Abstract

Although $\pi_1 V^3$ is an obstruction for killing stably the 1-handles of an open simply connected 3-manifold $V^3$, one can always get rid of the 1-handles of $V^3 \times B^n$, for high enough $n$, at the price of a certain nonmetrizable slackening of the topology.

1. Introduction

One of the roots for the present work is the first author’s paper [8]. It will be helpful to start by giving a modern, up to date version, of what was going on in that old paper. But for that, first we need a definition. A smooth manifold $M^n \geq 3$ is said to be Dehn exhaustible (DE) if for every compact $k \subset M^n$ there is commutative diagram, with $j$ an inclusion,

\[
\begin{array}{ccc}
M^n & \xrightarrow{j} & P^n \\
\downarrow g & & \downarrow \\
M^n & \xrightarrow{k} & P^n 
\end{array}
\]

such that $P^n$ is a compact simply connected smooth $n$-manifold and $g$ is a (smooth) immersion which satisfy the following Dehn-type condition:

\[
jk \cap \{\text{the set } M_2(g) \subset P^n \text{ of the double points of } g\} = \emptyset.
\]

With this, what the modern version of [8] says is the following

**Proposition A.** Let $M^n$ be an open smooth $n$-manifold such that, for some $p \geq 1$, the $M^n \times B^p$ is geometrically simply connected (GSC). Then $M^n$ is DE.

The notion GSC stems from differential topology, where it means the existence of a handlebody decomposition where the 1-handles and 2-handles are in canceling position. But this same notion also makes sense for cell-complexes, in general, see [7].

**Corollary B.** Under the conditions of Proposition A, if $n = 3$, then

$$\pi_1^\infty M^3 = 0.$$  

This is actually what [8] proves, but between the lines, the proof of Proposition A should be readable there too. Having these things in the background, we will describe next what the present paper does.

**Theorem C.** Let $V^3$ be any open simply-connected 3-manifold, and let also $m \in \mathbb{Z}_+$ be large enough. There is then an infinite collection of smooth $(m + 3)$-manifolds, all of them non-compact, with very large boundary, connected by a sequence of smooth embeddings

$$X_1 \subset X_2 \subset X_3 \subset \cdots$$

such that

1) $X_1$ is GSC and each of inclusion in (3) is either an elementary Whitehead dilatation or the addition of a handle of index $\lambda > 1$.

2) When one considers the union of the objects in (3), endowed with the weak topology, call this new space $\lim X_i$, then there is a continuous bijection

$$\lim X_i \xrightarrow{\psi} V^3 \times B^m.$$  

Notice also there in the context of Theorem C there is no reasonable topology which is usable other than weak one. The reader is reminded that in the weak topology, a set $F \subset \lim X_i$ is closed iff all the $F \cap X_i$ are closed. Also, the inverse of $\psi$ is not continuous here; would it be, this would certainly contradict [8], since $V^3$ may well be the Whitehead manifold $W_3$. This, via Brouwer, also means that $\lim X_i$ cannot be a manifold (which would automatically be then GSC coming in conflict with Proposition A). Also, exactly for the same reasons why $\lim X_i$ is not a manifold, it is not a metrizable space either.

In the context of formula (4) the only place where things go wrong, i.e. where the inverse map of $\psi$ fails to be continuous and where $\lim X_i$ is not a manifold, is a codimension one smooth proper $\Sigma(\infty) \subset V^3 \times \partial B^m$. This bad locus $\Sigma(\infty)$ is quite well defined in terms of Theorem I from [15].

Actually, in the main body of the present paper, it is not $V^3$ which occurs but a variant of it $V^3_h$, the “$V^3$ with very many holes”, but this is a rather irrelevant technically which we will skip over in this introduction.

In order to explain the interest of Theorem C, let us go back to the context of DE. From this concept, S. Brick, M. Mihalik and J. Stallings [1,16] have abstracted the notion QSF (quasi-simply filtered). Here is the change from DE to QSF. In the context of (1) $M^p$ becomes a locally compact simplicial complex $X$ and, most importantly, $g$ becomes just a simplicial map $f$ satisfying the Dehn Property. One of the interesting features of the QSF is that, contrary to DE as such, it is a group theoretical notion too. More explicitly the following happens.

If $K_1, K_2$ are two finite simplicial complexes such that $\pi_1 K_1 = \pi_1 K_2 = \Gamma$ then

$$\bar{K}_1 \in \text{QSF} \iff \bar{K}_2 \in \text{QSF},$$

hence it makes sense, in this case, to say that $\Gamma$ is QSF. Nothing like (5) holds for DE. The QSF is also quite deeply connected with GSC. Quite trivially GSC implies QSF but, at least in the groups theoretical context, there is a weak kind of converse to this, see here [6].

By now the first author has proved that all finitely presented groups are QSF. An outline of the proof is to be found in [6]. The complete details are object of a trilogy, the first of which should be out in print soon [7]. The last two parts, recently completely revised and rewritten, are in the process of being typeset at IHES. Reference [4] should be useful too.

The bad locus $\Sigma(\infty)$ already mentioned above is one of the main dramatic personae in the trilogy. Incidentally too, the present paper relies heavily on [6] the companion paper [14] of which shows that the bad locus $\Sigma(\infty)$ could become chaotically wild instead of being smooth. This pathology if we would not control it, would be disastrous for the trilogy.

As explained in [6], one of the difficulties in proving that all the $\Gamma$’s are QSF, is to manage to stay safely away from two “barriers” which play against each other, the so-called Stallings barrier (see [6]) and the nonmetrizability barrier, which is epitomized by our Theorem C above. That what theorem exhibits is what happens when one actually hits the nonmetrizability barrier. Although coming very close to it, the proof the all $\Gamma$’s are QSF has to stay safely away from it. In the same sense, this should be seen as the “negative” virtue of Theorem C, while its contrast to Proposition A should be seen as its “positive” virtue.
2. The main theorem

After this more general kind of an introduction, we will start making things precise. So we fix from now on an arbitrary open simply connected 3-manifold \( V^3 \). We consider an appropriately chosen \( V^3_h \), have a proper stratified smooth submanifold of \( V^3_h \)

\[
V^3_h \supset \Sigma_2(\infty) = r^{-1}(f(\lim M_2(f))) \overset{f}{\rightarrow} f(\lim M_2(f))
\]

where \( M_2(f) \) denotes the set of double points of \( f \) and \( r \) the canonical retraction \( 
\text{Nbd} \setminus \overset{\circ}{fX^2} \).

In (2.87) from [15] this \( \Sigma_2(\infty) \) was actually called \( \Sigma(\infty) \), but we reserve now this later notation for (6) below.

Under the conditions above we consider the standard smooth ball \( B^n \) of dimension \( n \geq 3 \) and the non-compact manifold with non-empty boundary

\[
V^3_h \times B^n \supset \partial (V^3_h \times B^n) = V^3_h \times S^{n-1}.
\]

The proper (stratified) smooth submanifold of codimension one (with only strata of codimension 1 and 2)

\[
\Sigma(\infty) \overset{\text{def}}{=} \Sigma_2(\infty) \times S^{n-1} \subset V^3_h \times S^{n-1}
\]

will be called the **bad locus**, the reason for this terminology will become clear quite soon. Our main result is the following theorem, where for an **arbitrary** open simply-connected \( V^3 \) an appropriate version “with holes”, \( V^3_h \), has to be picked up.

**Theorem 2.1.** For any given \( n \geq 2 \), there exists a sequence of smooth non-compact \((n + 3)\)-dimensional manifolds with non-empty boundaries

\[
X^0_0 \subset X^0_1 \overset{g_1}{\rightarrow} X^1_1 \overset{g_2}{\rightarrow} X^2_2 \overset{g_3}{\rightarrow} \cdots
\]

with the following list of properties.

0) The manifold \( X^0_0 \) has a handlebody decomposition without handles of index one.

1) All the maps \( g_i \) are smooth proper embeddings. Moreover each \( g_i \) is either a Whitehead dilatation or the addition of handle of index \( \lambda = 2 \).

