated separately in each cell.

We assumed [5] that the prediction at a future time point u depends only upon the temporal lag between u and the event at time t. The impact of the event occurred at time t is weighted by the following weight function that measures how two observations located in a cell c are positively correlated:

$$\omega_c(u-t) = \rho_{1,c}^{u-t} + \rho_{2,c}^{u-t} \rho_{3,c}^{\sin^2\left(\frac{\pi(u-t)}{24}\right)} \rho_{4,c}^{\sin^2\left(\frac{\pi(u-t)}{168}\right)}, \quad c \in \{1, \ldots, C\} \tag{5}$$

where ρ_1 describes any short-term seasonality, ρ_3 and ρ_4 express daily and weakly seasonality respectively and ρ_2 is a discount factor. Since using a likelihood approach to estimate these coefficients is prohibitive due to the computational costs, we implemented the algorithm suggested in [5]. Hence $\rho_1, \ldots, \rho_4$ have been estimated by minimizing the following quantity:

$$\min_{\rho_{j,c}, j \in \{0, \ldots, 4,\}} \sum_{l=1}^{M} (A_c^+(l) - \rho_{0,c}\omega_c(l))^2 \tag{6}$$

where A_c^+ represents the positive part of the autocorrelation function of the proportion of events in the spatial cell c, M is the maximum lag considered in the autocorrelation function and $\rho_{0,c}$ is a normalizing constant. The minimization problem was worked out using the *optim* function of R [6].

3 Results and conclusions

We trained the algorithm described in section 2.1 using the data from 2015. The number of factors K was identified via an external cross validation based on the dataset collected in 2016. $K = 4$ is the optimal value suggested by the procedure. Finally the model has been tested using again the 2016 data. The results are displayed in Figure 2 where the scatter plot of the predicted counts versus the observed counts is reported. A boxplot of predictions is drawn at each observed frequency to improve the graph readability. Patterns somehow similar were found for the two years. Despite a great variability and some potential outlying values, the predictions seem to replicate reasonably well the observed data both for the train set (year 2015) and for the test set (year 2016).

The spatial dynamic has been estimated using the procedure detailed in Section 2.2. First we solved the minimization problem mentioned above to obtain an estimate of the coefficients for the weight function. Then we estimated the spatial density using Equation 4 for one particular day. To exemplify the procedure we considered two maps for the 26th of September 2017, one estimated at 02:00 AM and the other estimated at 2:00 PM. The results are displayed in Figure 3 where darker areas are associated to higher values of the spatial density. There are clear differences between the two plots: during daytime hours the events are mostly concentrated around popular places and crossing points such as the Duomo area or the Central Station areas whereas during the night interventions are more scattered over the whole territory of the municipality.

This study demonstrates how resorting to a spatio-temporal non homogeneous Poisson model is adequate to represent the temporal and the spatial patterns that are present in the EMS data of Milan. Some areas and some hours of the day are found more critical for emergency events and this is a preliminary step to support local authorities in optimally allocating ambulances and resources in the territory. From the statistical modelling perspective some further enhancements can be introduced to improve the diagnostic, for instance developing algorithms to simulate events from the estimated model and to create measures of the prediction performance. Moreover, alternative specifications for the weight function should be also considered. Finally, a comparison between the temporal and spatial model suggested in this paper and other approaches such as machine learning algorithms (for instance, boosting or random forest) can be also useful to identify the best modelling strategy to support authorities in the day by day activity.

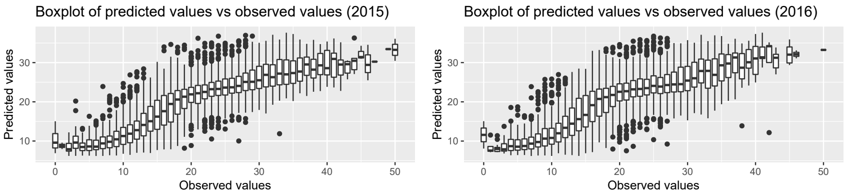

Fig. 2 In these two plots we display the predictive performance of the dynamic latent factor model for the training data (2015, left plot) and for the test data (2016, right plot). We can see that, despite high variance in the estimates, both plots show good predictive performances.

