Awareness · Chronic obstructive pulmonary disease · Adherence · Patient-reported outcomes

Abstract

Background: Disease awareness is a challenge in the management of chronic obstructive pulmonary disease (COPD). **Objectives:** The aim of this analysis was to explore the association between COPD optimal and suboptimal awareness, clinical parameters, and the following patient-reported outcomes: modified Medical Research Council (mMRC), Treatment Satisfaction Questionnaire (TSQM-9), COPD Assessment Test (CAT), Morisky Medication-Taking Adherence Scale (MMAS-4), and Brief Illness Perception Questionnaire (B-IPQ). **Methods:** This post hoc analysis of the SAT study included all enrolled patients for whom awareness (Disease Awareness in COPD Questionnaire – DACQ) was assessed at baseline and 12 months. DACQ scores ≥ 80 were considered

an indicator of an optimal awareness. **Results:** 367 patients (25.8% women, median age 72 years) were included in the analysis. At enrollment, 74 patients (20.2%) had a DACQ score ≥ 80 . Patients with suboptimal awareness, compared to those in which awareness was optimal, had higher median scores for CAT ($p = 0.0001$) and mMRC ($p = 0.0031$), a lower median TSQM-9 global score ($p < 0.0001$), and higher median B-IPQ score ($p < 0.0001$). The proportion of patients who had exacerbations during the previous year was higher in patients with suboptimal COPD awareness than in those with DACQ score ≥ 80 (42.8 vs. 21.4%, $p = 0.0009$). During the 12-month observation period, illness perception, adherence, and treatment satisfaction were found to be independent factors significantly associated with level of disease awareness. **Conclusion:** The results of our post hoc analysis suggest that patients' awareness of their COPD disease is related to both clinical outcomes and how they perceive and manage their condition.

Introduction

Improved disease awareness has been identified in recent years as one of the major public health and medical challenges for the detection and management of chronic obstructive pulmonary disease (COPD) because of the potential impact on the morbidity and mortality associated with this condition [1, 2]. Major efforts to increase public knowledge about COPD prevalence, symptoms, diagnosis, and treatment have been undertaken over the past decades, by means of campaigns, education and advocacy programs, and activities in more than 50 countries worldwide [3–5]. However, recent studies show that COPD remains highly underrepresented in the public interest [6] and among subjects who are at high risk of developing the disease [7, 8]. Furthermore, the low awareness of the disease is considered the first factor that limits early COPD management [9].

Being informed about the characteristics, consequences, and treatment of COPD is a necessary step toward improving disease management. However, even when patients have a good overall knowledge of their health condition, they may have difficulties in understanding, accepting, and managing it. This happens because the issue is more complex than to be informed [10]. Awareness has been defined as “a reasonable or realistic perception or appraisal of one’s situation, functioning or performance, or of the resulting implications, expressed explicitly or implicitly” [11]; it depends not only on the correctness of information but refers to a complex process in which patients assign a personal meaning to their knowledge and integrates feelings and cognition into their disease experience [12]. The Disease Awareness in COPD Questionnaire (DACQ) has been recently validated to assess patients’ awareness of COPD [13] by exploring different dimensions: the mastery of a correct knowledge on COPD; the level of subjective view on necessity and role of COPD therapy; the patient perceptions of COPD in terms of features and consequences; and the individual acceptance of thoughts and feelings related to COPD.

The DACQ has been developed and tested in the context of the “SATisfaction and adherence to COPD treatment” (SAT) study [14] and demonstrated to be a reliable and valid tool. The analysis of the DACQ scores highlighted that, despite the fact that patients were diagnosed and cared for in specialist COPD settings, the level of awareness was suboptimal. Using the data of the SAT study, we explored the association between COPD optimal and suboptimal awareness, clinical parameters, and patient-reported outcomes.

Material and Methods

Study Design

This is a post hoc analysis of the SAT study (ClinicalTrials.gov number NCT02689492). The methodology and results from the SAT study have been reported previously [12]. In brief, the SAT study was a multicenter, observational perspective cohort study. 401 consecutive COPD patients, referred to specialist centers for a follow-up visit, were enrolled over a period of approximately 8 months. Patients were followed up for 1 year, with an intermediate evaluation after 6 (+/–1) months from enrollment (compatible with current clinical practice in Italy for COPD patient management), from November 2015 to October 2017.