2) We also have smooth, but not necessarily proper embeddings \( X^0_{j+3} \overset{I(j)}{\rightarrow} V^3_h \times B^n \), giving rise to commutative diagrams

\[
\begin{array}{ccc}
X^0_j & \overset{g_{j+1}}{\longrightarrow} & X^1_{j+1} \\
\downarrow I(j) & & \downarrow I(j+1) \\
V^3_h \times B^n & \overset{I(j)}{\rightarrow} & V^3_h \times B^n
\end{array}
\]

The \( I(j)X^0_{j+3} \)'s exhaust \( V^3_h \times B^n \). If we consider \( \lim X^0_{j+3} \overset{\text{def}}{=} \cup I(j)X^0_{j+3} \end{array} \) endowed with the topology of inductive limit (= the weak topology), then the natural map ("the identity")

\[
\lim X^0_{j+3} \overset{I(\infty)}{\rightarrow} V^3_h \times B^n
\]

is a continuous bijection. [Caution, \( \lim X^0_{j+3} \) is, generally speaking, not a manifold, actually not even a metrizable space.]

3) The space

\[
W^{n+3} \overset{\text{def}}{=} \lim X^0_{j+3} \setminus I(\infty)^{-1}(\Sigma(\infty))
\]

has a natural structure of smooth manifold with non-empty boundary, compatible with the weak topology of \( \lim X^0_{j+3} \). Moreover \( \text{int} W^{n+3} = \cup I(j) \text{int} X^0_{j+3} \).

4) The map

\[
W^{n+3} \overset{I(\infty)W^{n+3}}{\rightarrow} V^3_h \times B^n \setminus \Sigma(\infty)
\]
is a diffeomorphism, while the map
\[ \lim X^n_j \xrightarrow{I(\infty)^{-1}} V_h^3 \times B^n \]
fails to be continuous exactly along the bad locus \( \Sigma(\infty) \).

Complement to Theorem.

I. There exists an infinite, locally finite, properly embedded 2-dimensional subcomplex \( K^2_0 \subset X_0^{n+3} \), such that \( \star X_0^{n+3} \) is compact in the direction transversal to \( K^2_0 \), in the sense that \( X_0^{n+3} \) is a smooth bona fide regular neighborhood of \( K_0 \).

II. When we restrict \( I(\infty) \) to \( I(\infty)^{-1} \Sigma(\infty) \subset \lim X_j^{n+3} \) endowed with its induced topology
\[ I(\infty)^{-1} \Sigma(\infty) = \lim \left( X_j^{n+3} \cap I(\infty)^{-1} \Sigma(\infty) \right) \],
then we get a homeomorphism
\[ I(\infty)^{-1} \Sigma(\infty) \approx \Sigma(\infty) \subset V_h^3 \times B^n. \]
So we have a uniquely well-defined topological space \( \Sigma(\infty) \) endowed not only with its natural embedding into \( V_h^3 \times B^n \) but also with an embedding \( \Sigma(\infty) \subset \lim X_j^{n+3} \), such that the following diagram commutes
\[ \lim X_j^{n+3} \xrightarrow{I(\infty)} V_h^3 \times B^n \supset V_h^3 \times S^{n-1} \]
Our Theorem 2.1 above is part of the circle of ideas which are involved in the first author’s work [6] and one should also see here [3].

3. Higher-dimensional thickenings

The aim of this section is to give a number of very explicit pictures which will be useful later on. The apparent pedantry of the discussions which follows is due to the fact that, eventually, the elementary steps which we describe here will be part of an infinite iteration; and if we want this infinite iteration to converge in any reasonable sense, then some more of extra precision is required, as far as the elementary steps to be iterated are concerned. We will start by reviewing very briefly the elementary facts concerning the 4-dimensional thickening functor from [12]. In [12] we had worked with a compact 2-dimensional singular polyhedron \( X \xrightarrow{f} M^3 \) and/or with the singular compact 3-dimensional manifolds \( \Theta^3(X) \)’s obtained by thickening \( X \) 3-dimensionally, via the recipe \( f \). But that whole story extends immediately to locally compact \( X \)'s which are singular locally finite generalized polyhedra, in the sense of [15], and to their obviously defined \( \Theta^4(X) \)'s. Remember that such an \( X \xrightarrow{f} M^3 \) continues to be completely standard (i.e. a locally finite simplicial complex) at the source, and that it is only the map \( f \) which can become more exotic, leading to an \( fX \subset M^3 \) which is a bona fide generalized polyhedron (in the sense of [15]) and hence fails to be a simplicial complex, not even one which is not locally finite. But we will never talk about objects like \( \Theta^3(fX), \Theta^4(fX, \varphi) \) (which do not make any sense) \( \ldots \), and only about the open regular neighborhoods \( \text{Nbd}(fX) \subset M^3 \) and their product with \( B^n \).

In [13] we have introduced desingularizations \( \varphi \) for \( X \) and/or for \( \Theta^3(X) \) denoted by \( \Theta^4(X, \varphi) \) and/or \( \Theta^4(\Theta^3(X), \varphi) \), giving rise to smooth blow-ups
\[ \tilde{\Theta}^3(X) = \tilde{\Theta}(X)(\varphi) \xrightarrow{\pi(\varphi)} \Theta^3(X). \]
For each \( \varphi \) we have a canonical 4-dimensional regular neighborhood of \( X \) and/or of \( \Theta^3(X) \); moreover, there is a canonical embedding
\[ \tilde{\Theta}^3(X) \hookrightarrow \partial \Theta^4(X, \varphi). \]
This thickening functor \( \Theta^4(\cdots) \), which is just the product by \( I \) in the case of a smooth \( \Theta^3(X) \), has good gluing properties and it is invariant under acyclic \( O(i) \)-moves. Finally, our 4-dimensional thickening \( \Theta^4(\cdots) \) also has the following two properties where the desingularization \( \varphi \) plays a key role.
i) Consider an acyclic $O(i)$-move $X \xrightarrow{p} X_1$ and a subset $E \subset X - \text{Sing} X$ which is such that $p|X$ injects and that $pE \subset X_1 - \text{Sing} X_1$. Then we have a diagram

$$
\begin{array}{c}
\Theta^4(X, \varphi) \xrightarrow{\approx} \Theta^4(X_1, \varphi) \\
\downarrow \quad \downarrow \\
\tilde{\Theta}^3(X) \quad \tilde{\Theta}^3(X_1) \\
E
\end{array}
$$

where the upper horizontal arrow is the canonical diffeomorphism and where the other maps are the obvious inclusions.

If for every $x \in E \cap M_2(p)$ we have $\varphi(x) = N$ (and not $\varphi(x) = S$), then the diagram (7) commutes.

ii) To a coherent $O(3)$-move $X_1 \xrightarrow{p} X_2$ there corresponds an embedding

$$
\Theta^4(X_1, \varphi) \hookrightarrow \text{int} \Theta^4(X_2, \varphi)
$$

such that the associated cobordism $\Theta^4(X_2, \varphi) - \text{int} \Theta^4(X_1, \varphi)$ means just addition of a handle of index two, in other words we find that

$$
\Theta^4(X_2, \varphi) = \Theta^4(X_1, \varphi) + ([\text{a handle of index } \lambda = 2]).
$$

We fix now once and for all an integer $n > 4$. We have the following elementary fact

**Lemma 3.1.** Let $\varphi_1, \varphi_2$ be two desingularizations of $X$. There is a canonical diffeomorphism

$$
\Theta(X, \varphi_1) \times B^{n-4} \xrightarrow{d} \Theta(X, \varphi_2) \times B^{n-4}.
$$

(8)

So, for each $n > 4$ there is a uniquely well-defined $n$-manifold

$$
\Theta^n(X) \overset{\text{def}}{=} \Theta^4(X, \varphi) \times B^{n-4}.
$$

(9)

Of course, this is a triviality; but it will be useful to have a very explicit description of (8). We will start by reviewing the construction of $\Theta^4(X, \varphi)$, as it is given in [11]. For $X^3 \overset{\text{def}}{=} \Omega^3(X)$ having as singularities the little squares $\sigma_1, \sigma_2, \ldots, \sigma_r$, we have the canonical decomposition (2.6) from [11], which we rewrite here as

$$
X^3 = X^3(\text{smooth}) \cup \sum_{i=1}^r K(\sigma_i)
$$

where each $K(\sigma_i)$ is split from the rest of $X^3$ by the punctured torus $\delta K(\sigma_i)$. When we give ourselves a desingularization $\varphi$ of $X$, each $\sigma_i$ comes equipped with an embedding (leading to a Heegaard splitting of $S^3$)

$$
\tilde{K}(\sigma_i) = \tilde{K}(\sigma_i, \varphi) \subset S^3 = \partial B^4(\sigma_i);
$$