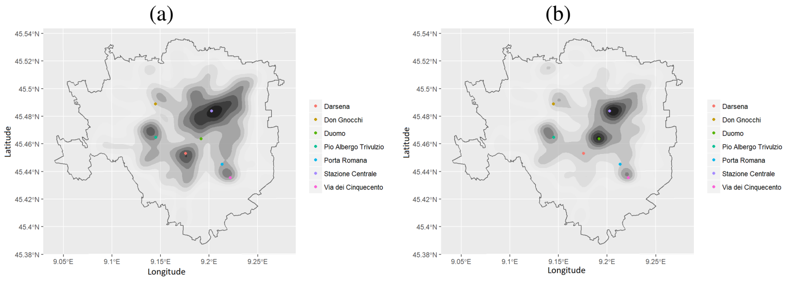

Fig. 3 Spatial density estimate for the 26th of September 2017 at 02:00 AM (a) and 02:00 PM (b). Some important places of the city are highlighted on both maps. Darker areas are associated to higher values of the spatial density.

SPATIAL SEGREGATION OF IMMIGRANT HOUSEHOLDS IN MESSINA

Segregazione spaziale delle famiglie di immigrati nella città di Messina

Angelo Mazza and Massimo Mucciardi

Abstract We investigate spatial segregation of the most representative groups of foreign immigrants in the city of Messina.
We use spatial modeling with point level data to assess attraction among migrants' households of the same ethnicity while adjusting for spatial inhomogeneity in the cost of housing, job availability and other factors. This work is still in progress; first results show more dispersed settlements patterns for ethnicities more involved with household services than for those devoted to commerce and peddling.
Abstract *In questo lavoro vengono analizzati i modelli insediativi dei gruppi di immigrati più rappresentativi nella città di Messina. Attraverso l'impiego di modelli spaziali per dati puntuali misuriamo l'attrazione tra nuclei familiari della stessa etnia, al netto delle eterogeneità spaziali nel costo degli affiti e nella disponibilità di lavoro. Il lavoro è ancora in progress; i primi risultati mostrano modelli insediativi meno concentrati per quei gruppi etnici maggiormente coinvolti nei servizi alle famiglie rispetto a quelli maggiormente impegnati nel commercio e nella vendita ambulante.*

Keywords: Spatial Clustering, Voluntary Segregation, Migrant Households

Introduction

Ethnic residential segregation has long been investigated in the USA and South Africa; however, only recently this topic has become prominent in Europe as well, following from a debate that links segregation with the perceived failure of integrating immigrants into host societies (Kalandides and Vaiou, 2012, Andersson, 2013). A minority ethnic group is segregated when the arrangement of minority households departures from expectations based upon a random spatial allocation. Following Schelling (1971), we distinguish two sources of spatial segregation. The first is mostly economically induced, and it is mainly ascribed to within-city inhomogeneity in the price of residential property, and in the availability of jobs. The second is attraction, i.e., individuals prefer living in areas where their group is a majority or near-majority (Clark and Fossett, 2008). Moreover, newly arrived minority migrants may benefit from positive spillovers in settling close to their compatriots, and transnational social networks play an important role in channeling arriving migrants into specific neighborhoods.

Whereas economic induced segregation might explain some initial degree of segregation and raises questions of social equity, the Schelling (1971) model highlights the importance of individually motivated segregation and posits that even mild preferences for living with similar neighbors carry the potential to be strong determinants for residential segregation (Clark and Fossett 2008).

From a methodological point of view, traditional indices of spatial segregation rely on data aggregated by areal unit, typically census tracts (Mazza and Punzo, 2015; Mucciardi, Mazza and Altavilla, 2017); however these analyzes could suffer from the modifiable area unit problem (i.e., alternative zoning or a different scale may yield different results; see Openshaw, 1984 and Wong, 2009) and do not allow to distinguish between the two sources of segregation. Instead, in this paper, we use individual point data, and we apply the inhomogeneous K-function (Baddeley et al., 2000), which allows assessing spatial attraction among migrants while adjusting for spatial inhomogeneity (Mazza and Punzo, 2016). To avoid the risk of confounding the two sources of clustering, spatial inhomogeneity is estimated following a case-control approach. Cases will be, in turn, migrants of each nationality, while the controls will be a random sample of native household locations.