At each visit, patients filled the DACQ along with the following validated questionnaires (Italian versions):

- The Treatment Satisfaction Questionnaire for Medication (TSQM-9) [15, 16], a 9-item tool aimed to evaluate the satisfaction with pharmacological treatment. The TSQM-9 provides scores on 3 scales: effectiveness, convenience, and global satisfaction, the higher the score and the higher the level of satisfaction.
- The Brief Illness Perception Questionnaire (B-IPQ) [17], a 9-item questionnaire designed to rapidly assess cognitive and emotional representation of illness. The total score ranges from 8 to 80: a higher score reflects a more threatening view of the illness.
- The Morisky Medication-Taking Adherence Scale (MMAS-4) [18], a self-reported, medication-taking behavior scale. It consists of 4 questions about the way patients might experience drug errors or omissions. The total score ranges from 0 to 4; a higher score indicates better adherence to therapy.
- The COPD Assessment Test (CAT) [19], an 8-item unidimensional measure of health status impairment in COPD. The scores range from 0 to 40; higher scores represent worse health.
- The Modified Medical Research Council (mMRC) scale [20], a widely used tool for grading the effect of breathlessness on daily activities [21]. The physician asks the patient about his/her perceived breathlessness and uses the modified MRC dyspnea scale to classify it from 0 (breathless with strenuous exercise) to 4 (too breathless to leave the house or breathless when dressing or undressing).

For TSQM-9, B-IPQ, and MMAS-4 scales, the authors reported no validated cutoff values for minimal clinically important difference [22], defined as the smallest change in an outcome measure perceived as beneficial by patients. This post hoc analysis included all evaluable enrolled patients who filled in the DACQ at enrollment and at 12-month follow-up. The level of awareness for each item is evaluated on a four-point scale: optimal (4), suboptimal (3), scarce (2), or absent (1). Domain scores are normalized to a scale ranging from 0 to 100 with higher scores corresponding to a better level of awareness. Similar to other PROs for which scores of 80% or higher are reflective of the achievement of the outcome [23, 24], normalized scores ≥ 80 have been considered an indicator of an optimal level of awareness.

The analyzed endpoints were (1) the percentage of patients who achieved an optimal level of COPD awareness at enrollment; (2) the differences in terms of clinical characteristics and PROs between patients with and without optimal awareness of COPD; (3) the rate of exacerbation in the previous year and the CAT scores in patients with optimal and suboptimal awareness; and (4) the relationship between DACQ total score and clinical characteristics/PROs during the 12-month observation period.

Table 1. Demographics, clinical characteristics, and patient-reported outcomes of patients at enrollment

	DACQ total score at enrollment		
	<80%	≥80%	total
Patients, <i>n</i>	293	74	367
Age at enrollment, years	72.0 (68.0–77.0)	72.0 (66.0–77.0)	72.0 (67.0–77.0)
COPD duration at enrollment, years	4.4 (1.9–9.1)	5.9 (2.4–10.1)	4.9 (2.1–9.4)
Age at COPD diagnosis, years	66.0 (61.0–71.0)	64.4 (57.7–71.1)	65.9 (60.1–71.1)
No. exacerbations in the year before enrollment	0.0 (0.0–1.0) <i>n</i> = 264	0.0 (0.0–0.0) <i>n</i> = 70	0.0 (0.0–1.0) <i>n</i> = 334
CAT score at enrollment	16.0 (10.0–21.0) <i>n</i> = 293	11.0 (8.0–16.0) <i>n</i> = 74	15.0 (10.0–21.0) <i>n</i> = 367
mMRC at enrollment	2.0 (1.0–3.0) <i>n</i> = 292	1.0 (1.0–2.0) <i>n</i> = 74	1.0 (1.0–3.0) <i>n</i> = 366
TSQM-9 effectiveness score at enrollment	66.7 (55.6–72.2) <i>n</i> = 292	72.2 (61.1–83.3) <i>n</i> = 74	66.7 (55.6–77.8) <i>n</i> = 366
TSQM-9 convenience score at enrollment	72.2 (66.7–83.3) <i>n</i> = 289	83.3 (77.8–94.4) <i>n</i> = 73	77.8 (66.7–88.9) <i>n</i> = 362
TSQM-9 global satisfaction score at enrollment	64.3 (57.1–78.6) <i>n</i> = 290	78.6 (64.3–85.7) <i>n</i> = 72	64.3 (57.1–78.6) <i>n</i> = 362
B-IPQ total score at enrollment	43.0 (37.0–50.0) <i>n</i> = 290	34.0 (26.0–43.0) <i>n</i> = 74	42.0 (34.0–50.0) <i>n</i> = 364
Disease severity at enrollment (GOLD 2017 classes)			
Class A	45 (17.1%)	20 (29.0%)	65 (19.6%)
Class B	184 (70.0%)	47 (68.1%)	231 (69.6%)
Class C	0 (0.0%)	0 (0.0%)	0 (0.0%)
Class D	34 (12.9%)	2 (2.9%)	36 (10.8%)
Not known	30	5	35

For numeric variables, the median (with 25th–75th percentiles) was shown. For categorical variables, percentages were calculated by column (considering the number of patients with available data as denominator). When the number of patients with available data for specific variables was lower than the number of patients specified in the table headings, this was specified.