(10)

there are exactly two embeddings (10) possible, for a given $\sigma_i$, corresponding to the possible desingularizations and each comes equipped with another embedding

$$
\delta \tilde{K}(\sigma_i) \times [0, 1] \subset \partial B^4(\sigma_i);
$$

(11)

here $\delta \tilde{K}(\sigma_i) \times 0 = \delta \tilde{K}(\sigma_i) \subset \partial \tilde{K}(\sigma_i)$ and the factor $[0, 1]$ is outgoing with respect to $\tilde{K}(\sigma_i)$. With this, we have

$$
\Theta^4(X, \varphi) \overset{\text{def}}{=} (X^3(\text{smooth}) \times [0, 1]) \cup \sum_{i=1}^r B^4(\sigma_i),
$$

the two pieces being glued together along $\sum_i \delta K(\sigma_i) \times [0, 1]$. Now, the crucial point is that (unless we are willing to reverse the parametrization of the $[0, 1]$ factor) the two possible embeddings (11) coming from the two distinct $\varphi_n$’s are NOT ISOTOPIC.

For $n > 4$, all this gives us a unique canonical isotopy class for the embedding

$$
\delta K(\sigma_i) \times [0, 1] \times B^{n-4} \subset \partial (B^4(\sigma_i) \times B^{n-4})
$$
Fig. 1. We see here \( \tilde{X}^2(\varphi) \subset \partial \Theta^4(X, \varphi) \).

which makes
\[
\left( X^3(\text{smooth}) \times [0, 1] \times B^{n-4} \right) \cup \sum_{1}^{r} (B^4(\sigma_i) \times B^{n-4}) \\
\delta K(\sigma_i) \times (0, 1] \times B^{n-4}
\]
independent of \( \varphi \). The manifold (12) is our (9). \( \square \)

When we replace \( \Theta^4(X, \varphi), \Theta^4(X_1, f) \) in (8) by \( \Theta^n(X), \Theta^n(X_1) \) respectively, then we get commutativity, whatever \( \varphi \) might have been. Also every O(3)-move functions now like a coherent one: for any O(3)-move \( X_1 \rightarrow X_2 \), independently of any \( \varphi \) considerations, we get now an embedding
\[
\Theta^n(X) \rightarrow \text{int} \Theta^n(X_1)
\]
where
\[
\Theta^n(X_1) - \text{int} \Theta^n(X) = \{n\text{-dimensional cobordism corresponding to a unique handle of index } \lambda = 2 \}.
\]

So four dimensions and the unstable coherence property (the impact of which is null as soon as we move to dimensions five or more) were an indispensable ingredient for the theory from [2] and [8–11].

The rest of this section develops the elementary properties of the \( \Theta^n(\cdots) \) thickening functor \( (n > 4) \), which will be useful later on.

Let \( \varphi \) be a desingularization of the singular 3-manifold \( X^3 = \Theta^3(X^2) \) and let \( \tilde{X}^3 = \tilde{X}^3(\varphi) \) be the corresponding desingularized \( X^3 \). We have, by definition, a projection map \( \tilde{X}^3 \rightarrow X^3 \) which blows up the singularities, and which is the identity on \( X^3(\text{smooth}) \). But there is also an obvious inclusion map
\[
\tilde{X}^3(\varphi) \xrightarrow{i} X^3(\text{smooth})
\]
(14)

Except in a neighborhood of \( \pi^{-1}(\text{singularities}) \), where it is only well-defined up to isotopy, the map \( i \) (by definition) is rigidly equal to the identity. We will pick up, once and for all, a base point \( \star \in \partial B^{n-4} \), which allows us to define unambiguously the embedding
\[
\Theta^4(X^4, \varphi) = \Theta^4(X^3, \varphi) \times (\star) \subset \partial \Theta^n(X^3)
\]
\[
= (\Theta^4(X^3, \varphi) \times \partial B^{n-4}) \cup (\partial \Theta^4(X^3, \varphi) \times B^{n-4})
\]
(15)

The induced embedding \( \tilde{X}^3(\varphi) \subset \partial \Theta^n(X^3) \) can be extended (see (14)) to an embedding \( X^3 \subset \partial \Theta^n(X^3) \).

In term of Fig. 1, the embedding \( \tilde{X}^2(\varphi) \subset X^2 \) is obtained by adding a 2-cell along the circle \( \gamma \). Because of the point \( x \in \gamma \) (Fig. 1) which is buried deep inside \( \tilde{X}^2(\varphi) \), this cannot be achieved inside the 3-dimensional \( \partial \Theta^4(X^3, \varphi) \). But as soon as an extra dimension is available there are no more problems.

At least if \( n \) is high enough, this embedding of the singular \( X^3 \) is also uniquely defined up to isotopy (irrespective of \( \varphi \)). We consider next a surface \( \Sigma \subset X^3 \) with the following properties.

If $\sigma$ is the singularity of $X^3$, then either $\sigma \subset \Sigma$ or $\sigma \cap \Sigma = \emptyset$.

b) If $\sigma \subset \Sigma$, then the local situation of the pair $(X^3, \Sigma)$, in the neighborhood of $\sigma$, can be described as follows. We start by considering the following two pieces of $R^3 = (y, x_1, x_2)$ which, in a first stage, will be thought of as being completely disjointed objects (see also Fig. 2)

$$A_1 = \{ y \in [-M, M], x_1 \in [-M, M], x_2 \in [-\epsilon_2, \epsilon_2] \},$$

$$A_2 = \{ y \in [-M, M], x_1 \in [-\epsilon_1, \epsilon_1], x_2 \in [-M, M] \} \setminus \{ y \in [-M, 0], x_2 \in [-\epsilon_1, \epsilon_1], x_1 \in (-\epsilon_2, \epsilon_2) \}.$$

Let also

$$\Sigma \cap A_1 \equiv \{ (y \in [-M, 0], x_1 \in [-\epsilon_1, \epsilon_1], x_2 = \pm \epsilon_2) \cup (y = 0, x_1 \in [-\epsilon_1, \epsilon_1], x_2 \in [-\epsilon_2, \epsilon_2]) \} \subset A_1.$$

The boundary of $A_2$ contains an obvious isomorphic copy of $\Sigma \cap A_1$ which we will call $\Sigma \cap A_2$. Let $B = A_1 + A_2$ be the two pieces being glued together along the identified $\Sigma \cap A_1 = \Sigma \cap A_2$ and let

$$\delta B = \{ (y = \pm M, x_1 \in [-M, M], x_2 \in [-\epsilon_2, \epsilon_2])$$

$$\cup (y \in [-M, M], x_1 \in \epsilon M, x_2 \in [-\epsilon_2, \epsilon_2]) \} \cup \{ (y = \pm M, x_1 \in [-\epsilon_1, \epsilon_1], x_2 \in [-M, M] \}$$

$$\cup (y \in [-M, M], x_1 \in [-\epsilon_1, \epsilon_1], x_2 = \pm M) \}$$

the two pieces being glued together along the little square

$$\{ y = -M, x_1 \in [-\epsilon_1, \epsilon_1], x_2 \in [-\epsilon_2, \epsilon_2] \}.$$

This $B$ is a neighborhood of the singularity $\sigma = (y = 0, x_1 \in [-\epsilon_1, \epsilon_1], x_2 \in [-\epsilon_2, \epsilon_2])$ in $X^3$, separated from the rest of $X^3$ by $\delta B$.

c) When we are far from the singularities, $\Sigma$ is a proper submanifold of $X^3$ (with $(\Sigma, \partial \Sigma) \subset (X^3, \partial X^3)$).

d) We have a splitting of $X^3$ along $\Sigma$ into two pieces $X_1^3$ and $X_2^3$

$$X^3 = X_1^3 \cup_X X_2^3,$$

where

d-i) in the context of b) we always have $A_1 \subset X_1^3$, $A_2 \subset X_2^3$ (i.e. for the singularities contained in $\Sigma$ we have $\sigma \cap \text{int} X_1^3 \neq \emptyset = \sigma \cap \text{int} X_2^3$).