The model: the inhomogeneous K-function

The spatial distribution of household locations may be represented by a point pattern. The simplest theoretical model for a spatial point pattern is the homogeneous Poisson process (HPP), in which the expected number of events occurring within a unitary region $u \in R$ follows a Poisson distribution, whose intensity $\lambda(u)$ is uniformly distributed over R (Diggle, 2003). The inhomogeneous point process (IPP) is a generalization of the HPP obtained replacing the constant intensity λ by a spatially varying intensity function $\lambda(u)$; clustered patterns occur, with regions where $\lambda(u)$ is higher receiving a higher number of events. Ripley's *K*-function, usually denoted with $K(d)$, is used to detect clustering (or inhibition) in point processes with constant intensity; at every spatial distance d, $\lambda\ K(d)$ is the expected number of additional points of the process X located in a circle b of radius d surrounding an arbitrary event x. Baddeley et al. (2000) generalized Ripley's K-function to non-homogeneous point processes, by weigthing each point x_j by $w_i = \frac{1}{\lambda(x_i)}$. The inhomogeneous K-function is defined as

$$K_{\text{inhom}}(d) = \mathrm{E}\left[\sum_{x_j \in X} \frac{1}{\lambda(x_j)} 1\{0 < \|u - x_j\| \leq d| \quad u \in X\}\right] \qquad (1)$$

where $\|u - x_j\|$ is the Euclidean distance between points u and x_j and $1\{\dots\}$ is the indicator function. Clustered point patterns arise from the joint action of spatial inhomogeneity and spatial attraction. To distinguish between these two sources is challenging task, since many spatial processes are "equifinal", i.e. one realization of a point process may be consistent with underlying processes involving clustering due to either spatial inhomogeneity or spatial attraction (Harvey, 1966). Mazza and Punzo (2016) deal with this issue using a case-control approach. In case-control studies, data consist of a realization of two spatial point processes, one representing cases of a condition of interest and the other representing controls drawn at random from the population at risk. Assuming that the size of the population at risk tends to infinity and the sampling fraction to zero, the controls constitute a realization of an IPP with intensity $\lambda^*(u)$; the cases form a second, independent, point process – which may or may not be a Poisson process – with intensity $\lambda(u)$. The question of interest is whether the cases form an IPP with intensity proportional to that of the controls, i.e., $(u) = \rho\lambda^*(u)$, or whether they exhibit additional spatial structure.

Diggle et al. (2007) propose that the ratio between the intensity functions may be modeled to depend on a vector of m spatially referenced covariates

$$\mathbf{z}(u) = \left(z_1(u), \dots, z_m(u)\right)', \text{i.e. }; \lambda(u) = \lambda^*(u) f(\mathbf{z}(u); \boldsymbol{\theta}) \qquad (2)$$

where $f(\cdot)$ is any nonnegative function, either nonlinear parametric with parameters θ as in (2), or nonparametrically specified.

Our controls are a random sample of native household locations, and economic constraints are taken into account through explanatory spatial covariates related to the cost of residential property and job availability.

Data at hand come from the administrative register of the city of Messina, at December 31, 2016. Register data have been integrated within a geographical information system, and all the residential addresses geocoded. Other data used are the rent cost per square meter for private residential properties, as collected by the Italian Revenue Agency (OMI database). Computations are carried out by means of the spatstat package (Baddeley and Turner, 2005) for the R computing environment (R Core Team, 2017).

Main results

Our investigation will cover the most representative groups of foreign immigrants in the city of Messina. We expect a differentiated spatial trend for the different nationalities, with higher values in the more central parts of the city for those groups involved mainly in retailing and peddling activities. We will compute the estimates for the inhomogeneous K-function at various distances d. We will also report confidence envelopes based on Monte Carlo simulations for the null hypothesis of absence of interaction. First results show more dispersed settlements patterns for ethnicities more involved with household services than for those devoted to commerce and peddling. Furthermore, a higher spatial attraction emerges for those groups for whom the effects of chain migrations and family reunifications have been stronger.