Statistical Analysis

Descriptive statistics were used to evaluate sociodemographic and clinical variables and PROs at the enrollment visit and at final study visit. For numeric variables, median values (with interquartile range) were calculated. Categorical variables were reported as absolute and relative frequencies. Two-sample *t*-test (or respective analogous nonparametric tests, when appropriate) was used to evaluate the statistical significance of differences in numeric variables between different groups. Fisher exact test was used to assess the association between categorical variables. Repeated measurement linear regression models were used to calculate the regression β coefficients for (i) the evaluation of the associations between level of COPD awareness (dependent variable) and the independent variables such as clinical characteristics (number of annual exacerbations, mMRC dyspnoea grade) and patient-reported outcomes (B-IPQ total score, MMMS-4 score, and TSQM-9 scores) at enrollment and at 12-month follow-up visits and (ii) the evaluation of the associations between CAT score (dependent variable) and independent variables such as clinical characteristics or PROs during the 12-month observation period. The statistical analysis was performed with SAS[®] 9.4 software.

Results

A total of 401 patients were enrolled in the SAT study; 367 of them (25.8% women) were eligible for inclusion in the post hoc analysis since DACQ were incomplete or

missing for 34 patients at enrollment visit. Demographics, clinical characteristics, and PROs at enrollment are reported in Table 1.

- *Percentage of patients' who achieved a good level of COPD awareness at the enrollment.* At enrollment, an optimal level of awareness (DACQ total score ≥ 80) was identified in 74 patients (20.2%), whereas 293 patients (78.8%) did not achieve this level.
- *Between-group differences in socio-demographics, clinical characteristics and in PROs according to level of awareness.* At enrollment, no difference between the 2 groups was found in terms of age, age at COPD diagnosis, and MMAS scores. Overall, patients with suboptimal awareness, compared to those in which awareness was optimal, had a higher median CAT score (difference: 5.0 points; *p* value = 0.0001), a higher median mMRC score (difference: 1.0 point; *p* value = 0.0031), a lower median duration of COPD (difference: 1.4 years; *p* value = 0.0428), a lower median TSQM-9 effectiveness score (difference: 5.6 points; *p* value = 0.0002), a lower median TSQM-9 convenience score (difference: 11.1 points; *p* value < 0.0001), a lower median TSQM-9 global satisfaction score (difference: 14.3 points; *p* value < 0.0001), and a higher median B-IPQ total score (difference: 9.0 points; *p* value < 0.0001).

Fig. 1. Difference in the proportion of patients with an optimal awareness (DACQ total score ≥ 80) in the group with CAT < 10 and in the group of with CAT ≥ 10 at the 12-month follow-up ($p = 0.0022$).

- *Exacerbation history and CAT scores in patients with optimal and suboptimal awareness.* At enrollment, the proportion of patients who had exacerbations during the previous year was higher in patients with suboptimal COPD awareness (DACQ total score < 80) than in those with an optimal level of awareness (42.8 vs. 21.4%, p value = 0.0009). At the 12-month follow-up, the proportion of patients with an optimal awareness (DACQ total score ≥ 80) was significantly higher in the group of those with CAT < 10 than in the group of those with CAT ≥ 10 ($p = 0.0022$) (Fig. 1).
- *Relationship between COPD awareness and clinical characteristics/PROs during the 12-month observation period:* a repeated measures regression model was implemented to assess the relationship between DACQ total score and clinical parameters. In particular, TSQM-9 scores, B-IPQ score, level of adherence (MMAS-4 score), and number of annual exacerbations were considered as independent variables; CAT and mMRC scores were not included as covariates in the model because they were both highly correlated to B-IPQ score (Spearman's correlation coefficients > 0.65 and > 0.55 , respectively; $p < 0.0001$ in both cases). The following independent factors were found to be significantly associated with level of awareness: illness perception, adherence, and treatment satisfaction (Table 2). The relationship between CAT and awareness, as measured at enrollment and at 12-month follow-up visits, was evaluated by means of another repeated

Table 2. Relationship between DACQ total score and PROs over the 12-month observation period (repeated measures regression model for numeric variables)

Effect	Estimate (β)	Standard error	Pr $> t $
B-IPQ score	-0.3135	0.04224	< 0.0001
MMAS-4 score	1.7239	0.4693	0.0003
TSQM-9 effectiveness score	0.06700	0.03021	0.0270
TSQM-9 convenience score	0.1275	0.03289	0.0001
TSQM-9 global satisfaction score	0.09590	0.03270	0.0035

Only patients with information on the investigated parameters available at both enrollment and 12-month follow-up were included in the model ($N = 244$). CAT and mMRC scores were not included in the model because they were both highly correlated to B-IPQ scores (Spearman's correlation coefficients > 0.65 and > 0.55 , respectively; $p < 0.0001$ in both cases).

measures regression model using DACQ total score (≥ 80 vs. $< 80\%$) as independent variable. The DACQ total score was found to be significantly associated with CAT ($\beta = -2.4420$; p value = 0.0015).