d-ii) Each of the $X_j^3$ ($j = 1, 2$) is a singular 3-dimensional manifold and (obviously)

$$\text{Sing } X_j^3 = (\text{Sing } X^3) \cap X_j \cap (\text{Sing } X^3) \cap \Sigma$$

We will call $\Sigma$ a splitting surface for $X^3$. It will be noticed that in the splitting (16) which is induced by such a $\Sigma$, the two halves do not play a symmetrical role. Let us also consider a desingularization $\psi$ for $X^3$. Since $\Sigma \subset X_1^3 - \text{Sing } X_2^3$ (with $j = 1, 2$) we have embeddings $\Sigma \subset \hat{X}_j^3 = \hat{X}_j^3(\psi) \subset \partial \Theta^4(X_j, \psi|X_j)$ and $\Sigma \times [0, 1] \subset \partial \Theta^4(X_j, \psi|X_j)$ with $\Sigma \times 0 = \Sigma$ and where the $[0, 1]$ factor is outgoing with respect to $\hat{X}_j^3$. 

\[ \text{Fig. 2. } A_1 \text{ and } \Sigma \cap A_1 \supset \sigma \text{ (doubly hatched). This } \sigma \text{ is burred inside } A_1. \]
Lemma 3.2.

1) If for every singularity \( \sigma \subset \Sigma \) we have
\[
\varphi_\sigma(A_1) = N, \quad \varphi_\sigma(A_2) = S
\]
then we have the reconstruction formula
\[
\Theta^4(X^3, \varphi) = \Theta^4(X_1^3, \varphi|X_1^3) \cup \Theta^4(X_2^3, \varphi|X_2^3).
\] (18)

[One should remember here that \( A_1 \subset X_1^3 \); if we reverse (17), even at a single \( \sigma \), then the reconstruction formula (18) will, generally speaking, become false.]

2) For \( n > 4 \) we have the unrestricted reconstruction formula
\[
\Theta^n(X^3) = \Theta^n(X_1^3) \cup \Theta^n(X_2^3).
\] (19)

Here the two halves from the right-hand side are glued via the two canonical embeddings \( \Sigma \times [0,1] \times B^{n-4} \subset \partial \Theta^n(X^3) \).

(The canonical embeddings mentioned above come from
\[ \Sigma \times [0,1] \subset \partial \Theta^n(X_1^3), \partial \Theta^n(X_2^3) \times (\bullet) \subset \partial \Theta^n(X^3), \partial \Theta^n(X^3) \times B^{n-4} \subset \partial \Theta^n(X^3) \]
(see (15)) the first of these embeddings being induced by \( \Sigma \subset \bar{X}_j^3 \subset \partial \Theta^n(X_j^3, \varphi) \) with the \([0,1]\)-factor outgoing with respect to \( \bar{X}_j^3 \).

We consider now an elementary move of type O(0), O(1) or O(3) (the O(2)'s will never occur in our present context) \( X \xrightarrow{\zeta} X_1^3 \), which is localized in a region \( \Theta^3(k) \subset X^3 \), like in the formula (2.13) from [5], formula which we rewrite here for the convenience of the reader as
\[
X^3 = Z^3 \cup \Theta^3(k) \xrightarrow{\text{incl}(Z^3) \cup \zeta \delta \Theta^3(k)} Z^3 \cup \Theta^3(k_1) = X_1^3.
\] (20)

Here one should remember, of course, that \( \delta \Theta^3(k) = \delta \Theta^3(k_1) \).

We consider a desingularization \( \varphi \) accompanying (20) and if (20) is of type O(3) we assume that we are in a coherent situation. As it was already explained in [5] we have then an embedding
\[
\Theta^4(X^3, \varphi) = \Theta^4(Z^3, \varphi) \cup \Theta^4(\Theta^3(k), \varphi) \xrightarrow{\text{incl}(Z^3) \cup \zeta \delta \Theta^3(k)} \Theta^4(Z^3, \varphi) \cup \Theta^4(\Theta^3(k_1), \varphi) = \Theta^4(X_1^3, \varphi),
\] (21)

which is such that \( g(\Theta^4(Z^3, \varphi) = \text{id} \) and \( g(\Theta^4(\Theta^3(k_1), \varphi)) \subset \text{int}(	ext{target}) \) (see Fig. 3). Hence we will also have similar embeddings, which we will denote with the same letter \( g \), for \( n \geq 5 \)
\[
\Theta^n(X^3) \xrightarrow{g} \Theta^n(X_1^3).
\] (22)

The O(0) case. We will start by discussing the case of a trivial O(0)-move, where no triple points are actually involved. Once this will be understood, the rest will just follow.
Fig. 4. A movie: at the moment $y = 0$ the two rectangles are glued together along the (doubly hatched) singularity $\sigma$. For $y > 0$ we pull the $A_1$ ($\varphi = S$) part towards the positive $t$ direction, which looks towards the observer. The fat lines are in $\delta\Theta^3(k)$, except that at the extreme moments $y = \pm M$ everything is in $\delta\Theta^3(k)$ (in particular both the fat contour rectangles at $y = M$).

Fig. 5. The two rectangles become much slimmer along their waists.

We can as well consider that $k$ is our

$$A_1 \cup A_2 \quad \frac{A_1 \cap \Sigma = A_2 \cap \Sigma}{(A_1 \cap \Sigma = A_2 \cap \Sigma)}$$

(see Fig. 2), where any reference to $\Sigma$ is now forgotten (and hence also the asymmetry of the splitting [16]; these things were only necessary in the context of the reconstruction formulae). It is understood that $G$ performs the obvious identifications in the region $y \in [0, M/2]$, zipping away from the singularity $\sigma$, which is changed into the new $k_1$-singularity

$$\sigma_1 = \{ y = M/2, x_1 \in [-\varepsilon, \varepsilon], x_2 \in [-\varepsilon, \varepsilon] \}.$$

Also, once it is understood that $A_1, A_2$ really play now a symmetrical role, we just set conventionally $\varphi_\sigma(A_1) = S$, $\varphi_\sigma(A_2) = N$ (the other case being completely similar). We have an obvious map (which is not injective)

$$\Theta^3(k) \overset{j}{\rightarrow} R^3 \overset{\varphi}{\rightarrow} R^4(y, x_1, x_2, t).$$

Now we change the map $j$ into an injection

$$\Theta^3(k) \overset{j}{\rightarrow} R^4$$

by pulling the specified branch ($A_1$ in our case) towards the positive $t$-direction, and the corresponding regular neighborhood will be our $\Theta^3(\Theta^3(k), \varphi)$; the $[0 \leq t \leq 1]$ arc appearing in the parametrization of $R^4$ is the $[0, 1]$-factor appearing in the definition of $\Theta^3(X, \varphi)$. Fig. 4 gives an idea of what $j$ is supposed to do.

This figure presents $j \Theta^3(k) \subset R^4$ as a movie, with the arrow of time running in the $y$-direction, while the $t$-direction sticks out from the plane of the page, towards the observer. It will be convenient, for later pedagogical purposes, to change any of the $y > 0$ pictures into something like in Fig. 5, where the two rectangles become much slimmer along their waists. We will denote our various $j \Theta^3(k)|_y$ by $k_y$ and we will use the notation $\delta k_y = k_y \cap \delta\Theta^3(k)$. So, for all $y \leq 0$ the $k_y$'s
are connected (and isomorphic) while for $y > 0$ they are again isomorphic, but now they have two connected components instead of one. Also, the singularity $\sigma$ is contained in $k_0$ and we have $k_{\pm M} \subset \partial \Theta^3(k)$. On the left side of Fig. 6 we see the “basic 3-cell” $B_0 = B_0^3 \subset (0, x_1, x_2, t)$, which presents itself as a thickened cross, and which is supposed to be a regular neighborhood of $k_0$. For typographical convenience, the $B_0^3$ in Fig. 6 has been rounded up, but strictly speaking it is supposed to be exactly (i.e. metrical speaking),

$$B_0^3 = \left([ -M \leq x_1 \leq M, -\varepsilon_2 \leq x_2 \leq \varepsilon_2 ] \cup [ -\varepsilon_1 \leq x_1 \leq \varepsilon_1, -M \leq x_2 \leq M] \right) \times [0 \leq t \leq 1],$$

(23)

with $k_0 = B_0^3 \cap (t = \frac{1}{2})$.