Supervised Learning for Link Prediction in Social Networks

Link prediction nelle reti sociali attraverso l'utilizzo di metodi e modelli di apprendimento supervisionato

Riccardo Giubilei, Pierpaolo Brutti

Abstract Link prediction is an estimation problem that has drawn a great deal of attention in recent years. In this work, a supervised learning approach is adopted to perform link prediction on data retrieved from Facebook. The specific goal, then, is to estimate the probability of two users to become friends in order to recommend them to one another whenever this probability turns out to be sufficiently high. On social platforms like Facebook, friendship recommendation is clearly a crucial ingredient since, when properly implemented, it plays a key role in determining the network growth. The contribution of this work consists in performing friendship recommendation on Facebook using a supervised learning approach that takes explicitly into account vertices' attributes; that is, all the personal information that users make available on their profiles.

Abstract La link prediction ha attirato molta attenzione negli ultimi anni. In questo lavoro, un approccio di apprendimento supervisionato viene utilizzato per fare link prediction su dati provenienti da Facebook. L'obiettivo è quindi quello di stimare la probabilità che due utenti diventino amici, in modo da suggerire gli uni agli altri quanto tale probabilità è alta. La raccomandazione delle amicizie è un problema molto importante poiché il suo corretto funzionamento è fondamentale per la crescita delle reti, che è l'obiettivo primario di siti come Facebook. Il contributo di questo lavoro è quello di fare ciò utilizzando un approccio di apprendimento supervisionato che prenda esplicitamente in considerazione anche gli attributi dei vertici, ovvero le informazioni personali che gli utenti inseriscono nel proprio profilo.

Key words: Link Prediction, Social Network Analysis, Network Science, Graph Theory, Supervised Learning, Machine Learning, Binary Classification.

1 Introduction and background

A social network is a popular way to model the interaction among people belonging to a group or a community. It can be represented using a graph, where each node is a person and each link indicates some form of association between two people.

In this framework, performing link prediction consists in predicting which nodes are likely to get connected. More precisely, the goal is to predict the likelihood of a future association between two unconnected nodes. This is carried out supposing the likelihood of link formation depends on the similarity between the two nodes.

In 2004, Liben-Nowell and Kleinberg [3] proposed one of the earliest link prediction models that works explicitly on social networks. The learning paradigm in this setup typically extracts the similarity between a pair of vertices exploiting various graph-based similarity metrics and uses the ranking on the similarity scores to predict the link between two vertices.

Subsequently, Hasan et al. [2] extended this work in two ways. First, they showed that using external data outside the scope of graph topology (namely, the vertices' attributes) can significantly improve the prediction results. Second, they used several similarity metrics as features in a supervised learning setup where the link prediction problem is posed as a binary classification task. Since then, the supervised classification approach has been popular in various other works on link prediction.

2 Motivation

The popularity of online social network services has thrived in recent years, attracting an increasingly large number of users. By connecting users with similar professional backgrounds or common interests, they open up new channels for information sharing and social networking. Creating connections not only helps to improve user experience, but also increases the chance of producing larger and more well-connected networks, which is the primary goal of these sites.

Consequently, link formation is fundamental. In Facebook, a link is formed whenever two people become friends. To increase the probability of link formation, users with the highest probability of becoming friends may be suggested to one another. This is achieved through the friendship recommendation system, that aims to find the most similar users in terms of their profile contents or their behavior so as to offer them to each other.

The scope of this analysis is to apply link prediction methods and techniques to perform friendship recommendation on Facebook data. The problem is tackled using a supervised learning approach that blends together both topological features and users' personal information. Incorporating the latter as covariates is everything but trivial so, in the following, we introduce a relatively simple method to handle effectively this crucial modelling step.

3 Data

The data was collected in 2014 by Julian McAuley (UC San Diego) and Jure Leskovec (Stanford University) using a Facebook application that asked to a pool of volunteers the permission to download their Facebook's profile information via Facebook API. In order to ensure the volunteers' privacy, all the data have been completely anonymized by assigning users and features sequential IDs. The data collection proceeded in the form of ego networks, i.e. starting from a central node (the person who gave the permission), and then expanding the network considering his friends and the mutual friends between them and the central node. 110 ego networks were collected, making a total of $27,520$ Facebook users. For each of these users, public information contained in their profile was also recorded.