Discussion

COPD poses a major health challenge globally, currently being cause of morbidity, mortality [23], and substantial direct and indirect costs [24]. At the population level, undiagnosis of COPD is common and remained unchanged over 2 decades [25]. Awareness is essential for consciousness and long-term management of chronic diseases, such as COPD. It has been defined as a competency that facilitates self-monitoring [26] and that gives rise to "knowing intentionality" and allows "discerning attitude regarding what to act out and what not" [27]. In other words, awareness goes beyond knowledge. In fact, coping with COPD, patients are confronted by information from external sources (about disease characteristics, causes, prognosis, and treatment) and internal sources (thoughts, emotions, and body sensations) and these are integrated in the complexity of personal experience.

Crucially, to be aware, a patient has not simply to know what COPD is, but also has to recognize the necessity and the role of treatments, to make sense and accept the disease. Our results show that an optimal level of awareness was achieved only for about 1 patient out of 5. The com-

parison of patients with DACQ scores ≥ 80 (optimal awareness level) and patients with DACQ score < 80 (sub-optimal awareness level) showed that they had a different profiles. Patients with suboptimal awareness had a shorter median duration of COPD by 1.4 years and lower treatment satisfaction for the effectiveness and convenience factors and for the global score. Moreover, they had higher B-IPQ scores, indicating a more threatening view of the illness, a worse health status, as testified by CAT, and higher level of dyspnea. In addition, twice as many patients with low COPD awareness, compared to those with good awareness, had one or more exacerbations during the year previous to enrollment. The relationship between COPD awareness and clinical characteristics/PROs during the entire 12-month observation period was explored by repeated measures regression models, as described in the statistical analysis paragraph. The level of awareness was significantly associated with CAT scores, illness perception, adherence, and treatment satisfaction, and the association was in the expected direction. Moreover, during the 12-month observation period, patients with DACQ scores ≥ 80 had significantly lower CAT scores by 2.4 points on average.

The results of our study seem to show level of awareness is related to a different way to perceive COPD and cope with it and to different clinical outcomes. Awareness seems to be a competency that allows patients to not be passive actors [25] with their disease, but to accommodate changes, to better tolerate their experience, and to increase the positive dimensions of life despite the presence of COPD. To our knowledge, this is the first study that explores the clinical relevance of awareness as a factor that could optimize the long-term management of COPD. Education programs to raise the level of knowledge of patients and their families and to implement recommendations for effective treatment and prevention of COPD are welcome. However, the concept of awareness should take into account also perception, attitudes, and emotions due to their global effect on the ability to adopt strategies for coping with COPD and strengthening of adherence to treatment.

The limitations of our study must be considered. First, patient selection was performed following the inclusion/exclusion criteria of the SAT study, and the units participating in the study were chosen as a sample of convenience. Moreover, the sample includes only patients who had been referred to tertiary centers. Therefore, in terms of external validity, our study findings should not be generalized to the whole population of patients with COPD, but rather to subjects with similar characteristics than our

patient sample. However, it is likely that COPD awareness would have been even lower in a nonspecialist setting. Moreover, it is not possible to assess whether changes of awareness are a direct consequence of changes in clinical outcomes and PROs. We acknowledge that further studies are needed to corroborate the results of our exploratory analysis and to complement them also in more heterogeneous cohorts (including patients with severe COPD features and frequent exacerbations). Nevertheless, our findings could provide input data for developing personalized interventions to improve the level of awareness and to assess their effects on patients' well-being.

Statement of Ethics

This study protocol of this multicenter, observational prospective cohort study was approved by Ethics Committee of University of Genoa (Comitato Etico Regione Liguria c/o IRCCS A.O.U. San Martino-IST; Protocol N°: 343REG2015) and by the institutional Ethics Committees of the centers involved in this study: Comitato Etico della Provincia di Ferrara c/o A.O.U. di Ferrara, Comitato Etico Area Pavia c/o IRCCS Policlinico San Matteo, Comitato Etico Milano Area A c/o A.O.