It should be stressed that $\delta k_0 \subset \partial B_0^3$. We will denote by $B_y$ the isomorphic copy of the $B_0 = B_0^3$ (see Fig. 6 and formula (23)), obtained via translation from the moment $y = 0$ to the moment $y$; we will denote this operation by $T_y$. When $y \leq 0$ we have $k_y = T_yk_0 \subset B_y$, but when $y > 0$, then $k_y \neq T_yk_0$. It will be nevertheless understood that $k_y \subset B_y$; the purpose of the waist-thinning from Fig. 5 was just to make this embedding possible, in the context of the “round” $B_y$ (i.e. $B_0$ at the time $t = y$) from Fig. 6.

[In the more realistic context where (23) will be used to define $B_0$ and $B_y$, the thinning of the waist will take place only in the vertical $B^0$-direction, and no longer in the ($x_1, x_2$)-plane.] In our present context, the pair $(D^4, D^3)$ from Lemma 2.0 of [5] is

$$(D^4, D^3) = \left( \bigcup_{y \in [-M, M]} B_y, \bigcup_{y \in [-M, M]} (B_y \cap (t = 0)) \right).$$

In the context of [5] we had worked under the assumption that $\partial \Theta^3(k) \cap \partial D^4 = \partial \Theta^3(k)$, but for the purpose of the present paper we work with a larger $\Theta^3(k)$, since now $\Theta^3(k) = \bigcup_y k_y$ and $k_0 \cap \partial B_0 = \partial k_0$, etc. It will be only along the waists, in the vertical $B^0$-direction that things will be buried inside our present $D^3$ (we will come back to this later). But before this, we will describe now, in similar terms, the regular neighborhood

$$\Theta^4(k, \varphi) = \Theta^4(\Theta^3(k), \varphi) = \text{Nbd}(\Lambda^3(\Theta^3(k))) \subset R^4.$$

This time, at moment $y$ we will find a 3-dimensional thickening $K_y$ of $k_y$ and the union of the $K_y$’s will be our $\Theta^4(\Theta^3(k), \varphi)$. For $y \leq 0$ we will have $K_y = T_yB_0$ (see (23) and Fig. 6). As already said $\partial B_0 \cap k_0 = \partial k_0 \supset \partial k_0$, and the four hatched disks which we can see on $\partial B_0$ are $(\partial \Theta^3(k) \times [0, 1]) \cap (y = 0)$. We denote their union by $\delta B_0$, and completely isomorphic objects $\delta B_y \subset \partial B_y$ will appear for all $y \in (-M, M)$. For $y \in [-M, 0]$ we have $K_y = B_y$. But for $y > 0$ we get $K_y$ from $B_y$ via the following operations. Remembering that we are discussing for the moment the case when $\varphi(A_1) = S = \varphi(A_2)^*$ we consider to begin with, the two curves $\Gamma_\pm \subset \partial B_y - \delta B_y$ which we can see in Fig. 6. These curves bound two parallel, disjoined and properly embedding disks $\Delta_\pm \subset B_y$. We start by deleting from $B_y$ the region intermediary between $\Delta_-$ and $\Delta_+$ and afterwards one lets each piece become very thin along its waist. So $K_y = K_y^1 + K_y^2$ with the waist $w^y$ being a tubular neighborhood of a properly embedded disk which we call again $w^y \subset K_y^y$. The right hand side of Fig. 6 and Fig. 9 can give a complete idea of the situation. The right hand side of Fig. 6 corresponds exactly to the right hand side of Fig. 9. Anyway, isotopically speaking, what we are doing is to split $B_{y>0}$ along $\Delta_+$ or along $\Delta_- \approx \Delta_+$ (see Fig. 8). In the same vein, if $\varphi(A_1) = N = \varphi(A_2)^*$, then the splitting would have to be done along the two disks $D_+$ or $D_-$ from Fig. 8. This $K_y$-movie is a complete description of $\Theta^4((\Theta^3(k), \varphi), up to isotopy, and one should notice that in $\partial B_y - \delta B_y$ the curve $\Gamma_+$ (respectively $\Lambda_+$), is homotopic (i.e. isotopic too) to $\Gamma_-$ (respectively to $\Lambda_-$), while the curves $\Gamma_{\pm}$ respectively $\Lambda_{\pm}$ are not homotopic.

We go from $\Theta^4(\Theta^3(k), \varphi)$ to $\Theta^4(\Theta^3(k_1), \varphi)$ by replacing, for $y \in (0, \frac{M}{2}]$ each $K_y$ by $B_y$. 

---

**Fig. 6.** In the right hand side we see $K_y = K_y^1 + K_y^2$ which is obtained by deleting the region intermediary between $\Delta_\pm$ (= the disks cobounding $\Gamma_\pm$) and then letting each $K_y^1$ become thin along the waist $w^y$. 

---

It will be understood that inside $B_y \times 0$ the two pieces of $K_y$ are very slim along their waists. It is convenient to think of the waists as being properly embedded 2-disks. We pass from the (21) so defined to (22) simply by multiplying with a $B^{n-4}$ factor, so that in a first approximation we have now an $(n - 1)$-dimensional movie (with $n \geq 5$) running in the $y$-direction, with $K_y$ replaced by $K_y \times B^{n-4}$. But in a slightly more precise version, for each $y > 0$ each of the $K_y \times B^{n-4} \subset B_y \times B^{n-4}$ has to be thinned, afterwards along its full $(n - 2)$-dimensional waist $w^n \times B^{n-4}$. For pedagogical reasons, we will start by describing first this process of “waist-thinning” in the not so precise context of Fig. 8, and go to the **metrically correct** (23) context only afterwards. In terms of Fig. 9, what happens can be described as follows: one starts with the $A_1 = B_y \cap (x_2 = 0)$, one rotates it along the transversal $(t_1, \ldots, t_{n-4})$ factor and then one slims it along the waist, so that in the neighborhood of $x_1 = 0$ the new “$K_y^1 \times B^{n-4}$” lives completely in the interior of $B_y^3 \times B^{n-4}$. As far as the real “$K_y^2 \times B^{n-4}$” what we see for $x_2 = 0$, $y = y_{\text{fixed}} > 0$ is [the disk $w^2$ from Fig. 9] × [a ball concentric to $B^{n-4}$, but of much smaller radius]. The point is that, with this, because $n - 4 > 0$ the asymmetry between the two halves of Fig. 9 has vanished.

Now $(B_y^3 \times B^{n-4} - K_y^1 \times B^{n-4}) \cap (x_2 = 0)$ is connected and $(K_y^2 \times B^{n-4}) \cap (x_2 = 0) \sim w^2 \times B^{n-4}$ is a small $(n - 2)$-ball centered at $*(y) \in \text{int}(B_y^3 \times B^{n-4} - K_y^1 \times B^{n-4}) \cap (x_2 = 0)$. When $x_2$ varies from $x_2 = 0$ to $x_2 = \pm \varepsilon_2$, our $(n - 2)$-ball continues to stay centered at $*(y)$ but increase its size. For later convenience we state the following trivial fact.

**Lemma 3.3.** If $n \geq 6$, then for any fixed boundary conditions the map

$$ y \in [-\mu', \mu'] \longrightarrow (B_y^3 \times B^{n-4} - K_y^1 \times B^{n-4}) \cap (x_2 = 0) $$

this is independent of $y$ given by $y \longmapsto *(y)$ is unique, up to homotopy.

This is an immediate consequence of the fact that $(B_y^3 \times B^{n-4} - K_y^1 \times B^{n-4}) \cap (x_2 = 0)$ can be retracted onto $S^{n-4}$, which is simply connected as soon as $n \geq 6$.

There is another way to look at the disappearance of the $\varphi$-dependence when $n \geq 5$. One can observe, to begin with, that the $(K_y^1, K_y^2)$ pairs corresponding to Figs. 7, 8 respectively, are connected by a regular homotopy (see also Fig. 4) which crosses $K_y^1$ with $K_y^2$. After multiplying with $B^{n-4}$ this can be changed into an isotopy, giving us a uniquely well-defined embedding (22).