Therefore, the dataset is composed by 110 distinct files, which correspond to the 110 ego networks, and by the additional file that contains the users' attributes. In this work we focus our attention on two specific ego networks. The first one is associated to user $6,934$ and has been selected as the train dataset being the largest among those that do not contain links to users from other ego networks. It is formed by 773 nodes, including the central one, and by $26,023$ links between them. Since the number of nodes is 773, the number of potential links in the network, given by all the possible combinations between the nodes, is $268,278$. Therefore, the number of actual links is approximately the 9.70% of all the possible links. The second one is the ego network of user $3,236$, and has been chosen as the test dataset for being structurally different from the first one. Indeed, it is composed of 345 nodes and $4,013$ links among them, which correspond to the 6.76% of the $59,340$ possible links.

4 Experimental setup

The link prediction problem is formalized as a supervised classification task, where each instance corresponds to a pair of vertices in the social network graph. Instances are characterized by features describing the similarity between the two nodes and a label denoting their link status. In particular, the instance is classified as positive if there exists a link between the nodes, or negative otherwise. The output of the models is a score for each non-observed link which quantifies how likely it is that it will actually become a link. The instances classified as positive are those that exceeds a certain threshold score.

Since each instance corresponds to a pair of vertices, the features should necessarily represent some form of proximity between them. In existing research works on link prediction, the vast majority of the features are related to the graph topology. Typically, they are built by computing similarities based on the node neighborhoods or on the set of paths that connect those two nodes. However, as anticipated in the Introduction, Hasan et al. [2] have proposed to extend the set of features in order to include also the vertices' attributes.

Now, coming back to our specific application, since we are dealing with ego networks, their topology immediately implies a diameter equal to 2. As a consequence, any feature based on paths is definitively not very informative and will not be included in the analysis. On the other hand, five neighborhood-based similarity indices that single out different aspects of the link formation phenomenon are selected. More specifically we consider: *Common Neighbors*, *Jaccard Index*, *Preferential Attachment Index*, *Adamic-Adar Index* and *Resource Allocation Index* [5]. For what concerns other *local* indices available in the literature, it is enough to say that they will not be considered here mainly because they have already shown to not lead to significant improvements in similar analyses.

Attributes-based features are built considering the file containing the users' attributes related to their personal Facebook profile. However, this file contains some redundant information, and, in addition, many of the attributes collected are not available for the majority of the users. Redundant attributes, such as the first, the middle, the full name and the ID, are excluded from the analysis. Likewise, all attributes that have been recorded for less than $1,000$ users are not considered. Among the remaining ones, some additional feature selection is carried out, eliminating variables with little to no informativeness. In order to build similarity indices from the remaining attributes, it is important to underline that a user may have more than a value for the same attribute. Consequently, the idea is to count, for each pair of nodes and for each attribute, the number of values they have in common for that attribute. This is motivated by the belief that the larger the number of characteristics two unconnected users have in common, the higher the probability that they will be linked in the future. This procedure leads then to a data-matrix, with the rows corresponding to the pair of vertices, and the columns being the attributes. The generic entry for this matrix is the number of times the values of a certain attribute coincide for the pair of nodes considered.

5 Models and results

Five binary classification models are considered: *Random Forest*, *Neural Network*, *Gradient Boosting*, *Naive Bayes* and *Logistic Regression*. For each model, a careful parameter tuning is carried out. In order to evaluate the predictive abilities of these models, a 10-fold cross validation is performed on the train data. The models are then evaluated using a number of metrics, including *accuracy*, *specificity*, *recall*, *precision*, *F1 score*, *Area Under the Receiver Operating Characteristic curve* (AUROC) and *Area Under the Precision-Recall Curve* (AUPRC).

Table 1 shows the performance comparison for the different classifiers considered. For the fixed-threshold metrics, the threshold has been set to 0.5. The results are very good for almost every metric. However, the choice of the best model is performed by considering only the metrics that are independent of the threshold chosen to convert the probability scores to class labels, i.e. AUROC and AUPRC.

Consequently, the best model is the Gradient Boosting, which is then used to make prediction on the test data.

Model	Accuracy	Specificity	Recall	Precision	F1 score	AUROC	AUPRC
Random Forest	89.97%	89.48%	94.57%	49.11%	64.65%	97.24%	79.43%
Neural Network	94.37%	97.53%	64.88%	73.87%	69.09%	97.11%	78.74%
Gradient Boosting	94.49%	97.64%	65.15%	74.81%	69.45%	97.24%	79.53%
Naive Bayes	92.31%	93.29%	83.26%	57.15%	67.77%	96.44%	74.86%
Logistic Regression	91.07%	91.01%	91.69%	52.27%	66.58%	96.99%	76.72%

Table 1: Evaluation metrics for the models considered using a 10-fold cross validation.

6 Prediction

The results obtained using the Gradient Boosting model on the test data are reported in Table 2. In addition to the threshold-independent metrics AUROC and AUPRC, also recall and precision are included, being of interesting and useful interpretation in the specific context. In fact, a recall of 82.63% indicates by definition that a little more than 8 people out of 10 a user may want to add are indeed suggested. On the other hand, a precision equal to 70.17% means that users would add approximately 7 people out of 10 suggested.

Model	Recall	Precision	AUROC	AUPRC
Gradient Boosting	82.63%	70.17%	98.06%	84.66%

Table 2: Evaluation metrics for the prediction on the test data.

Figure 1 allows to visualize the predictive results obtained using the model. In particular, all the effectively existing links are reported in the figure, coloring them

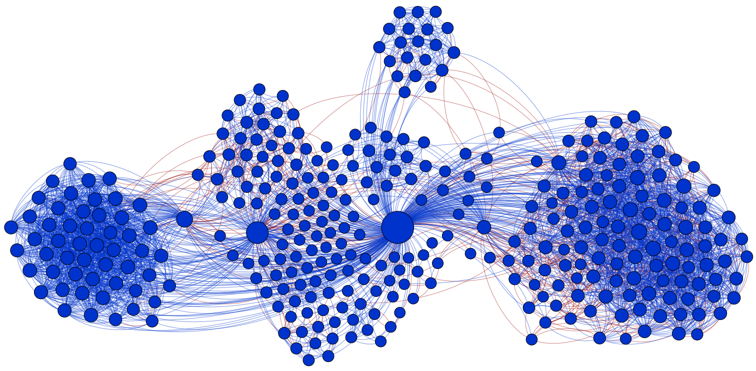

Fig. 1: Correctly predicted links (blue) and missed links (red) in the test ego network.

differently based on the predictions: correctly predicted link are colored in blue and missed links are colored in red. Therefore, it is possible to note that the model manages to reconstruct a massive part of the graph. This is achieved at the cost of suggesting only 3 people that a user would not be interested in adding every 10.

7 Conclusions and future work

The results obtained show that the link prediction task has been accomplished in a satisfying way. In particular, the inclusion of attribute-based features seems to be extremely useful, allowing to make very good predictions. This aspect is of great importance for both confirming that including them actually improves the predictive abilities of the models, and for validating the procedure used to build them starting from the users' personal information. In addition, the supervised learning approach has proved to be effective also for performing link prediction on Facebook data, with particular reference to ego networks.

In the future, it would be interesting to consider larger graphs, and study specific methods and techniques that scale well on "big data" networks.

In addition, the possibility to retrieve and consider the time-stamps of the links is certainly an aspect which would help in link prediction. For example, they may be included by treating more recent links as more important than older ones. Important contributions on this extension, also defined time-aware link prediction, are those by Ahmed et al. [1] and by Tylenda et al. [4].

The techniques and models presented here may be exploited to perform link prediction outside the specific task of recommending friends on Facebook. For example, the case of directed networks may be considered, being of great importance in other online social networks like Twitter. In the end, link prediction is a very relevant problem in almost every kind of networks, and it would be interesting to consider applications also in these other domains.

Women's empowerment and child mortality: the case of Bangladesh

Il ruolo della donna nella lotta alla mortalità infantile: il caso del Bangladesh

Chiara Puglisi[1] and Annalisa Busetta[2]

Abstract Bangladesh is the Southern Asian country that has been experiencing the highest absolute decline in the Under Five Mortality Rate in the past 15 years. This paper focuses on the importance of women's education and empowerment variables in explaining this extraordinary result. We use a two-level multilevel logistic regression to take into account the great differences among territorial communities in terms of child mortality reduction. It emerges that the importance of woman's empowerment - measured as individual and as mother - remains relevant even when the context is considered. A sensitivity analysis has been conducted to test the relevance of different indicators of female empowerment.