**4. The operation of slackening the topology**

We will begin with some abstract nonsense, and for the purpose of clarity, we will not try to avoid certain redundancies in what follows next. But, on the other hand, we will not attempt either, to expand our abstract nonsense in a more general form than the one which is really needed for our later purposes in this paper.

We will consider a smooth non-compact $n$-manifold $Y$ with $\partial Y \neq \emptyset$ and an infinite exhaustion of $Y$ by smooth, not necessarily compact $n$-manifolds

$$ X'_0 \subset X'_1 \subset \cdots \subset X'_m \subset X'_{m+1} \subset \cdots \subset X'_\infty \overset{\text{def}}{=} Y. $$

We make the following assumptions.

1) Each of the inclusions $X'_i \subset X'_j$, where $i < j \leq \infty$, is a smooth embedding which is **proper** in the sense of general topology, i.e. the inverse image of a compact subset is compact. [We will also need to consider, later on, the case when things get improper.]

We have $Y = \bigcup_0^\infty X'_m$ and $\text{int} Y = \bigcup_0^\infty \text{int} X'_m$. 

2) For each \( m \in \mathbb{Z}^+ \) there exists a codimension zero submanifold \( M = M_{m-1} \subset \partial X_m' \) such that for the natural inclusion \( X_m' \hookrightarrow X_{m+1}' \) we have \( i^{-1}(\partial X'_{m+1}) = M \). Moreover \( \partial X_m' \) and \( \partial X'_{m+1} \) are tangent along \( \partial M \).

3) For each point \( p \in \partial M_m \) there is a neighborhood \( p \in U_0 \subset M \) which is touched only by finitely many \( (X'_\ell - X'_{\ell-1})'s \). [We do not require anything like this for points \( p \in \text{int } M_m \) and this will eventually lead to what we will call the bad locus; (see also Fig. 10.)] It is a priori clear that a point \( q \in Y \) which possesses arbitrarily small neighborhoods \( q \in U \subset Y \) such that \( U \) meets an infinity of distinct \( (X'_\ell - X'_{\ell-1})'s \), must be of the form \( q \in M_m \cap M_{m+1} \cap \cdots \). What we are assuming here is that this is never the case when \( q \) is of the more special form \( q \in \partial M_m \cap M_{m+1} \cap \cdots \).

4) For a point \( q \) which is of the form (25), there is a neighborhood \( q \in U_1 \subset Y \) such that if we consider the sequence

\[
U_1 \cap M_m \supset U_1 \cap M_m \cap M_{m+1} \supset \cdots,
\]

then the following things happens:

3.i) Each \( U_1 \cap M_m \cap M_{m+1} \cap \cdots \cap M_{m+k+1} \) is a codimension zero submanifold of \( U_1 \cap M_m \cap M_{m+1} \cap \cdots \cap M_{m+k} \) and after finitely many steps our sequence stabilizes at some

\[
U_1 \cap M_m \cap \cdots \cap M_{m+\ell} = U_1 \cap M_m \cap M_{m+1} \cap \cdots \cap M_{m+\ell} \cap M_{m+\ell+1} = \cdots.
\]

3.ii) We also have \( U_1 \cap \partial Y \cap \partial X_m' = U_1 \cap M_m \cap \cdots \cap M_{m+\ell} \). For the point \( q \in \partial M_m \cap M_{m+1} \cap M_{m+2} \cap \cdots \) from Fig. 10,

this region is suggested as a fat interval starting at \( q \) and going towards the left side of the figure.

In the concrete situations which will be of interest for us, the local situation around the \( q \)'s which verify (25) will actually be particularly simple, as we shall see later. It should be stressed that 3.i), 3.ii) are really local statements. In general, the sequence

\[
M_m \supset M_m \cap M_{m+1} \supset \cdots
\]
does not stabilize and \( \partial Y \cap \partial X'_m = \bigcap_{i=m}^{\infty} M_i \) is not a submanifold of \( \partial Y \) and/or of \( \partial X'_m \) (see in particular the fat points labeled by \( p_\infty \in \Sigma' \) in our Fig. 10, which serve as an accumulation point both for \( i \in \mathbb{N} \) and for \( \partial X'_m \cap \partial M_i \)). We define the **bad locus** \( \Sigma' \subset Y \) of the exhaustion (24) as follows. A point \( p \in \mathbb{N} \subset Y \) meets infinitely many \( (X'_m - X'_{m-1})'s \). It is obvious that \( \Sigma' \) is a closed subset of \( \partial Y \) and by our assumptions \( \Sigma' \cap \partial M_m = \emptyset \) for any \( m \). The point \( p_\infty \) from Fig. 10 belongs to the bad locus.

We will consider now the **inductive limit** of the \( X'_m \)’s, denoted by \( \lim_{m \to \infty} X'_m \) and which is endowed with the **weak topology**. This means, to begin with, that setwise \( \lim X'_m = \bigcup_{m=1}^{\infty} X'_m \), i.e. as a set \( \lim X'_m \) is just \( Y \), but the topology of \( \lim X'_m \) is different from the topology of \( Y \). As far as \( \lim X'_m \) is concerned, a set \( F \subset \bigcup_{m=1}^{\infty} X'_m \) is closed (respectively open) iff for every \( m \in \mathbb{Z}^+ \) the intersection \( F \cap X'_m \) is closed (respectively open). The obvious continuous bijection (i.e. the “identity map”) of the \( \lim X'_m \)’s is not metrizable, talking of sizes of its parts is only a metaphor.

[Fig. 10. We see here a piece of \( Y \) (which is hatched). In passing from the topological space \( Y \) to the topological space given from the inductive limit of the \( X'_m \)’s (which as a set is just \( Y \)), a sequence of the type \( q_1 \in X'_{m+1} - X'_m, q_2 \in X'_{m+2} - X'_{m+1},... \) like in the figure, which from the standpoint of \( Y \) converges to \( p_\infty \in \Sigma' \) does not converge any longer from the viewpoint of the inductive limit of the \( X'_m \)’s. But in the inductive limit of the \( X'_m \)’s as well as in \( Y \) we still find that \( p_1, p_2,... \) converges to \( p_\infty \). The bumps \( X'_{m+1} - X'_m, X'_{m+2} - X'_{m+1},... \) from our figure become smaller and smaller from the viewpoint of \( Y \) (where they converge to \( p_\infty \)) while they stay “large” (i.e. with a “size bounded from below”) from the viewpoint of the inductive limit of the \( X'_m \)’s; any sufficiently small neighborhood of \( p_\infty \in \Sigma' \) in the inductive limit of the \( X'_m \)’s avoids them all. Of course, since the inductive limit of the \( X'_m \)’s is not metrizable, talking of sizes of its parts is only a metaphor.

The space \( \lim X'_m \) associated to (24) is, by definition, a “**proper**” and **global** slackening of \( Y \). [Here the adjective “**proper**” refers to the one appearing in 1) above while “**global**” refers to the fact that \( Y \) is a global manifold and not just a coordinate chart.] Fig. 10 is supposed to give an idea of the slackening operation (26). One should notice that if \( \Sigma' \neq \emptyset \), which we will constantly assume to be the case, then we can find sequences \( p_1, p_2,..., p_n,... \) of \( \lim X'_m \) converging to some \( p_\infty \in \lim X'_m \) but which are such that for arbitrarily chosen neighborhoods \( p_i \in U_i \) we can find sequences

\[
q_1 \in U_1, q_2 \in U_2,...,q_n \in U_n,...
\]

which do not converge in \( \lim X'_m \). This also means that \( \lim X'_m \) is not a metrizable space and hence not a manifold either; of course the map \( I'(\infty)^{-1} \) is not continuous even, but just bijective. The topology of \( \lim X'_m \) depends on the whole data (24) and not just on the pair \((Y, \Sigma')\). Here are a number of easy but useful properties.

5) The set of discontinuity points of the map \( I'(\infty)^{-1} \) is exactly the bad locus \( \Sigma \subset Y \).