Introduction

The importance of female education for child survival in developing countries has been widely acknowledged [3;12]. Mosley and Chen [13] have been among the first scholars highlighting the importance of the mother's role, by arguing that women's education has positive effects on children's chances of survival. They argued that education allows mothers to increase their capabilities concerning nutrition, hygiene and treatment of illnesses, which in turn allows

them to properly take care of their children. Women's education appears to affect child mortality both directly and indirectly, i.e. through its influences on gender equality and female empowerment [1].

In particular, research also showed that female empowerment is positively associated to child survival [7;8;10]. Authors who have been exploring such relationship, though, have been conferring to the term "empowerment" a wide meaning, for instance as a general holding of autonomy [7], by measuring it through several proxies: as decision-making power in the household, freedom of movement and employment status [8], as control of resources [10] and so on, hence implying for the relationship between female empowerment and child mortality to always retain its positivity, independently of how empowerment is measured. Kabeer [9], on the other hand, argued that "what mattered for achievements in relation to children's wellbeing was women's agency as mothers rather than as wives" [9:450]. She suggested to focus on indicators that are strictly related to women's ability to take action in safeguarding their children's healthcare, rather than on the ones concerning, for instance, equality within the marital relationship.

In this paper we aim to evaluate the relative importance of female empowerment and whether its importance changes if measured as possibility of agency towards the children's healthcare compared to female empowerment measured in terms of equality in the relationship between the parents of the children or in terms of women's agency in the social context.

The case study: Bangladesh.

Bangladesh makes an especially interesting case study because of its impressive improvements in terms of child survival: it is the country that, among all Southern Asian states, has been experiencing the highest absolute decline in the Under Five Mortality Rate in the past 15 years [6].

Comparing several rounds of Bangladesh Demographic and Health Surveys (BDHS) it emerges that as female schooling increase child mortality decreases, and this relation is steady over time. In Bangladesh DHS 2004 women who had no education have an Under Five Mortality rate (U5MR) equals to 114‰ live births whereas those with higher education have an U5MR of 58‰ live births. In BDHS 2014 they decrease respectively to 63‰ live births and 24‰ [6]. Moreover, a great deal of attention has been paid to Bangladesh in the literature concerning the role of female education and empowerment in child survival: empowering women has been pointed out as one of the most important factors behind the so-called "Bangladesh paradox", consisting in the sharp contrast between excellent health performances and reduction of mortality, and the malnutrition and low use of basic health services that still characterize the country [5].

Data and methods

The data utilized for this study derive from the Bangladesh DHS 2014. It is the 7th survey implemented by the DHS Program in the country, and it involved men and women in reproductive age, who provided also information about their children. The survey has been conducted on all the ever-married women, aged 12 to 49 years, selected through a two stage stratified sampling procedure: the first stage involved the selection of 600 territorial units (clusters) - 207 urban clusters and 393 rural ones; in the second stage, for every cluster has been selected an average of 30 households. Our study has concerned all the children born in the 10 years preceding the survey and their mothers. The response variable of the analysis was under-five death - that is, the death of a child before reaching his or her fifth birthday - recorded as a dichotomous variable[4]. The data for estimating child mortality derive from the birth history of the Women’s Questionnaire, where were collected information about all their live born, such as sex, month and year of birth, survival status, age at the moment of the interview or age at death in case of deceased child [10]. The subsample utilized in our study concerned a total of 16,439 children born in the 10 years preceding the survey and 10,856 women, that is, the mothers of such children.

As already mentioned, the main focus of this work is the effect of different indicators of female empowerment. In particular, we compare the results of:

- A measure concerning female empowerment as education, categorized in four modalities: no education, primary education, secondary and higher education. Note that this variable only concerns women who had completed their education before getting married;
- Three indicators measuring women’s empowerment in terms of equality within the couple: an indicator concerning the woman’s freedom of movement; a variable measuring the number of decisions to which women participate in the household; a variable quantifying the number of occasions in which women tend to justify violence from the husbands;
- An indicator concerning the woman’s possibility to act towards her children’s wellbeing: a variable investigating who has the final say final say on children’s health care.

All the models estimated in the next section control for individual characteristics of the child (sex, birth order, birth interval), of the mother (mother’s cohort and age at birth), of the household (wealth index (WI)[4] and availability of electricity)

[4] We excluded those born less than 59 months before the end of the survey, as they were not exposed to five full years of risk of dying.

[5] WI is a composite measure of a household's cumulative living standard calculated by DHS. It relies on household’s ownership of selected assets (such as televisions and bicycles), materials used for housing construction and types of water access and sanitation facilities.

and of the context (percentage of uneducated men, uneducated women, rich and richest households, households with electricity in the cluster, and type of residence).

We employ a two-level multilevel logistic regression approach, based on the calculation of adjusted odds ratios of under-five mortality according to the selected explanatory variables. The choice of a multilevel approach is consistent with the very clustered nature of the DHS data; the use of a multilevel approach allows for the correction of the bias that may occur in the estimation of the parameters resulting from such clustered structure. This option has been selected to give relevance to the influence that territorial context may have on children's survival. As Matteson et al. argued, even though there may be optimal individual-level conditions, "*the absence of adequate health care in the community, living in a congested urban environment or living in the context of high poverty may have independent negative consequences for her [a mother's] infant's well-being and survival*" [11:1884].

Preliminary results

To analyse how the five different measures of women empowerment influence under-five mortality in Bangladesh we fitted 10 multilevel random slope models (see Table 1) with individual and contextual variables: models 1, 3, 5, 7 and 9 control only for individual determinants, whereas models 2, 4, 6, 8 and 10 add the control of contextual determinants to highlight the significance of the effect of community.

Model 1 and 2 provide odds ratios of under-five death according to the educational level of the mother without and with the contextual-level variables. It emerges that mother's education has a strong protective effect in terms of child survival: the odds of under-five mortality among children born to women with a secondary or higher education are 29% lower than the probability of those born to uneducated women. Such effect is retained also including contextual factors (model 2): having a "higher" educational level retains its protective effect in terms of under-five survival, and this result is still statistically significant even when controlling for the percentage of uneducated males and females in the cluster, which means that the low educational level of the mother has a significant impact on child mortality independently from the average educational level of men and women within the cluster. As the literature on the matter showed, educated mothers are more likely to bring their children to healthcare facilities [4], are more conscious and more enlightened (which helps them to make better decisions for themselves as well as for the family) and can better communicate and interact with health service providers to get required care for themselves as well as for their newborn [2].

Models 3 to 8 display the odds ratios of under-five mortality in correspondence of a) mothers that have freedom of movement; b) mothers who participate to decisions within the household and c) mothers who justify wife-beating. We can see that mothers' possibility to move freely (that is, alone or with her children), her decisional power inside the couple and her attitudes towards wife-beating do not affect the odds of child mortality. Such results remain unchanged even when controlling for contextual-level variables.

n.s.: not statistifically significant at 10%, *p<0.10; **p<0.05, *** p<0.01; all models include constants. Note that all the odds ratio should be interpreted in terms of association, and not of causality.

Eventually, models 9 and 10 allow us to shed more light on the relationship between the women's empowerment as mothers – measured as possibility of agency when it comes to their children's healthcare - and their children's survival. It appears that such measure of women's empowerment does have a protective effect in terms of child survival: children born to women who have the final say in decisions concerning their kids' healthcare have 29% lower odds to die before reaching their fifth birthday, compared to those born to women who do not have any say on kids' healthcare. Such protective effect is retained even when the contextual factors are included in the model as control, and the result stays statistically significant.

Hence, it appears that women's education has a statistically significant effect on child mortality both when controlling only for individual-level variables and when including the contextual-level ones, and so does women's empowerment – when measured in terms of possibility to act when it comes to their children's healthcare. This latter result is consistent to what Kabeer [9] argued, that is, that what matters is women's agency as mothers rather than as wives. Indeed, in our analysis the measure focusing on women's ability to take action in safeguarding their children's healthcare has a significant, protective effect on children's survival, whereas measures of empowerment in terms of equality within the marital relationship do not show any significant impact on the chances of child survival.