6) Let us consider the subset \( I'(\infty)^{-1} \Sigma' \subset \lim X'_m \) with its induced topology, i.e. \( \lim I'(\infty)^{-1} \Sigma \cap X'_m \). The subspace \( \lim X'_m - I'(\infty)^{-1} \Sigma' \subset \lim X'_m \) has a natural smooth \( n \)-manifold structure, compatible with its topology inherited from \( \lim X'_m \) and, moreover, the restriction map

\[
\lim X'_m - I'(\infty)^{-1} \Sigma' \xrightarrow{I'(\infty)^{-1}} Y - \Sigma'
\]

is a diffeomorphism.
Assume now that the following condition is also fulfilled.

A) For any $p \in \Sigma'$ there are a neighborhood $U$ of $p$ in $Y$ and an $m \in \mathbb{Z}^+$ such that $\Sigma' \cap U \subset X'_m$.

Under the assumption below, the map

$$l'(\infty)^{-1}\Sigma' = \lim(l'(\infty)^{-1}\Sigma' \cap X'_m) \xrightarrow{l'(\infty)[l'(\infty)^{-1}Y']} \Sigma' \subset Y$$

is a homeomorphism onto its image. Under such conditions, we will simply write $\Sigma'$ for left hand side of (27) and we will not make any distinctions between the two sides of (27). In all the cases of interest for us, the condition A) will always be fulfilled.

8) The proper global slackening operation has good gluing properties which are obvious; we leave it to the reader to make them explicit.

9) Two proper and global slackening

$$\lim X'_p \longrightarrow Y \longleftarrow \lim X''_q$$

will be called equivalent if the filtration $\{X'_p\}, \{X''_q\}$ are cofinal; i.e. if for every $p$ there are an $N$ with $X'_p \subset X''_N$ and for every $q$ an $M$ with $X''_q \subset X'_M$.

Examples.

a) Assume that there is a sequence of $n$-manifolds $X'_0, Y_1, Y_2, \ldots$ such that our filtration takes the form $X'_m = X'_0 + \sum^m_{i=0} Y_i$ (closed decomposition). Then any permutation of the $Y_i$’s gives an equivalent slackening.

b) On the other hand, if in the context of Fig. 10 we add to $X'_m$ a small “hill” in each of the larger hills $X'_N - X'_{N-1}$ ($N > m$) so as to include in the new $X''_m$ something like a sequence $q_1, q_2, \ldots$ (see Fig. 10) converging to $p_\infty$ (in the new $X''_m$), then we get a new slackening which is not equivalent to the original one any longer; the “identity map” which connects the two slackening in question is no longer a homeomorphism.

In passing from one slackening to an equivalent one nothing changes, as far as the space $\lim X'_m$, the map $l'(\infty)$ and the bad locus $\Sigma'$ are concerned. In other words one gets a commutative diagram where the vertical arrows are homeomorphisms

$$\begin{array}{ccc}
\Sigma' \subset \lim X'_p & \approx & Y \\
\downarrow & & \downarrow \approx \downarrow \\
\Sigma' \subset \lim X''_q & \approx & Y
\end{array}$$

(28)

We reserve the name weak equivalence for the existence of diagram like (28); the distinction between the two definitions of equivalence will become relevant when we will talk about improper slackening.

10) Let us define $\delta X'_t = \partial X'_t - \partial Y$. Then any neighborhood of a point $p \in \Sigma'$ meets infinitely many distinct $\delta X'_t$, in regions where $\delta X'_t$ separates $X'_{t+1} - X'_t$ from $X'_t$, and conversely.

We define now a local proper slackening of $Y$, as follows. We start with an open covering $Y = \bigcup U^i$ and then, for each $U^i$ individually we give a filtration like (24)

$$X'_0 \subset X'_1 \subset \cdots \subset X'_m \subset X'_m+1 \subset \cdots \subset X'_\infty \overset{\text{def}}{=} U^i$$

which is a proper slackening of $U^i$. The filtration (29) gives rise to a slackening map for $U^i$

$$\lim X'_m \xrightarrow{l'(\infty)} U^i$$

with a bad locus which we denote by $\Sigma^i$. It is assumed that up to equivalence the slackening (29)$|(U^i \cap U^j)$ and (29)$|(U^j \cap U^j)$ (where now in (29) is $i = j$) are the same. This allows us to define the continuous bijection

$$\bigcup_i \lim X'_m \xrightarrow{l'(\infty)} \bigcup Y$$

(30)

and its bad locus $\Sigma = \bigcup \Sigma^i$. Mutatis-mutandis, the various properties of the global proper slackening remains true for the present local proper slackening (30).

We pass now to global improper slackening. We will never bother to consider local improper slackening, which we do not need. We start by giving ourselves a commutative diagram of smooth injective immersions between manifolds of dimension $n$
where the $g_i$'s are PROPER, but not necessarily the $I(m)'s$. We will actually assume from now, in the context of something like (31), that all the $I(m)'s$ are indeed IMPROPER. It is assumed that the subsets $I(m)X_m$ exhaust $Y$ and also that the $I(m)$ int $X_m$'s exhaust int $Y$. We will assume constantly that the conditions 2), 3), 4) from the definition of the PROPER slackening remain true for our (31); one should notice here that the 2), 3), 4) in question are just local conditions. In the same spirit we will define the bad locus $\Sigma \subset Y$ as the set of points $p \in Y$ possessing arbitrary small neighborhoods which meet infinitely many $(I(m)X_m - I(m - 1)X_{m-1})'s$.

The obvious continuous bijection

$$\lim_{m \to \infty} X_m \xrightarrow{I(\infty)} Y$$

is, by definition, a global and IMPROPER slackening of $Y$ attached to (31). In order to simplify the notations we will write, from now on, just $X_m \subset X_{m+1}$ in lieu of $X_m \xrightarrow{g_{m+1}} X_{m+1}$. The preceding set-up (31) is much too general for our purpose and we will only use the special case described below in this present paper. The special feature which we will eventually describe is the possibility to “reduce”, locally, the global IMPROPER slackening to a local PROPER one.

We assume now that there is a clopen decomposition for each $X_m$

$$X_m = X_m(1) + X_m(2) + \cdots$$

which is such that:

- **i** Each $I(m)|X_m(\ell)$ is PROPER, for all $m$'s and $\ell$'s.
- **ii** We have $X_m(1) \subset X_{m+1}(1)$ and for each $X_m(\ell)$ there exists an $M = M(m, \ell) > m$ which is such that

  $$X_m(\ell) \subset \text{int } X_M(1) - X_{M-1}(1) \subset X_M(1).$$

Notice that the inclusion $X_m(\ell) \subset X_M(1)$ is always proper. It is understood here that for fixed $m$ we have

$$\lim_{\ell \to \infty} M(m, \ell) = \infty.$$ This clearly implies that if $p \in I(m)X_m - I(m)X_m \subset Y$,

then $p$ possesses arbitrarily small neighborhoods which meet infinitely many $(X_{\ell+1}(1) - X_{\ell}(1))'s$.

- **iii** It is also understood that for fixed $\ell > 1$ we have

  $$\lim_{m \to \infty} \left\{ \inf_{L_i \ni M(m, \lambda)} \right\} = \infty.$$

- **iv** Let $\delta X_m(1) = \partial X_m(1) - \partial Y$, be like in (10) above. For each $m$ there is a tubular neighborhood $N(\delta X_m(1)) \subset Y$ which is such that $N(\delta X_m(1))$ is not touched by any $X_b(b)$ with $b > 1$. It follows that we have

  $$\{N(\delta X_m(1)) \cap (X_{m+1}(1) - X_m(1))\} \cap X_m = \emptyset.$$ (Actually iv) follows from the previous conditions. For the simplicity’s sake, whenever there is no danger of confusion, we will write $X_m(1)$ in lieu of $I(m)X_m(1)$.

We will denote by $\varphi_m$ the inclusion $X_m(1) \subset X_m$ and consider the obvious bijective map

$$\lim_{m \to \infty} X_m(1) \xrightarrow{\varphi_m} \lim_{m \to \infty} X_m.$$ (34)

[Here is our typical example of an IMPROPER slackening.] We start with Fig. 10 which is redrawn as Fig. 11. With this, we introduce

$$X_m = X'_m + \sum_{1}^{\infty} B_1, \quad \text{with } X_m(1) = X'_m,$$

$$X_{m+1} = X'_{m+1} + \sum_{2}^{\infty} B_1, \quad \text{with } X_{m+1}(1) = X'_{m+1},$$

$$\vdots$$

The point here is that, although $q_1, q_2, \ldots, p_\infty$ are now all in $X_m$, the sequence $q_1, q_2, \ldots$ does not converge to $p_\infty$ in $X_m$ (but only in $Y$). This is unlike what would have happened in the counterexample b) from 9) above.
Fig. 11. Here the \( Y \) is exactly the same as in Fig. 10. For each \( q_i \) (see also Fig. 10) we consider now a “ball” \( B_i \) contained in the interior \( X'_m - X'_{m+1} \) from Fig. 10, with center in \( q_i \).

\[
X_m = X'_m + \sum_{i=1}^{\infty} B_i
\]

Fig. 12. The open 2-manifold. The point \( x = p, z = 0 \) denoted here by \( p \).

Fig. 13. \((-\infty < x < \infty) \times (-1 \leq t \leq 1) \supset A\) (white).

This makes possible the following fact: although the filtration \( \{ X_m \}, \{ X'_m = X_m(1) \} \) are not cofinal, they do define nevertheless "weakly equivalent" slackening. Here is a small refinement of this construction which will be useful. Let us consider instead of just \( B_i \subset X'_m - X'_{m+1} \) a sequence of concentric balls of increasing radii, but with a limit radius still staying very small

\[
B_i \subset 2B_i \subset 3B_i \subset \cdots \subset X'_{m+i} - X'_{m+i-1}.
\]

With this we define, in lieu of the improper slackening from above
\[ X_m = X'_m + \sum_{1}^{\infty} B_i, \]
\[ X_{m+1} = X'_{m+1} + \sum_{2}^{\infty} 2B_i, \]
\[ \vdots \]
\[ X_{m+k} = X'_{m+k} + \sum_{\lambda}^{\infty} \lambda B_i. \]

**Lemma 4.1.** Under the conditions above, the following things happen:

1) The filtration (which because of ii) above exhausts \( Y \)

   \[ X_0(1) \subset X_2(1) \subset \cdots \subset X_m(1) \subset X_{m+1}(1) \subset \cdots \subset Y \]

   is a proper global slackening of \( Y \) which we denote by

   \[ \lim X_m(1) \xrightarrow{I(\infty)} Y. \]  

(35)

2) The map \( \varphi \) (see (34)) is a homeomorphism and the following diagram is commutative

\[ \begin{array}{ccc}
\lim X_m(1) & \xrightarrow{\varphi} & Y \\
\downarrow_{I(\infty)} & & \downarrow_{I(\infty)} \\
\lim X_m & &
\end{array} \]

(36)

3) The bad locus \( \Sigma \subset Y \) of (32) coincides with the bad locus of (35). We will say that (35) is a proper global equivalent reduction of the improper slackening (32) and the properties 5, 6 from the beginning of this section hold not only for (35), but also for (32).

4) We also make from now on the assumption that for every \( p \in \Sigma \) there are a neighborhood \( p \in U \subset Y \) and an \( m \in \mathbb{Z}^+ \) such that \( \Sigma \cap U \subset X_m(1) \). Then all the arrows in the following commutative triangle are homeomorphisms

\[ I_1(\infty)^{-1} \Sigma = \lim_{\rightarrow \Sigma} I_1(\infty)^{-1} \Sigma \cap X_m(1) \]

\[ \psi|_{I_1(\infty)^{-1} \Sigma} \quad \xrightarrow{I(\infty) I_1(\infty)^{-1} \Sigma} \quad \Sigma \subset Y \]

\[ I(\infty)^{-1} \Sigma = \lim_{\rightarrow \Sigma} I(\infty)^{-1} \Sigma \cap X_m(1) \]

which will allow us to talk about a uniquely well-defined object \( \Sigma \). It follows among other things, from everything we have said, that the slackening \( \lim X_m(1), \lim X_m \) are like in the definition of “weak equivalence” (which strictly speaking was introduced only in the context of the proper slackening).

**Proof.** By definition, a set \( F \subset \lim X_m \) is closed iff each \( F \cap X_m \) is closed. But then each \( F \cap X_m(1) \) is also closed, and so \( \varphi^{-1} F \) is closed as a subset of \( \lim X_m(1) \). Conversely a set \( G \subset \lim X_m(1) \) is closed iff each \( G \cap X_M(1) \) is closed. Hence, in view of the fact that for each \( X_m(\ell) \) we have a proper inclusion \( X_m(\ell) \subset X_{m(\ell)}(1) \), the set \( G \cap X_m(\ell) \) is also closed for all \( (m, \ell) \). Since \( X_m(1) + X_m(2) + \cdots \) is a clopen decomposition of \( X_m \), it follows that every \( G \cap X_m \) is closed. This implies that \( \varphi G \) is closed in \( \lim X_m \), and all these things prove point 2) from our lemma.

We will denote now by \( \Sigma \subset Y \) the bad locus of (32) and by \( \Sigma_1 \subset Y \) the bad locus of (35). If \( p \in \Sigma \) then any neighborhood \( p \in U \subset Y \) is touched by infinitely many \( (X_m - X_{m-1}) \)'s. But clearly \( U = U \cap (X_0(1) + \sum_1^{\infty} (X_{j+1}(1) - X_j(1))) \) and so, if only finitely many \( (X_{k+1}(1) - X_k(1)) \)'s touch \( U \) then \( U \subset X_j(1) \) for some \( j \), which is in contradiction with \( p \in \Sigma \); so \( p \in \Sigma_1 \) too. Conversely assume now that \( q \in \Sigma \) i.e. that an arbitrary neighborhood \( q \in V \subset Y \) is touched by infinitely many \( (X_{m+1}(1) - X_m(1)) \)'s and hence also by infinitely many \( \delta X_m(1) = \delta X_m(1) - \delta Y \) in regions where \( \delta X_m(1) \) effectively separates \( X_{m+1}(1) - X_m(1) \) from \( X_m(1) \). But then (33) tells us that \( V \) meets infinitely many \( (X_{m+1} - X_m) \)'s, and hence \( q \in \Sigma \).
As far as 4) is concerned, our hypothesis makes \( I_1(\infty) | I_1(\infty)^{-1} \Sigma \) a homeomorphism (see condition A) and \( (27) \). On the other hand, the vertical arrow in \( (37) \) is a homeomorphism since the same is true for \( \psi \) in \( (36) \). Finally, since \( (37) \) is commutative, \( I(\infty) | I(\infty)^{-1} \Sigma \) has to be a homeomorphism too.

Under the conditions of Lemma 4.1 (see in particular point 3) we can allow slightly more general reductions, in particular of the following type. We consider a \textit{local} proper slackening \( (30) \) such that for each \( U^i \) the \{global\} proper slackening \( \lim_{m \to \infty} X_m^i \) and \( \lim X_m(1)U^i \) equivalent.

We will still call \( (30) \) a \textit{proper} (but this time, local) equivalent reduction of \( (32) \), and the content of Lemma 4.1 remains essentially valid in this slightly more general context.

\textbf{Definition 1.} We consider an \textit{improper} slackening \( (31), (32) \) of \( Y \). We will say that the slackening is \textit{locally reducible} if there exists an open covering \( Y = \bigcup U^i \) such that the following things happen:

a) We have a local proper slackening \( (29), (30) \) of \( Y \) based on the covering \( U^i \).

b) Each \( \lim X_m^i \xrightarrow{I(\infty)} U^i \) (see \( (29), (30) \)) is a proper equivalent reduction of the restriction \( \lim X_m \xrightarrow{I(\infty)} Y \bigcup U^i \).

Under the conditions of the definition above, we can extend Lemma 4.1 as follows.

\textbf{Lemma 4.2.} The obvious map

\[
\bigcup_i \lim X_m^i \xrightarrow{\psi} \lim X_m
\]

is a homeomorphism and the following diagram is commutative

\[
\begin{array}{c}
\bigcup_i \lim X_m^i \\
\downarrow \psi \\
\bigcup_i I(\infty) \\
\downarrow \psi \\
\lim X_m
\end{array}
\]

The bad locus \( \Sigma \) of the improper slackening coincides with the bad locus of its \textit{proper} local reduction.

So, apart from the filtration \( (31) \) itself, the improper slackening (as far as the change of topology of \( Y \) is concerned, a.s.o.) is undistinguishable from its proper local reduction.
